Vascular Access

Jonathan Himmelfarb, M.D. • Laura M. Dember, M.D. • Bradley S. Dixon, M.D.

HISTORY

The inception of hemodialysis for the treatment of patients with acute renal failure occurred with temporary access to the circulation in 1943.[1] However, the development of hemodialysis therapy for the maintenance treatment of end-stage renal disease (ESRD) required repeated access to the circulation. This became feasible with the introduction of the external arteriovenous Quinton-Scribner shunt in 1960.[2] The pioneering accomplishments of Willem Kolff and Belding Scribner in the development of dialysis were recognized with the Lasker Award for General Medical Research in 2002. The Quinton-Scribner cannula, made of silastic tubing connected to a Teflon cannula, shunt developed frequent problems with thrombosis and infection and typically functioned for a period of months. In 1966, Brescia and colleagues[3] developed the endogenous arteriovenous fistula, which remains the hemodialysis access of choice today. Interpositional bridge grafts were developed in the late 1960s and 70s. Initial grafts consisted of autogenous saphenous veins, bovine carotid arteries, and human umbilical veins. In the late 1970s, synthetic bridge grafts made of expanded polytetrafluoroethylene (ePTFE) were introduced.[4,5] Expanded PTFE can be placed in the majority of patients, are usable within weeks of surgical placement, and are relatively easy to cannulate. Expanded PTFE grafts remain the most frequently utilized graft biomaterial today and continue to be a highly prevalent permanent dialysis access in the United States.

Although the advantages and disadvantages of each type of dialysis access will be discussed later, it is clear that autogenous vein arteriovenous fistulas are preferable to all other currently available vascular access options. Current clinical practice guidelines recommend that patients with chronic kidney disease should be referred to create a primary arteriovenous fistula when the creatinine clearance falls below 25 mL/min, when the serum creatinine level is greater than or equal to 4 mg/dL, or within 1 year of the anticipated need for dialysis therapy.[6]

The use of catheters for hemodialysis access also parallels the history of dialysis. In 1961, Shaldon and colleagues[7] first described femoral artery catheterization for hemodialysis access. Uldall and colleagues[8] first reported the use of guidewire exchange techniques and subclavian vein puncture for placement of temporary dialysis catheters in 1979. In the late 1980s the use of surgically implanted tunneled, cuffed, double-lumen catheters was introduced.[9] Recently, subcutaneous placed vascular ports have been introduced as an alternative to the cuffed tunneled catheter.[10] While the major use of catheters for hemodialysis access is as a bridging device to allow time for maturation of a more permanent access, or for patients who need only temporary vascular access, catheter use as a permanent vascular access in patients for whom all other options have been exhausted is increasing in frequency.[11]

EPIDEMIOLOGY

The rapid growth of end-stage renal failure programs in the United States and worldwide has been accompanied by a tremendous increase in dialysis vascular access-associated morbidity and cost. Indeed, vascular access continues to be referred to as the "Achilles Heel" of the hemodialysis procedure.[12] The creation, maintenance, and replacement of vascular access in hemodialysis patients is recognized as a major source of morbidity and cost within the United States End-Stage Renal Disease Program, with recent estimates that annual costs likely exceed $1 billion within the Medicare program.

There is now compelling evidence that there are large differences in patterns of vascular access usage between Europe and the United States. The Dialysis Outcomes and Practice Patterns Study (DOPPS) compared vascular access use and survival in Europe and the United States.[13] Autogenous arteriovenous fistulas were used by 80% of European patients compared to 24% of prevalent dialysis patients in the United States. Arteriovenous fistula use was significantly associated with male sex, younger age, lower body mass index, absence of diabetes mellitus, and a lack of peripheral vascular disease. However, even after adjustment for these risk factors, there is a 21-fold increased likelihood of arteriovenous fistula use in Europe versus in the United States. A follow-up study from DOPPS suggests that pre-dialysis care by a nephrologist does not account for the substantial variations in the proportion of patients commencing dialysis with an arteriovenous fistula, and the time to fistula cannulation after creation also varies greatly between countries.[14] Enormous facility variation has also been noted within the United States, with the prevalence of arteriovenous fistulas ranging from 0% to 87%.[12] There is also large variation in access type by geographic region, sex, and race within the United States.[15] Thus, practice pattern variations in vascular access are determined by local preference, in addition to patient-related factors.

The importance of vascular access care has been emphasized by data from the United States Renal Data System (USRDS) demonstrating that adjusted relative mortality risk is substantially higher for patients with a central venous catheter compared to an arteriovenous fistula in both diabetic and nondiabetic patient populations (Figure 17–1).[16]
Figure 17–1 Adjusted patient survival based on dialysis access type. *AVF,* arteriovenous fistula; *AVG,* arteriovenous graft; *CVC,* cuffed venous catheter. (Reproduced with permission from Dhingra RK, Young EW, Hulbert-Shearon TE, et al: Type of vascular access and mortality in U.S. hemodialysis patients. Kidney Int 2002; 60:1443-1451.)

For diabetic patients, the use of arteriovenous grafts is also associated with significantly higher mortality risk compared to arteriovenous fistulas. Mortality due to both infectious and cardiovascular causes is implicated.

Data from Medicare and the USRDS indicate that the prevalence of arteriovenous fistula use is increasing in the United States. The increase in fistula placement coincides with the publication of Dialysis Outcome Quality Initiative (DOQI) Guidelines in 1997.[6] However, the K/DOQI clinical practice guidelines recommending that an autologous fistula be placed in 40% of prevalent hemodialysis patients is currently not being met. Furthermore, the use of tunneled catheters as the primary means of hemodialysis access appears to be rising. Thus, considerable challenges remain in attempting to optimize vascular access practice patterns in the future.

CATHETERS

Temporary Dialysis Catheters

Acute hemodialysis refers to the provision of hemodialysis for patients with acute renal failure, for the removal of ingested toxins, and for patients with chronic renal failure who require dialysis but do not have a functioning permanent vascular access. Vascular access requirements for acute hemodialysis are best served by the use of dual-lumen noncuffed temporary catheters. These catheters are made of a variety of materials, including polyurethane, polyethylene, and polytetrafluoroethylene (PTFE). Although temporary dialysis catheters may be placed in a number of anatomic locations, they are most commonly placed in the femoral vein, subclavian vein, or jugular vein. Each of these sites has advantages and disadvantages, depending on the specific clinical circumstances.

In most patients, the femoral vein is the easiest site of catheter insertion and is also associated with a lower risk of life-threatening complications. The major disadvantages are that patients must remain recumbent while the catheter is in place and there is a higher rate of infection. A femoral vein

catheter is particularly practical in acute renal failure or after acute intoxications, in which it is anticipated that only one or two dialysis treatments will be necessary. Femoral catheters 24 cm in length are preferable to 15-cm catheters to reduce recirculation.[17] In a patient who is receiving acute hemodialysis because of nonfunction of a renal transplant, the femoral vein site contralateral to the allograft should be cannulated to avoid potential injury to the renal transplant or its vasculature.

For patients who require longer periods of renal replacement (>72 hours but <3 weeks), a noncuffed dialysis catheter placed in the internal jugular vein is preferable. The acute complications associated with both jugular and subclavian line insertions are similar. However, subclavian line insertions are associated with the longer-term complication of subclavian venous stenosis,[18] thereby compromising the potential for permanent vascular access. Catheters inserted under aseptic conditions in either the jugular or subclavian vein may be left in place for up to 3 weeks.

The complication rate associated with either subclavian or jugular catheter insertion is considerably higher than that for femoral line insertion. Complications associated with subclavian or jugular catheter insertion include pneumothorax, arterial puncture, venous puncture, and air embolism. A chest radiograph must be obtained after insertion of either jugular or subclavian lines and before initiation of hemodialysis to exclude the development of a pneumothorax or hemothorax and to confirm that the catheter's position is appropriate. Catheters should be inserted immediately prior to use, and real-time ultrasound-guided venous puncture is recommended for catheter insertion. Infection is the most common complication of dialysis catheters. Careful attention to aseptic technique, including the use of full-body sterile drape can decrease the risk.[19]

Cuffed Venous Catheters

Cuffed tunneled dialysis catheters have the advantage of relatively easy placement and immediate usability. Additionally, cuffed tunneled catheters can be used as a permanent vascu-

lar access for those patients who have exhausted all options for placement of an arteriovenous fistula or graft.[11] However, the high rate of infections and thrombotic complications associated with catheter use and the epidemiologic data suggesting higher mortality in patients using catheters make the current trend towards increased prevalence of catheter use in the U.S. dialysis population a disconcerting one. It has been suggested that the use of cuffed venous catheters is "a conundrum" and that we "hate living with them, but can't live without them."[20]

Infections are the most frequent serious complication of cuffed venous catheter use. The importance of sepsis as a cause of mortality in patients with end-stage renal disease has been emphasized because mortality secondary to sepsis is approximately 100- to 300-fold higher in all dialysis patients compared with the general population.[21]

Prospective studies demonstrate that the use of cuffed venous catheters is associated with a high rate of bloodstream infections in hemodialysis patients.[22,23] In most studies, the frequency of catheter-associated bacteremia is approximately 2 to 4 episodes per 1000 patient days, equivalent to 0.7 to 1.5 bacteremias per catheter year. In contrast, the frequency of infections or bacteremias associated with the use of arteriovenous fistulas is approximately 0.05 per patient year.

Catheter-related bacteremia in hemodialysis patients causes serious morbidity and mortality. An important study reported on the poor outcome of attempted catheter salvage (i.e., antibiotic therapy without catheter removal or exchange) in hemodialysis patients.[21] Only 32% of catheters were successfully salvaged, and of the 41 patients with bacteremia (inclusive of those in whom catheters were exchanged and salvage was attempted), 6 patients developed osteomyelitis, 1 patient developed septic arthritis, 4 patients developed infective endocarditis, and 2 patients died. These results underscore the seriousness of catheter-related bacteremia in hemodialysis patients.[24]

There have been reports of successful strategies for dealing with catheter-related bacteremia in hemodialysis patients. In one approach, patients with catheter-related bacteremia were stratified into three groups based on clinical presentation[25]:

1. Patients with minimal septic symptoms and a normal-appearing tunnel and exit site
2. Patients with minimal septic symptoms but with exit site or tunnel infection
3. Patients with severe septic symptoms

Each group received a 3-week course of appropriate antibiotic therapy based on organism identification and antibiotic sensitivity determination. Group 1 underwent catheter exchange over a guide wire, while Group 2 underwent catheter exchange over a guide wire with a creation of a new tunnel. In Group 3, catheters were removed with delayed replacement until defervescence. Utilizing this strategy, reported cure rates were 88%, 75%, and 87%, respectively. Another study compared the results of catheter exchange over a guide wire with catheter removal followed by delayed catheter replacement.[26] Each patient group received 3 weeks of appropriate systemic antibiotic therapy. Infection-free catheter survival time was similar in both groups. In a recent study, these investigators reported on a strategy of attempted catheter salvage by installation of an antibiotic lock solution into the catheter lumen (to eradi-

cate luminal biofilms) in addition to a 3-week course of antibiotics.[27] This protocol was successful in 51% of cases, and overall catheter survival with this strategy was similar to that observed among patients managed with catheter replacement. Several studies have also suggested that the prophylactic application of topical mupirocin or bacitracin to catheter exit sites can markedly reduce catheter-related bacteria, sepsis and can prolong catheter survival.[28–30]

Venous catheters are also subject to frequent episodes of thrombosis requiring either thrombolytic therapy or replacement of the catheter. A prospective randomized, placebo-controlled trial of "mini-dose" warfarin for the prevention of dialysis catheter malfunction, did not demonstrate a significant effect on thrombosis-free catheter survival.[31] The long-term use of cuffed venous catheters may also lead to the development of right atrial thrombi. In a concerning report, intravascular ultrasound prospectively identified the presence of right atrial thrombi in 22% of hemodialysis patients with indwelling venous catheters.[32] In a recent report, large atrial thrombi were associated with a 68% chance of concurrent infection and an overall mortality of 27%.[33] Further research will be required to identify to what extent this poses a risk for hemodialysis patients. The use of cuffed venous catheters also predisposes patients to the development of central venous stenosis. Because subclavian vein stenosis may preclude the subsequent successful placement of ipsilateral arteriovenous fistulas or grafts, the use of subclavian venous catheters is generally contraindicated in dialysis patients unless utilized as a last resort.[18,34–38]

SUBCUTANEOUS PORTS

Vascular access ports are access devices that are entirely implanted into subcutaneous tissue and therefore have no external components. For hemodialysis access, a vascular catheter is inserted into a central vein and then subcutaneously tunneled to connect with the port device. Access to the port is then obtained by the use of specialized needles. Vascular access ports have commonly been adapted for use in oncology and are generally reported to have lower infection and thrombosis rates than traditional cuffed tunneled catheters.

Two hemodialysis port systems have recently been developed and are now in clinical use.[39] The LifeSite hemodialysis access system consists of two separate ports and catheters, one each for aspirating and returning blood during hemodialysis. The catheters are separately tunneled and a 14-gauge needle is inserted into the valve entry site to gain access to the LifeSite port. The LifeSite port is also designed to allow irrigation of the valve with an antimicrobial solution. In initial clinical trials, the LifeSite port has achieved excellent blood flows with a lower catheter-related bacteremia rate than traditional cuffed tunneled catheters.[10]

The Dialock hemodialysis access system also consists of an implantable subcutaneous port, in this case with two separate passages connected to a single lumen vascular catheter. Insertion of a 15-gauge needle opens a septum valve mechanism and provides access to the connecting vascular catheter. Studies using the Dialock access port suggest that excellent blood flows can be achieved with a low catheter-related bacteremia rate.[40]

AUTOGENOUS FISTULAS

Construction

The autogenous arteriovenous fistula is constructed by a surgical anastomosis between an artery and a vein. The exposure of the vein to the arterial blood flow results in dilatation and thickening of the vein wall, a process referred to as maturation. Maturation must be adequate to allow frequent needle cannulation and to support the blood flow of the dialysis circuit. Fistula maturation usually takes 8 to 16 weeks.

Upper extremity fistulas can be created in the forearm or in the upper arm (Figure 17–2). The Brescia-Cimino fistula, created via an anastomosis of the radial artery and cephalic vein at the wrist, was the first type of autogenous fistula described and is the fistula that should be considered initially in a patient who has not had a previous forearm arteriovenous access.[41] Ulnar artery-basilic vein and radial artery-basilic vein anastomoses are additional approaches for creation of a forearm fistula that are used relatively infrequently. In the upper arm, construction of the brachial artery-cephalic vein fistula is the most straightforward from a surgical standpoint. However, because many patients have had multiple prior cannulations of the cephalic vein in the antecubital space, stenoses are often present that preclude use of the vein for an upper arm fistula. An alternative is the brachial artery-basilic vein fistula. Construction of the brachiobasilic fistula requires dissection and subcutaneous tunneling of the basilic vein to reposition it superficially and laterally and thereby enable needle cannulation. Thus, the creation of a brachiobasilic fistula (often referred to as the basilic vein transposition fistula) is relatively laborious, but its use is becoming more widespread due to its favorable short-term and long-term outcomes.[42,43] At most centers, the creation of the anastomosis and the transposition of the vein are performed during a single surgical procedure.

Arguments have been made for a two-step procedure in which the vein repositioning is performed several weeks after the anastomosis creation.[44] The potential advantage of the two-step approach is that damage to the vein wall during dissection and tunneling is reduced because of the remodeling that has occurred during the preceding weeks.

Fistulas can be constructed with an end-to-side or a side-to-side vein-artery anastomosis. Advantages of the end-to-side anastomosis include the ability to create a 90-degree rather than an acute-angle anastomosis, reduced likelihood of venous hypertension in the distal extremity, and the ability to bring together vessels that are far apart. Side-to-side anastomoses are technically easier to create and distension of distal veins can be prevented by ligating the vein distal to the anastomosis. However, the acute angle between the vessels that results from a side-to-side anastomosis is associated with increased turbulence that may contribute to stenosis development.[45] End-to-end anastomoses are usually avoided because of the risk of distal extremity ischemia with ligation of the artery.

Advantages of the Autogenous Fistula

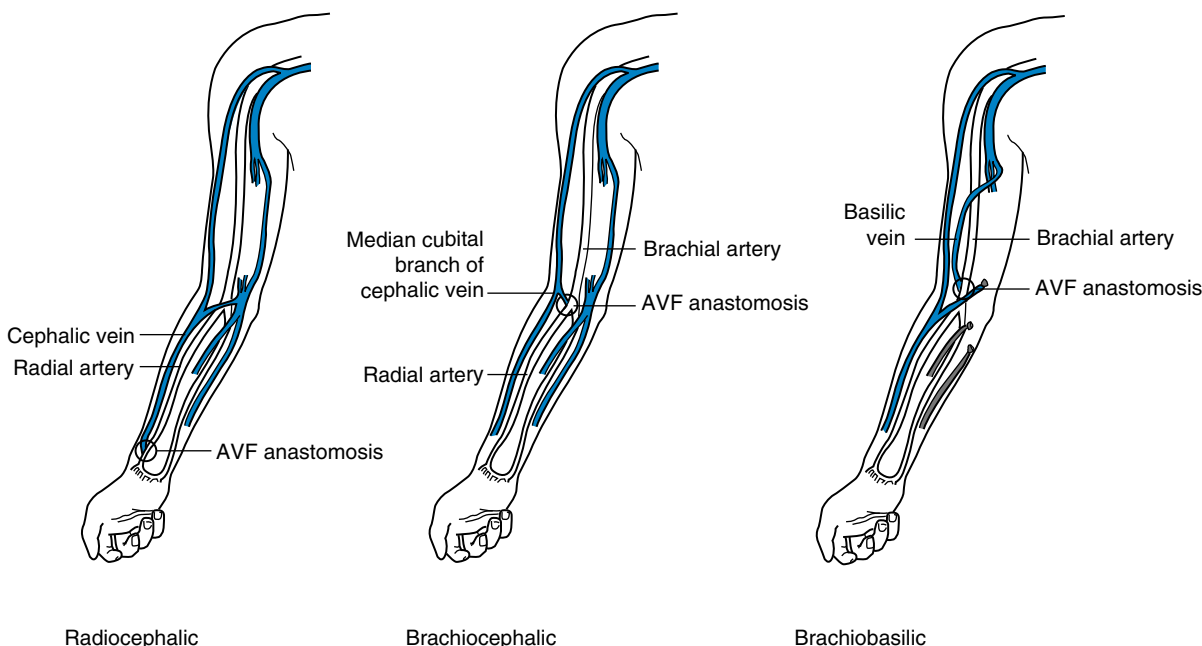
Multiple studies indicate that rates of thrombosis and need for salvage procedures are substantially lower for autogenous fistulas than for synthetic grafts.[46–49] Cumulative survival, meaning survival until access abandonment, has also been shown in several analyses to be better for fistulas than grafts, despite aggressive and often successful efforts to restore patency of thrombosed grafts.[47] It should be recognized that many of the studies comparing outcomes of grafts and fistulas did not include primary failures, that is, accesses that fail before ever being used for dialysis. It has been suggested that if primary failures are included in such analyses, the cumulative survival of fistulas and grafts are similar.[42] Nonetheless, there is general


Figure 17–2   Types of autogenous fistulas. (Adapted with permission from Allon M, Robbin ML: Increasing arteriovenous fistulas in hemodialysis patients: Problems and solutions. Kidney Int 2002; 62:1109-1124.)

agreement that once mature, a fistula is much less likely than a graft to require intervention. In addition, infections occur much less frequently in fistulas than in grafts. For these reasons, a concerted effort to increase the prevalence of autogenous fistulas is one of the major recommendations of the National Kidney Foundation K/DOQI Clinical Practice Guidelines.[6]

An additional potential but unproved advantage of the autogenous fistula is that it does not contribute to the chronic inflammatory state evident in a large proportion of patients on maintenance dialysis. With accumulating evidence implicating chronic or recurrent inflammation in the cardiovascular disease of ESRD, it is reasonable to infer that reducing exposure to inflammatory stimuli by using autogenous vessels rather than synthetic material for vascular access may provide benefits that extend beyond access-related events.

Why the Low Prevalence of Autogenous Fistulas?

Despite the recognition of the advantages of the autogenous fistula, only approximately 25% of patients in the United States receive hemodialysis via an autogenous fistula, and nearly 50% are dialyzed with a synthetic graft.[13,46] Two interrelated factors that contribute to the low prevalence of autogenous fistulas are (1) their high rate of early failure and (2) the widespread practice of initially placing a graft rather than attempting construction of an autogenous fistula.

Primary failure of autogenous fistulas occurs as a result of either thrombosis within the first several weeks following surgical creation (early thrombosis) or inadequate maturation of the vein. Series published during the past 10 years report autogenous fistula primary failure rates of 20% to 50%.[50] The wide range of failure rates in these reports likely reflects differences in characteristics of the patients in whom fistula creation was attempted and possibly variation in presurgical evaluation and surgical approaches. Factors found by various investigators to be associated with primary failure include older age, female sex, obesity, diabetes mellitus, black race, and low blood pressure.[51–55] Attempts to identify serologic or other biochemical predictors of fistula failure have not been revealing.

The tendency to place synthetic grafts before attempting autogenous fistula construction has evolved because of the ability to use grafts soon after surgery, the good short-term outcomes in patients with vessels that appear unsuitable for fistula construction, referral of patients to nephrologists when dialysis initiation is imminent rather than earlier in the course of the renal disease, and the technical ease of graft placement relative to fistula creation, particularly when vein transposition is needed.[6,12,50] Although some of these factors are not readily modifiable, marked geographic variations in fistula prevalence that persist after adjustment for demographic characteristics or comorbid conditions suggest that clinical practice patterns are important contributors to the types of accesses created.[56,57] Reports from centers that have implemented multidisciplinary access programs involving nephrologists, vascular surgeons, and dialysis staff suggest that substantial increases in fistula creation attempts can be achieved, and that the higher attempt rates are accompanied by increases in the prevalence of functioning fistulas (Table 17–1).[58,59]

Table 17–1 Components of a Multidisciplinary Autogenous Fistula Program

Team Members
Nephrologists
Dialysis nurses and patient care technicians
Vascular surgeons
Interventional radiologists
Vascular ultrasonographers
Vascular access coordinator

Goals
Early placement of vascular access
Creation of upper arm and transposition fistulas, if radiocephalic fistula not possible
Vascular mapping for identification of suitable vessels
Replacement of failed synthetic grafts with autogenous fistulas
Salvage interventions for fistula maturation failures
Reduction in duration of central venous catheter use

Approaches
Develop consensus regarding goals of program
Prospective tracking of vascular access types and outcomes
Active monitoring of fistula maturation after anastomosis creation
Ongoing education of patients and dialysis facility staff
Ongoing dialogue among team members to modify approaches

Assessment of Vessel Quality

There are several approaches to evaluating vessels preoperatively to identify those that are suitable for fistula creation. The simplest method is physical examination of the veins prior to and after placement of a tourniquet proximally. Although this allows assessment of the diameter of superficial veins, it does not identify proximal stenosis or thrombosis that could interfere with fistula maturation. In addition, physical examination may fail to identify deeper veins that would be suitable if transposed and, thus, could lead to an inappropriate decision to place a graft rather than attempt fistula creation. More information about the vasculature can be obtained with either ultrasonography or venography (i.e., vascular mapping). Ultrasound evaluation of the extremity provides information about vein diameter and the presence of stenosis, thrombosis, and sclerosis. In addition, arterial characteristics can be assessed (e.g., diameter and flow). Vascular mapping with ultrasonography is time-consuming and operator-dependent and is most successful when a specific protocol is followed to ensure uniform measurements and reporting by multiple operators (Table 17–2). Venography also provides information about vessel size and patency and is probably better for identification of stenoses and assessment of central vessel patency than is ultrasound. However, venography does not enable evaluation of arteries, it exposes patients to contrast, and it carries the risk of vein damage from cannulation or phlebitis that could render the vein unsuitable for fistula construction.

Several recent studies have demonstrated increases in rates of attempted fistula creation after implementation of

Table 17–2   Protocol for Vascular Mapping Using Ultrasonography

1. Examine **radial artery** at wrist for flow, peak systolic velocity, quantitative blood flow (should be ≥10 mL/min) and diameter (should be ≥2.0 mm).
2. Examine **ulnar artery** at wrist for flow, peak systolic velocity, quantitative blood flow, and diameter (should be ≥2.0 mm).
3. Examine **brachial artery** just above antecubital fossa for peak systolic velocity, quantitative blood flow, and diameter (should be ≥2.0 mm).
4. Place tourniquet at upper forearm. Examine **cephalic vein** at wrist:
   - Measure diameter at wrist (should be ≥2.5 mm).
   - Follow to elbow, examine for stenoses or occluded segments. Measure diameter at mid and upper forearm.
5. Place tourniquet at upper arm. Examine cephalic vein above elbow:
   - Measure diameter of vein above elbow at low, mid, and upper arm (should be ≥2.5 mm).
   - Follow to shoulder, examine for segmental stenoses or occluded segments.
   - Determine whether vein is superficial for most of its course (within 1 cm of skin).
6. Examine **basilic vein** in upper arm:
   - Measure diameter of vein above elbow at low, mid, and upper arm (should be ≥2.5 mm).
   - Follow to axilla, examine for segmental stenoses or occluded segments.
7. Remove tourniquet. Examine subclavian and internal jugular veins for stenoses or occlusions.

preoperative vascular mapping protocols.[60–63] In most of these studies, the increased rates of fistula creation attempts were accompanied by a reduction in the primary failure rates and, among those studies that reported it, an increase in the fistula prevalence at the center. None of these studies was a randomized, controlled trial, and it is possible that the improvements seen were due to factors other than vascular mapping, such as changes in surgical approaches, better preoperative protection of vessels, or earlier referral for access creation. Thus, although preoperative vascular mapping provides a substantial amount of information about vessel quality, its ultimate impact on fistula outcomes is not yet clear.

Selection of the Location for Autogenous Fistula Creation

In general, it is preferable to use the distal extremity for initial arteriovenous access placement and move to more proximal sites, if necessary, because of access failure. It is also usually preferable to use the nondominant arm to limit the functional disability that might occur with perioperative complications, such as vascular steal syndrome or peripheral neuropathy. Thus, if the forearm vessels appear suitable, a radio-cephalic fistula in the non-dominant arm should be created as the initial access.

Decisions about access type and location are less straightforward, if the forearm vessels do not appear suitable for an autogenous fistula or if a forearm autogenous fistula is created initially but fails. Until recently, the approach in many centers would have been to place a forearm arteriovenous graft. However, with the recognition of the long-term benefits of autogenous fistulas and recent studies suggesting a lower primary failure rate for upper arm than forearm fistulas, some centers will create an upper arm autogenous fistula as an initial access in individuals who do not have suitable forearm vessels.[49] Whether such an approach is preferable to that of initially placing a forearm synthetic graft and subsequently creating an autogenous fistula in the upper arm if the graft fails, is not known. A potential advantage of the latter approach is that alterations in upper arm veins that occur as a result of increased flow via the forearm graft could ultimately enhance the suitability of the upper arm veins for autogenous fistula creation.

Preoperative Preparation for Autogenous Fistula Creation

Because the quality of the vein is so critical to successful autogenous fistula creation, every effort should be made to protect the veins in the extremity that will be used for access creation. Venipuncture for obtaining blood specimens and intravenous catheter placement should be avoided at sites proximal to the planned arteriovenous anastomosis. Fistula creation should be performed many months before vascular access use is required to prevent the need for central venous catheter placement and the associated risk of central vein stenosis. These measures for preserving quality are more feasible for patients undergoing initial access placement than for those who have already had multiple failed accesses.

Pharmacologic Approaches to Improving Autogenous Fistula Outcomes

Several studies have evaluated the efficacy of antiplatelet agents for preventing early thrombosis of autogenous fistulas.[64] Ticlopidine, microencapsulated aspirin, and sulfinpyrazone all appeared effective in small studies. In the largest of these trials, 260 patients were randomized to ticlopidine or placebo starting 3 to 7 days before fistula creation and continued for 28 days after surgery. The rates of fistula thrombosis in the placebo and ticlopidine groups were 19% and 12%, respectively, but this difference was not significant, possibly because of insufficient sample size. A pooled analysis of all placebo-controlled studies of ticlopidine showed a 25% thrombosis rate in the placebo group compared to a 12% thrombosis rate in the ticlopidine group, indicating a statistically significant benefit of ticlopidine. None of the studies of antiplatelet agents reported the proportions of fistulas able to be used for dialysis. Based upon the results of these multiple small studies, a large, multicenter, randomized, placebo-controlled trial is underway to evaluate the effect of clopidogrel on patency and maturation of newly constructed autogenous fistulas.

At present, the understanding of the physiology of vein maturation is limited. Studies in animal models suggest roles for nitric oxide and prostacyclin, but details about the relevant

signaling pathways and regulatory influences are scant.[45] Additional investigation of the systemic and local factors involved in vein dilatation and remodeling could lead to the identification of pharmacologic targets for enhancing fistula maturation.

Initial Cannulation of New Fistulas

Premature cannulation of autogenous fistulas predisposes to infiltration and compression of the vein from extravasated blood that can result in fistula thrombosis. Thus, careful examination of the fistula by experienced team members should be performed prior to initial use, and additional time for maturation should be employed, if the fistula appears unsuitable or if initial attempts at use are unsuccessful. Specific recommendations about when to initiate cannulation vary. The K/DOQI guideline is to allow the fistula to mature for 3 to 4 months before initial use.[6] Data from the DOPPS suggest that in some countries, fistula cannulation within 4 to 6 weeks after creation is common and is not associated with reduced fistula survival.[14] Given the substantial long-term benefits of a functioning fistula, it is advisable to exercise caution with regard to early use of new fistulas. However, the risks associated with the extended use of central venous catheters that can accompany cannulation delays should not be discounted.

Salvage of Failing Fistulas

Regular examination of new fistulas should begin early after anastomosis creation to evaluate the maturation process. Two potentially modifiable causes of maturation failure are stenosis of the draining vein and the presence of vein branches that decrease the blood flow through the draining vein. Balloon angioplasty of identified stenoses can enhance maturation as can surgical ligation of vein tributaries.[65,66] Because the use of radiographic contrast may hasten the need for initiation of dialysis, ultrasonography may be preferable to angiography as the diagnostic study for patients who have not yet started dialysis. Surgical superficialization can convert a deep fistula that has matured adequately but is unsuitable for use because of cannulation difficulty, to an effective vascular access.

In many centers, surgical or radiologic thrombectomy of a thrombosed fistula is not attempted because of the technical difficulties and poor outcomes. However, recent reports suggest that with innovative approaches, percutaneous declotting of mature autogenous fistulas can be performed with reasonable success rates.[67–69] Salvage is rarely applied to fistulas that thrombose within the first few weeks after creation; such fistulas are usually abandoned.

Monitoring Mature Fistulas for Stenoses

Stenosis development is less frequent in autogenous fistulas than in synthetic grafts, and the utility of routine monitoring for fistula stenosis has not been established. The methods for monitoring arteriovenous accesses for stenosis are described in the graft section of this chapter. Venous pressure measurement is not as sensitive for fistula stenosis as it is for graft stenosis, in part, because monitoring venous pressure will identify only those stenoses that are downstream of the venous needle. In contrast to grafts, in which the majority of stenoses occur at or near the venous anastomosis, stenoses in fistulas occur anywhere along the length of the draining vein and thus might be upstream of the venous needle. Even if the stenosis is downstream of the venous needle, the development of collateral veins often prevents the venous pressure from increasing substantially. Thus, for monitoring fistulas, a more direct determination of access blood flow (e.g., ultrasound dilution or Doppler ultrasound) is more appropriate than is venous pressure measurement. However, optimal blood flow criteria for confirmatory angiography are still being defined.[70]

Complications of the Autogenous Fistula

Vascular steal syndrome is a potentially devastating complication that can occur with either placement of a synthetic graft or creation of an autogenous fistula. The reduction in perfusion to the distal extremity that results from shunting of blood through the arteriovenous access can produce mild symptoms or irreversible ischemic injury. Steal syndrome occurs predominantly in individuals with underlying vascular disease, and its incidence may be increasing with the growing proportion of elderly and diabetic patients comprising the ESRD population. With a fistula, steal syndrome usually develops gradually over several weeks after creation of the surgical anastomosis as the fistula blood flow increases with progressive vein maturation. In contrast, severe arterial compromise can occur immediately after graft placement. Access ligation is often necessary in severe cases, although banding procedures to reduce, but not eliminate access blood flow, can also be attempted. Banding procedures may result in access thrombosis or fistula maturation failure.

Congestive heart failure is a relatively rare complication resulting from the shunting of blood from the arterial to the venous circulation through either an autogenous fistula or a synthetic graft. It occurs more often with upper arm than forearm accesses because of the greater blood flow in the former. Accurately attributing cardiac failure to access-related high output states can be difficult. If the diagnosis is questionable, demonstration of functional changes, such as decreased heart rate or cardiac output, during manual compression of the access, can be attempted before treating with access banding or ligation.

Aneurysm formation occurs in autogenous fistulas when the vein wall becomes damaged and replaced with tissue that provides less resistance than the contiguous vessel wall. Repetitive cannulation in the same regions of the access and proximal stenosis both predispose to aneurysm formation. Buttonhole cannulation of the exact same two access sites has been suggested to reduce aneurysm formation but may be difficult in practice to achieve. Pseudoaneurysms are usually caused by extravasation of blood after needle removal. Both true aneurysms and pseudoaneurysms can limit sites for needle placement and can rupture if the overlying skin is compromised.

In contrast to synthetic grafts, autogenous fistulas rarely become infected. Antibiotic therapy alone is often sufficient for eradication of fistula infections, although aneurysmal infections may require surgical resection because of intra-aneurysmal stasis or thrombus.

ARTERIOVENOUS GRAFTS

Terminology

In patients for whom an autogenous arteriovenous fistula cannot be constructed by direct anastomosis of adjoining vessels, one option is to interpose a graft that serves as a conduit between the artery and vein. This type of hemodialysis access is referred to as a *non-autogenous access* or an *arteriovenous graft* (AVG).[71] The graft allows for selection of the optimal arterial and venous sites for surgical anastomosis and provides an easy target for cannulation. The graft can be composed of either synthetic material, such as ePTFE, or a biologic material. The latter is referred to as a biograft. The biograft may be an autograft (i.e., from a different site in the same individual, such as the saphenous vein), an allograft (i.e., from a genetically different individual of the same species), or a xenograft (i.e., from a different species, such as a bovine vessel). Allografts are also referred to as homografts, and xenografts are also called heterografts.

Graft Location and Configuration

Depending on the target vessels that are available, there are a number of anatomic variations of arteriovenous graft that can be created. The forearm straight graft typically originates from the radial artery in the forearm and terminates in the cephalic vein at the level of the antecubital fossa. The forearm loop graft typically originates from the brachial artery and terminates in either the cephalic or basilic vein at the level of the antecubital fossa. Most commonly, blood flows through the forearm loop graft from medial (arterial side) to lateral (venous side) in the direction indicated by the extended thumb (Figure 17–3). However, the direction of flow may be reversed in some forearm loop grafts, and the surgeon needs to record this informa-tion in the patient's chart at the time of access placement. Arteriovenous grafts placed in the upper arm typically originate from the brachial artery at the antecubital fossa and terminate in the cephalic vein in the upper forearm. If access sites have been exhausted in the arms, then a femoral loop graft may be placed in the leg between the femoral artery and vein. In exceptional circumstances in which other options have been exhausted, heroic types of accesses have been constructed. These include the necklace graft that connects the axillary or subclavian artery to the contralateral jugular or subclavian vein and the arterial interposition graft in which the artery (e.g., subclavian, femoral, or brachial artery) is transected and a loop of graft material is inserted connecting the proximal and distal ends of the transected artery.

Graft Materials

The history leading to the development of modern vascular grafts has been reviewed.[72] The ideal graft material would be biocompatible, nonthrombogenic, easy to cannulate, easy to surgically manipulate, low cost, resistant to infection, and able to withstand multiple cannulations without degeneration or pseudoaneurysm formation.[73] As listed in Table 17–3, many types of materials have been tried, but to date the perfect graft material and design have not been found. Currently, the preferred graft material is expanded polytetrafluoroethylene.

In 1969 Gore discovered that polytetrafluoroethylene (PTFE), the polymer in Teflon invented by DuPont, could be rapidly stretched to create a strong microporous plastic with useful properties. This was called expanded PTFE (ePTFE). Early studies demonstrated that expanded PTFE worked better than woven PTFE for small vessel prosthesis.[74] In 1976, Baker and colleagues[4] reported on the first clinical experience using ePTFE as an arteriovenous graft for hemodialysis patients. Subsequent studies in the late 1970s suggested that

ePTFE was equal to or better than other available synthetic grafts or biografts in terms of long-term patency and had an acceptable complication rate; hence ePTFE rapidly became the preferred choice of many surgeons as graft material for secondary arteriovenous access in hemodialysis patients.[73,75–80] There are several commercial types of ePTFE grafts but the two best known are Gore-Tex and Impra. Both types of ePTFE graft have similar pore size but the Gore-Tex brand is thicker and is reinforced by an external circumferential layer of PTFE not used in Impra grafts. Several randomized controlled trials directly comparing Gore-Tex and Impra hemodialysis grafts have been performed, and there was no significant difference in terms of long-term patency or the rate of complications.[81,82] Some recent experimental studies have suggested that larger pore ePTFE grafts (e.g., 60–90 μm) may have better rates of angiogenesis and graft surface endothelialization.[83,84] However, the available evidence suggests that there is no clinical advantage in terms of long-term patency of such grafts for hemodialysis access.[85]

Polyurethane has also been studied as a vascular access graft.[86–90] Although problems have been reported with some of the polyurethane graft designs,[87,89,90] recent studies have suggested that the polyurethane Vectra graft (Thoratec Lab Corp, CA) is comparable to ePFTE in terms of patency and complications.[86,88] The Vectra graft has an inner and outer porous layer that allows tissue ingrowth and a central core made of Thoralon, which is a self-sealing polyurethane material.[86] The central self-sealing core reportedly allows for earlier graft cannulation after surgery without the problems of bleeding, seroma formation, and thrombosis seen with early cannulation of ePTFE grafts.[86] More information will be needed on this graft. One concern that has been raised is that the Vectra graft is difficult to image by Doppler ultrasound, thus making it difficult to use this technique to look for access stenosis.[91]

Graft Patency

There is a wide variation in the reported long-term patency of ePTFE vascular access grafts. Recent studies demonstrate

that primary failure in the United States occurs in half of all new ePTFE grafts within 6 months or less of placement, which is the same as for autogenous fistulas placed in the forearm.[92–95] Synthetic grafts can often be salvaged leading to improved secondary patency rates. The better salvage rate for failed arteriovenous grafts compared to autogenous fistulas leads to nearly equivalent 1- and 2-year rates of secondary patency.[92,94,96–100] This is achieved, however, at the expense of significantly more graft revisions and complications.[92,94,96,99–102] With extended follow-up beyond 2 years most studies demonstrate that autogenous fistulas maintain functional patency longer and with fewer complications than grafts.[13,92,94,97–99,102]

GRAFT COMPLICATIONS

Thrombosis

Thrombosis is the most common graft complication and the most common cause of access failure. Thrombosis has been reported as the cause of 70% to 95% of all graft failures.[47,94,103–107] The rate of graft thrombosis in the literature ranges from about 0.25 to 1.4 thrombotic episodes per patient-year.* The large variation undoubtedly reflects case mix, intensity of access surveillance, and local access management practices. Most recent studies report graft thrombosis rates exceeding 0.5 episodes per patient-year.† As pointed out by Virchow over 150 years ago, the predisposition to thrombosis is dependent on abnormalities in blood flow, blood constituents, and the vessel wall. As applied to the problem of vascular access thrombosis (Table 17–4), abnormalities that predispose to graft thrombosis include: (1) impaired blood flow resulting from vascular stenosis and hematorheological alterations at the graft-vessel anastomosis; (2) vessel wall abnormalities, including the thrombogenic graft-blood interface and endothelial damage or dysfunction; and (3) abnormalities in blood constituents, including acquired or inherited abnormalities in platelet, coagulation, or fibrinolytic pathways. Although most studies have focused on the role of vascular stenosis in graft thrombosis, each of these factors is interrelated, and more than one factor ultimately determines whether thrombosis occurs in a given individual.

Vascular stenosis due to neointimal hyperplasia is the most common underlying cause of access thrombosis. Early surgical studies reported access stenosis in 34% to 63% of

thrombosed grafts.[115] However, more recent angiographic studies find that vascular stenosis exists in over 85% of thrombosed or failing grafts.[47,95,111,116–121] The most common site of stenosis is at the vein-graft anastomosis (Figure 17–4).* Most of the remaining stenoses are found either in the downstream vein or within the body of the graft. Central venous stenosis is seen in at least 3% to 6% of patients in most studies[†] but may be as frequent as 40% in patients who have had a prior subclavian central catheter for dialysis.[115,126,127] Stenosis also occurs at the artery to graft anastomosis but less frequently than seen in autogenous fistulas. The importance of access stenosis in the pathophysiology of access thrombosis is underscored by the observation that prospective access monitoring to detect and prophylactically treat stenosis decreases the frequency of thrombosis.[‡] There are at least two mechanisms whereby stenosis can lead to thrombosis. First, a hemodynamically significant venous stenosis produces a decrease in access flow rate and an increase in intra-access pressure.[128,135–137] The consequence of this is a decrease in the shear rate and altered surface tension at the blood-graft interface leading to an increased interaction of platelets and clotting factors with the surface of the graft.[138] Second, the stenosis itself creates an increase in blood velocity and wall shear stress at the level of the stenosis that can activate platelets and promote platelet adhesion and aggregation.[139,140] Hence, access stenosis with its attendant alterations in blood rheology, platelet activation, and endothelial dysfunction predisposes to thrombosis and is the major underlying cause of access failure.

However, access stenosis is not the sole cause of thrombosis. Access thrombosis has been reported to occur without radiologic evidence of a significant stenosis in up to 15% of grafts.[141] While imaging studies can miss hemodynamically significant stenosis, studies using prospective flow monitoring have also shown that access thrombosis occurs despite having a high access flow rate (over 1000 mL/min) and without a

significant change in access flow rate in the preceding months.[125,133,136,142–144] Clinical observation also suggests that many episodes of thrombosis occur in the night often after a preceding dialysis session. This suggests that volume depletion postdialysis with the resulting hemoconcentration and low cardiac output may predispose to access thrombosis. Thus, other factors likely contribute to the high rate of thrombosis in grafts.[145]

Acquired or inherited abnormalities in blood constituents, including platelets or components of the coagulation or fibrinolytic pathways, have also been examined as a possible cause of access thrombosis.[145,146] Overall, platelet function has been shown to be impaired and contribute to the hemostatic defect seen in people with ESRD.[146] However, platelet activation by the high shear stress and abnormal luminal surface posed by the arteriovenous graft likely contributes to graft thrombosis. In addition, hemodialysis has been shown to activate platelets and thus could contribute to graft thrombosis.[146,147] Patients with ESRD have evidence for an acquired hypercoagulable state that may underlie the increased risk for atherothrombotic events.[145,146] The prevalence of antiphospholipid antibodies, including anticardiolipin antibodies and to a lesser extent the lupus anticoagulant, is increased in people on hemodialysis.[148,149] Of the antiphospholipid antibodies, the lupus anticoagulant appears to be associated with a higher risk for thrombosis than anticardiolipin antibodies.[150] Several studies have reported an association between the presence of antiphospholipid antibodies and hemodialysis access thrombosis.[151–154] However, this association has not been confirmed in all studies.[149,155,156] Homocysteine is a risk factor for venous and arterial thrombosis.[157,158] Plasma homocysteine levels are elevated in people with end-stage kidney disease, and two studies have reported an association between plasma homocysteine levels and vascular access thrombosis.[159,160] On the other hand, several studies have failed to find an association between plasma homocysteine and access thrombosis.[133,136,161–164] Evidence for the hypercoagulable state includes an activated tissue factor pathway documented by increased circulating tissue factor and factor VII activity as well as evidence for thrombin activation, including increased circulating prothrombin activation fragments (F1+2) and thrombin-antithrombin complexes (TAT).[165–175] Elevated D-dimer levels are also found suggesting increased activation of both the thrombotic as well as the fibrinolytic pathways.[166,172,174–176] Coagulation pathways are also activated by inflammatory stimuli[169,177] that fluctuate with time in people with renal failure.[178,179] Hence, the risk for thrombosis likely will vary depending on inflammatory insults to the patient.[180] Insertion of a vascular access graft itself induces an inflammatory stimulus[179] that may contribute to the enhanced risk of thrombosis compared to an autogenous fistula.

Infection

Infections and their complications account for about 14% of the annual mortality in ESRD patients.[181] Infection of the vascular access graft is a particularly serious complication that can be difficult to manage and has been increasing as a cause of admission for hemodialysis patients.[181] In case series, the percentage of grafts that become infected has been reported to range between 2% and 35%, with most studies reporting rates between 5% and 15% over the duration of the observation.* One report found that the infection rate was

higher in the first year after access placement compared to the second year.[93] The majority of infections are due to *Staphylococcus aureus*.[182,185] Less commonly encountered organisms include *Staphylococcus epidermidis*, Streptococcal species, gram-negative bacteria, and occasionally, candida or other fungal species.[185] Infection or abscess around the graft may present with localized erythema and tenderness over the graft site, but graft infection can also present with fever and systemic symptoms without localized evidence of infection.[186–188] An indium-tagged WBC scan has been used to detect occult graft infections.[186,187,189,190] Serious complications of graft infection include: graft thrombosis, metastatic seeding leading to endocarditis, osteomyelitis, or murantic abcess as well as sepsis and death.[191] Nasal carriage of *S. aureus* has been reported as a risk factor for access infection.[192] Other factors that predispose to graft infection include frequent access surgeries and procedures, poor personal hygiene, intravenous drug abuse, and skin rash or infection.[182] Attention to bactericidal cleansing of the skin and infection control practices at the time of needle insertion in the dialysis unit is an important quality control measure. The use of preoperative vancomycin prior to access surgery has been recommended to decrease the frequency of subsequent post-operative graft infections.[193]

Management of graft infection usually requires excision of the infected graft material and treatment with antibiotics.[182,185,186] Vancomycin with addition of gram-negative coverage, if the patient is septic, is appropriate.[182,186] However, indiscriminant use of vancomycin has led to an emerging epidemic of vancomycin-resistant organisms. Hence, long-term use of vancomycin should be avoided and alternate antibiotics chosen as soon as the results of antibiotic sensitivity testing are known. A strategy to limit vancomycin use consists of initiating therapy with a first generation cephalosporine and an aminoglycoside until culture and sensitivity results are known and then adjusting the antibiotic regimen accordingly.[186] If alternate access sites are limited and the infection is localized outside the graft, local incision and drainage of the access site without removing the graft can be attempted.[182,188,194] Skin grafting may be required to close the wound over the graft after the infection has resolved. An alternate approach studied recently is to replace the infected prosthetic graft with a biograft that is more resistant to infection.[195–197] If an endovascular source of infection is present, it should be treated for 6 weeks with appropriate intravenous antibiotics to reduce the risk for late sequelas from metastatic seeding.

Arteriovenous Steal

Impaired perfusion of the extremities below the level of the vascular access is a serious and debilitating complication that can occur after placement of either an arteriovenous fistula or graft.[107,198–202] Distal ischemia occurs when the relatively low resistance shunt accommodates more flow than can be delivered by antegrade flow through the inflow artery feeding the fistula.[202] In this case, the fistula also "steals" blood from the artery below the fistula (Figure 17–5). This retrograde flow lowers the perfusion pressure in the distal extremity, and if this falls below a critical level, it will lead to tissue ischemia.

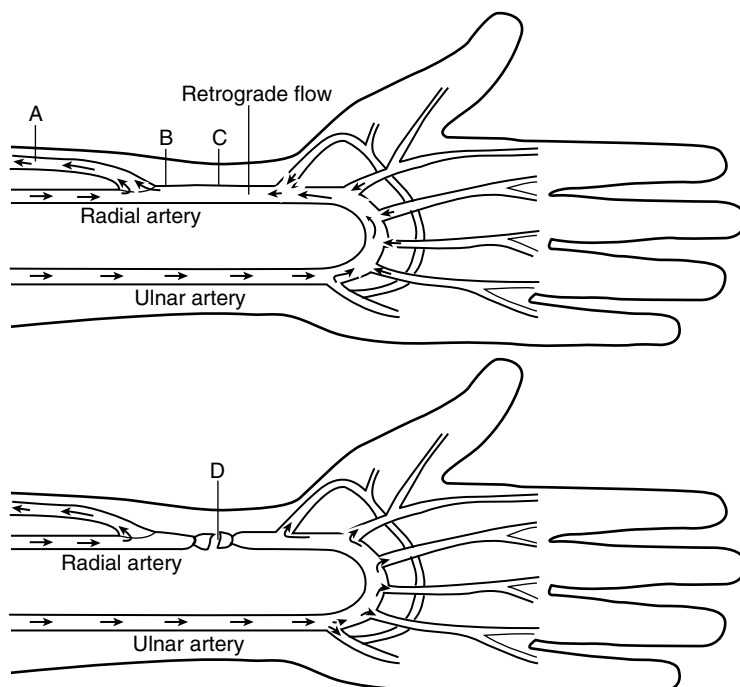
Ischemic monomelic neuropathy, a syndrome characterized by acute pain, weakness, and paralysis of the extremity often in association with sensory loss is a rare complication occurring in patients who get an upper arm access involving the brachial artery.[200,203] It is due to impaired blood supply to nerves in the forearm leading to axonal degeneration without


Figure 17–5 Pathogenesis of arteriovenous steal. Steal occurs when the arteriovenous fistula *(A)* receives both antegrade and retrograde *(C)* flow from the radial artery. (*B* is the arteriovenous anastomosis). Steal can be corrected by ligation of the radial artery below the fistula *(D)*. (From Miles AM: Vascular steal syndrome and ischaemic monomelic neuropathy: Two variants of upper limb ischaemia after haemodialysis vascular access surgery. Nephrol Dial Transplant 1999; 14:297-300. By permission of Oxford University Press.)

evidence of ischemic damage to muscle or other tissues in the forearm. In contrast to the classic steal syndrome the radial pulse is usually palpable, and digital pressure is usually greater than 50 mmHg. The patients are typically diabetic, older, and with preexisting neuropathy or vascular disease. Symptoms occur immediately or within hours after access placement in the upper arm and are very difficult to reverse unless the problem is recognized and treated immediately. It is important to recognize the signs and symptoms rapidly at the time of access placement so the access can be ligated before further irreversible damage occurs.[200,203]

Mild symptoms of steal occurring shortly after access placement can be treated symptomatically and observed. In more severe cases, ligation of the access will cure the problem but leaves the patient without an arteriovenous access for dialysis. A number of surgical approaches have been suggested to deal with this problem while leaving the access intact for dialysis.[204] One approach is to decrease flow through the fistula by banding or plicating the fistula until pressure in the hand is measured to be above 50 mmHg.[205,206] This can relieve the symptoms of ischemia, however, most accesses fail shortly after banding due to thrombosis.[198,201,205] An alternate procedure was described by Schanzer and colleagues[207,208] in 1988, in which the artery distal to the fistula is tied off to prevent retrograde flow from stealing blood from the periphery, and then a vein graft is used to place an arterial bypass from the inflow artery above the fistula to a site on the artery just below the ligation. The arterial bypass maintains arterial pressure in the ligated distal artery, thus preventing steal and allowing perfusion of tissue below the fistula. This surgery was later christened the distal revascularization-interval ligation (DRIL) procedure and appears to be quite effective at eliminating steal symptoms while maintaining a functional hemodialysis access.[209,210]

Heart Failure

High output cardiac failure that resolves with closure of the arteriovenous shunt is a well documented but uncommon complication of arteriovenous grafts and autogenous fistulas.[211–214] The greatest risk appears to be in people with an autogenous fistula placed in the upper arm (e.g., brachiocephalic fistula).[211–214] However, high output failure has been reported with ePTFE grafts.[183]

Blood flow in a functional hemodialysis access generally runs between 0.75 to 2.5 liters per minute with occasional patients having blood flows up to 4 or more liters per minute.[92,133,212,214–217] Most patients can maintain this access blood flow over many years without developing clinical evidence of heart failure.[92,218,219] However, this high access flow may contribute to the development of LVH in some patients.[220] Measurement of access blood flow by itself does not identify those with existing or impending high output failure.[212] A drop in heart rate of 7 bpm or more after shunt closure is one sign used to detect a hemodynamically significant shunt (Nicoladoni-Branham's sign) but may be absent in dialysis patients with high output failure.[212,214] A decrease in cardiac output with shunt closure that is significantly less than the measured shunt flow in the unclamped fistula may also be an indication of high output failure due to an arteriovenous shunt.[212] However, this observation needs further validation. If myocardial function cannot be improved by other means,

then the arteriovenous shunt may need to be ligated to resolve the high output failure. Banding of the access in an attempt to decrease access flow has been tried but is usually met with limited success either due to inadequate reduction in flow on one hand or access thrombosis on the other.

Aneurysm/Pseudoaneurysm

True aneurysms occur when the vessel wall becomes weak and dilates. Pseudoaneurysms occur due to vessel trauma most commonly at needle puncture sites leading to a localized extravasation of fluid in which the wall is composed of perivascular adventia, fibrous tissue, and hematoma. Most commonly the etiology for these aneurysms is "one site-itis" in which there are frequent repetitive needle sticks into one or two regions of the access. However, infection may also be a cause of aneurysm formation, particularly in biografts. Aneurysms and pseudoaneurysms occur more commonly in biografts than in the currently used reinforced synthetic grafts. Aneurysms and pseudoaneurysms that occur in grafts can be surgically resected and replaced with a new section of graft that preserves the access site for future use.

Venous Hypertension

An increase in venous pressure is a physiologic consequence of all arteriovenous shunts. If the venous valves are incompetent, then retrograde flow may result. In most cases the symptoms are mild and resolve with time. The presence of significant venous hypertension results in dilated veins, swelling of the distal extremity, and bluish discoloration of the skin. Over time, severe and persistent venous hypertension can lead to chronic venostasis changes, such as thickening and discoloration of the skin as well as skin ulceration and pain.[221] A central venous stenosis is the most common etiology for severe venous hypertension occurring after placement of a hemodialysis graft. Angiography of the proximal venous outflow tract and central veins is indicated. If a stenosis is located it can be treated with angioplasty and stenting in an attempt to decrease symptoms and preserve access function.[222–225] In severe cases, the access may need to be ligated to preserve the extremity.

ACCESS STENOSIS

Pathophysiology

Access stenosis is the most common underlying etiology for access thrombosis and failure. The stenotic lesion at the venous anastomosis has been characterized pathologically as a dense neointimal hyperplasia.[226–231] Histochemically, the neointimal thickening consists predominantly of alpha smooth muscle actin containing cells (vascular smooth muscle cells and myofibroblasts) along with associated extracellular matrix material.[226–229,231] Prominent capillary infiltration (angiogenesis) is found throughout the neointima and particularly at the intima-media boundary.[228,229,231] Macrophages are found lining the surface of the graft, infiltrating the graft matrix, in the adventitia of the vein and in association with capillaries in the neointima.[227,229,231] Immunohistochemical studies reveal that the neointima stains strongly for the smooth muscle mitogens PDGF, FGF, insulin-like growth

factor and endothelin, the matrix stimulating cytokine TGFβ, and the endothelial mitogens VEGF and FGF.[230,232,233] Indices of increased oxidative stress have been reported within the neointima.[230,233] Increased cellular proliferation is present throughout the lesion in the neointima, media, and adventia.[227,229,231] Proliferation of smooth muscle cells is frequently associated with proliferation of nearby endothelial cells.[227,229,231] In contrast to advanced atherosclerotic lesions, a lipid core and fibrous cap are not seen.[227,229,231] These findings document that vascular access stenosis is a dense lesion characterized by a high rate of proliferation of both vascular smooth muscle and endothelial cells along with abundant extracellular matrix material.

The exact pathophysiology leading to the venous neointimal hyperplasia in arteriovenous grafts is not known but is assumed to involve some of the same processes leading to neointimal hyperplasia seen after arterial injury.[234–236] The predominant localization of stenosis at the graft-vein anastomosis and in the immediate downstream vein suggests that mechanical injury at the time of surgery, the inflammatory reaction to the graft material, venous hypertension, increased turbulence, and altered wall shear stress may all be factors that contribute to neointimal hyperplasia.

MONITORING TO DETECT GRAFT STENOSIS

Longitudinal observational studies have shown that an active access surveillance program can decrease the rate of graft thrombosis and may increase overall access survival.[111,114,128,237] Based on these studies, the guidelines from the National Kidney Foundation/Dialysis Outcomes Quality Initiative (K/DOQI) recommended an organized approach to access surveillance with regular assessment and tracking of access function to detect and treat access stenosis.[114] Several approaches are used for access surveillance (Table 17–5).[114,238] The optimal approach would have a high sensitivity and specificity for the detection of access stenosis, be easy to perform at each dialysis session, and inexpensive. Currently, no surveillance technique has been shown to meet all of these criteria.

Clinical examination of the graft and downstream vein by an experienced observer can detect hemodynamically significant access stenosis, particularly when it occurs at the venous anastomosis or immediate downstream vein.[239] The examination should focus on noting the presence and location of any palpable thrills, the character of the pulse, and the nature of the audible bruit (Table 17–6). Development of significant swelling in the access arm suggests the presence of a central vein stenosis most likely from a prior central catheter or cardiac pacemaker. In the hands of an experienced examiner a careful clinical exam reportedly has a positive predictive value of 92% to detect a hemodynamically significant stenosis.[95, 239]

From basic fluid mechanics, access flow rate (Qa) is determined from the pressure drop across the access ($\Delta P = MAP - CVP$) divided by the access resistance (R).

$$Qa = \Delta P \div R = (MAP - CVP) \div R \quad (1)$$

where MAP is the mean arterial pressure and CVP is the central venous pressure. Access stenosis in the range of 50% to 60% leads to an increase in resistance that can be detected by a measurable decrease in access flow rate.[240] Most of the resistance in an arteriovenous access occurs on the arterial side of the access.[215,241,242] In a well functioning graft, resistance on the arterial side of the graft is two to three times that on the venous side of the graft.[215,241,242] Development of a stenosis at the venous anastomosis leads to an increase in the venous resistance such that the venous resistance becomes equal to or greater than the arterial resistance. This leads to an increase in the intra-access venous pressure (P_{IA}) upstream of the stenosis and a decrease in access flow rate. Assuming MAP and cardiac output are constant and there is no change in peripheral shunting through other vascular beds, a decrease in access flow rate or an increase in P_{IA} can be used to detect venous access stenosis.[215,242] When access flow rate significantly falls below the speed of the dialysis blood pump, then recirculation develops and blood from the venous return needle is drawn into the arterial needle (recirculated). Adequate solute clearance during dialysis is then limited by the access flow rate. Hence, measurement of access recirculation, intra-access pressure, and flow rate are all techniques that have been used to detect access stenosis. However, access recirculation only detects critical access stenosis that produces an access flow rate less than the dialyzer blood pump speed, and this may be too late to intervene and prevent access stenosis from leading to thrombosis.[136,243] In addition, measurement of recirculation will miss a critical stenosis that occurs within the body of the graft between the arterial and venous needles.

Table 17–6 Clinical Examination to Detect Access Stenosis

Parameter	Normal	Stenosis*
Thrill	Only at arterial anastomosis	At site of stenotic lesion
Pulse	Soft, easily compressible	Water-hammer
Bruit	Low-pitched	High-pitched
	Continuous	Discontinuous
	Diastolic and systolic	Systolic only

*Abnormalities listed are for the two extremes: completely normal and severe stenosis. With lesser degrees of stenosis the findings will be between these two extremes. (From Beathard GA: Physical examination of the dialysis vascular access. Semin Dial 1998; 11:231-236.)

Venous pressure within the access has been used to detect the presence of access stenosis.[238] The simplest technique is to use the venous pressure measured in the post-dialyzer venous drip chamber during dialysis as an index of intra-access pressure. A dynamic venous drip chamber pressure (P_{DC}) greater than 150 mmHg measured 30 minutes into dialysis at a dialyzer pump speed of 200 mL/min is predictive of access stenosis.[111] While monitoring P_{DC} has been shown to detect venous stenosis in grafts and decrease access thrombosis[111,124,242]; its accuracy to detect stenosis and prevent thrombosis is reduced compared to other measures, including intra-access pressure at zero flow or access flow rate.[48,142,242,244,245]

Intra-access venous pressure P_{IA} can be measured directly from a needle inserted into the access.[132,316,325] When normalized for blood pressure (e.g., P_{IA}/MAP, the venous access pressure ratio, VAPR), a VAPR above 0.5 has been shown to have a relatively high sensitivity (81%) and low false-positive rate (20%) for the detection of a 50% diameter stenosis.[242,246] Routine use of intra-access pressure monitoring has been shown to decrease the rate of access thrombosis and prolong access survival compared to historical controls.[128,245] However, two more recent studies have concluded that the VAPR lacked the necessary sensitivity and specificity needed to accurately predict access thrombosis.[247,248] Further study will be needed to sort out the reasons for these discrepancies. In addition, direct measurement of intra-access pressure requires special equipment and is not practical for routine screening.

Using access flow monitoring an access flow of less than 600 mL/min or a 20% decrement in flow that falls below 1000 mL/min has been reported to predict the presence of a greater than 50% stenosis or an increased risk of thrombosis in a graft.[114,135,136,142–144] Several studies have also reported that routine monitoring of access flow rate can decrease the frequency of access thrombosis and overall cost of access management.[129,131,237,245] However, several recent studies that examined the receiver operating characteristic (ROC) curves have questioned whether measurement of access flow rate has the necessary performance characteristics (e.g., sensitivity and specificity greater than 80%) to be a good screening tool to prevent access thrombosis.[247,249,250] Moreover, two recent prospective randomized studies in subjects with established grafts found that routine monthly monitoring of access flow rate led to an increased rate of angioplasty but failed to decrease access thrombosis or prolong graft survival, compared to a control group that received usual graft monitoring.[133,251] In one study, the angioplasty rate in the control group (0.61 per patient year) was already comparatively high, and the baseline thrombosis rate (0.41 per patient year) as well as the overall graft survival rate were much better than generally reported in the United States. This suggests that there may be a threshold rate of angioplasty and that addition of access flow monitoring and additional angioplasty onto an aggressive and successful access monitoring program may not be beneficial.[251]

An alternative to hemodynamic measurements is direct visualization of the access by Duplex ultrasound, angiography, or magnetic resonance angiography (MRA).[238,252–257] An additional advantage of Duplex ultrasound and MRA is that they can provide information on access flow rate.[253,255,256] Several studies have documented the ability of routine Duplex ultrasound monitoring to detect access stenosis and decrease the rate of access thrombosis.[131,133,258] As discussed above, a recent randomized prospective trial also reported that quarterly Duplex ultrasound studies were better than monthly access flow monitoring in detecting access stenosis and preventing access thrombosis. However, overall access survival was not prolonged.[133] Moreover, Duplex ultrasound requires specialized equipment and training and may not be practical for routine monitoring in most dialysis units. Similarly, the use of MRA or angiography are not practical or cost-effective to use for routine access screening but are useful to confirm the suspected stenosis and to plan the appropriate therapeutic intervention.

In summary, careful monitoring of grafts to detect and treat stenosis has been shown to decrease the thrombosis rate at the expense of an increase in the angioplasty rate. Despite this trade-off, a routine monitoring program has been reported to decrease overall access costs and certainly converts the "crisis" of unexpected access thrombosis into a more manageable program of scheduled intervention and treatment. Based on these observations, K/DOQI guidelines recommend an organized approach to access surveillance with regular assessment and tracking of access function to detect and treat access stenosis. At this time, there is no single preferred technique that is low cost and easily performed at each dialysis session and also has the high sensitivity and specificity desired of a screening test. Each hemodialysis unit will need to decide on an approach that works best to fit their needs. Further research and technologic advances are needed in this area. Moreover, despite careful monitoring, access thrombosis and failure will continue to be a problem, and better treatments to prevent and treat graft stenosis and thrombosis are needed.

TREATMENT AND PREVENTION OF GRAFT FAILURE

Graft stenosis detected on routine screening can be treated by either surgical resection or percutaneous transluminal angioplasty. Depending on the site of the stenosis, surgical treatment may consist of an outflow patch graft to widen the venous anastomosis, resection of a stenotic segment, or bypass of the stenosis often requiring anastomosis to a new segment of artery or vein. Angioplasty has become the preferred method in most centers for the initial treatment of access stenosis because it can be done at the time of confirmatory angiography, and it preserves vessels for future surgery.[259,260] The stenotic lesions are denser than typical atherosclerotic lesions and require a higher balloon pressure (up to 20 atm for at least 1–2 minutes) to achieve a satisfactory result (typically defined as <30% stenosis after angioplasty).[259,261] Restenosis occurs rapidly after angioplasty with a median patency of about 6 months.[95,116,122,260] Use of endovascular stents has not been shown to prolong the primary patency after angioplasty of graft stenosis.[262–264] However, stents may be useful in selected situations, such as rapid recurrent re-stenosis, significant elastic recoil after angioplasty or where alterautogenous surgical options are limited.[265] Endovascular stents are also frequently employed to treat central venous stenosis where surgical options are limited.[222–225,266] However, multiple reintervention is often

necessary to maintain patency of the central veins. Endovascular stents have been used to treat access complications, such as venous rupture after balloon angioplasty or pseudoaneurysms.[267,268]

If access thrombosis has occurred, percutaneous thrombolysis or surgical thrombectomy is required to restore patency and should be followed by angiography or other imaging technique to detect and treat any underlying stenosis. A crossed-catheter pharmaco-mechanical approach using a thrombolytic agent is most frequently used for percutaneous thrombolysis, but mechanical thrombolysis using saline has also been shown to be effective.[117,119,261,269–272] Percutaneous thrombolysis and surgical thrombectomy have been reported to be similarly effective at restoring short-term patency as long as stenotic regions are identified and treated.[123,273–276] Advantages and disadvantages of both approaches have been debated.[118,277] For both approaches, re-stenosis after thrombosis occurs more rapidly (median patency about 90 days) than after angioplasty for stenosis without thrombosis.[112,118–120,365] Although repeated angioplasty can preserve access function temporarily, access patency tends to decline with each angioplasty.[3] Ultimately, surgical revision or placement of a new access is required in most people who suffer recurrent bouts of graft stenosis and thrombosis.

Given the high costs and patient morbidity associated with treating graft stenosis and thrombosis, increasing attention has been directed to the primary prevention of these complications. Since thrombosis is the ultimate cause of access failure, treatment with anticoagulants and antiplatelet agents have been tried.[150] In uncontrolled trials, anticoagulation with warfarin or heparin has been reported to prolong access survival in people who have had frequent access thrombosis often in association with antiphospholipid antibodies.[151,152] In a small study of 16 people with anticardiolipin antibodies and recurrent thrombosis, the use of warfarin (target INR of 2–3) also produced a small but statistically significant increase in graft survival.[278] However, a recent randomized controlled trial of low dose warfarin, targeting an INR of 1.4 to 1.9, found no benefit (and possible harm) of warfarin over placebo in preventing access thrombosis in subjects who received a new hemodialysis graft.[279] Use of anticoagulants should not be used as a general strategy to prevent graft thrombosis, however, in selected patients with frequent graft thrombosis and known prothrombotic conditions these agents can be considered if the benefit appears to outweigh the risk.

Antiplatelet agents have been examined in randomized controlled trials to prevent graft occlusion.[280,281] In one study, 84 people who received a new graft were randomized to treatment with either aspirin, dipyridamole, aspirin plus dipyridamole, or placebo and found that aspirin alone did not prevent and, in fact, tended to increase the risk of graft thrombosis.[282] Surprisingly, dipyridamole alone or in combination with aspirin was found to decrease the risk of graft thrombosis.[282] Since dipyridamole alone is a weak antiplatelet agent, this suggested that the effect of dipyridamole to inhibit graft thrombosis might be mediated by another mechanism. This concept is currently being tested in a large randomized clinical trial. More recently, the results of the randomized controlled VA Cooperative trial have been reported looking at the effect of the combination of aspirin (325 mg/day) plus clopidogrel (75 mg/day) compared to placebo on graft thrombosis in 200 subjects with prevalent grafts.[283] The study was terminated early due to a twofold increased risk of bleeding in the treatment group without observing any overall benefit of the therapy to reduce graft thrombosis. However, the study did note a trend towards improved graft survival using aspirin plus clopidogrel in the subgroup of subjects who had never suffered an episode of graft thrombosis.[283] Aspirin has also been noted to be associated with a decreased risk of graft thrombosis in two recent prospective observational studies.[251,284] Taken together, the results from randomized controlled trials do not currently support the use of antiplatelet agents to prevent graft thrombosis. However, given the positive results from the observational studies and the benefit of these agents in other arterial vascular diseases, the question of whether an antiplatelet agent can reduce graft thrombosis and prolong graft survival remains unresolved. The question may well be whether the benefit to prevent graft thrombosis will outweigh the increased risk of bleeding.

Fish oil capsules containing omega-3 polyunsaturated fatty acids have been shown in several randomized controlled trials to reduce the risk of atherothrombotic events (i.e., recurrent myocardial infarction and death) in people who have known coronary artery disease.[285,286] In 1990, a small pilot study of fish oil was done in seven hemodialysis patients who had frequent recurrent graft thrombosis and found no effect on graft thrombosis at 6 months, but the study was underpowered.[287,288] Recently, a randomized, double-blind trial of fish oil capsules (4 g/day) compared with a corn oil control was performed in 24 subjects (12 in each group) who received a new ePTFE graft.[289] The study medication was started within 2 weeks after access surgery and follow-up was for 1 year or until access thrombosis developed. A dramatic reduction in the incidence of graft thrombosis was seen in the subjects treated with fish oil (primary patency at 1 year was 14.9% in the control and 75.6% in the fish oil-treated groups).[289] A larger randomized trial of fish oil is needed for confirmation of this effect.

At this time, there is no proven therapy that can delay or prevent graft failure. Many new therapies are on the horizon that offer promise to prevent neointimal hyperplasia and prolong graft survival.[290] Local therapy applied at the vein-graft anastomosis at the time of graft surgery is a new approach that can limit systemic drug toxicity and allow a therapeutic agent to be focused at the major site of neointimal hyperplasia. An example of this therapy is the recent successful trial of an oligonucleotide decoy to the E2F transcription factor applied to vein grafts at the time of coronary artery bypass surgery.[291] A trial of this therapy for dialysis grafts (PREVENT V) is currently underway. Other local therapies applied either to the luminal or advential side of the vein-graft anastomosis are being considered, but concerns regarding impaired healing and aneurysm formation leading to vein rupture will need to be monitored.

Finally, in addition to graft design and pharmacologic therapy, attention to details in surgical placement, graft cannulation, and infection control practices, as well as maintenance of facility access databases to monitor outcomes, are all aspects of routine care that are difficult to quantitate but are likely to contribute to prolonging access survival.

Biocompatibility of Hemodialysis Membranes

Bertrand L. Jaber, M.D. • Brian J.G. Pereira, M.D., M.B.A.

During hemodialysis (HD), blood comes into contact with several components of the extracorporeal circuit. These include: (1) the dialyzer itself (dialysis membrane, sterilants used during the manufacturing process, and substances that leach from the dialyzer), (2) extracorporeal circuit (temporary vascular access, bloodlines, and cannulas), (3) chemicals used for reprocessing (germicides and cleansing agents), and (4) contaminants in the dialysate. Exposure to each of the above components can result in perturbations of cellular or plasma components of blood. This chapter will restrict its focus on the dialyzer membrane. To date, there is no precise definition of "biocompatibility," which is uniformly agreed upon by nephrologists and bioengineers. In general, a biocompatible dialysis membrane refers to one that elicits little or no reaction from the patient as the result of blood contact with the biomaterials. Reactions resulting from ultrafiltration of fluid or exchanges of electrolytes through the semipermeable membrane are usually excluded from these discussions. This chapter will focus on the alterations in cellular and noncellular elements induced by the blood-membrane interactions during hemodialysis.

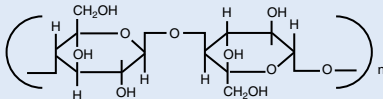
BIOMATERIALS USED FOR ARTIFICIAL KIDNEY MEMBRANES

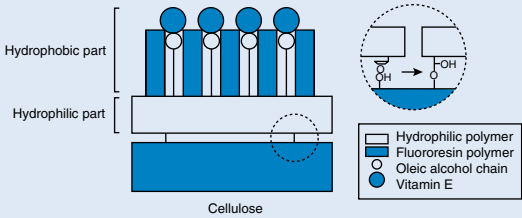
Biomaterials for hemodialysis membranes are broadly classified into unsubstituted cellulose, substituted (modified) cellulose, and synthetic[1] (Table 18–1).

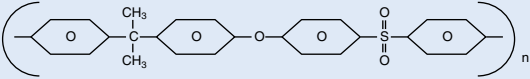
Unsubstituted Cellulose

Cellulose membranes are composed of regenerated cellulose in which the basic structure is a linear chain of glucosan rings with free surface hydroxyl groups. The first hemodialysis membranes that were used clinically in the 1940s were tubes of cellophane, regenerated from cellulose and originally manufactured for sausage casings. Unfortunately, these cellophane tubings were not very stable and leaked frequently, necessitating immediate repair *in situ*. Virtually all hemodialysis membranes used until the late 1960s were made from cellophane or similar materials.

During the 1960s, cuprophan (CU) membranes were developed by regeneration of cellulose using the cuprammonium process (a modification of the process for preparing cellophane). These cuprammonium membranes have been used extensively for hemodialysis since they can be made thin, are mechanically strong, and provide good diffusive transport properties for small solutes. The cuprophan trademarked name

has become so popular that the generic terms "cuprophan" and "cuprophane" are frequently used to describe all cuprammonium membranes, even though cuprammonium membranes are manufactured by several other companies and are not all identical.






Regenerated cellulose, predominantly as cuprammonium membranes, continues to be used in more than 50% of all dialyzers throughout the world due to their low cost.[2] In the United States, however, there has been a persistent decline in the use of these membranes, at the expense of an increase in the use of substituted cellulose and synthetic membranes (Figure 18–1).[3] All regenerated cellulose membranes are highly hydrophilic because of the large number of free hydroxyl groups on the cellulose monomer, and they are homogeneous in structure; their porosity is similar throughout the entire membrane thickness. Although the original membranes made, using the cuprammonium process, had low permeability to solutes larger than urea, cuprammonium membranes with high permeability to larger solutes are currently available.

Substituted (Modified) Cellulose

The substitution of the free surface hydroxyl groups on cellulose membranes results in substituted or modified cellulose membranes. Accordingly, substitution of an increasing fraction of the surface free hydroxyl groups with acetyl residues leads to cellulose acetate (CA) or diacetate (80% substitution), and cellulose triacetate (CTA) (100% substitution) membranes, respectively. Cellulose acetate and cellulose triacetate membranes are more hydrophobic than regenerated cellulose membranes because of acetylation of the hydroxyl moieties on the cellulose monomer. Substitution of 1% of the hydroxyl radicals on cellulose with the tertiary amino residue, diethylaminoethyl (DEAE) is the principle behind the manufacture of hemophan membranes.[4–6] All of the above modified cellulose membranes are morphologically homogeneous under scanning electron microscopy. In general, substituted/modified cellulose membranes have substantially less complement activating potential than unsubstituted cellulose membranes. However, to what extent the number of free hydroxyl groups determines the degree of complement activation by cellulose membranes remains controversial and will be discussed subsequently.

A new generation cellulose membrane, excebrane, has recently been developed by covalent binding of synthetic block polymers to the hydroxyl groups on cellulose. In addition to the reduced complement-activating potential, the oleyl alcohol and vitamin E that are incorporated into the synthetic

Table 18–1 Classification of hemodialysis membranes

Biomaterial	Chemical structure	Common name
Cellulose		Cuprophan
DEAE-substitued cellulose		Hemophan
Cellulose diacetate and triacetate		CA, CTA
Multi-layer vitamin E–coated cellulose		Excebrane
Polysulfone		F-series Optiflux-series
Polyamide		Polyflux-series
Polyacrylonitrile and methallyl sulfonate		AN-69
Polyacrylonitrile and methacrylate		PAN
Polymethylmethacrylate		PMMA

surface reduce thrombosis and provide antioxidant reserves, respectively.[7,8] Compared with CA and polyamide (PA) membranes, excebrane membranes have been associated with better immune function parameters, as measured by lower IL-6 production levels and less activation of mononuclear cell-Jun N-terminal kinase.[9,10] Although surface modification of CU dialyzers with vitamin E may enhance biocompatibility and improve cytokine levels as well as immune function, the clinical significance of these findings in terms of outcomes is unclear.

Synthetic (Noncellulose) Polymers

Various synthetic membranes were developed during the 1970s primarily for use as hemofilters, although some of them were also used as hemodialysis membranes. AN69 was originally prepared from a copolymer of acrylonitrile and methallyl sulfonate. The latter polymer contains negatively charged ionizable groups. This property was originally deemed desirable for a dialysis membrane because a negatively charged membrane might mimic the glomerular basement

Table 18–2 Biologic Responses Elicited by Blood-Hemodialysis Membrane Interactions

Blood Components	Biologic Responses
Humoral Components	
Complement system	Alternate pathway activation
	Anaphylatoxin (C3a, C5a) production
Coagulation system	Factor XII activation
	Intrinsic pathway activation
	Increased tissue plasminogen activator
Cytokines	Equivocal increased circulating levels
Cellular Components	
Platelets	Platelet activation
	Increased platelet adhesion
	Thrombocytopenia
	Thromboxane A2, adenosine diphosphate (ADP) and platelet factor 4 release
Erythrocytes	Hemolysis (rare)
Neutrophils	Leukopenia
	Increased expression of adhesion molecules
	Degranulation and release of proteolytic enzymes
	Release of reactive oxygen species
	"Exhaustion" and decreased responsiveness to subsequent stimuli
Lymphocytes	T-lymphocyte activation
	Impaired T-lymphocyte proliferative responses
	B-lymphocyte activation
Monocytes	Increased intracellular interleukin-1 mRNA and protein expression
	"Exhaustion" and decreased responsiveness to subsequent stimuli

membrane.[11] However, recent studies demonstrate that such negative charges may impart a specific bioincompatible characteristic. The AN69 membrane is also morphologically homogeneous.[12] Polysulfone and polyamide membranes, too, were originally developed for use as hemofilters and were highly asymmetric and hydrophobic. Such membranes required a thick supporting layer to provide mechanical strength to the thin and highly porous inner skin of the hollow fiber. Diffusion rates for small solutes across these membranes were therefore low. Addition of polyvinylpyrrolidone into the manufacturing process[13,14] led to membranes that exhibited high diffusive as well as high convective permeability properties. Such membranes are asymmetric[12,15] but exhibit a sponge- or foam-like structure not the large finger-like pores of the original membranes. Polysulfone membranes with various porosities are now commercially available. Other synthetic membranes in clinical use include polyacrylonitrile (PAN), polymethyl methacrylate (PMMA), polyethersulfone (PES), and polycarbonate.[16] With the exception of polycarbonate, all these synthetic membranes are hydrophobic and tend to adsorb cells and plasma proteins. In contrast, hydrophilic membranes, such as polycarbonate, do not adsorb cells or proteins but activate cells and proteins. However, the manufacturing methods for a given biomaterial can vary between manufacturers and, consequently, the biocompatibility of a given membrane too. Biologic responses elicited by blood-hemodialysis membrane interactions are summarized in Table 18–2.[17]

High flux refers to membranes with larger pore size, which possess high ultrafiltration coefficients ($K_{UF} > 14$ mL/hr/mmHg), and permit clearances of middle molecules (β_2 microglobulin clearance >20 mL/min). Although high-flux dialyzers were originally manufactured with synthetic membranes, cellulose membranes can also be configured to have larger pore sizes, by altering the manufacturing process. Conversely, synthetic membranes can be manufactured as low-flux dialyzers. Dialyzers with cellulose membranes are often termed "conventional" dialyzers because of the modest urea clearances and relatively small pores. However, the urea clearance can be significantly enhanced by larger surface area, and these dialyzers are termed "high efficiency" dialyzers. Given the differences in clearances, flux and biocompatibility characteristics among the many different types of dialyzers, a detailed knowledge of membrane properties is necessary to ensure appropriate dialyzer prescription.

COMPLEMENT ACTIVATION

Activation of the Complement System by Dialysis Membranes

Since the early 1980s, complement activation has been the standard for assessment of dialysis membrane biocompatibility. Consequently, membranes are often classified as biocompatible or bioincompatible, based on their ability to activate complement. The complement system is comprised of two cascades of plasma proteins that can be sequentially activated

by proteolytic enzymes.[18] Activation of either the classic pathway or alternative pathway leads to activation of C_3 and, under conducive conditions, activation of the terminal components (C_5, C_6, C_7, C_8, C_9). Complement activation on cuprophan and cellulose acetate membranes occurs primarily via the alternative pathway (Figure 18–2),[19–22] although the classic pathway may also contribute. The mechanism by which complement activation occurs on other membranes is less certain.

Biologic Activity of Complement Activation Products

Activation of C_3 results in the generation of anaphylatoxin C_{3a} (M_r ~9 kDa),[18] which is usually released into the serum. Larger fragments such as C_{3b} (M_r ~186 kDa) and its degradation product $_iC_{3b}$ are also produced. These larger fragments may also be important because they can modulate cellular functions by interacting with specific cytoplasmic membrane receptors.[23] For example, $_iC_{3b}$ mediates cell adherence[24] and induces the release of intragranular proteolytic enzymes[25] by interacting with complement receptor type 3 (CR_3, Mac_{-1}, or CD_{11b}/CD_{18}) on neutrophil surface. It is important to recognize that assessment of complement activation during hemodialysis, using plasma C_{3a} and C_{5a} as markers, may not adequately reflect its effect, because the larger $_iC_{3b}$ fragment may remain in the plasma and exert its biologic effects, whereas the smaller markers (C_{3a} and C_{5a}) may be lost from the plasma into the dialysate or by adsorption onto the dialysis membrane surface.

Anaphylatoxins C_{3a} and C_{5a} are spasmogenic, increase vascular permeability,[26] release histamine from mast cells,[27] stimulate contraction of smooth muscles,[28] induce degranulation from neutrophils,[29] and promote the transcription and/or release of cytokines from monocytes. Intracoronary bolus infusion of human C_{3a} produces tachycardia, atrioventricular conduction defect, left ventricular failure, and coronary vasoconstriction in animals.[30] Complement C_{5a} induces neutrophil chemotaxis, aggregation,[31–33] attachment to pulmonary endothelial cells, release of leukotriene B_4,[34] oxygen radicals,[35] and intragranular enzymes,[33,36,37] as well as altered expression of cell surface receptors.[38] C_{5a} has also been shown to release β_2-microglobulin from peripheral blood mononuclear cells[39] and stimulate the release of leukotrienes from guinea pig lung strips.[40]

Anaphylatoxins C_{3a} and C_{5a} are degraded by carboxypeptidase N in the serum[41] into $C_{3a\ desArg}$ and $C_{5a\ desArg}$, respectively.
Figure 18–2 Schematic diagram of complement activation via the alternative pathway on the membrane surface. Underlined text inhibits reaction.

The desarginine derivatives are considerably less spasmogenic than their precursors,[41–43] but they retain certain leukocyte-directed activities. Activated terminal complement components (C5b-9 or membrane attack complex) that are released into the plasma are inactivated by binding to plasma S protein to form the SC5b-9 complex. Limited data suggest that terminal complement components activated in association with hemodialysis membranes have biologic activities *in vitro*.[44]

Assays for Complement Activation

Because C3 activation does not necessarily lead to activation of the terminal components and each activated complement product (e.g., C3a, C5a, and C5b-9) has its own biologic activities, ideally, each level of the activation pathway should be assessed.[45] The radioimmunoassays (RIA) for human C3a that are commonly used detect both the anaphylatoxin C3a and $C3a_{desArg}$. Practically all the C3a in clinical plasma samples are in the form of $C3a_{desArg}$. Immunoassays for iC3b are also commercially available. The RIA for C5a also detects both C5a and $C5a_{desArg}$. The membrane attack complex (SC5b-9) can also be quantitated using immunoassays. C3a and C5a can also be assessed by commercially available enzyme-linked immunosorbent assays.[46]

Complement Activation Associated with Different Hemodialysis Membranes

Based on plasma $C3a_{desArg}$ concentrations, cuprophan and unsubstituted cellulose membranes are the most potent complement activators among dialysis membranes (Figure 18–3).[19,47,48] Plasma $C3a_{desArg}$ concentrations usually peak between 10 and 20 minutes after starting dialysis and decline to almost baseline values by the end of the treatment. On a molar basis, plasma $C5a_{desArg}$ and SC5b-9 levels are usually lower than those of $C3a_{desArg}$[19,44,48] because activation of the late components of complement is usually less efficient than that of C3.[49] Binding of C5a to its receptor on neutrophil surfaces may also lower its plasma levels to a modest extent.[25]

Substituted cellulose membranes such as cellulose acetate and hemophan are associated with lower C3a levels than cuprophan.[50] Cellulose triacetate membranes and the synthetic polymer membranes are associated with lower plasma C3a levels than cuprophan or cellulose acetate.[19,44,51,52] Nonetheless, all dialysis membranes in clinical use, without exception, are associated with complement activation, albeit to differing degrees.

Complement activation by cuprophan membrane can be attenuated by either cooling the extracorporeal blood,[53] chelating Mg^{++} in the plasma during citrate hemodialysis,[54] or increasing the amount of heparin in the circuit.[55] Cuprophan membranes reprocessed with formaldehyde or peracetic acid are also associated with less complement activation and leukopenia than new dialyzers.[48,51,56] This reduction is presumably because of the presence of inactive C3 fragments[21] or other proteins on the used membrane surface, which inhibit amplification of the alternative pathway. Cleansing of reprocessed cuprophan membranes with sodium hypochlorite restores complement activation and leukopenia to levels similar to those with new dialyzers.[56] This is presumably because sodium hypochlorite effectively removes the proteins on the membrane surfaces.[21]

In Vivo Consequences of Complement Activation

Animal Models

The acute effects of complement activation or exposure of blood to hemodialysis membranes have been examined in rabbit,[57] sheep,[58–60] and swine[61–63] models. Injection of plasma exposed to cuprophan membranes into animals has variably produced acute peripheral leukopenia, systemic arterial hypoxemia, pulmonary hypertension, increase in mediastinal lymphatic drainage (presumably reflecting an increase in pulmonary interstitial fluid), cardiac arrhythmias, decrease in cardiac output, and fluctuation in systemic arterial pressure.[57,59,61] These changes are apparently initiated by the exposure of blood to cuprophan membranes, which results in complement activation and the formation of anaphylatoxins C3a and C5a. C5a and $C5a_{desArg}$ bind to the neutrophil surface, which along with other activation events (such as alteration in number and configuration of cell surface adhesion molecules and cytoskeleton) induce neutrophil aggregation and attachment to pulmonary endothelial cells, resulting in peripheral leukopenia. Both C3a and C5a constrict the pulmonary blood vessels and cause pulmonary hypertension (Figure 18–4), probably through the release of thromboxanes and/or leukotrienes. These hemodynamic changes occur independently of the accompanying leukoagglutination. Indeed, the hypoxemia is probably caused by airway constriction induced by anaphylatoxins and arachidonic acid metabolites, pulmonary interstitial edema induced by anaphylatoxins, and/or transient lung injury produced by oxygen radicals released
Figure 18–4 Hemodynamic responses to intravenous bolus of 0.7 mL/kg body weight of cuprophan-activated plasma in the swine. *SAP*, systemic arterial pressure; *CO*, cardiac output; *PAP*, pulmonary arterial pressure; **, $p < .01$. (Reprinted with permission from Cheung A, LeWinter M, Chenoweth D: Cardiopulmonary effects of cuprophan-activated plasma in the swine: Role of complement activation products. Kidney Int 1986; 29:799-806.)

from activated neutrophils. Pulmonary leukosequestration or pulmonary hypertension per se does not lead to systemic hypoxemia. It should be emphasized that not all the effects of exposure to dialysis membranes are necessarily due to complement activation, since other blood components, such as the contact proteins, are also altered as a result of membrane exposure.[58,64,65]

Clinical Dialysis

The acute effects of intradialytic complement activation on patients are more controversial. These effects are primarily

inferred from the known biologic activities of complement activation products and the fact that the complement system is activated during dialysis. Dialysis-induced peripheral leukopenia has traditionally been attributed to C5a and its ability to modulate neutrophil surface adhesion molecules, although there is evidence that noncomplement factors, such as platelet-activating factors, are also involved. Anaphylatoxins may also cause acute pulmonary hypertension (which has been demonstrated during sham hemodialysis in uremic patients using cuprophan membrane[66]) and contribute to the development of hypoxemia. Because of their ability to release histamine from mast cells, anaphylatoxins may be responsible for some of the allergy-like symptoms on dialysis. Since the spasmogenic properties of anaphylatoxins are markedly diminished when they are degraded to their desarginine derivatives by serum carboxypeptidase, the ability of these peptides to induce acute intradialytic symptoms would not be as great as their plasma levels (as determined by immunoassays) may indicate. However, during hemodialysis, carboxypeptidase activity can decrease.[67] Depending on the magnitude of generation, the rate at which they are inactivated and catabolized, as well as the sensitivity of the end organs, anaphylatoxins may rarely cause anaphylactoid reactions in susceptible individuals. However, some investigators dispute this association.

More recent investigations have concentrated on the potential subacute and chronic effects of complement activation during hemodialysis. Both C5a and iC3b are well known to have neutrophil modulating properties. Stimulation of neutrophils by these complement proteins promotes the release of oxygen radicals[35] and intragranular proteases[25,36,37] from the cells, which may result in catabolism of plasma proteins and injury of other tissues, such as the kidneys. C5a has also been shown to promote the production of cytokines from monocytes[68] and the release of β_2-microglobulin from peripheral blood monocytes,[39] which may contribute to the development of amyloidosis. Definitive demonstration of the roles of complement in clinical problems associated with hemodialysis may require the ability to inhibit its activation. Inhibition of complement activation during hemodialysis using specific inhibitors, such as soluble complement receptor type I (sCR1) has been studied in vitro only.[69] Chelation of divalent cations and the administration of protease inhibitors can also inhibit complement activation, but their effects are relatively nonspecific.

BLEEDING AND CLOTTING ABNORMALITIES

Clotting of blood inside the dialyzer is a problem that has plagued dialysis since the early days of artificial kidney treatment. Although it is very seldom life threatening, it contributes to anemia, reduces the effective surface area of the dialysis membrane for solute transport, and reduces the reuse potential of the dialyzer. Clotting in dialysis circuits is the result of complex protein and cellular interactions, of which we have only a rudimentary understanding.

Activation of Coagulation Proteins

Plasma proteins are adsorbed onto foreign surfaces immediately upon contact with blood, followed by the adhesion of platelets, leukocytes, and, to a lesser extent, erythrocytes.[70, 71] The degree and types of proteins adsorbed depend on the nature of the surface. Negatively charged surfaces favor the binding of the contact protein Hageman factor (factor XII), leading to the activation of the intrinsic coagulation pathway[72,73] (Figure 18–5). In addition, high molecular weight kininogen is converted into kinins during the activation of contact proteins.[74] Bradykinin is a potent peptide that increases vascular permeability, diminishes arterial resistance, and mediates a variety of inflammatory responses. The anionic sulfonate domains of the AN69 membrane favors the binding and activation of factor XII, which lead to the subsequent conversion of high molecular weight kininogen to kinins.[72–75] Besides catalyzing the formation of angiotensin II, angiotensin converting enzyme (ACE) also functions as a kininase, which inactivates bradykinin. The use of an ACE inhibitor, therefore, allows the accumulation of bradykinin that is generated as a result of blood contact with the AN69 membrane. Conversion of kininogen to bradykinin by AN69 membrane has been demonstrated in vitro.[65] Intradialytic anaphylactoid reactions have been associated with the use of AN69 membrane and the generation of kinins, especially among those using ACE inhibitors.[75, 76]

Activation of either the intrinsic or extrinsic pathway also leads to the conversion of prothrombin to thrombin. Thrombin, in turn, activates platelets.[77] Clinical studies have failed to clearly demonstrate the activation of factor XII during hemodialysis.[78] However, in vitro studies have shown that different dialysis membranes activate Hageman factor to various degrees.[64]

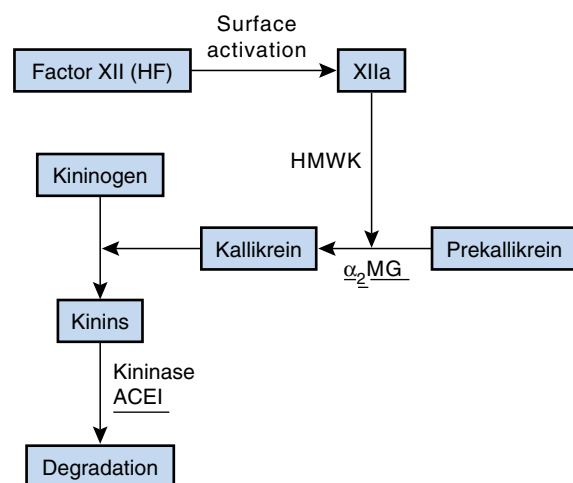
Significant activation of the coagulation cascade leads to overt thrombosis in the extracorporeal circuit. More subtle activation can be detected by a decrease in the half-life of fibrinogen or by an increase in plasma fibrinopeptides.[55,79–81] Fibrinopeptide A (FPA) and fibrinopeptide B (FPB) are fragments cleaved from fibrinogen by thrombin during its activation. Adequate heparinization prevents the cleavage of fibrinogen and, therefore, prevents an increase in plasma FPA


Figure 18–5 Schematic diagram of kinin generation on a negatively charged membrane surface. HF, Hageman factor; *HMWK,* high molecular weight kininogen; α_2MG, alpha 2 macroglobulin; *ACEI,* angiotensin converting enzyme inhibitor. Underlined text inhibits reaction.

level.[55,80,81] FPA is usually eliminated by the kidneys and is retained in renal failure.[82] Thus, baseline plasma levels in dialysis patients are usually above normal. Plasma FPA levels have been used as markers of intradialytic clotting. However, the relatively low molecular weight of this peptide ($\sim$1.5 kDa) makes it readily removable by most dialysis membranes.[55] This should be taken into consideration when interpreting levels of FPA in the hemodialysis setting.

Under physiologic conditions, activation of the coagulation cascade is counteracted by the simultaneous activation of the fibrinolytic system.[75, 83] Plasmin is a major plasma fibrinolytic protein, and its precursor, plasminogen, can be activated by tissue plasminogen activator. Increased plasma concentration of tissue plasminogen activator antigen has been demonstrated during the first hour of hemodialysis with cellulose membranes.[84] This is accompanied by a decrease in the plasma concentration of tissue plasminogen activator inhibitor. The stimuli for the release of the plasminogen activator in this setting are unknown. However, a potential source is the pulmonary vascular bed in response to injury by activated complement and granulocyte proteases. Theoretically, activation of the fibrinolytic system during hemodialysis with cellulose dialyzers could help prevent intradialysis thrombosis.

Adhesion and Activation of Platelets

As in the physiologic clotting process, platelets probably play an integral role in thrombosis of dialyzers. The tendency of platelets to adhere to artificial surfaces depends on the nature of the proteins adsorbed.[70] For example, albumin-coated surfaces are relatively resistant to platelet adhesion. In contrast, surfaces coated with glycoproteins that contain oligosaccharide chains, such as fibrinogen and γ-globulins, promote platelet adhesion. The adhered platelets undergo morphologic changes characterized by pseudopod formation and spreading of the cytoplasm over the foreign surface.[71,85] In response to stimulation by thrombin, mechanical trauma, and other humoral factors, platelets also undergo release reactions.[73,75] A variety of cellular products are thereby released into the circulation, including thromboxane A_2 (TXA_2) and adenosine diphosphate (ADP). These substances promote coagulation by further inducing aggregation and release reactions by platelets. The importance of platelets in thrombosis of dialyzers can be underscored by the effectiveness of antiplatelet agents, such as aspirin and dipyridamole in preventing these events.[86,87] Aspirin is a well-known inhibitor of the cyclooxygenase pathway of arachidonic acid metabolism and the production of TXA_2. Dipyridamole is a cAMP phosphodiesterase inhibitor and increases the level of cAMP, which, in turn, inhibits platelet aggregation induced by ADP. In addition, prostacyclin (PGI_2), a potent stimulator of adenyl cyclase and inhibitor of platelet aggregation, has been successfully used as the sole anticoagulant during hemodialysis.[88–90]

Other intracellular substances released by the activated platelets include platelet factor 4 (PF4) and β-thromboglobulin (β–TG).[91–93] Plasma levels of these substances have been used as specific markers for platelet activation. PF4 is of particular interest because it binds to and neutralizes heparin. Differences in PF4 release may partially account for the differences in heparin requirements during hemodialysis among individual patients. Special caution needs to be exercised to correctly interpret data using these markers. PF4 is normally cleared through binding to the endothelium. Administration of heparin during hemodialysis can increase the plasma concentration of this protein by releasing it from the endothelial cells in the absence of platelet activation.[91] β–TG is normally eliminated by the kidney. Therefore, circulating levels in dialysis patients are often above normal.[92] Nonetheless, an acute increase in plasma β–TG levels above the elevated baseline levels probably reflects platelet activation. When thrombosis is effectively prevented with the use of adequate anticoagulants, such an increase does not occur.[94]

Plasma coagulation proteins, such as thrombin, are known activators of platelets. In addition, platelets can be activated by mechanical disruption during hemodialysis,[95] an event that is probably dependent on the nature of the dialyzer membrane surface and the shear in the blood path. Platelet activating factor released from neutrophils[34,96] and TXA_2 released (from lungs and other tissues) by activated complement[62] can also activate platelets.

Dialyzers appear to differ from each other in their abilities to activate platelets. Hemodialysis with cuprophan dialyzers has been associated with greater thrombocytopenia compared to with PMMA dialyzers.[97] Plasma β–TG levels increase during dialysis with cuprophan but not with polyacrylonitrile.[85,98] Adhesion and morphologic changes of platelets were more profound with cuprophan compared to polycarbonate.[85] It should be noted that several of these clinical studies were not conducted under strict control of experimental conditions, such as heparin dosage and geometry and surface area of the dialyzers. In a well-controlled study in which blood was pumped from the human body through the dialyzers without heparin in a single-pass fashion, hemophan was found to be associated with a lower increase in plasma PF4 than cuprophan.[5] A recent study demonstrated that platelet-activating factor (PAF) is produced during HD with CU and AN69 membrane and may contribute to dialysis-related leukopenia and thrombocytopenia.[99, 100]

A recent study comparing the effects of CTA and PS membrane on GPIIb/IIIa (the receptor for fibrinogen that mediates platelet aggregation and adhesion) and platelet activation demonstrated a significant increase in the level of platelet-bound GPIIb/IIIa with PS and not CTA membrane.[101]

Leukocyte-Platelet Aggregation during Hemodialysis

Recent studies have also demonstrated the formation of platelet-leukocyte aggregates during hemodialysis using cuprophan and synthetic membranes.[86,102] Binding between these two cell types is mediated by various adhesion molecules, including GMP140 on platelets and CD15s on leukocytes (Figure 18–6).[103] Presumably, platelet-leukocyte binding facilitates communications and cross-signaling between the two cells, resulting in an enhancement in inflammatory response. More recently, increased platelet-monocyte aggregates with reduced leukocyte P-selectin glycoprotein ligand-1 (PSGL-1) expression in patients with ESRD, irrespective of dialysis modality, was associated with an increased risk of cardiovascular disease, suggesting a novel mechanism by which accelerated atherosclerosis may occur in uremic patients.[104]

Assessment of Platelet Activation during Hemodialysis

Several methods have been employed, including:

1. Degree of acute thrombocytopenia, because adhesion of activated platelets on the dialyzer membrane surface, aggregation in the blood, or formation of mural thrombi may result in peripheral thrombocytopenia.[85,97,105]
2. Changes in the morphology of platelets on the dialyzer membrane as examined by electron microscopy.[85]

3. Acute increases in plasma β–TG and PF4 concentrations[5,98] with the caveats noted earlier.
4. Acute increases in plasma TXA_2 concentration.[97] However, it should be noted that platelets are not the only source of TXA_2. The lungs may produce significant amounts of TXA_2 in response to stimulation by the complement anaphylatoxins generated during hemodialysis using cuprophan membrane.[62]

Clinical Consequences of Platelet Activation by Dialysis Membranes

The independent effect of dialysis membranes on clinically significant bleeding abnormalities is incompletely defined. However, although extremely rare, significant thrombocytopenia leading to hemorrhage has been reported following hemodialysis.[106] Further, dialysis with cuprophan membrane is associated with acute dysfunction of platelets, such that the cells become relatively resistant to collagen-induced aggregation and prolonged bleeding time.[85,107] Dialysis with other membranes does not appear to cause such abnormalities. Further, defective platelet adhesiveness and prolonged bleeding time in patients dialyzed with cuprophan has been shown to improve following transfer to polyacrylonitrile membranes.[108] Interestingly, in a retrospective analysis, patients chronically dialyzed with polyacrylonitrile membranes had fewer episodes of arteriovenous fistula thrombosis, leg thrombosis, and fatal pulmonary embolism than those dialyzed with cuprophan membrane.[109] Although definitive conclusions cannot be drawn from these data, they suggest that dialyzers differ from each other in their effects on platelets. However, existing data do not permit the classification of dialysis membrane materials according to their thrombogenic potentials.

The considerations notwithstanding, it should be emphasized that several factors other than the dialysis membranes can affect clotting in the dialyzer circuit. These include dialysis-related factors, such as the type and amount of anticoagulant employed, blood flow rate, geometry of the blood path (including stenosis in the inflow and outflow tracts of the fistula, cannulas, tubing and blood chamber, and blood compartment of the dialyzer), and ultrafiltration rate. In addition, a variety of patient factors, such as hematocrit, number and functional state of the platelets, coagulation proteins, fibrinolytic proteins, and other elements in the blood and endothelium, can also affect clotting in the dialysis circuit.

ERYTHROCYTE ABNORMALITIES

Significant hemolysis during hemodialysis is rare. Several causes of hemolysis associated with the dialysate have been identified, including contamination of the dialysate with chloramine, overheating of dialysate, and dialysate hypotonicity from improper proportioning of the concentrate.[110] Mechanical trauma of blood as it passes through the blood pump is another cause.[111] The dialyzer itself rarely causes hemolysis directly. Theoretically, shearing of erythrocytes at the dialyzer membrane surface or defective dialysis tubing[112,113] produces trauma to the cell. Formaldehyde employed for reuse processing has been incriminated in the development of antibodies directed against the N antigen of erythrocytes.[114–116] These anti-N antibodies are cold agglutinins that

can cause hemolysis at low temperatures. Thorough rinsing of the dialyzers to eliminate the formaldehyde prior to reuse or discontinue the use of formaldehyde has markedly diminished the prevalence of anti-N antibodies in the dialysis population.[116] Activation of the terminal components of the complement system leads to the formation of the membrane attack complex. These complexes have been detected on erythrocyte fragments in patients undergoing cardiopulmonary bypass[117] and on neutrophil surfaces in patients undergoing hemodialysis.[44] It is not known whether these complexes increase the fragility of erythrocytes or whether they induce hemolysis during or after hemodialysis. Other causes of hemolysis that may develop during dialysis are reviewed in depth in Chapter 22.

NEUTROPHILS ABNORMALITIES

Hemodialysis-Induced Leukopenia

Leukopenia during hemodialysis has been one of the earliest indices of membrane bioincompatibility. The onset is usually rapid, occurring within the first 2 to 3 minutes and maximum of 10 to 15 minutes.[19,118] Leukocyte counts usually return to normal by the end of dialysis and sometimes exceed the predialysis values. The rebound leukocytosis has been ascribed, in part, to an increase in circulating levels of granulocyte colony-stimulating factor (G-CSF).[119] Neutrophils and other granulocytes are primarily affected. Although granulocytes are readily seen on the dialyzer membrane surface under microscopy,[24, 120] the disappearance of these cells from the circulation is primarily due to sequestration in the pulmonary vasculature. Pulmonary leukosequestration has been demonstrated using radiolabeled cells in clinical studies.[121] Binding of C5a and C5a$_{desArg}$ to their specific receptors has been considered to be the primary mechanism behind dialysis-induced neutropenia. In general, the degree of complement activation correlates closely with the degree of leukopenia.[5,6,48,50,51,53,54,97] Alterations in several other neutrophil surface receptors (such as Mac-1 or CR3, LAM-1, CD15) have also been incriminated in the development and resolution of dialysis-induced leukopenia. Platelet-activating factor and leukotriene B$_4$ released from the activated neutrophils can further promote cell aggregation.

Transient neutropenia during hemodialysis by itself may be of less significance than the accompanying events, such as the release of reactive oxygen species from stimulated neutrophils and dysfunction of circulating neutrophils. However, the degree of neutropenia may, under some but not all circumstances, serve as a marker of these other events.

Degranulation

Several proteins that are stored in the azurophil and specific granules of neutrophils possess proteolytic, antimicrobial, and/or cell modulating properties. Release of these intracellular constituents (degranulation) in response to specific inflammatory stimuli is essential for host defense.[102] Although neutrophil degranulation during hemodialysis has been well documented,[122–124] the mechanisms that mediate this process have not been elucidated. Based on in vitro degranulating activities of C3a and C5a,[29,36,37] these anaphylatoxins have been postulated to participate in dialysis-induced neutrophil

degranulation. However, plasma concentrations of the granular proteins during clinical dialysis do not correlate closely with plasma C3a levels. For example, dialysis with PMMA membranes is associated with lower plasma C3a levels but higher plasma elastase levels than with cuprophan.[122–124] Additional evidence suggests that noncomplement plasma factors also contribute to neutrophil degranulation induced by cuprophan membranes[25] and perhaps other membranes as well (Figure 18–7).[125] Mechanical shearing of the cells possibly plays a role in this phenomenon. In support of this hypothesis, is the observation that clinical dialysis using cuprophan plate dialyzers induced higher plasma levels of elastase and lactoferrin than with hollow fiber dialyzers.[126] Proteolytic enzymes that are released into plasma as a result of neutrophil degranulation may contribute to the protein catabolic state that is observed during clinical dialysis.[127,128]

Release of Reactive Oxygen Species

The release of reactive oxygen species (ROS) is an important mechanism by which neutrophils injure foreign tissues. Clinical studies have shown that cuprophan membranes induced substantially greater ROS production than PMMA membranes (Figure 18–8).[129] One of the mediators in this process is likely to be C5a. The release of ROS by activated neutrophils during dialysis may alter surrounding tissues, such as plasma proteins and lipids.[130] Endothelium that is exposed to activated neutrophils sequestered in the lungs[131] and in the kidneys[132] may potentially be affected as well.

Dysfunction

When neutrophils are activated by hemodialysis membrane, they temporarily lose their ability to respond to subsequent
Figure 18–7 Release of lactoferrin from polymorphonuclear cells in the course of dialysis. stimuli. The resultant abnormalities include alterations in cell surface receptors, decrease in aggregation and adherence,[133, 134] and defective oxidative metabolism and chemiluminescence.[135, 136] These abnormalities are often above and beyond those observed with uremia per se. An early study showed that although cellulose acetate membranes adversely affected phagocytosis and random motility of neutrophils in vitro, polysulfone membranes did not.[137] In a subsequent study, fifteen incident patients with end-stage renal disease were randomly assigned to initiate dialysis with a low-flux cuprophan or low-flux polysulfone membrane.[138] Although both groups experienced deterioration in neutrophil function upon initiation of chronic hemodialysis, the deterioration with cuprophan was greater than that with polysulfone (Figure 18–9). Neutrophil dysfunction following exposure to dialysis membrane may impair host defense mechanisms when infectious microorganisms are subsequently encountered. Therefore, dialysis membrane bioincompatibility probably contributes to impaired immunity in hemodialysis patients.

Modulation of Programmed Cell Death

Apoptosis, or programmed cell death, is an active form of cell death that is initiated by a number of stimuli and is intricately regulated. Apoptosis in both excessive and reduced amounts has pathologic implications. Evidence suggests that apoptosis may play a role in the pathophysiology of immune dysfunction in uremia.[139] The lifespan and functional activity of neutrophils can be extended in vitro by incubation with pro-inflammatory mediators, such as C5a, IL-1β, and TNF-α[140–143] The generation of these mediators varies between

different dialyzer membranes, which results in a differential impact on the fate of circulating neutrophils. During dialysis, the apoptosis-inducing activity of uremic plasma is modulated by the use of dialyzers with different degrees of biocompatibility.[144] Indeed, compared with neutrophils harvested from healthy volunteers and exposed to pre-dialysis uremic plasma samples, a significantly lower proportion of apoptosis was observed in neutrophils exposed to 15-minute plasma samples obtained from patients dialyzed with CU but not with CTA or PS dialyzers (Figure 18–10). By contrast, cells incubated directly with CU membranes undergo accelerated apoptosis.[145] It remains to be determined whether *in vivo*, direct contact with the dialysis membrane is a stronger determinant of the fate of neutrophils than the generation of pro-inflammatory mediators, which may modulate survival pathways.

LYMPHOCYTES AND NATURAL KILLER CELLS

Limited data are available on the effects of dialysis membranes on lymphocytes, probably because significant intradialytic lymphopenia is not a common event, the effects of complement on lymphocytes are less prominent,[146, 147] and the methods of studying lymphocytes are often more complicated. Activation of T lymphocytes during hemodialysis has been detected by changes in cell surface markers, such as interleukin-2 receptor (IL-2R). In the presence of interleukin-1 (IL-1), stimulation of T-lymphocytes by antigens leads to the release of interleukin-2 (IL-2) and the expression of its receptor (IL-2R) on the cell surface. Binding of IL-2 to IL-2R is important in T-cell proliferation and the development of
Figure 18–10 Percentage change in neutrophil apoptosis after 24-hour incubation with uremic plasma collected at 15 minutes of dialysis with different dialyzer membranes. Compared with pre-dialysis plasma, in the presence of plasma collected at 15 minutes of dialysis, apoptosis of neutrophils collected from healthy subjects decreased by 35% (*P* < .001), 17% (*P* =.11) and 7% (*P* =.80) in the cuprophan (CU), cellulose triacetate (CTA), and polysulfone (PS) membrane groups, respectively. (Reprinted with permission from Jaber BL, Balakrishnan VS, Cendoroglo M, et al: Apoptosis-inducing activity of uremic plasma during hemodialysis. Blood Purif 1999; 16:325-335.)

functionally active effector T cells.[148] Expression of IL-2R is increased when T-lymphocytes are activated. The high affinity IL-2R receptor is comprised of an α and a β chain. Under certain conditions, the α chain (Tac or p55) is released into the plasma and is known as soluble IL-2R. Plasma soluble IL-2R retains the ability to bind IL-2, thereby reducing the availability of the cytokine to interact with cell surface IL-2R. Elevated plasma level of soluble IL-2R therefore reflects both a state of T-lymphocyte activation and a downregulation of IL-2 effects.

Different dialysis membranes affect T cells differently. Zaoui and colleagues[149] observed that dialysis with cuprophan membranes was associated with greater expression of IL-2R on T-lymphocytes compared to with PMMA membrane. When the cells were stimulated in vitro using phytohemagglutinin, those that had been exposed to cuprophan responded poorly. Others have shown that in vitro proliferation of T-lymphocytes obtained from patients on chronic dialysis with polysulfone membrane was normal but impaired among patients on cuprophan membranes. These data suggest that T-lymphocytes are activated during hemodialysis with cuprophan membranes and, subsequently, become dysfunctional. The mechanism(s) by which T cells are activated by cuprophan membranes is unclear, but it may be related to its ability to activate complement[149] and monocytes.[150] Abnormal T-cell function may predispose dialysis patients to various infections.

Natural killer (NK) cells are normal peripheral leukocytes with cytotoxic activity against tumor cells, microorganism, infected cells, and transplanted tissues. NK cell counts have been shown to increase during chronic clinical dialysis using cuprophan membranes, but their *in vitro* cytotoxic function (against K562 cells) was impaired.[151] *In vitro* studies suggest that different types of dialysis membranes have different effects on NK cell function, with cuprophan faring worse than cellulose acetate or polycarbonate membranes.[152,153] Whether the higher incidence of malignancy among ESRD patients[154, 155] is related to NK cells dysfunction has not been determined.

B-lymphocytes can be activated during dialysis using cuprophan, cellulose acetate, or polysulfone membranes, but not with AN69.[156] The mechanisms behind intradialytic B-cell activation are unknown.

MONOCYTE ACTIVATION

Cytokines are polypeptides with molecular weights of 10 to 45 kDa. These are highly potent molecules, active at picomolar and femtomolar concentrations, and are synthesized by cells in response to infection, inflammation, or trauma.[157–159] There are currently more than a dozen cytokines that have been designated as interleukins.[160] In addition, cytokines, such as tumor necrosis factor, interferon, transforming growth factor, and colony stimulating factors, continue to be known by their original names.[160] In 1983, the Interleukin Hypothesis was proposed, incriminating IL-1 produced during dialysis as the cause of hypotension, fever, and other acute phase responses observed in patients receiving hemodialysis[161] (Table 18–3). Indeed, both studies using *in vitro* models of hemodialysis as well as clinical studies in patients on hemodialysis have demonstrated increased production of a variety of pro-inflammatory cytokines, such as interleukin-1 (IL-1) and tumor necrosis factor (TNF) during hemodialysis.[158,159,162] Over the decade since this hypothesis, a better understanding of the biologic effects of pro-inflammatory cytokines and the close similarities between dialysis-related morbidity and the biologic effects of these cytokines have further strengthened the possibility that cytokines could be involved in dialysis-related symptoms.[158,159,162]

Plasma Cytokine Levels

Pre-dialysis plasma levels of IL-1 and TNF have been shown to be elevated in patients on chronic hemodialysis using cellulose membranes.[163–168] Interestingly, undialyzed patients with ESRD did not show evidence of elevated IL-1 levels,[167] leading to the conclusion that the hemodialysis procedure itself, rather than renal failure, leads to increased IL-1 production. This hypothesis was further strengthened by the observation that hemodialysis with these "bioincompatible" cellulose membranes leads to a further rise in plasma levels of TNF-α[167,169,170] In contrast, dialysis with "biocompatible" membranes, such as PAN, was not associated with a further rise in plasma levels of TNF-α[169,170] In fact, in some studies, plasma levels of TNF-α declined during dialysis with PAN membranes.[170] However, others have failed to show elevated plasma levels of IL-1β or TNF-α before, during, or after a hemodialysis treatment.[171–173]

Pre-dialysis plasma levels of IL-1β and TNF-α in hemodialysis patients have been shown to be higher than those in healthy subjects.[174] However, plasma levels of IL-1β and TNF-α were also elevated in undialyzed patients with chronic kidney disease (CKD) and patients on continuous ambulatory peritoneal dialysis (CAPD), and there were no significant

Table 18–3 Potential Relationship Between the Biologic Effects of Interleukin-1 and Dialysis-Related Morbidity

Biologic Effects of Interleukin-1	Proposed Consequences in Hemodialysis Patients
Fever, sleepiness, anorexia, myalgia, arthralgia, headache, gastrointestinal disturbances, and hypotension	Fever, sleepiness, anorexia, myalgia, arthralgia, headache, gastrointestinal disturbances, and hypotension
Proliferation of vascular smooth muscle cells	Accelerated atherosclerosis
Stimulation of platelet derived growth factor	
Up-regulation of adhesion molecules	
Atherosclerotic plaques	
Synthesis of collagenases	Bone and joint disease
Osteoblast activation	
Suppression of albumin gene expression	Hypoalbuminemia
Increased expression of positive acute phase reactants	Elevated circulating interleukin-6, C-reactive protein and ferritin level
Inhibition of erythropoiesis	Anemia
Suppression of erythrocyte maturation	RHuEPO hyporesponsiveness
Muscle proteolysis	Muscle wasting
	Negative nitrogen balance
Glomerular mesangial cell activation	Loss of residual renal function
Activation of phospholipase A_2 and cyclooxygenase	Delayed recovery from acute renal failure

(Reprinted with permission from Pereira BJ: Balance between pro-inflammatory cytokines and their specific inhibitors in patients on dialysis. Nephrol Dial Transplant 1995; 10:27-32.)

differences in the plasma levels of these cytokines between these patient groups (Fig. 18–11). Similar studies have found elevated plasma levels of TNF-α and IL-6 in both undialyzed patients with Stage 5 CKD as well as those on HD.[167,175] Elevated plasma cytokine levels in patients with CKD could be due to increased production and/or decreased clearance. Indeed, several studies have demonstrated a strong linear correlation between plasma cytokine levels and serum creatinine levels.[174,176] This correlation suggests that the kidney has an important role in the metabolism and/or clearance of these molecules. Further, the fact that the plasma levels of IL-1β and TNF-α were not significantly different between patients with CKD and those receiving CAPD or HD suggests that these dialysis modalities may not significantly affect the clearance of these proteins. Interestingly, studies in septic patients on continuous arteriovenous hemofiltration with PAN membranes have shown that TNF-α is removed from the circulation by adsorption to the membrane and to a lesser extent by ultrafiltration.[177] This suggests that although these proteins may, to some extent, be cleared by dialysis, the clearance may not match the natural excretion by the kidney.

Cytokine Production by Peripheral Blood Mononuclear Cells (PBMC)

PBMC from patients on chronic hemodialysis show signs of mononuclear cell activation. Interleukin-1β is present in the mononuclear cells of patients on dialysis.[164,178–180] In contrast, mononuclear cells isolated from healthy subjects do not contain IL-1β protein or mRNA for IL-1β using northern hybridization or polymerase chain reaction. Even after 24 hours of incubation, there is no evidence of IL-1β synthesis in the mononuclear cells of healthy donors.[181,182] However, incubation of mononuclear cells from patients undergoing chronic HD in the absence of exogenous stimuli results in spontaneous IL-1β production.[178,180] When stimulated with LPS, PBMC produce as much as fivefold more IL-1β compared to mononuclear cells from normal subjects.[164,178–180] Similar results have been reported for the production of TNF-α and IL-6.[183–185]

In vitro studies have shown that when human blood is circulated through a hollow fiber cuprophan membrane, transcription of mRNA for IL-1β is apparent within 2 hours. However, in the absence of endotoxin in the dialysate, there is no translation into IL-1β protein.[186] Similarly, mononuclear cells drawn from the arterial limb of the dialysis circuit in patients on chronic HD contain a small but significant amount of IL-1β and TNF-α.[187,188] However, within 5 minutes of dialysis with a new cuprophan membrane, the mononuclear cells in the blood from the venous limb demonstrate abundant messenger RNA for IL-1β and TNF-α. Interestingly, the mononuclear cells returning to the dialyzer from the arterial side do not show evidence of IL-1β gene expression.[188] A single pass through a cuprophan membrane is apparently sufficient to trigger transcription, and, once activated, the mononuclear cells do not return into the circulation during the course of the dialysis session. In contrast to cuprophan membranes, cytokine genes are not activated by membranes that are weak complement activators, during either in vitro or in vivo dialysis.[186,188]

Thus, in patients on hemodialysis with cellulose membranes, cytokine gene expression takes place in the absence of contaminated dialysate. These cells can either degrade their mRNA without translation into cytokine protein or receive a second signal from ongoing infection or illness, leading to rapid and efficient translation into cytokine protein. However, the most likely source of a second signal is the dialysate (Figure 18–12).[189] In the absence of a second stimulus, it is unclear where the mRNA-primed mononuclear cells exit the circulation during the 5 hours of HD. Certainly, a large pool of cells could be adhering to endothelium, particularly in the lung. Further, receptors on monocytes and adhesion molecules on endothelial cells may attract activated monocytes to the synovium or into other tissues.
Figure 18–11 ***A,*** Plasma levels of interleukin-1β *(IL-1β)* and interleukin-1 receptor antagonist *(1L-1Ra)* in normals, undialyzed end-stage renal disease *(ESRD)*, continuous ambulatory peritoneal dialysis *(CAPD)*, and hemodialysis *(HD)* patients. Plasma levels of 1L-1β were not significantly different between patient groups and normals. Plasma levels of 1L-1Ra in ESRD (*P* =.03), CAPD (*P* <.001) and HD (*P* =.0004) were significantly higher than those in normals. However, the differences between ESRD, CAPD, and HD were not significant. ***B,*** Plasma levels of tumor necrosis factor α *(TNFα)* and soluble TNF receptor *(TNFsRp55)* in normals, undialyzed end-stage renal disease *(ESRD)* continuous ambulatory peritoneal dialysis *(CAPD)* and hemodialysis *(HD)* patients. Plasma levels of TNF-α were not significantly different between patient groups and normals. Plasma levels of TNFsRp55 in ESRD (*P* <.001), CAPD (*P* <.001), and HD (*P* <.001) were significantly higher than those in normals. However, the differences between ESRD, CAPD, and HD were not significant. (Reprinted with permission from Pereira BJ, Shapiro L, King AJ, et al: Plasma levels of IL-1 beta, TNF alpha and their specific inhibitors in undialyzed chronic renal failure, CAPD and hemodialysis patients. Kidney Int 1994; 45:890-896.)

Cytokine Production as an Index of Transmembrane Passage of Bacterial Products from the Dialysate

The increasing popularity of high-flux as well as high efficiency membranes and the associated risk for backfiltration[190] have raised concerns that patients dialyzed with these membranes may be at a high risk of being exposed to bacterial contaminants in the dialysate.[191] Further, the risk of passage of bacterial products from the dialysate to the blood compartment could potentially be exacerbated by reprocessing of high-flux dialyzers, which has been shown to increase the permeability of the membranes.[192,193] Indeed, the Centers for Disease Control and Prevention (USA) has reported a significant correlation between pyrogen reactions during dialysis and the use of high-flux as well as reprocessed dialyzers.[194] In contrast, others have not found an increased incidence of pyrogen reactions among patients dialyzed with high-flux dialyzers compared to conventional or high-efficiency dialyzers.[195]

The molecular weight of endotoxins is estimated to be approximately 10^6 Da. On the basis of their sizes, endotoxins are not expected to traverse intact dialysis membranes, including high-flux membranes. However, cytokine-inducing products derived from bacteria are not limited to the whole endotoxin particles. The lipid-A portion of endotoxins and other fragments of bacteria, such as muramyl peptides, also possess monocyte-stimulating activities. Indeed, cytokine production by PBMC is a sensitive indicator of the presence of endotoxin.[157] Consequently, several authors have designed in vitro models of HD in which the reverse transfer of cytokine-inducing substances from intentionally contaminated dialysate was used to assess the permeability of different HD membranes to bacterial products (Figure 18–13).[196–200] Using cytokine production as an index of the reverse transfer of bacterial products from the dialysate to blood compartment, several studies have demonstrated that high-flux synthetic membranes, such as polyamide or polysulfone, are less likely to permit the transfer of bacterial products from the dialysate than low-flux cellulose membrane, such as cuprophan or hemophan.[196,199] Further, transmembrane passage of bacterial products has been shown to occur in the absence of backfiltration, suggesting an important role for diffusive transfer of these toxins across dialysis membranes.[196] Synthetic membranes, such as PS and PAN, bind significantly higher amounts of I^{125}-labeled LPS than CU membranes.[201] Hence, it is postulated that the interaction between hydrophobic domains on the synthetic membranes and hydrophobic domains on the bacterial toxins lead to avid adsorption of these toxins on the dialysate side of the membrane and prevent the transfer into the blood compartment.[202] This characteristic could be considered to be another index of biocompatibility.

Clinical Effects of Dialysis-Induced Monocyte Activation

The hypothesis that cytokine production is a contributing cause of several of the acute and chronic metabolic and
Figure 18–12 Potential mechanisms for cytokine production during dialysis: The double hit hypothesis. Complement activation by dialysis membranes leads to transcription of mRNA for interleukin-1 *(IL-1)* and tumor necrosis factor *(TNF)* in monocytes. In the absence of a "second signal," the mRNA for those cytokines is not translated into protein. The second signal could potentially come from the dialysate, leading to synthesis of IL-1β and TNF-α. Concurrently, proteases cleave the extracellular fragment of the TNF receptors resulting in soluble TNF receptors *(sTNFR)*. Thus, the hemodialysis procedure serves as a stimulus for cytokines such as IL-1β and TNF-α, as well as their specific antagonists. (Reprinted with permission from Pereira BJ, Dinarello CA: Role of cytokines in patients on dialysis. Int J Artif Organs 1995; 18:293-304.)

Figure 18–13 Production of TNF-α by human mononuclear cells (MNC) incubated with samples from the blood compartments of the *in vitro* circuits containing 10% plasma in culture medium (MEM), before and after challenge of the dialysate with *P. maltophilia* filtrate (0.2 μg/mL LAL active material. "Control" represents 10% plasma in MEM without contact to the circuit, not preincubated (0') or preincubated at 37°C for 2 hours. Hatched bars represent the averaged TNF-α–inducing activities of samples drawn at 30 and 60 minutes from the blood side during dialysis sterile tissue culture medium as dialysate. Closed bars depict averaged activities of samples drawn at 90 and 120 minutes from blood side following challenge of the dialysate side with *P. maltophilia* filtrate. Results are expressed as the mean ± SEM of TNF-α–inducing activity (ng/2.5×10^6 MNC/18 hr). inflammatory changes associated with hemodialysis is based on similar signs and symptoms also observed in (1) healthy volunteers or experimental animals administered cytokines and in (2) diseases, such as rheumatoid arthritis, inflammatory bowel disease, some chronic infections and cancers, and various collagen vascular diseases, where the pathophysiology is largely attributed to enhanced cytokine production.[157–159] Healthy human volunteers administered IL-1β in doses of 10 to 100 ng/kg develop fever, sleepiness, anorexia, myalgia, arthralgia, headache, and gastrointestinal disturbances, and in larger doses (>300 ng/kg), hypotension.[157–159] Likewise, when injected into humans at low concentrations (less than 1μg/kg), TNF-α produces hypotension and leukopenia as well as several metabolic dysfunctions. Indeed, IL-1β and TNF-α are highly synergistic in both animal and in *in vitro* studies and act synergistically in the production of hemodynamic shock.[203] IL-1β and TNF-α also induce a rapid increase in slow wave sleep.[157–159] The similarity between these signs and symptoms observed during experimental administration of pro-inflammatory cytokines and the fever, hypotension, fatigue, somnolence, and other acute phase responses observed during HD, was the basis of the Interleukin Hypothesis.[161] However, the further understanding of the biologic actions of these cytokines has expanded the scope of the role of cytokines in dialysis-related morbidity. In experimental models, cytokines lead to proliferation of vascular smooth muscle cells and stimulation of platelet derived growth factor and atherosclerotic plaques.[157–159] Consequently, cytokines may have a role in the accelerated atherosclerosis and cardio-

vascular morbidity observed in hemodialysis patients. Further, IL-1β and TNF-α induce osteoblast activation and increase gene expression for phospholipase A_2 and cyclooxygenase.[204] In isolated tissues perfused with IL-1β, prostaglandin E_2 increases rapidly in the perfusate.[205,206] Consequently, cytokines may contribute to various bone, articular, and periarticular diseases. In addition, IL-1β increases the hepatic production of amyloid A (AA), which may contribute to the development of AA amyloidosis. Although amyloid deposits in hemodialysis patients are often composed of $β_2$-microglobulin, AA amyloid is also seen. The presence of macrophages stained positive for IL-1β and TNF-α in chronic renal failure patients' bones that are afflicted with severe $β_2$-microglobulin amyloidosis[207] suggests the possibility that these cytokines also participate in the pathogenesis of this disease as well. IL-1β and TNF-α are also appetite suppressants, but their mechanism of action as anorectic agents is thought to be due to peripheral effects on hepatic metabolism rather than in the central nervous system. Further, IL-1β, TNF-α and IL-6 stimulate hepatic acute phase proteins, such as C-reactive protein, and suppress albumin synthesis, induce muscle proteolysis and a negative nitrogen balance. Taken together, these actions could contribute to the malnutrition observed in dialysis patients. However, to date, a definitive link

between dialysis-induced cytokine production and clinical symptoms, signs, or outcomes has not been demonstrated.

As in the case of neutrophils and T-lymphocytes, chronic low-grade activation of monocytes induced by hemodialysis leads to dysfunction of these cells. Monocytes obtained from patients dialyzed with cuprophan membranes for 2 weeks released less IL-1β and TNF-α when stimulated by phytohemagglutinin *in vitro* than cells from patients who were dialyzed using low-flux PMMA membranes.[208] Presumably, this subnormal response would represent a diminished ability of the host to respond appropriately to foreign materials, such as infectious microorganisms.

CLINICAL IMPLICATIONS OF DIALYSIS MEMBRANE BIOCOMPATIBILITY

Hemodialysis-Induced Hypoxemia and Pulmonary Hypertension

A decrease of 10 to 15 mmHg in systemic arterial partial oxygen tension (pO_2) commonly occurs during hemodialysis using cuprophan membrane and acetate dialysate.[57,209,210] This hypoxemia is obviously undesirable for patients with underlying cardiopulmonary diseases. There is little question that acetate dialysate is the major contributor to dialysis-induced hypoxemia, presumably because of the loss of carbon dioxide from blood into dialysate[211] and the metabolism of acetate by the body.[212] Both mechanisms lead to hypoventilation and a decrease in the respiratory quotient. However, there is substantial evidence to support the contribution of membrane bioincompatibility:

1. Patients on mechanical ventilators with constant minute volume and constant inspired oxygen concentration can still develop hypoxemia during hemodialysis.[213]
2. Decrease in pulmonary diffusion capacity (DLCO)[57, 214–216] and transthoracic impedance,[215] widening of alveolar-arterial oxygen tension gradient,[209,216] as well as increase in closing volume[57] and dead space to tidal volume ratio,[211] have all been demonstrated during hemodialysis. These aberrations are suggestive of impairment in intrapulmonary gas exchange and cannot be explained by hypoventilation alone.
3. The degree of peripheral leukopenia has been correlated with the degree of hypoxemia.[217]
4. Dialysis using cuprophan membranes has been associated with a larger decrease in diffusion capacity compared to PAN membranes.[218]
5. Replacement of unsubstituted cellulose membranes with PMMA[210] or PAN[209,219] membranes can ameliorate the hypoxemia.
6. During dialysis with cuprophan membranes, replacement of acetate with bicarbonate dialysate does not necessarily abolish the hypoxemia,[217, 218] but dialysis using the combination of reused cuprophan membrane and bicarbonate dialysate does.[220]
7. Infusion of cuprophan-activated plasma into humans[215] or experimental animals[61, 215] causes hypoxemia.
8. Sham hemodialysis without dialysate in normal human volunteers produces hypoxemia.[221] Therefore, it appears

that membrane bioincompatibility does play a role in the development of dialysis-induced hypoxemia. This effect is probably more prominent during the early phase of the treatment, when complement activation and leaching of noxious substances is most intense.

Invasive monitoring of pulmonary arterial pressure has documented the development of pulmonary hypertension during dialysis with cuprophan membranes but not with polycarbonate membranes.[66] In some instances, this hemodynamic derangement can lead to clinical symptoms.[222] In vitro and animal studies described earlier suggest that the mechanisms by which dialysis membrane bioincompatibility causes pulmonary hypertension and hypoxemia involve the activation of complement and other humoral factors. Anaphylatoxins cause smooth muscle contraction[28] and in vivo activation of C3 and/or C5 results in pulmonary hypertension in animals.[63] Anaphylatoxins stimulate the production of thromboxane and leukotrienes, which are potent airway constrictors.[223] In addition, anaphylatoxins increase vascular permeability[26] and may thus cause transient pulmonary interstitial edema. Pulmonary leukosequestration (leukocyte thromboemboli) is likely to be a result of intradialytic complement activation but is unlikely to be the cause of pulmonary hypertension or hypoxemia.

Dialyzer Reactions

Occasionally, severe reactions during hemodialysis can be life threatening. These reactions, by definition, cannot be attributed to the acute loss of fluid, changes in electrolytes, improper composition of dialysate, and malfunctioning of the dialysis machine. The severity and time of onset are variable. The manifestations include various combinations of hypertension or hypotension, dyspnea, coughing, sneezing, wheezing, choking, rhinorrhea, conjunctival injection, headache, muscle cramps, back pain, abdominal pain, chest pain, nausea, vomiting, fever, chills, flushing, urticaria, and pruritus. Death occasionally occurs.[224–236] The term *hypersensitivity reaction* has been used to describe these signs and symptoms. Whether some of these patients are indeed hypersensitive to the offending agents are unclear since the nature and amount of the agents are frequently unknown. Consequently, a more appropriate term is *dialyzer reaction*. Causes of dialyzer reactions are diverse and have been reviewed in detail in Chapter 22.

β₂-Microglobulin (β₂MG) and Amyloidosis

Amyloid deposit containing β_2MG is well recognized as a complication of long erm dialysis.[237, 238] The pathogenesis of this disease is unclear, although recent data suggest that some alterations of the β_2MG peptide (e.g., by glycosylation[239] or proteolytic cleavage[240,241]) favor its deposition into tissues. Plasma β_2MG levels in ESRD patients are, in general, markedly elevated to 30 to 60 μg/mL[242–247] compared to those in normal subjects of approximately 1 μg/mL. It is likely that the high plasma concentrations in these patients also promote its deposition. To this end, efforts have been directed to decreasing the plasma β_2MG levels in ESRD patients.

In vitro incubation of PBMC with various types of dialysis membranes in the presence of plasma showed that cuprophan

membrane induced the release of more β_2MG than did PMMA or AN69 membrane. Stimulation of mononuclear cells with C5a or IL-1β also enhanced β_2MG release,[39] suggesting that the effect of cuprophan on β_2MG release is mediated both by its ability to activate complement and indirectly by inducing cytokine generation. In contrast, incubation studies performed in the absence of plasma showed that β_2MG release was inhibited to a greater extent by cuprophan (rather than enhanced) compared to hemophan or PAN membranes.[248] β_2MG is also a constituent of neutrophil granules.[249] Theoretically, dialysis membrane induced neutrophil degranulation may also increase plasma β_2MG levels. However, the intragranular content of β_2MG is small, and therefore the contribution of this mechanism to plasma β_2MG increase during dialysis is modest at most. Nonetheless, these experiments indicate that there is a cellular basis for dialysis-induced release of β_2MG. The presence of macrophages in bone tissues afflicted by β_2MG deposits also suggests the possibility that dialysis membrane-induced activated monocytes contribute to the local inflammatory or destructive process.[207]

Whether there is a real increase in total extracellular β_2MG during dialysis using cuprophan membrane has been debated. Some investigators have argued that the apparent increase in plasma β_2MG concentration is due to a hemoconcentration effect as a result of ultrafiltration,[250,251] whereas others have reported a 3% to 15% increase in plasma β_2MG levels despite correction for hemoconcentration.[242,243] Some investigators have failed to demonstrate an increase in plasma β_2MG levels during sham hemodialysis with CU membranes.[251] In contrast, when whole blood was circulated through CU hemofilters in vitro, a 70% increase in plasma β_2MG levels was seen in 15 minutes.[252] Abolishment of the increment by leukocyte depletion in this study further suggested that these cells were the source of the additional β_2MG. The plasma appearance rate of β_2MG has been estimated using radiolabeled β_2MG turnover techniques. A higher plasma appearance rate in the patient would suggest that the enhanced release of this protein by activated leukocytes. Clinical data on this issue have been inconclusive. β_2MG appearance rates in patients dialyzed with cuprophan membrane were 30% to 50% higher than those in normal subjects, but the differences did not reach statistical significance.[244, 245] The β_2MG appearance rates in patients dialyzed with AN69 membranes were normal, and were lower than the values for patients dialyzed with CU membranes. However, the differences between AN69 and CU were not statistically significant.[245]

Clinical dialysis with high-flux synthetic membranes decreases plasma β_2MG levels, probably by both membrane adsorption and transfer to the dialysate.[247] Cuprophan membrane induces an increase, whereas high-flux synthetic membranes induce a decrease in plasma β_2MG levels. Hence, one may postulate that patients dialyzed with the latter would suffer from less β_2MG-related amyloidosis. Studies have shown that patients dialyzed with AN69 membrane had less bone cysts and required less decompression surgery for carpal tunnel syndrome than those dialyzed with CU membrane (Figure 18–14).[253–255] These data are suggestive, but not definitive; since they are retrospective, there was overlap between the study groups, and histologic confirmation for β_2MG was not uniformly obtained.

If β_2MG-related amyloidosis in the ESRD patients results only from high plasma β_2MG levels as a result of kidney failure,
Figure 18–14 Kaplan-Meier survival curves without carpal tunnel syndrome *(CTS)* (upper panel) or without amyloid bone cysts (lower panel) in patients treated exclusively with either AN69 *(thin line)* or cellulose membranes *(thick line)*. Survival without amyloid bone cysts is significantly different for the two groups. (Reprinted with permission from van Ypersele de Strihou C, Jadoul M, Malghem J, et al: Effect of dialysis membrane and patient's age on signs of dialysis-related amyloidosis. The Working Party on Dialysis Amyloidosis. Kidney Int 1991; 39:1012-1019.)

it should not be considered as a biocompatibility issue. Decreasing the plasma levels by using high-flux membranes, if it partially prevents β_2MG-related amyloidosis, is an issue of dialysis efficiency and not biocompatibility. However, to the extent that dialysis membrane may increase the release of the peptide from circulating leukocytes[39] and may activate leukocytes such that they promote β_2MG deposition by altering its structural properties[240,241] or potentiate the local inflammatory process in the tissues,[207] β_2MG is a biocompatibility issue. To what extent bioincompatibility contributes to clinical β_2MG amyloid disease is difficult to determine.

Susceptibility to Infection

Deactivation of neutrophils, T lymphocytes, monocytes, and natural killer cells after exposure to the dialysis membrane has been discussed earlier. Hypothetically, this would impair the ability of the leukocytes to subsequently combat infections and malignant cells. Indeed, chronic hemodialysis patients are prone to infections and have a higher incidence of malignancy than the general population.[154, 155] Bacterial infections are common, but many of them are at least partially related to anatomic abnormalities, such as vascular access. Nonetheless,

dialysis-related immunodeficiency exaggerates the problem. Chronic hemodialysis patients have frequent viral infections, abnormal antibody response to vaccines and hepatitis B viral infection, cutaneous anergy, prolonged graft survival, and altered response to and, perhaps, increased incidence of tuberculosis. These are disorders that are probably due to T-cell dysfunction. Whether this propensity to infections and perhaps malignancy is related to dialysis membrane bioincompatibility is, however, unclear. In a prospective study in which new ESRD patients were started on chronic HD using either CU or PS membrane, the cuprophan group had more significant deterioration of their neutrophil metabolism in response to phagocytic stimuli.[138] In addition, three out of the eight patients in the cuprophan group, and none of the seven patients in the polysulfone group, developed an episode of sepsis during a follow-up period of 20 weeks. However, the sample size in this study was small, precluding definitive conclusions.

Protein Catabolism

Membrane bioincompatibility has been incriminated as a cause of protein catabolism in dialysis patients. There are two potential cellular mechanisms by which this may occur: neutrophil degranulation and release of cytokines from monocytes. Intragranular proteins, such as elastase, are known to be proteolytic enzymes.[102] Elastase released into plasma is usually complexed to plasma α_1-proteinase inhibitor, which limits its functional activity. However, it has been shown that ROS potentiate the effect of elastase on protein degradation, even in the presence of the plasma inhibitor.[256] The simultaneous release of ROS[129] and proteases[122–124] from neutrophils during hemodialysis could therefore damage plasma proteins.[127,128] Another candidate is IL-1β, which is known to induce protein breakdown by releasing prostaglandin E_2.[257]

Using plasma free amino acids as an indicator of protein catabolism, sham HD without dialysate using cuprophan membranes in normal human has been shown to induce more protein catabolism than sham dialysis using AN69 membranes.[258] The enhanced release occurred almost 3 hours after the completion of the dialysis treatments and could be partially inhibited by a cyclooxygenase inhibitor. Based on this latter observation, it would be reasonable to postulate that AN69 membrane induces less monocyte activation and, therefore, it causes less protein catabolism. In vitro[259] and clinical[180] data on monokine release by AN69 membrane, however, do not support this hypothesis. A more recent clinical study using a radiolabeled amino acid turnover technique did not suggest an increase in protein catabolism associated with cuprophan membranes.[260] The issue of protein catabolism induced by membrane bioincompatibility is unsettled at present.

Outcomes Among Patients with Acute Renal Failure (ARF)

Activated neutrophils release oxygen radicals and proteolytic enzymes that can injure surrounding cells. Indeed, neutrophils stimulated by C5a, release oxygen radicals, which damage endothelial cells.[35,131] Since neutrophils are activated to release oxygen radicals[129] and proteolytic enzymes[122–124] during hemodialysis, it is possible that they could cause injury to various organs, including the kidneys. In support of this hypothesis is that rats with ischemic ARF and exposed to cuprophan-activated plasma recover renal function at a slower rate compared to those exposed to PAN membrane-treated plasma.[132] Infiltration of the glomeruli by neutrophils could be further demonstrated in the cuprophan group. Zymosan-activated plasma produced similar results as cuprophan-activated plasma. These data suggest that complement fragments mediate the effect of the cuprophan membrane.

In the past decade, several prospective studies have compared the effects of cellulose-derived or synthetic dialyzer membranes on clinical outcomes of patients with ARF. Table 18–4 summarizes the essential attributes of these reports.[17] There are several general limitations inherent to all the studies, as well as individual study limitations that are worthy of mention.

Overall, there were differences in the quality of the studies, the inconsistent randomization process, the absence of a

dialyzer blinding process, and the incomplete documentation of statistical procedures, mainly power analyses. In some studies, the comparison of synthetic to substituted rather than unsubstituted cellulose membranes may have confounded the results because these dialyzers are not as bioincompatible. Further, the expected mortality range among those with ARF is very wide, rendering comparison between studies even more difficult. Most studies used the Acute Physiological and Chronic Health Evaluation (APACHE) II scores to define the severity of illness. Although there have been reports of its successful use as a predicative instrument in ARF prognosis,[261] this score is not fully validated to ensure inclusion of all the baseline comorbid conditions.[262] None of the statistical analyses adjusted for the dialysis dose or the center effect. In fact, the dialysis prescription may be an important determinant of outcome, although targets for adequate dialysis in ARF have not yet been established.

In terms of individual study limitations, Schiffl and colleagues[263] originally examined patients with postoperative ARF. This study was criticized on many counts, including the use of dialyzers with different flux characteristics, the subsequent publication of a report inclusive of the authors' original findings[264] and possible imbalance between study groups. In the study by Hakim and colleagues[265] almost 30% of subjects in the synthetic dialyzer group recovered renal function after a single dialysis session, raising once more, the possibility of imbalance between the groups. The study by Kurtal and colleagues[266] was criticized for an imbalance in the etiologies of ARF, which may have confounded the results. Assouad and colleagues[267] reported on their findings in an abstract that did not undergo peer review. Finally, in the original report by Himmelfarb and colleagues[268] dialyzer assignment was made in alternating order, and dialyzer selection as well as treatment practices varied among participating centers.

Three additional trials were published on this issue. Jörres and colleagues[269] reported on a randomized controlled trial (RCT) comparing low-flux CU to PMMA dialyzers and used a pre-defined sample size determination for adequate statistical power. Fourteen-day adjusted survival rates were not different between the two groups. In subgroup analyses, outcomes were not different for oliguric and nonoliguric patients in contrast to other studies, where the benefit of synthetic membranes was more evident in nonoliguric subjects. The study limitations include the exclusion of almost 10% of patients from the original intention-to-treat analysis, outcome assessment at 2 weeks, which may not have been adequate to assess clinical outcomes reliably, and most importantly, the author's handling of dialysis modality switches. Indeed, a significant number of patients who were converted to continuous renal replacement therapy (CRRT) were included in the analysis and counted as alive at 14 days. Nevertheless, the lack of a definite dialyzer benefit in this large randomized study cannot be disregarded. Similarly, Gastaldello and colleagues[270] performed an RCT where patients with ARF were allocated to a low-flux CA, low-flux PS, or high-flux PS dialyzer. This well-conducted study did not detect any effect of membrane type or flux property on mortality or recovery of renal function. Once again, differences in membrane biocompatibility were subtle because no unsubstituted cellulose was used. Finally, Albright and colleagues[271] compared low-flux CA to high-flux PS dialyzers in a relatively small number of patients with ARF. Thirty-day

survival was not different between the two groups. In a subgroup analysis of patients confined to the intensive care unit, there was a small benefit in renal recovery in the CA dialyzer group. Unfortunately, as acknowledged by the authors, although the study was originally randomized during the course of patient enrollment, dialyzer assignment was switched over to an alternating order, which might have significantly biased the results.

All the previously mentioned study limitations have precluded a clear answer to the role of membrane biocompatibility in the setting of ARF. The heterogeneity of individual studies reduced the strength of the conclusion. More importantly, the definition of bioincompatible and biocompatible membranes adopted in this analysis assumed that all cellulose-derived and synthetic membranes behaved similarly. Two meta-analyses summarizing all trials published to date, comparing the impact of dialysis membranes on clinical outcomes of patients with ARF receiving HD[272,273] yielded conflicting results. This may be so because these studies were rarely randomized, employed different study designs, collected different data, may have failed to adjust for severity of illness, and may have assessed different end points.[274] Second, because so few of these dialysis membrane trials were randomized, these meta-analyses included nonrandomized controlled trials and observational studies to accrue a larger sample size, and, therefore, to have enough power, to find a clinically and statistically significant difference between two therapies, if one truly exists. In summary, because mortality associated with dialysis-requiring ARF has remained so high, studies comparing dialysis membranes need to be better focused and appropriately powered to answer these questions.

Outcomes Among Patients with Chronic Kidney Failure

Several retrospective studies have examined the association between dialyzer type and clinical outcomes among patients on chronic dialysis. In one such study, patients receiving dialysis with PS dialyzers had an 80% to 90% lower relative risk (RR) of death from all-cause, cardiovascular disease and infection.[275] Although these risks were adjusted for age, gender, race and cause of ESRD, dose of dialysis and flux may have confounded the analysis. Likewise, in a comparison of non-contemporaneous cohorts, other studies have observed a 76% lower RR of death among patients on high-flux PS dialyzers compared with those on cellulose dialyzers.[276] However, differences in the dose of dialysis, flux, and albumin levels in the polysulfone group may have also influenced these results. In a historic prospective cohort study, 2400 prevalent patients on chronic dialysis were followed in the early 1990s until death, transplantation, transfer to peritoneal dialysis, or end of study observation (median duration of 1.4 years).[277] Dialyzers were classified as unsubstituted cellulose, modified cellulose and synthetic, and were used by 66%, 16%, and 18% of patients, respectively. Compared with patients on unsubstituted cellulose dialyzers, patients on modified cellulose and synthetic dialyzers had a 28% lower relative risk of death.[277] The analysis remained robust after adjustment for the dialysis dose.[277] In another study examining the relationship of dialysis membrane and cause-specific mortality, compared with patients dialyzed with unmodified cellulose membranes, the adjusted relative mortality risk from infection was 31% lower

and from coronary artery disease was 26% lower for patients dialyzed with modified cellulose and synthetic membranes.[278]

The results of these studies offer support to reported experimental and observational clinical studies that have found that unmodified cellulose membranes may increase the risk for both infection and atherogenesis. However, for several reasons, these conclusions need to be viewed with caution. The fact that the majority of biocompatible dialyzers were also high-flux dialyzers raises the possibility that flux rather than biocompatibility may be the factor that resulted in better outcomes. Also, the possibility that the use of biocompatible dialyzers (which are more expensive) may reflect greater attention to improvements in dialysis technology and commitment of greater resources to patient care, which, in turn, leads to better outcomes, needs to be considered. Whereas further studies are necessary to evaluate the possibility of confounding factors, such as flux properties of membranes, to compare more specific membrane types, and to determine the pathophysiology linking membrane type to cause-specific mortality, the results of a recent multicenter study examining the impact of dialysis dose and use of high-flux dialyzers on clinical outcomes failed to demonstrate a survival advantage to the use of high-flux dialyzers,[279] raising more questions on this controversial issue.

Outcomes in Renal Transplant Recipients

There are few clinical reports that have addressed the impact of biocompatibility of dialyzer membranes on rate of recovery of renal function in the setting of delayed graft function immediately following transplantation. The rationale for these studies was the concern that recovery from delayed graft function, primarily due to ischemic reperfusion injury could be prolonged by the use of unsubstituted cellulose membranes. Valeri[280] first reported on the results of an RCT of 30 patients with delayed graft function following cadaveric renal transplantation who were maintained on HD with either a CU or PMMA dialyzer. Baseline demographic characteristics, including age, gender, and immunosuppresive therapy, were similar between the two groups. The mean number of dialysis sessions and duration of dialysis (in days) were comparable, and no survival outcome was measured. The authors concluded that the dialyzer type had no significant impact on the course of recovery from delayed graft function following cadaveric renal transplant. Romao and colleagues[281] subsequently reported on the results of an RCT involving 53 patients with delayed graft function following cadaveric renal transplantation who were dialyzed with either a CU or PS dialyzer. The performance characteristics of the membranes were not stated. The number of dialysis sessions, oliguric days, and hospital days did not differ between the two groups. The authors framed similar conclusions to the previous study. Woo and colleagues[282] also reported on 42 patients with delayed graft function who were randomly assigned to dialysis with either a CU or PS dialyzer and observed longer duration of ARF in the PS compared to the CU group. The author speculated that PS membranes may in fact delay recovery of renal function in this setting.

It is difficult to draw any definite conclusions from these preliminary studies due to small sample size, overall limited information, and the fact that most of these studies were published in abstract format. In addition, most of these authors assumed that delayed graft function was due to ischemic ATN, although other possibilities, such as acute rejection or drug toxicity, were not appropriately ruled out. This may have confounded the measured outcomes.

Chapter 19

Reprocessing of Hemodialyzers

Bhamidipati V.R. Murthy, M.D., D.M. • Donald A. Molony, M.D.

Reprocessing of hemodialyzers was originally introduced in the 1960s to reduce the expense of coil and Kiil dialyzers.[1, 2] Although the cost of dialyzers decreased with the advent of hollow-fiber dialyzers, a few dialysis centers in the United States continued the practice of multiple uses of dialyzers in the 1960s and 1970s to reduce further the cost of dialysis. In the 1970s, some researchers observed increased biocompatibility of the cellulosic membranes following reprocessing and decreased reactions to the dialyzer membrane or sterilant, thus "justifying" medically the practice of reuse.[3-5] Although these cellulosic dialyzers were designed for single use, reuse continued with little regulation. The Association for Advancement of Medical Instrumentation (AAMI) provided standards and guidelines for dialyzer reprocessing.[6] First provided in 1983, these guidelines have been revised multiple times. Currently, it is mandated by law that the manufacturers of dialyzers label the product, whether it is for single use or for reuse.

Dialyzer reuse is less widespread in Europe and in Asia and is prohibited by law in France and in Japan. Dialyzer reuse has been cited as the reason for the observed difference in mortality between Europe and the United States.[7] While controversies regarding the direction and magnitude of any effect of reuse on morbidity and mortality remain, the predominant factor driving the current practice of reuse of dialyzers in the United States is economic. This chapter will outline the growth of dialyzer reuse in the United States, describe the effect of reuse on solute clearances and biocompatibility, describe the adverse effects of exposure to germicides used for reprocessing of dialyzers, and evaluate the strength of the evidence that dialyzer reuse is associated with adverse patient outcomes.

METHODS OF DIALYZER REPROCESSING

Disinfectants for Reuse

Reuse was originally performed with formaldehyde or formalin as the germicide, using manual techniques.[2] Reuse was initially practiced with Kiil dialyzers. When hollow-fiber dialyzers were introduced, these same methods were adapted for their reuse as well. Formaldehyde remained the only disinfectant in use until the early 1980s for lack of a better alternative, despite the concern of toxicities with formaldehyde. When peracetic acid/hydrogen peroxide mixture (marketed as Renalin) was introduced, it gradually gained ground over the next few years, as shown in Figure 19–1, such that by 1992, peracetic acid was more frequently used than formaldehyde.

Glutaraldehyde is another agent that has been used in place of either of these agents, but the toxicity of glutaraldehyde is greater than that of formaldehyde and, therefore, it has not

gained wide acceptance. Currently, only 5% of dialysis centers use glutaraldehyde as the disinfecting agent.[8] Over the last decade, heat has been developed as a disinfectant facilitated by the development of membranes and potting compounds that are heat stable. Initially, a temperature of 105°C was used. This temperature has been reduced to 95°C by performing heat sterilization in the presence of 1.5% citric acid, a method that has proven to be safe and effective. Although pyrogen adverse reactions are significantly reduced with this method of reprocessing, this method is limited to dialysis membranes that are heat resistant and, hence, useful for *polysulfone* dialyzers only.[9]

Bleach has been used as a cleansing agent to improve the appearance of the dialyzer, particularly with formaldehyde, and less often with peracetic acid mixture reprocessing. Although bleach does improve the appearance of the dialyzer, over repeated exposures to bleach modifies the structure of the membrane such that diffusion properties of the dialyzer are altered. These are described in more detail in the section on clearance of solutes with reuse.

Manual Versus Automated Reuse

Until the mid 1980s, reprocessing of dialyzers with either formaldehyde or peracetic acid was accomplished by manual methods only. With the availability of automated systems, most dialysis units have adopted this method because it offers several advantages. Automated systems offer safety to the personnel with less contact with toxic chemicals, decrease the risk of human error, and ensure delivery of the exact specified concentration of the sterilant. They also facilitate proper testing for the integrity of the dialyzer. They ensure proper documentation of the disinfection process, store data for subsequent reference and analysis, and generate appropriate labels for identifying the dialyzers with a given patient. They are also time-efficient because four to eight dialyzers can be processed simultaneously depending on the machine used. The process is reliable and reproducible. Automated machines are available for both formaldehyde and peracetic acid methods of disinfection. The automated machines currently in use perform routinely three major tests on each reprocessed dialyzer. They test the coefficient of ultrafiltration (KUF), the total cell volume (TCV) or percent of total dialyzer surface area that is available for diffusion/ultrafiltration, and the membrane integrity or for the absence of leaks. Although ultrafiltration failure and membrane leaks are rare, decrease in TCV and its effect on solute clearances is still a significant concern with reuse. This is discussed in more detail in the section on clearance of solutes with reuse. For more details of the technology of dialyzer reuse and the sterilants, the reader is referred to the publication *AAMI Standards and Recommended Practices for Dialysis*[6] that should be available at every dialysis unit.
Figure 19-1 Graph showing comparative use of formaldehyde and peracetic acid/hydrogen peroxide mixture (Renalin) for reprocessing of hemodialyzers in the United States. (Modified from Tokars JI, Frank M, Alter MJ, Arduino MJ: National surveillance of dialysis-associated diseases in the United States, 2000. Semin Dial 2002; 15:162–171.)

GROWTH OF DIALYZER REUSE IN THE UNITED STATES

Since its early practice, reuse of dialyzers has had a persistent growth in the United States. In 1976, only 18% of dialysis units reprocessed their dialyzers. A sudden increase in dialyzer reprocessing occurred in the early 1980s with the introduction of composite rate of reimbursement for hemodialysis. With the composite rate remaining constant since its introduction, driven by economics, reuse has grown still further in the United States. In 1982, 43% of dialysis centers reprocessed their dialyzers and, in 1997, 82% of dialysis centers practiced reuse.[8] In recent years, it has stabilized and, in 2000, 80% of centers reprocessed their dialyzers.[8]

Although formaldehyde was the only reprocessing agent available during the 1970s, peracetic acid was introduced as a less toxic alternative in the early 1980s. In 1983, 94% of dialysis centers reprocessed their dialyzers with formaldehyde, 5% with peracetic acid, and less than 1% with glutaraldehyde. Since then, however, use of formaldehyde has steadily and significantly decreased because of the concern of toxicities to patients and personnel. In contrast, use of peracetic acid has consistently increased, replacing formaldehyde in the majority of centers. As shown in Figure 19–1, in the year 2000, only 31% of centers reprocessed their dialyzers with formaldehyde, and 59% of centers reprocessed with peracetic acid.[8] Glutaraldehyde reprocessing had increased to 9% in the early 1990s but subsequently decreased to 5% by 2000.[8] Reprocessing with heated citric acid remains low at 4% in 2000.[8]

Reuse policy is largely dictated by the dialysis unit. However, reuse is medically contraindicated when patients have had a previous reaction to either the germicide or to the cleansing agent. As will be discussed later in the chapter, reuse is not recommended in patients who are carriers of hepatitis B virus because of the risk of transmission to personnel reprocessing the dialyzers. In addition, most units choose to not reuse dialyzers in patients positive for human immunodeficiency virus (HIV) for the same reason. The remaining patients in whom reuse is not medically contraindicated are given a choice whether or not to participate in a reuse program. To understand more fully the differences between patients who choose to participate in reuse and those who do not, an analysis from the Dialysis Mortality and Morbidity Study (DMMS) observed that 8% of patients were not treated with reprocessed dialyzers among 1095 dialysis units that practiced reuse.[10] In 34% of these non-reuse patients, reasons for "no reuse" were not recorded; patient refusal accounted for 26% of patients not on reuse, and hepatitis and other medical conditions accounted for the remaining 40%.[10] Since many of the patients not on reuse in dialysis centers that conducted reuse were excluded from reuse for medical reasons, it would be expected that this subset of patients may represent a sicker subset of patients. Indeed, patients treated with non-reprocessed dialyzers had lower serum albumin levels and received a lesser dose of dialysis.[10] These differences may reflect a sicker population with more severe comorbidities and, hence, one in which it is more difficult to achieve target doses of dialysis, rather than negative effects of treatment with single-use dialyzers.

EFFECT OF DIALYZER REPROCESSING ON SOLUTES CLEARANCE AND PROTEIN LOSSES

Effect of Dialyzer Reuse on Clearance of Uremic Toxins

Guidelines by the Association for Advancement of Medical Instrumentation (AAMI) require that urea clearance of reprocessed dialyzers should be within 10% of the urea clearance by a new dialyzer.[6] However, it is impractical to measure urea clearance before each reuse. Therefore, based on studies by Gotch,[11] showing that a decrease in TCV of reprocessed hollow-fiber dialyzers by 20% decreases the urea clearance by only 10%, the AAMI guidelines recommend that a hollow-fiber dialyzer may be reused until its TCV is 80% or less of the original volume.[6] However, the observations of Gotch[12,13]

were based on *in-vitro* studies of "low-flux" dialyzers at low blood flow rates on just a very few of dialyzers and without rigorous statistical analysis. The applicability of these parameters to the dialysis membranes in current practice has not been evaluated and remains unproven.

Clearance of Small Molecular Weight Solutes

Cellulose or substituted cellulose dialyzers

The majority of *in-vitro* and *in-vivo* studies indicate that reprocessing with either formaldehyde (with or without bleach) or peracetic acid does not affect small molecular weight solute (urea or creatinine) clearances of cellulose or substituted cellulose dialyzers. These studies have evaluated the performance of dialyzers by direct measurement of dialyzer clearances after either a small number of reuses (up to 10)[14,15] or large number of reuses (20–30).[16] In one study, the pre-dialysis urea and creatinine concentrations were measured, and no clinically or statistically significant difference between single-use dialyzers and those reprocessed with formaldehyde/bleach up to five times was observed.[17] In a study by Vanholder and colleagues,[18] urea and creatinine clearances and ultrafiltration capacity of cuprophan dialyzers reprocessed with formaldehyde remained unaltered for the small surface area dialyzers (1.0 m^2). However, these investigators observed a small but significant decrease in urea and creatinine clearance for those cuprophan dialyzers tested with the largest surface areas (1.8 m^2). There was a substantial volume loss in these large surface area dialyzers, which may have been the reason for the decrease in dialyzer clearance. In contrast, in a more recent *in-vivo* study of cellulose dialyzers reprocessed with formaldehyde and bleach, Murthy and colleagues[19] observed no such decline in urea or creatinine clearance with reuse.

Reprocessing with peracetic acid does not seem to affect small molecular weight solute clearance of cellulose dialyzers. Vanholder and colleagues[18] observed that reprocessing small or large surface area cuprophan dialyzers with peracetic acid resulted in neither a loss of volume nor a loss of clearance. Likewise, Leypoldt and colleagues[20] observed that the small molecule (urea and phosphate) clearances of low-flux cellulose (TAF175) or substituted cellulose dialyzers (CA210) reprocessed with peracetic acid did not decrease significantly between the 1st and 15th use.

Urea clearances were measured in the HEMO study for several different dialyzer types and for various reprocessing methods on a large number of patients. For low-flux dialyzers (that included cellulose acetate and polysulfone dialyzers), urea clearances decreased by only 1% for every 10 reuses with no significant differences between the various reprocessing methods noted.[21] In the same study, urea clearances of cellulose high-flux dialyzers (CT190G) decreased more with peracetic acid reprocessing than with formaldehyde/bleach reprocessing. However, with either method, the urea clearances of CT190G dialyzers were well above the 90% requirements as estimated from the TCV, for up to 20 reuses.[21]

In summary, neither the small molecule clearances nor the ultrafiltration capacity of cellulose/substituted cellulose dialyzers is affected with reuse, irrespective of the germicide used.

Synthetic dialyzers

With respect to high-flux synthetic dialyzers, the magnitude of the decrease in urea or creatinine clearances with reprocessing appear to be higher than with low-flux cellulose dialyzers. On a small number of patients, Murthy and colleagues[19] observed that reprocessing of F80B dialyzers with formaldehyde decreased the urea clearance from 280 ± 4 mL/min for new dialyzers to 253 ± 7 mL/min after 20 reuses, at a blood flow rate of 400 mL/min. Although the HEMO study observed that the loss of urea clearance of high-flux dialyzers with reuse was much smaller (1.4% decrease for every 10 reuses), this decrease was larger than with substituted cellulose dialyzers for the same reprocessing method.[21] Similarly, peracetic acid reprocessing with or without bleach only modestly affects the urea clearance, as observed in the earlier studies[18,20,22] as well as the more recent HEMO study.[21]

Very limited studies are available on the behavior of other synthetic membranes. Vanholder and colleagues[18] observed that urea clearance of PAN membrane dialyzers reprocessed with formaldehyde decreased from 117 mL/min during the first use to 91 mL/min during the seventh use (22%). Likewise, the ultrafiltration capacity decreased from 1.01 mL/min/mmHg during the first use to 0.41 mL/min/mmHg during the seventh use.[18] Similarly, the same investigators observed that PAN or AN69 dialyzers, reprocessed with peracetic acid, showed a significant decrease of urea and creatinine clearances with reuse, with a concomitant fall of ultrafiltration capacity.[18]

Of all the currently available sterilizing methods used in the reprocessing of dialyzers, heat and citric acid reprocessing has the smallest adverse effect on small molecule clearances. The average decrease in the urea clearance is 1% for every 10 reuses.[21] One of the drawbacks of the physical methods of reprocessing such as heat and citric acid is the limited number of reuses obtainable. Despite improvements in the technique over the years, use of this reprocessing technique is very limited in the United States, where only 4% of centers use this method.[8]

Thus, small molecular weight solute clearances with either cellulose/substituted cellulose or synthetic dialyzers decrease only modestly with reprocessing, with minor differences between different methods. These decreases may be functionally insignificant if a higher dialysis dose is prescribed in units that reprocess dialyzers to account for the temporal decline in clearances with multiple reuses. The clinical implications of changes in clearance of larger molecules will be considered in the next section.

Clearance of Middle Molecular Weight Solutes

β_2 microglobulin (molecular weight 11,800 daltons [Da]) has been used as a convenient marker for assessment of the clearance of solutes in the middle molecular weight range. The HEMO study group has adopted a clearance of β_2 microglobulin of greater than 20 mL/min as a marker of high-flux dialyzers.[21] The β_2 microglobulin clearance of low-flux dialyzers is less than 5 mL/min and remains so with formaldehyde and bleach reprocessing across 20 reuses.[19] In the HEMO study, reprocessing with bleach resulted in a small but statistically significant increase in β_2 microglobulin clearance of these low-flux dialyzers. The increase was more pronounced with non-polysulfone dialyzers (0.52 mL/min per reuse) than with the polysulfone dialyzers (0.25 mL/min per reuse).[21] A similar increase in β_2 microglobulin clearance occurred with peracetic acid and with glutaraldehyde (with bleach) reprocessing,

and the rate of increase did not differ significantly from that of formaldehyde.[21]

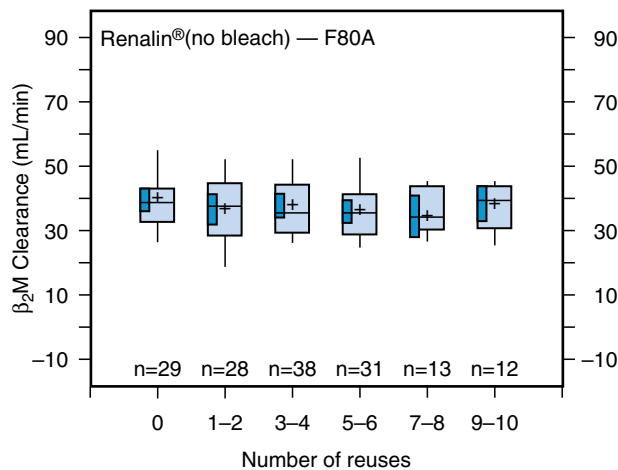
Several investigators have confirmed the increase in β_2 microglobulin clearance with high-flux polysulfone dialyzers reprocessed with bleach. Kaplan and colleagues[23] observed that during clinical dialysis with polysulfone dialyzers (F80) reprocessed with formaldehyde and bleach, the dialysate β_2 microglobulin concentration increased with increasing number of reuses. The mean dialysate β_2 microglobulin concentration during clinical dialysis with F80 dialyzers reprocessed greater than 10 times (1.54 ± 0.15 mg/L) was significantly higher than that with new F80 dialyzers (1.05 ± 0.13 mg/L) or dialyzers reprocessed greater than 10 times without bleach (0.5 ± 0.15 mg/L).[23] Murthy and colleagues[19] also observed that the plasma β_2 microglobulin clearance of F80B dialyzers reprocessed with formaldehyde and bleach, increased from a mean of 15.8 mL/min for new dialyzers to 35.8 mL/min for dialyzers reused up to 20 times. Similarly, data from the HEMO study show that the β_2 microglobulin clearance with polysulfone dialyzers (F80A and F80B) reprocessed with bleach increased with reuse (Figure 19–2) but when bleach is not employed, the clearance decreased with reuse (Figure 19–3). For F80B dialyzers, the β_2 microglobulin clearance increased from 21.3 mL/min at 0 reuse (new dialyzers) to 49.5 mL/min at 20th reuse with formaldehyde/bleach reprocessing and from 21.3 mL/min at 0 reuse to 41.9 mL/min at 20th reuse with peracetic acid and bleach reprocessing.[21] With peracetic acid reprocessing without bleach, the β_2 microglobulin clearance decreased from 41.1 mL/min at 0 reuse to 36.5 mL/min at tenth reuse.[21]


Figure 19–2   Effect of reprocessing using formaldehyde with bleach *(A)*, Renalin with bleach *(B)*, and glutaraldehyde (Diacide) with bleach on ß$_2$M clearance by polysulfone high-flux (F80B) dialyzers. The box and whisker plots show the 10th, 25th, 50th (median), 75th, and 90th percentile values. The plus sign (+) represents the mean and the hatched region represents the 95% confidence interval for the mean. (From Cheung AK, Agodoa LY, Daugirdas JT, et al: Effects of hemodialyzer reuse on clearances of urea and beta-2-microglobulin. The Hemodialysis [HEMO] Study Group. J Am Soc Nephrol 1999; 10:117-127, with permission.)
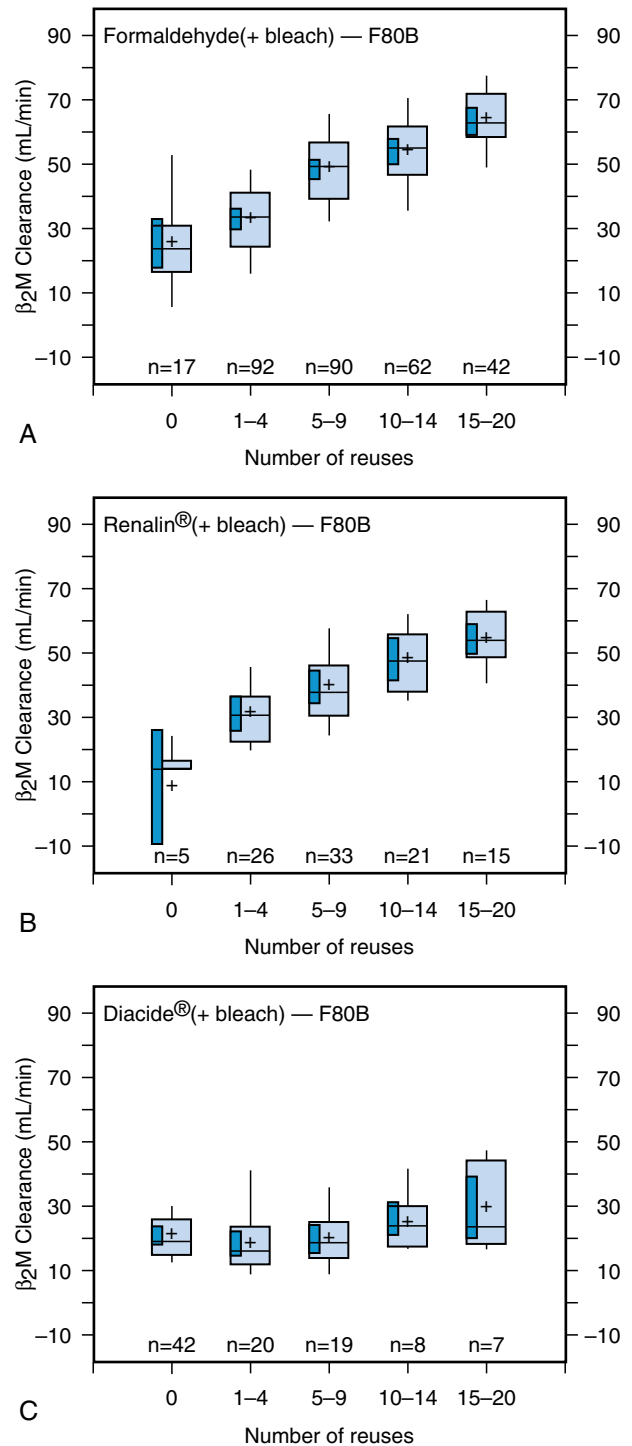

Figure 19–3   Effect of reprocessing using Renalin *without* bleach on ß$_2$M clearance by polysulfone high-flux (F80A) dialyzers. The box and whisker plots show the 10th, 25th, 50th (median), 75th, and 90th percentile values. The plus sign (+) represents the mean and the hatched region represents the 95% confidence interval for the mean. (From Cheung AK, Agodoa LY, Daugirdas JT, et al: Effects of hemodialyzer reuse on clearances of urea and beta-2-microglobulin. The Hemodialysis [HEMO] Study Group. J Am Soc Nephrol 1999; 10:117-127, with permission.)

In contrast to high-flux polysulfone dialyzers, the β_2 microglobulin clearance of high-flux cellulose dialyzers (CT190G) reprocessed with bleach does not increase with reuse. Moreover, peracetic acid reprocessing (without bleach) is associated with a marked decrease in β_2 microglobulin clearance, particularly during the first four reuses.[21]

Studies on the behavior of synthetic membranes other than polysulfone, reprocessed with bleach or peracetic acid, are limited. The principal mechanism of β_2 microglobulin clearance with high-flux polymethyl methacrylate (PMMA) membranes is by adsorption to the dialysis membranes.[24] The efficacy of β_2 microglobulin removal with PMMA is expected to decrease when reprocessed with peracetic acid, because peracetic acid does not strip the membrane of the protein coat formed from an earlier exposure of the membrane to blood. However, during clinical dialysis with PMMA dialyzers, Westhuyzen and colleagues[25] observed that serum β_2 microglobulin concentrations decreased significantly at 15, 60, and 240 minutes into dialysis compared to the pre-dialysis values during the first use, as well as during the second and fourth uses, suggesting an increase in β_2 microglobulin clearance. The dialysate concentrations of β_2 microglobulin increased significantly with reuse from the first to the fourth use. This increased appearance of β_2 microglobulin in the dialysate may have accounted for an increased clearance of β_2 microglobulin during the fourth use of the membrane when compared to its first use. The exact mechanisms underlying this increased clearance into the dialysate are unknown. It is also probable that when reused beyond four times, the β_2 microglobulin removal by these dialyzers may decline. Indeed, Kerr and colleagues[26] observed a decrease in β_2 microglobulin clearance with peracetic acid reprocessed PMMA hemofilters, after the fourth use.

AN69 dialyzers also remove β_2 microglobulin by both adsorption and filtration.[24] *In-vitro* studies observed that reprocessing of these dialyzers with peracetic acid significantly decreased their ability to clear β_2 microglobulin, but bleach reprocessing did not.[24] This observation is consistent with the fact that bleach strips the membrane of the protein coat from a previous exposure to blood, but peracetic acid alone does not. Data on β_2 microglobulin clearance of AN69 dialyzers are limited and are derived from dialyzers reused only a few times. An *in-vivo* study observed that the percent removal of serum β_2 microglobulin by AN69 dialyzers reprocessed with peracetic acid showed no significant decrease up to the fourth use.[25] Whether the removal of serum β_2 microglobulin increases significantly with higher number of reuses of these dialyzers, is a matter of conjecture. In contrast to the PMMA dialyzers, the dialysate concentrations of β_2 microglobulin with AN69 dialyzers did not increase following reprocessing with peracetic acid.[25]

A consistent pattern emerges from the studies discussed above. For polysulfone dialyzers, employing bleach in the reprocessing method with either formaldehyde or peracetic acid as the germicide increases, and reprocessing with peracetic acid alone decreases β_2 microglobulin clearance. A similar but more profound decrease of β_2 microglobulin clearance is observed with high-flux cellulose dialyzers when peracetic acid alone is used but not when bleach is added as a cleansing agent. The mechanism by which bleach increases β_2 microglobulin clearance of polysulfone dialyzers is unclear, but it has been hypothesized that bleach leaches the polyvinyl pyrrolidone (PVP), a copolymer in the membrane, thus increasing the sieving coefficient of the membrane.[27] This has not been proven under actual clinical conditions. The marked decline in β_2 microglobulin clearance of high-flux cellulose dialyzers may be secondary to a protein layer formation that is ineffectively removed by peracetic acid alone.

Protein and/or Albumin Loss

In 1992, with *in-vitro* experiments, Donahue and colleagues[28] showed that the clearance of small (1400 Da) and middle molecular weight (10,000 Da) polymers by polysulfone dialyzers (F60) increased significantly following reprocessing with 1% bleach and formaldehyde, suggesting that reprocessing with bleach alters the membrane permeability of polysulfone dialyzers. Subsequently, Kaplan and colleagues[23] observed that reprocessing of polysulfone dialyzers (F80) with bleach led to a loss of proteins and albumin into the dialysate, and the degree of protein and albumin loss was directly related to the number of times the membrane was reprocessed with bleach (Figure 19–4). The mean dialysate protein concentrations progressively increased from 1.5 mg/dL during the 1st use, to 19.9 mg/dL after 23 to 25 reuses. The mean dialysate protein losses (in the entire spent dialysate) increased progressively from 1.2 g at 1st use to 17.5 g during the 23rd through 25th reuses. In contrast, dialyzers reprocessed without bleach had significantly lower protein losses and did not demonstrate a relationship with reuse. The mean dialysate protein concentrations of the dialyzers with nonbleach reprocessed polysulfone dialyzers after 10 reuses (2.1 mg/dL) were not significantly different from that of the 1st use (dry pack) of the dialyzers (1.5 mg/dL).[23] In addition, Kaplan and
Figure 19–4 Effect of reprocessing of high-flux polysulfone (F80) dialyzers using formaldehyde with bleach on dialysate albumin losses. (From Kaplan AA, Halley SE, Lapkin RA, Graeber CW: Dialysate protein losses with bleach processed polysulfone dialyzers. Kidney Int 1995; 47:573-578. Reprinted with permission.)

colleagues[23] observed that the mean serum albumin levels ranged from 3.5 to 3.6 g/dL during the 6 months prior to discontinuing the bleach from the reprocessing cycle, compared to 3.8 to 3.9 g/dL 3 weeks after discontinuing bleach, in the same patients. These data support the contention that the decrease of serum albumin among these patients may be due to the excessive protein and albumin leak from the dialyzers reprocessed with bleach. Following this study, the manufacturer changed the membrane configuration of F80 dialyzers such that protein leak decreased significantly. Indeed, in a subsequent study, Murthy and colleagues[19] observed that albumin loss from bleach reprocessed F80B dialyzers was negligible for up to 20 reuses. Currently, albumin leak does not seem to be a significant problem anymore with F80B dialyzers reprocessed with bleach.

Protein losses from polysulfone dialyzers (F80) reprocessed with peracetic acid have been shown to be much lower compared to that of dialyzers reprocessed with formaldehyde/bleach. Protein loss after 15 or more uses of polysulfone dialyzers (HF80) reprocessed with peracetic acid was 3.2 ± 1.1 g, a value not significantly different from that with 1st use (dry pack) of the dialyzer.[29]

Reuse and Delivery of Dialysis Prescription

The mortality risk among hemodialysis patients is lower by 7% for each 0.1 increment in delivered Kt/V, and by 11% for each 5% increase in delivered URR.[30] One of the potential reasons for a decreased dialysis adequacy is a decline in dialyzer performance following multiple reuses of dialyzers. In a multicenter study, Sherman and colleagues[12] observed a significantly greater delivered Kt/V (urea) (1.08 vs. 1.02) in centers with low reuse of dialyzers (mean of 4 times) compared to centers with high reuse of dialyzers (mean of 14 times), suggesting a decline in performance of dialyzer with reuse. In 43% of the centers using formaldehyde reprocessing, the difference in Kt/V values between low and high reuses averaged 0.17.[12] However, this study showed a strong center difference, probably related to practices associated with differences in reprocessing techniques. In the context of an increased mortality risk with decreased dose of dialysis, this decline in dialysis dose with reuse was a matter of concern. However, subsequent studies did not confirm this trend. In a prospective study of patients randomized to single use or reuse of cellulose dialyzers with glutaraldehyde and bleach, Pereira and colleagues[31] did not observe a significant difference in URR between groups, over a period of 3 months. In another study using the USRDS data, Agodoa and colleagues[32] observed a higher delivered dose of dialysis as measured by Kt/V (urea) at units that reprocessed dialyzers compared to those that did not (1.22 vs. 1.19). This may be attributable in part to a higher frequency of use of high-flux dialysis among units that reused compared with those that did not (97% vs. 65%), in that study.

Thus, it is encouraging to note that reuse does not, at least, adversely affect the actual delivered dose of dialysis. Although all dialysis units monitor the delivered dialysis dose by measurement of URR or urea kinetic modeling, such measurements are usually performed only on a monthly basis and do not provide timely identification of suboptimal delivered dose from dialysis after many reuses. Dialysis units that practice reuse should be watchful that reuse can adversely affect dialysis adequacy. In such situations, the on-line monitoring systems (blood-side and dialysate-side monitoring of Kt/V) may help assess the efficacy of delivery of dialysis prescription during dialysis with reprocessed dialyzers.

EFFECT OF DIALYZER REPROCESSING ON MEMBRANE BIOCOMPATIBILITY

Complement Activation and Leukopenia

Complement activation and leukopenia during hemodialysis, first described more than 2 decades ago,[33] has now become the benchmark for biocompatibility of dialysis membranes. These changes are observed with cellulose and substituted cellulose dialyzers within the first 30 minutes of dialysis and typically improve to baseline levels prior to the completion of dialysis. These have been shown to be secondary to activation of the complement alternate pathway by these membranes.[4,34] Subsequent investigators have reported an improvement in levels of complement fragments C3a, C3b, and C5a with reprocessed dialyzers compared with first use,[3-5, 35] suggesting an improvement of biocompatibility with reprocessing of dialyzers. It has been shown that the reprocessing technique is also important in improving the biocompatibility of the membrane.[3,5,35] Although reprocessing with both formaldehyde and peracetic acid mixture are associated with improvement in complement activation, use of bleach does not provide the same benefit.[15,36] This protective effect is from coating of the membrane surface with the patient's blood proteins after the first use, which is further stabilized with formaldehyde and peracetic acid. Bleach strips the membrane of the protein layer, thus reverting to the original membrane configuration with loss of this acquired "biocompatibility." With the use of more biocompatible membranes such as synthetic polysulfone dialyzers, complement activation and leukopenia during dialysis have decreased significantly even with new dialyzers. Mitigation of complement activation and leukopenia, either with new dialyzers or with reused dialyzers, has not been shown to be associated with improved clinical outcomes.

Anaphylactoid Reactions

First use syndrome

Another advantage of reuse of dialyzers is a decrease in the incidence of "first use syndrome." This first use syndrome was first described in 1978 by Dolovich and colleagues[37] in a hemodialysis patient who was sensitized to ethylene oxide gas that was used for sterilization of blood tubings. These authors investigated whether the acute allergic reactions seen in other patients on hemodialysis might be similarly caused. They reported that in Hamilton, Ontario, 22 of the 27 patients with allergic reactions were positive for ethylene-oxide antibodies.[38] As described since, the syndrome ranges in severity from a mild chest and back pain to hypotension, bronchospasm, and anaphylaxis.[39] A decrease in the incidence of the syndrome with reprocessed dialyzers and preprocessing of dialyzer prior to first use[40] can be explained in part by the reduced content of residual ethylene-oxide in these situations. Interestingly, complement activation is also seen more often with new dialyzers[41] but less often with reprocessed dialyzers.[4]

This led to the confusion in the mid-1980s that the first use syndrome might be due to complement activation. The lack of correlation between the degree of complement activation and the incidence of the syndrome negated this view.[42] It is now believed firmly that first use syndrome is indeed the result of an IgE-mediated reaction to residual ethylene oxide gas. Although ethylene oxide is still used in the dry packs, better manufacturing processes to decrease the content of the gas have decreased significantly the incidence of the syndrome overall.

Reuse Syndromes

Anaphylactoid reactions attributed to reprocessed dialyzers have also been reported. Pegues and colleagues[43] observed 12 episodes of anaphylactoid reactions, all associated with reuse of dialyzers and none with new dialyzers. The sterilant used for reprocessing was peracetic acid with an automated reprocessing system, in this instance. Following termination of reuse, they reported that such episodes ceased to occur. Most of the patients with anaphylactoid reactions were on angiotensin-converting enzyme inhibitors (ACEI). Use of ACEI and AN69 membranes has been implicated in anaphylactoid reactions in dialysis patients.[44-46] These reactions have been attributed to the generation of bradykinin, as these reactions were observed in patients with high plasma bradykinin levels, even in the absence of ACEI but always with use of AN69 membranes.[47] Although not investigated, it is quite possible that anaphylactoid reactions with ACEI and peracetic acid reprocessing may have a similar bradykinin etiology. Interestingly, in an open label study of 406 hemodialysis patients on angiotensin receptor blocker, Losartan, for control of hypertension, Sarache and colleagues[48] observed only two episodes of anaphylactoid reactions over a 6-month period. About a fourth of these patients were dialyzed using AN69 membrane. Furthermore, nine patients who exhibited anaphylactoid reactions with ACEI and AN69 membranes did not have any episodes with Losartan despite continuing to dialyze with the same membrane.[48] These reports lend support to the bradykinin hypothesis because bradykinin levels are significantly less with Losartan compared with ACEI.

Chronic Inflammatory Response

During hemodialysis, blood leukocytes are exposed to the dialyzer membrane and tubing, soluble membrane constituents, complement, and other plasma products activated by the membrane-blood interactions. Leukocytes are also exposed to the bacterial products that diffuse from dialysate to the blood compartment (backfiltration). These interactions stimulate the leukocytes to produce pro-inflammatory cytokines.[49] Several studies in patients on hemodialysis have demonstrated evidence of increased cytokine production by blood leukocytes before and during hemodialysis.[50-52] Henderson and colleagues[49, 53] have hypothesized that hypotension and pyrogen reactions observed in hemodialysis patients and dialysis-related morbidity are secondary to interleukin-1 release by blood-membrane interactions during dialysis. To date, this hypothesis remains unproven, although the symptoms observed with cytokine release are similar to those seen during dialysis reactions.

With respect to reprocessed dialyzers, Lufft and colleagues[54] observed that cytokine-inducing substances, like

bacterial products, are retained in the protein layer formed during the first and subsequent uses, despite sterilization of the dialyzer. These products are biologically active in inciting a cytokine release *in vitro*. The bacterial products are likely to gain access to the dialyzer because the water that is used for reprocessing is neither sterile nor pyrogen free. Indeed, pyrogen reactions are more frequently observed among patients treated with reprocessed dialyzers than in patients treated with single use dialyzers.[55] However, these observations are not supported by clinical studies or studies under controlled laboratory conditions. In a single center study, Pereira and colleagues[31] studied plasma cytokine levels in 37 chronic hemodialysis patients randomized to either single use dialyzers or to dialyzers reprocessed with glutaraldehyde and bleach. They observed that levels of plasma IL-1Ra, C3a, lipopolysaccharide binding protein and bactericidal-permeability increasing factor were not significantly different between the two groups at baseline, 15 minutes into dialysis, or at the end of dialysis.[31] Even the endotoxin and IgG stimulated cytokine production by the peripheral blood mononuclear cells (PBMC) were similar in the two groups. In another study, the same investigators performed *in-vitro* dialysis using formaldehyde/bleach or peracetic acid mixture-reprocessed cuprophan dialyzers and compared the cytokine production by unstimulated and endotoxin-stimulated PBMC before and after *in-vitro* dialysis.[56] They observed that after a 3-hour *in-vitro* dialysis, the increase in IL-1α production by unstimulated PBMC was not statistically significant with either new or reprocessed dialyzers. In contrast, a statistically significant increase was observed in IL-1α production by endotoxin-stimulated PBMC with new as well as formaldehyde/bleach reprocessed dialyzers, but the increase with peracetic acid mixture reprocessed dialyzers was not significant. These findings argue against the notion that exposure to reprocessed dialyzers results in enhanced production of pro-inflammatory cytokines. The long-term clinical significance of elevated cytokine levels in dialysis patients is still debated.

Last, chronic kidney disease itself is considered a pro-inflammatory state with higher levels of plasma cytokines and C-Reactive Protein (CRP) levels observed in these patients even before start of dialysis, compared with controls.[50,57,58] Levels are even higher in hemodialysis patients.[57,59-61] While this chronic inflammatory state may be responsible, in part, for the high cardiovascular morbidity and mortality in dialysis patients, no convincing evidence has yet emerged that circulating CRP levels are any higher in patients treated with reprocessed dialyzers or that their cardiovascular morbidity or mortality is higher, compared with patients treated with single use dialyzers.

INFECTIOUS AND CHEMICAL HAZARDS OF DIALYZER REPROCESSING

Introduction

Reprocessing of dialyzers may have some additional direct adverse effects that could result in increases in morbidity, and possibly mortality, for patients on dialysis and adversely affect their quality of life. Some of the major types of adverse effects that have been attributed to reuse include[62]:

- Nosocomial bacterial infections, especially with gram-negative bacteria or non-tuberculous mycobacteria.
- Nosocomial viral infections with hepatitis B, C, and HIV.
- Pyrogenic reactions to preformed bacterial endotoxins.
- Toxic effects from acute exposures to germicides used to reprocess dialyzers.
- Effects after chronic exposures to low levels of germicides.
- Environmental and occupational issues related to reprocessing of dialyzers.

Serious adverse events attributable to reuse are currently identified through voluntary reporting to the Centers for Disease Control (CDC) and through CDC's investigation of adverse event clusters. This method of defining the risks from reprocessing of dialyzers depends on event recognition, proper attribution, and accurate reporting by clinicians. Such methods generally significantly underestimate the full impact of reuse on patient health and quality of life through underestimating the incidence of these adverse events.[63] The true magnitude of the risk and the scope of the adverse effects of dialyzer reuse can be ascertained only by proactively collected data on the entire cohort of dialysis patients.[64] More comprehensive data may be available in the future through a more proactive approach of surveillance as anticipated with the creation of the Dialysis Surveillance Network. The current best evidence available to define the types of potential risks of reuse still relies heavily on the reactive analysis of adverse events.

Current evidence demonstrates that the most common, albeit still remarkably uncommon, adverse events reported in clusters are those related to "nosocomial" infections or to endotoxins elaborated exogenously as a consequence of bacterial contamination.[8,55,65] Accidental exposures to chemical sterilants and/or germicides occur less commonly. Both pyrogenic reactions and first-use-like reactions appear to be related directly to acute exposures to one of the chemicals associated with dialysis, notably the sterilants used in packaging new dialyzers and the germicides that may become adherent to the dialyzer membranes during reprocessing. They are then released during subsequent hemodialysis treatments. Many of the outbreaks of pyrogenic reactions that are subjected to formal root cause investigations are determined to be related to exposure of patients to bacteria or bacterial endotoxins. It is uncertain to what degree pyrogenic reactions related to transient bacteremias are underreported.

Consistent with the rarity of the reported adverse events and with findings that many of these occur because of deviations from the formal AAMI reuse guidelines, the CDC has described reuse of dialyzers as safe if performed with strict adherence to AAMI reuse guidelines.[66,67] Although the current AAMI standards are based on expert opinion and have not been formally validated through rigorous controlled trials, the relative infrequency of both infection related and non-infectious adverse events when these standards are upheld provides relatively strong evidence of their efficacy. It should be emphasized, however, that if protocols based on these standards are breached, then serious nosocomial infections do occur.[65] Furthermore, these AAMI guidelines based on best current opinion and evidence have required modifications in response to the findings from adverse event investigations. Finally, epidemiologic evidence demonstrates that the type of reuse process matters when considering adverse events such as

nosocomial transmission of infections, and that automated reprocessing procedures reduce infection transmission and pyrogenic reactions.[68]

A detailed account of the risk of bacterial and viral infections associated with reprocessing of dialyzers is explained in another chapter. This section gives an overview of these risks.

Risks of Infection

Bacterial

Serious bacterial infections remain a major cause for morbidity and mortality in dialysis dependent patients,[65] and this infection rate is influenced by dialyzer reuse. As part of their annual survey of dialysis practices, the CDC have reported from 1986 through 2000 the incidence of pyrogenic reactions associated with dialyzer reprocessing, and a comprehensive analysis of the association of pyrogenic reactions with reuse and the risk factors for this reaction was conducted as part of the 1994 survey.[55] Tokars and colleagues[55] reported in their analysis of the 1994 data that 24% of centers conducting reuse compared to 14% of centers not conducting reuse reported pyrogenic reactions and that 3% of the former and only 1% of the latter reported clusters of these reactions. Both differences were statistically significant. On further analysis of these data, the CDC investigators demonstrated that both reuse and high-flux dialyses were independent predictors of the pyrogenic reactions. The latter is more likely to occur if reprocessing changes membrane characteristics to allow for higher rates of transmembrane flux and, in particular, backflux from the dialysate, of bacteria or endotoxins. The CDC investigators also determined that the increased risk of pyrogenic reactions was associated equally with reprocessing with the germicides formaldehyde or peracetic acid. In the same analysis, the CDC investigators were unable to demonstrate an association between reports of overt sepsis and reuse. For reasons specified above, these analyses are limited by the possibility of ascertainment biases.

An estimate of the risk of sepsis associated with reuse that is less influenced by reporting and ascertainment biases can be obtained from the analysis of the incident dialysis patient cohort assembled for the USRDS case-mix study.[69,70] These investigators conducted a series of analysis of the incidence of sepsis in this representative sample of incident dialysis patients followed prospectively over a 7-year period, where dialysis characteristics such as access type and reuse were determined at baseline. Hospital managed sepsis was defined by ICD-9 codes for a principle admitting diagnosis of sepsis on Medicare claims records submitted upon discharge and, thus, identification of sepsis incidents was not influenced by apriori hypothesis or dependent on voluntary targeted surveillance. Although their conclusions are somewhat limited by the potential impact of misclassification bias and of secular trends in dialysis care during the extended follow-up observation period, these authors provide the first evaluation of the impact of reuse on sepsis risk in a prospectively followed longitudinal cohort. They demonstrated that for the entire cohort of incident hemodialysis patients, assignment to reuse during the baseline period was associated with 28% increase in risk of hospital-managed sepsis.[69] In a separate analysis stratified for the presence or absence of diabetes mellitus, Jaar and colleagues[70] demonstrated that the increased relative risk of

sepsis with reuse was largely confined to patients with diabetes. A similar increase risk for non-diabetic patients could not be excluded.

Several hypotheses have been proposed for the possible etiologies of the increased risk of sepsis, bacterial infections without sepsis, and viral infections uniquely attributable to reuse. These include:

- Technical errors, including inadequate sterilization during reprocessing due to either limitations of the effectiveness of germicides at practiced concentrations or inadequate adherence to recommended concentrations.
- Changes in pore size or sieving characteristic of the dialysis membrane that allow for flux of bacteria and virus from the dialysate to the patient's bloodstream.
- Reuse-associated changes in the immune, hematopoietic, or vascular systems or in the nutritional status of patients on dialysis that could otherwise heighten their susceptibility to infection.

Investigations into outbreaks of infections have provided insights into these potential mechanisms. Reports from investigations of clusters of infection episodes have demonstrated clearly that severe sepsis can occur because of human errors with significant adverse effects on patient mortality and morbidity.[65,71-79] A common feature of many of these outbreaks is a "seeding" of the dialysis membranes, o-rings, caps, or other materials with bacteria from contaminated or inadequately purified or sterilized water used in the flushing of and subsequent cleansing of the dialyzers during reprocessing. This problem is then compounded by a failure of the sequential sterilization and storage techniques to ensure adequate sterilization of the dialyzers prior to their next use. Many of the incidents have, as a root cause, a break down in strict adherence to the AAMI reuse guidelines where critical steps in the process of reuse were either violated or by-passed or where concentrations of sterilant known to be inadequate were inadvertently used. A number of the failures in process were, however, defined only after investigations of particular outbreaks of infections revealed inadequacies in the process dictating changes in the AAMI standards. The random rate of occurrence in these incidences and a lack of a defined secular trend in reported outbreaks despite improvements in equipment and techniques support the hypothesis that much of the excess risk of sepsis might be related to human errors, accidents, or some fundamental problem in process yet to be identified.[64]

Two classes of bacteria have been implicated in the majority of dialysis related infectious outbreaks reported to date. Infections with gram-negative bacterial rods, including *Klebsiella* and *Pseudomonas aeruginosa* and *Enterobacter* species have been cultured from water sources and dialysate.[65,80,81] A number of infectious outbreaks traced to nontuberculous mycobacteria have also been identified with associated significant patient morbidity and mortality.[65] Three components are required for these nontuberculous mycobacteria to cause patient morbidity in association with reuse. They have been identified to occur commonly (50% of water samples in 83% of centers in one CDC survey) in the water used for preparation of dialysate and for reprocessing of dialyzers.[82] Patients are exposed to viable organisms either from contamination of the blood side of the dialyzers during reprocessing or across dialysis membranes during dialysis. The former

might occur if standard sterilization techniques are inadequate. Evaluation of a number of the early outbreaks in the 1980s revealed that these organisms were relatively resistant to chemical germicides and sufficient concentrations of either formaldehyde or peracetic acid were required to ensure bacterial killing.[82] Patients might be exposed additionally to these organisms if the water quality is substandard *and* if reprocessing of dialyzers alters the exclusion properties of the dialysis membranes sufficiently to allow for flux of viable organisms from dialysate to patient. This problem would be compounded if reprocessed dialyzers exhibit significant dialysate backflux with reuse. Although reprocessing does alter some flux properties of the dialysis membranes, there is no evidence that sterilants currently in use alter membranes sufficiently that in the absence of a frank blood leak, to permit flux of microorganisms from dialyzer to patient occurs.[83,84] Automated reprocessing techniques check for blood leaks and membrane integrity with each reprocessing, thereby ensuring patient safety, if strict adherence to AAMI guidelines is maintained.

Viral Hepatitis and HIV Infections

Through the national dialysis surveillance surveys and other tools, the CDC and others have evaluated the risk of transmission of hepatitis with reuse. The CDC has recommended isolation of hepatitis B patients since the early 1980s for control of the more virulent hepatitis B virus. Isolation procedures were responsible for a substantial reduction in new hepatitis B infections in patients and caregivers even before the introduction of effective hepatitis B vaccines. This risk of new infections has continued to decline despite incomplete vaccination rates.[8] Dialyzers from patients infected with the hepatitis B virus are not reused in the United States. The infectivity of hepatitis C virus and HIV are substantially lower than the infectivity of hepatitis B, and observational studies do not demonstrate an increased risk of new hepatitis C infection in patients on reuse, in the United States.[85] Hence, the CDC does not currently recommend isolation of patients with hepatitis C or HIV when universal precautions are strictly maintained.[86,87] However, in centers in Europe and Asia with high prevalence of hepatitis C infection, higher incidence of hepatitis C infection has been observed.[88] In addition, even a higher transmission rate of hepatitis C infection has been demonstrated in such centers when reuse is practiced. In addition, isolation of hepatitis C positive patients has decreased the incidence of hepatitis C transmission.[88] A prospective study looking at isolation of reprocessing area of dialyzers (to a separate room) in patients positive for hepatitis C infection has resulted in a lower relative risk of transmission of hepatitis C infection.[89] Though not in the United States, the results of these studies suggest that horizontal transmission of hepatitis C infection in dialysis units is a real risk in centers with high prevalence of hepatitis C infection among their patients, and that reuse of dialyzers adds to this risk. In addition, breaks in reuse protocols might put patients at risk and procedures that reduce the opportunity for error improve patient safety. Although hepatitis C transmission in dialysis units in the United States is low, the true incidence in dialysis units can be accurately determined only when active screening on a regular basis in dialysis units is enforced.[85]

Thus, evidence from both observational studies and prospective cohorts reinforces the conclusion that hemodialysis is an intrinsically potentially hazardous therapy and that breakdowns in strict adherence to validated AAMI guidelines leave patients at increased risk of infections with significant morbidities. These same studies demonstrate that when adherence to AAMI guidelines for reprocessing and reuse are ensured, dialysis can be conducted safely. These observational studies, however, do provide for a degree of uncertainty. The true risk of nosocomial infections attributable to reuse can be determined best by automatic and proactive surveillance of all dialysis patients and additional prospective randomized, controlled clinical trials. The potential risks of nontuberculous mycobacterial infections and from hepatitis C warrants continued consideration. Hepatitis C seroconversion rates for incident dialysis patients can be determined only when active screening for hepatitis C is performed.

Toxicity of Long-Term Exposure to Germicides

Germicides used in the reprocessing of dialyzers are toxic products and are, therefore, inherently dangerous. There are four potential consequences of the use of these agents in reprocessing of dialyzers that should be considered when evaluating their toxicity. These are

- Acute accidental exposures of patients to high concentrations of germicides either intravenously from dialyzers or water systems or dermal/inhalation exposures from accidental spills.
- Long-term low dose exposure of patients to germicides from residual concentration of germicides within the dialyzers.
- Acute toxicities of germicides to health care workers.
- Environmental consequence of exposures to germicides.

A number of acute exposures to germicides as noninfectious outbreaks have been reported to the CDC over the last 3 decades. These have involved principally accidents during sterilization of water systems used to prepare and/or deliver dialysate.[90] Formaldehyde was reported to the CDC as the causative agent in an outbreak in 1981.[90] In this case, patients experienced the acute effects of formaldehyde exposure within minutes of initiating dialysis. The acute effects of intravenous formaldehyde include hypotension, cardiovascular collapse, lactic acidosis, respiratory distress, hemolysis, and death.[91] The probable source for the formaldehyde was backflow of water containing formaldehyde from a recycling loop.[90] The frequency of accidental exposures to individual patients from a breakdown in mandated reprocessing procedures and failure to clear germicides from the dialyzers is unknown since recognition of a single major adverse event in a dialysis patient that can be attributed to reuse is difficult. Animal studies and reports from the occupational literature do not examine the effects of intravenous exposure to germicides. Our knowledge about the effect of intravenous exposures comes from the outbreak analyses. Germicides administered intravenously would be expected to result acutely in irritation of the blood vessels from infusion of intermediate amounts of germicides as may occur with incomplete washout after dialyzer reprocessing. Such events have been reported.[90] This is potentially problematic since the usual method to test for residual germicide such as the Schiff test for formaldehyde identifies only concentration greater than 5 ppm and does not protect against release during dialysis of retained reservoirs of germicides.[92]

Another potential acute toxicity to patients on reuse is an increased risk of acute allergic reactions.[90] A higher frequency of acute allergic reactions has also been reported in patients on angiotensin converting enzyme inhibitors and on reuse but is not associated with one particular germicide or another. The increased risk is associated with cleaning of the dialyzers with bleach or hydrogen peroxide during reprocessing, but the exact mechanism of this risk is unknown. This risk is detailed in earlier text.

The long-term consequences of low-dose exposure to germicides (e.g., <5 ppm) is unknown. During the 1970s and 1980s, patients treated with dialyzers reprocessed with formaldehyde were reported to develop cold agglutinins that were thought to increase kidney transplant allograft loss.[93] It was felt that the most likely cause for these cold agglutinins was formation of antibodies to blood group N during reprocessing. Reduction of formaldehyde levels to less than 2 ppm has reduced this problem substantially.[94] However, recent reports suggest that anti-N antibodies and other coombs positive reactions associated with reuse might remain an important toxicity form chronic long-term exposure. Ng and colleagues[95] demonstrated an increased prevalence of anti-N_{form} antibodies and coombs positive reactions in patients on reuse. A chronic low-grade hemolysis due to these antibodies and associated with reuse was assumed to have occurred in any patient whose hematocrit improved when reuse was discontinued.[95]

Health care workers and patients may also be exposed to the toxic effects of germicide concentrations in the ambient air or through dermal contact. Formaldehyde is an OHSA regulated substance. Ventilation of reprocessing area and air quality monitoring for toxic levels are mandated. It is uncertain, however, what constitutes a safe level of a chemical such as formaldehyde. Medical students with normal lung function participating in a gross anatomy laboratory with ventilation up to OHSA standards demonstrated substantial deterioration in pulmonary functions after relatively short periods of exposure. Recovery of their pulmonary functions occurred after exposure was discontinued.[91] Furthermore, formaldehyde has a documented carcinogenic potential that may be important for both health care workers and dialysis patients. In the latter group, an increased risk for carcinogenesis has yet to be demonstrated. This may be due to the relatively long lag time required for development of cancers after toxicant exposure and the relatively shorter life expectancy of current dialysis patients. In the future, as a larger number of these patients are successfully transplanted and treated with long-term immunosuppressant drugs or live longer due to improvements in overall dialysis care, the risk of carcinogenesis might be better defined. The direct toxicities of other germicides to health care workers and patients are less certain and appear to be far less potent.

Thus, in order to achieve adequate killing of bacteria and viruses, germicides for cold sterilization of dialyzers must be inherently toxic substances. The accepted methods of dialyzer reprocessing for reuse are designed to minimize the risks to health care workers and patients by substantially reducing the levels of potential exposures. However, the long-term consequences of low-level exposures remain uncertain. Furthermore, reuse of dialyzers provides opportunities for

accidental exposures of patient and/or health care workers to excess quantities of these agents that would not occur in the absence of reuse.

EFFECT ON HOSPITALIZATION AND MORTALITY

Reuse and Hospitalization

Currently, on an average, dialysis patients in the United States experience an inpatient hospital stay of 1.8 days per year.[96] The rate of hospital admissions has decreased by a mere 1% since 1993 for these patients.[97] However, length of hospitalization has decreased by 7% during the same period. Most of the admissions are currently for either cardiovascular or infectious causes, with vascular access related admission having declined by 9% to 14%.[97] Reports on hospitalization rate with the practice of multiple dialyzer use are relatively few. In one of the earliest reports, Kant and colleagues[14] reported no difference in number of hospital days spent per patient when the same patients were transferred from a non-reuse to a reuse dialysis unit. However, this was a single center study with a small study sample and with no ability to either adjust for comorbidities or correct for temporal effects. In another study, the same authors examined the hospitalization rates and length of stay in a larger sample of patients at two centers, Cincinnati, Ohio, and Detroit, Michigan.[98] They observed that either the hospitalization rate (1.63/year and 2.19/year at Cincinnati and Detroit, respectively) or the length of hospitalization stay (14.24 and 22.71 days, respectively) was no different from the contemporary local and national averages.

In a study using Medicare data on over 32,000 prevalent hemodialysis patients in 1989 and 1990 in the United States, Held and colleagues[99] observed that hospital admission rates were significantly higher for patients dialyzed in units that reused dialyzers compared with patients who were dialyzed in units that did not reuse dialyzers. However, this increase in hospitalization rates was observed with either peracetic acid or glutaraldehyde but not formaldehyde reuse (RR 1.11, $p < .01$ for peracetic acid, RR 1.12, $p < .03$ for glutaraldehyde, and RR 1.04, $p = .29$ for formaldehyde).[99] This study had limitations in that it included only *prevalent* patients and that the comorbidity adjustment was limited to a very few covariates. Feldman and colleagues[100] re-analyzed the Medicare data limiting to *incident* patients starting dialysis in 1986 and 1987 in freestanding and hospital-based dialysis units. Their total sample consisted of 27,264 patients. Significant differences were observed between freestanding and hospital-based units. For patients dialyzed in freestanding units that reused dialyzers, there was an 8% increase in hospitalization compared to patients dialyzed in units that did not reuse dialyzers. In addition, an increase in hospitalization was observed with either peracetic acid mixture (11% higher) or formaldehyde (7% higher) but not glutaraldehyde reuse.[100] These differences were not observed among patients dialyzed in hospital-based dialysis units. These findings confirmed those of the earlier study by Held and colleagues[100] referred to earlier. However, the analysis was limited to patients using conventional (low-flux) dialyzers and therefore, not representative of the current practices. In addition, because of limited information in this data set, comorbidity adjustment was limited to age, race, gender, and cause of ESRD.

To overcome the problem of comorbidity adjustment, the same group of investigators used the USRDS case-mix study data where comprehensive information on comorbidity was available at initiation of dialysis. The analysis was restricted to freestanding dialysis units. They observed that among 1491 incident dialysis patients, reuse of dialyzers was associated with a 37% higher hospitalization rate compared with patients treated with single-use dialyzers.[101] Hospitalization rates were 25% higher with formaldehyde reuse and 40% higher with peracetic acid mixture reuse.[101]

Although this data is compelling, a clear cause-and-effect relationship between dialyzer reuse and increased hospitalization cannot be drawn from any of the previously mentioned studies because of inability to control for aspects of care other than reuse, such as adequacy of dialysis, vascular access infections, and so forth. In addition, whether this difference in hospitalization rates with dialyzer reuse and reuse practices persists in the current practice of high-efficiency and high-flux dialyzer use allowing attainment of larger dialysis doses is unclear. Clearly more studies are required in this area to answer definitively these questions.

Reuse and Patient Survival

One of the potential reasons for decreased dialysis adequacy is a decline in dialyzer performance following reprocessing of dialyzers, and any significant decline in dialyzer performance with reuse could result potentially in an increase in overall mortality. In a study using Medicare data for prevalent patients, Held and colleagues[99] observed a 13% increase in mortality among patients treated with dialyzers that were reprocessed with peracetic acid, and a 17% increase in mortality when reprocessed with glutaraldehyde, compared with units that did not practice dialyzer reuse. They observed no significant increase in mortality among patients treated with dialyzers reprocessed with formaldehyde. This was the first study using a national sample that looked at mortality in patients treated with reprocessed dialyzers. The study, however, suffered from certain limitations. The analysis included only dialysis units that predominantly used conventional (low-flux) dialyzers, thus excluding adequate representation of the large number of patients who under current practice use high-flux dialyzers. Hospital-based dialysis units were excluded because of higher comorbidity and a greater variation in case-mix severity among patients treated in these units. Comorbidity adjustment in the statistical analysis was limited and therefore confounding could not be excluded. In addition, the study also suffered from a "survival bias" because only prevalent patients were included.

Feldman and colleagues[102] performed a similar study using Medicare data where they included only *incident* patients who began renal replacement therapy in 1986 and 1987 and followed up until January 31, 1991. They observed that among 27,938 patients, dialysis in freestanding facilities reprocessing dialyzers with peracetic acid mixture was associated with a greater mortality compared with facilities not reprocessing dialyzers (rate ratio 1.10, 95% CI 1.02–1.18).[102] In contrast, survival was not significantly different between facilities reprocessing dialyzers with formaldehyde or glutaraldehyde compared with facilities not reprocessing dialyzers. Among

hospital-based facilities, there was no difference in mortality between facilities that reprocessed dialyzers (with any reprocessing method) and those that did not.[102] These findings were similar to those reported by Held and colleagues despite eliminating most of the survival bias. This study also had limitations. First, unit-level data were used, not patient-level data. Second, comorbidity adjustment was limited because of nonavailability of data. Last, certain strong predictors of mortality such as adequacy of dialysis, anemia management and the like were not taken into consideration.

To address the issue of comorbidity adjustment, Feldman and colleagues analyzed patient survival in the USRDS casemix study data set where they analyzed hospitalization rates, as discussed earlier. In this data set, Feldman and colleagues[101] observed that patients treated with reprocessed dialyzers had a 25% higher mortality compared with patients who were not. Comparing the method of reuse, peracetic acid reuse was associated with a 28% increase whereas formaldehyde reuse was associated with a 29% increase in mortality, compared with single-use dialyzers.[101] This study confirms the increase in mortality with reuse in general, and peracetic acid reuse in particular, observed by Held and colleagues. Furthermore, Feldman and colleagues observed an identical increase in mortality with formaldehyde reuse.

Collins and colleagues[103] replicated the earlier study by Held and colleagues with patient-level data, adjusting for comorbidities, and including anemia treatment as well as profit-status of the dialysis units. Again, this analysis was restricted to units using predominantly conventional dialyzers. Seven major comorbidities were included in the analysis. The results showed that when all germicides were combined, significantly lower risks (0.93 CI 0.88–0.98 for each year period) were identified among freestanding units between 1991 and 1993 but not between 1989 and 1990. With profit status as a covariate, there was no significant effect of germicide on mortality in 1989 to 1990 for either type of unit designation (hospital-based or freestanding), but during 1991 to 1993, freestanding units with reuse had a significantly lower associated mortality risk. When hospital-based and freestanding units were combined for analysis, peracetic acid reuse was associated with a 15% higher mortality (RR 1.15, CI 1.01–1.31) compared to non-reuse only in the 1989 to 1990 period. This higher mortality risk was not seen during the 1991 to 1993 period (RR 1.03, CI 0.92–1.15). Formaldehyde and glutaraldehyde did not have any effect on mortality in these studies during either period. The results of this study indicate that the association of reuse practices with mortality vary in different dialysis unit settings. In addition, the mortality risks during the 1991 to 1993 period were significantly lower compared to the earlier period (1989–1990). Multiple explanations can be offered for this observation—a few being an improvement in reuse technique with more reliance on automated method of reuse; use of erythropoietin for anemia treatment on a more regular basis; and, in general, an improved quality of care over the years. Indeed, data from the USRDS suggest that the mean Kt/V has increased from 0.91 in 1986 to 1.37 for prevalent patients in 1996 to 1997, and URR from 63% to 68% during the same period.[104] However, the previous study by Collins and colleagues[105] also suffers from certain limitations. Incident patients were not analyzed separately in this study, and hence, the "survivor advantage" associated with prevalent patients may influence the results.

Patient-level and unit-level data were mixed and analyzed using complex statistical analyses. Interpretation of the results of this complex analysis have been questioned. Last, the "center effect" may not be actually due to a difference in reuse technique or germicide used but may depend on other policies of the dialysis units, physician practices, or other unknown confounding variables.

In addition, all of the previous studies collectively have certain limitations. These were restricted to dialysis units using predominantly conventional dialyzers and did not account for differences in dialysis dose. Thus, they exclude a large population of dialysis patients using high-flux dialyzers in whom reuse is almost universal.[8] With more frequent use of high-flux dialyzers in reuse units, a larger dialysis dose could be delivered to patients treated in these units. Indeed, Agodoa and colleagues,[32] using the USRDS data, observed a higher delivered dose of dialysis, as measured by Kt/V urea, at units that reused dialyzers compared to those that did not (Kt/V urea 1.22 vs. 1.19). In addition, the frequency of use of high-flux dialysis was higher among units that reused dialyzers compared with those that did not (97% vs. 65%).[32] Thus, an inability to adjust for flux and dialysis dose seriously limits the applicability of the results of these observational studies to the current dialysis practices. In addition, a lack of random assignment of patients to reuse or non-reuse limits the interpretation with regard to cause-and-effect relationship in these studies. Additionally, data on the Health Care Financing Agency (HCFA) 2728 form are subject to error because of incomplete and inaccurate recording of comorbidities. Indeed, a recent study observed a significant underreporting of comorbidities on the HCFA 2728 Medical Evidence form.[106]

Port and colleagues[107] used DMMS data (waves 1, 3, and 4) collected from dialysis units that were randomly selected and adjusted for demographics, comorbidities, dialysis dose, dialyzer flux, and facility type. They observed that overall, there was no significant difference in the adjusted death rates for patients at facilities that reused dialyzers compared with patients at facilities that did not reuse dialyzers (RR 0.96, 95% CI 0.86–1.08). Among patients who reused dialyzers, there was no significant difference in mortality risk between patients whose dialyzers were reprocessed with peracetic acid (without bleach) and with formaldehyde (with bleach) (RR 1.15 for peracetic acid, 95% CI 0.99–1.30). With regard to the type of membrane, patients treated with reprocessed synthetic membranes and use of bleach had the lowest mortality. When synthetic membranes were separately analyzed, low-flux membranes had a 24% higher relative risk of death compared with high-flux membranes, and no bleach use was associated with a similar 24% higher RR of death ($p = .04$ for both comparisons). Although this study is one of the best that has been conducted so far, it still suffers from limitations such as survival bias. Attribution of patients to dialysis modality (reuse or non-reuse) was done at enrollment into the study, and any subsequent change in modality was not captured.

In a retrospective analysis, Lowrie and colleagues[108] recently analyzed the association of reuse with mortality risk in 71,122 patients treated at dialysis units in the United States, owned by Fresenius Medical Care. Some facilities changed their policy from reuse to single use, and this offered the opportunity to study the effects of reuse and single use in patients treated at these units. In considering cumulative effects of either of the treatment options, a lag analytic strategy

was used to model the effects of reuse on mortality, with lag times of 30, 60, 90, and 120 days from the time of switch from reuse to single use. Analyses were adjusted for case-mix and follow-up was 12 months from entry into study. They observed a survival advantage with changing from reuse to single use with benefit improving as the lag time increased (hazard ratio 0.93, $p = .02$ at 6 months, and 0.92, $p = .01$ at 1 year).[108] Again, there are several limitations to this study. Some of these include:

1. Reprocessing method was not taken into consideration.
2. Membrane flux was not modeled.
3. Temporal effects could not be excluded despite the lag time analytic technique.
4. Study was restricted to prevalent patients only.

In addition, the study includes patients treated by a single dialysis provider.

In summary, studies that observed higher patient-mortality rates with reuse had several limitations. In addition, none of these studies have been able to show a direct cause-and-effect relationship between mortality and dialyzer reuse or use of a certain reprocessing technique. Nonetheless, the majority of observational studies are congruent in their findings of effect, indicating a potential for an increased mortality especially when reuse is performed with low flux dialyzers. Some of the more recent studies, however, also observed improved dialysis adequacy in centers that reuse dialyzers.[32] In the setting of falling reimbursement rates for ESRD care in the United States, reuse offers a means to deliver higher quality dialysis with potentially improved outcomes when high-flux dialyzers are used. In this regard, the results of the Hemodialysis Study that observed no additional benefit in survival of hemodialysis patients treated with high-flux dialysis compared with low-flux dialysis are of concern.[109] Experts continue to advocate use of high-flux dialyzers as they offer benefits beyond "flux," such as better biocompatibility, fewer dialysis reactions, and increased clearance of β2-microglobulin, and probably decreased incidence of dialysis-related amyloidosis. It is still unclear whether reuse is associated with a true increase in mortality in hemodialysis patients.

COST-EFFECTIVENESS OF DIALYZER REUSE

Currently, over 350,000 patients are receiving renal replacement therapy for ESRD in the United States.[97] The majority of these patients are supported through the Medicare ESRD Program of the federal government. While ESRD patients accounted for 0.6% of the total Medicare population, treatment cost of ESRD accounted for 6.4% of the total Medicare budget in the year 2001.[97] Thus, ESRD receives a disproportionate funding relative to its prevalence. Moreover, the costs have been rising every year because of increasing incidence of ESRD and longer life expectancy of patients on dialysis and after renal transplantation. For example, in 1991, ESRD expenditure in the United States was $8 billion, with Medicare paying $5.8 billion, the rest coming from non-Medicare sources such as private insurance.[97] By 2001, the costs of the program had risen to $22.8 billion, with Medicare paying $15.4 billion, three times the cost of 1991.[97] During the same period, overall Medicare expenditure increased only two

times. To contain the growing costs of the program, the federal government has kept the composite payment rate to dialysis providers constant, thus eroding their returns through inflation. In search of ways of limiting the costs of dialysis, dialysis providers have promoted reuse of dialyzers. Currently 80% of dialysis centers practice reuse.[8] Until recently, a critical cost-effectiveness evaluation of dialyzer reuse has not been undertaken.

In one of the earliest studies done from Canada, a cost-minimization analysis indicated that five uses of a dialyzer might save up to Can$3629 per patient yearly.[110] This would translate into Can$5.8 to $8.9 million annually if all eligible patients in Canada participated in a reuse program.[110] However, this study did not take into account the potential negative health effects of dialyzer reuse. Since this study, the cost of single use dialyzers has significantly decreased, thus narrowing the cost differences between single use and reuse methods. Reuse rates are much lower in Canada at 15%, and even lower in Europe at 10%.[111] In a cost-utility analysis, again from Canada, Manns and colleagues[111] compared single use with multiple uses of high-flux dialyzers. The reuse methods chosen were formaldehyde, and heated citric acid. The cost of formaldehyde reuse was estimated at Can$15.47 per patient per run, and that of heated citric acid was Can$12.66 per patient per run. The measure of effectiveness was quality-adjusted life-years (QALY), obtained from an earlier analysis from Canada.[112] For a dialysis facility with 320 patients, and assuming an average of 13.3 reuses, the 5-year cost of single use dialysis per patient was Can$218,284 and the average number of expected QALYs per patient over a 5-year period was 1.648.[111] For reuse with heated citric acid, per patient, the 5-year cost was estimated at Can$217,073, and the average number of QALYs was 1.644. The incremental cost with single use was Can$299,739 per QALY gained. Given the fact that reuse has not shown to increase mortality, the authors suggested that by switching to reuse, there could be significant cost savings for the payer.[111] In these analyses, formaldehyde method was not cost-effective.

While this is a well-conducted study, extrapolation of this data to the United States is difficult. First, heated citric acid is the least common method of dialyzer reprocessing in the United States; formaldehyde reprocessing is on the decline and peracetic acid is the commonest.[8] An analysis comparing peracetic acid and formaldehyde reuse with single use would be more applicable to the U.S. population. Second, the study assumes no increase in personnel in dialysis units that practice reuse, which is actually not the case in the United States, with centralized reuse being more popular. Last, mortality and hospitalization data were obtained from studies comparing conventional dialyzers. In the United States, conventional dialyzers have largely been replaced with high-flux synthetic dialyzers with over 70% units using exclusively high-flux dialyzers.[8] It is unclear whether the same hospitalization rates would apply to patients dialyzed with reprocessed high-flux dialyzers as well. Nevertheless, this happens to be the best study that is available to date on this subject.

Given the fact that the main benefit of reuse is economic, clearly, a robust cost-effectiveness analysis in the United States is required to answer the question of whether reuse is really worth the cost savings. The federal government continues to benefit indirectly from the ongoing practice of reuse through cost savings experienced by the providers, thus limiting the

pressure to raise the composite rate should a cost-effectiveness analysis indicate that single use programs should be implemented universally in the United States.[113] In the absence of data on compromised quality of care when reuse is practiced within accepted guidelines and standards, reuse is likely to continue.

SUMMARY

Reuse of dialyzers has had a persistent growth in the United States since its introduction in the 1960s. Although in 1982, only 43% of dialysis centers reused their dialyzers, currently 80% of the dialysis units practice reuse. Germicides used for disinfecting the reprocessed dialyzers include peracetic acid/hydrogen peroxide mixture, formaldehyde and glutaraldehyde, and, over the last decade, heated citric acid. In addition, bleach is used, predominantly with formaldehyde, to improve the appearance of the dialyzer. Automated machines are more popular than the manual methods of reprocessing of dialyzers. The predominant factor driving the current practice of reuse of dialyzers in the United States is economic. Concern regarding the preservation of integrity of the dialyzer membranes led to several studies on clearance of solutes by reprocessed dialyzers. These reveal that neither the small molecule clearances nor the ultrafiltration capacity of cellulose/substituted cellulose dialyzers are affected with reuse, irrespective of the germicide used. Similarly, small molecule clearances are only modestly affected with reprocessed synthetic dialyzers, and the significance of this decrease is likely clinically insignificant. Middle molecular solute clearances are not significant with low-flux cellulose or synthetic dialyzers and not significantly changed with reprocessing. However, for high-flux polysulfone dialyzers, reprocessing with bleach increases and reprocessing with peracetic acid decreases β_2 microglobulin clearance. Although earlier studies observed heavy protein and albumin losses with high-flux polysulfone dialyzers, a change in the membrane configuration by the manufacturer has essentially taken care of this problem. Despite its effect on clearances, albeit minor, it is encouraging to note that reuse does not adversely affect the delivered dose of dialysis.

Reprocessed dialyzers have been associated with decreased complement activation and leukopenia compared with new dialyzers. However, this mitigation of complement activation and leukopenia has not shown to be associated with improved clinical outcomes. In addition, there is no known evidence that dialysis with reprocessed dialyzers results in enhanced production of pro-inflammatory cytokines or an exaggeration of chronic inflammatory response seen in the uremic environment. Although several episodes of bacterial and viral infections and catastrophic toxicity of chemicals have occurred as a result of reuse, the common feature among most of these episodes is human error leading to a breakdown in strict adherence to the AAMI reuse guidelines.

In large observational studies, hospitalization rates of dialysis patients were 25% higher with formaldehyde reuse and 40% higher with peracetic acid mixture reuse. Because of inability to control for aspects of care other than reuse, a clear cause-and-effect relationship between dialyzer reuse and increased hospitalization cannot be drawn. Some observational studies on large patient populations observed higher patient-mortality rates with reuse, but these studies had several limitations. In addition, none of these studies has been able to show a direct cause-and-effect relationship between mortality and dialyzer reuse or use of a certain reprocessing technique. Some studies also observed improved dialysis adequacy in centers that reuse dialyzers compared with centers that practice single use dialyzers. It is unclear whether reuse is associated with a true increased mortality in hemodialysis patients.

In the setting of falling reimbursement rates for ESRD care in the United States, reuse offers a means to deliver more adequate clearances and potentially thereby improve quality of care with improved outcomes when high-flux dialyzers are used. These dialyzers offer potential benefits beyond "flux" such as better biocompatibility, fewer dialysis reactions, and probably decreased incidence of dialysis-related amyloidosis. Limited cost-effectiveness studies from Canada showed that there could be significant savings per quality-adjusted life year gained by moving from single use to reuse of dialyzers, particularly with heated citric acid reuse. Clearly, a robust cost-effectiveness analysis in the United States is required to answer the question of whether reuse is really worth the cost savings in this society. In the absence of data on compromised quality of care when reuse is practiced within accepted guidelines and standards, reuse is likely to continue.

Hemodialysis Adequacy

John K. Leypoldt, Ph.D.

THE UREMIC SYNDROME

For approximately 40 years, dialytic therapy has provided successful "long-term" life-sustaining replacement for absent renal function. This is reflected by the fact that many patients have received dialysis over 10 years, and some have survived for more than 25 years.[1,2] In its 2003 annual data report, the United States Renal Data System (USRDS) counted approximately 392,000 Americans with end-stage renal disease (ESRD), of whom 68% (approximately 265,000) were treated by maintenance hemodialysis.[3] Despite this success in treating ESRD, or the "uremic syndrome," with dialysis, our knowledge of what constitutes the uremic toxins is still incomplete and unsatisfactory. Furthermore, the relative amounts of various uremic toxins to remove with dialysis therapy are still unclear.

At its most fundamental level, the *uremic syndrome* is the result of the overall retention of multiple substances that interfere with physiologic and biochemical functions. Retained substances range in size from a molecular weight of less than 300 daltons (e.g., urea) to more than 32,000 daltons (e.g., interleukin-1β). Recent work by the European Uremic Toxin Work Group (EUTox) has classified uremic toxins into three main categories[4]: (1) low molecular weight water-soluble solutes, such as urea and creatinine; (2) molecules defined as middle molecules, that is, those with molecular weights greater than 500 daltons; and (3) low molecular weight solutes that are protein-bound. This categorization of uremic toxins can be helpful in understanding the relationship between the dose of uremic toxin clearance or removal and the adequacy of hemodialysis therapy.

The removal of uremic toxins is one of the major goals of maintenance dialytic therapy; however, one must also remember that the uremic syndrome is defined not only by retention of solutes or toxins, but also by deficiencies of other critical compounds (e.g., bicarbonate, erythropoietin,[5] 1,25-dihydroxycholecalciferol[6]) and certain trace elements (e.g., zinc, carnitine[7,8]). These concerns are also important to consider when defining an adequate hemodialysis therapy prescription.

HEMODIALYSIS ADEQUACY

The most practical, clinically applicable definition of *adequate* dialysis is a treatment regimen that:

- Minimizes short-term and long-term morbidity and mortality
- Is fiscally sound

- Can be routinely delivered
- Provides the patient with an outstanding quality of life (i.e., a balance between the inconvenience of remaining on the dialysis delivery system versus a healthier outcome)

This definition of dialysis adequacy indicates that there are a large number of clinical factors that contribute to an adequate therapy. As noted by others,[9,10] they include blood pressure control, fluid and electrolyte homeostasis, anemia correction, acidosis correction, and adequate toxin removal. A discussion of all of these factors, and their impact on hemodialysis adequacy, is beyond the scope of this review. This chapter will be limited to a discussion of the dose of solute or toxin removal as a measure of adequate dialytic therapy. Which solute to use as a guide continues to be debated; however, it is indisputable that the amount of dialysis matters.[11–19]

The EUTox categorization of uremic toxins, outlined previously, can be used as a guide for understanding the relationship between uremic toxin removal and hemodialysis prescription parameters (Table 20-1). The dose of uremic toxin removal can accordingly be divided into three separate categories: dose of low molecular-weight water-soluble toxins (small molecules), dose of middle molecules, and dose of low molecular-weight protein-bound toxins (protein-bound molecules). It is helpful to identify a marker solute for each category of uremic toxins. The dose of small solute removal or clearance is readily identified with urea and its commonly used dose parameter urea Kt/V (see later). The clearance for such solutes during hemodialysis is relatively high and is limited primarily by the blood flow rate to the dialyzer and the surface area of the hemodialysis membrane. The most common marker solute for middle molecules is β$_2$-microglobulin, and the dose of middle molecule clearance or removal is proportional to both the surface area and pore size of the hemodialysis membrane. Thus, middle molecules are removed to a significant extent during high flux hemodialysis only. Clearance or removal of protein-bound substances is difficult to quantify, and there is no current marker solute that can generally quantify the removal of such solutes. Marker solutes for protein-bound toxins currently under evaluation include *p*-cresol,[20] indoxyl sulfate, and hippuric acid.[4] It is important to note that the low clearance of such solutes from the body relative to urea is not due to a low permeability or pore size of the hemodialysis membrane but rather to biochemical or physiologic resistances to solute removal.[21]

HISTORICAL BEGINNINGS

Defining an appropriate dose of solute removal during maintenance dialysis therapy has long been a crucial interest, especially as mathematical models or formulations were being

---

The original chapter from the first edition was written by Titus W. L. Lau, M.D., and William F. Owen, Jr., M.D., and has been revised and updated by John K. Leypoldt, Ph.D.

Table 20–1 Categories of Uremic Toxins, Marker Solutes, Relative Clearances, and Important Hemodialysis (HD) Prescription Parameters

Uremic Toxins	Marker Solute	Relative Clearance	HD Prescription Parameters
Free water soluble	Urea	High	Blood flow rate Dialyzer surface area
Middle molecules	β_2-microglobulin	Low	Dialyzer surface area Membrane pore size
Protein-bound toxins	*p*-cresol	Low	Physiologic resistances (protein-binding & intercompartmental barriers) Treatment frequency

developed to assess the adequacy of hemodialysis. From the observation that uremic neuropathy did not develop in patients receiving peritoneal dialysis, despite higher blood urea nitrogen (BUN) and creatinine concentrations than in patients receiving hemodialysis,[22,23] it was proposed that the peritoneal membrane was able to remove selected uremic toxins of a higher molecular weight than urea with much greater efficiency. This proposal culminated in the *square meter-hour hypothesis*,[24,25] which related the dose of dialysis to the number of hours provided per week and to the surface area of the dialysis membrane. This hypothesis seemed intellectually sound, because the clearance of middle molecules was directly related to membrane surface area. According to this construct, therefore, an adequate dialysis therapy was thought to be related to the dose of middle molecule clearance or removal.

Later, the same investigators devised the *dialysis index*, which is the ratio of the calculated removal of a given molecular species to the minimum clearance of that molecular species necessary to maintain health.[26] In the absence of a pathobiologic and readily measurable molecular species, insufficient dialysis was discerned historically by measuring the motor nerve conduction velocity, electroencephalogram (EEG), and hematocrit, and these laboratory studies were combined with assessments of patient activity, performance level, and dietary intake.

A modest body of evidence suggests that middle molecules may be important in the pathobiology of a number of comorbid conditions observed in patients with ESRD.[27,28] For example, dialysis-associated amyloidosis is characterized by the accumulation of advanced glycation end product-modified β_2-microglobulin, and a small body of evidence suggests that the occurrence of the disease may be attenuated by selected membrane materials, some of which may have higher clearances for β_2-microglobulin (11,800 daltons).[29–31] Further, the characteristic-acquired lipoprotein lipase deficiency of chronic kidney disease[32] may be attenuated by the use of high-flux hemodialysis membranes and, thereby, may decrease the severity of lipid abnormalities.[33]

Despite the enthusiasm for middle molecules, as uremic toxins, to define the adequacy of dialysis, the continued failure to identify such solutes or appropriate marker molecules, which could be used to evaluate their removal, has undermined their clinical utility. Furthermore, outcome studies for ESRD patients treated by dialysis over the past 20 years have primarily used low molecular-weight solutes

(e.g., urea) as the surrogate uremic toxin to determine hemodialysis adequacy.[11–19]

The benchmark prospective study of hemodialysis adequacy is the National Cooperative Dialysis Study (NCDS). It was the first randomized trial to examine the effects of dose of small solute removal on patient outcome (morbidity).[11] Note that patient mortality was not a primary outcome parameter in this trial. This interventional trial was designed to evaluate two parameters thought to be critical outcome determinants related to hemodialysis adequacy:

1. Use of the time-averaged concentration (TAC) of BUN as a marker of low molecular-weight solute clearance.
2. Length of each hemodialysis session as a surrogate for the clearance of middle molecules.

The use of dialysis time as a surrogate for middle molecule clearance in this study was an approximation because the removal of large, less readily diffusible solutes is primarily a function of the duration of dialysis, but also depends on hemodialysis membrane surface area. Further, although it is often quoted that dialysis time was used in this study as a surrogate for middle molecule clearance, Wineman[34] has alternatively suggested that dialysis treatment time was selected to assess its importance as a practical hemodialysis prescription parameter.

As for urea or small solute clearance, the time-averaged BUN concentration over a full weekly dialysis cycle (TAC_{urea}) was the measurement selected for quantifying and targeting urea clearance during dialysis, instead of the more conventional and easily measured midweek pre-dialysis BUN. Arguably, the long-term toxicity of ESRD is more likely a function of average "toxin" exposure (TAC_{urea}) than of the peak plasma concentrations (midweek pre-dialysis BUN). This issue is important for the clinician as well, because the midweek pre-dialysis BUN can vary substantially, depending on both the patient's dietary protein intake as well as the amount of hemodialysis.

All patients in the study underwent rigorous and repeated kinetic modeling to achieve the specified TAC_{urea} for their assigned group.[35–37] The final study population consisted of 165 patients, randomized into four different intervention groups (2×2 factorial design), and all patient groups received dialysis three times per week. Groups I and III were treated to achieve a TAC_{urea} of 50 mg/dL, whereas groups II and IV were treated to achieve a TAC_{urea} of 100 mg/dL. Groups I and II were assigned the longer duration of hemodialysis, 4.5 to

5.0 hours; groups III and IV had dialysis sessions of 2.5 to 3.5 hours. The designated TAC_{urea} was achieved by variation of the blood and dialysate flow rates and by membrane surface area of the dialyzers. All patients were observed for a minimum of 24 weeks.

The TAC_{urea} proved to be the most important determinant of patient morbidity or withdrawal from the study.[11, 35–39] The proportion of patients not withdrawn for medical reasons or death by 9 months was 89% (group I, long dialysis time) and 94% (group III, short dialysis time) versus 55% and 54%, respectively, for groups II and IV. The duration of dialysis treatment had no effect on patient withdrawal. The TAC_{urea} was also a highly significant determinant of the rate of hospitalization, with fewer hospital admissions occurring in the low TAC_{urea} groups. Also, group I had fewer hospitalizations than group III; similarly, group II had fewer hospitalizations than group IV. However, the effect of the treatment time was statistically significant in the high TAC_{urea} groups (groups II and IV) only.[37,38]

A stepwise, linear logistic regression analysis of the data from the NCDS was performed to determine the effect of multiple treatment variables on the probability of an adverse outcome.[39] Subsequent death, withdrawal from the study, or hospitalization during the first 24 weeks of follow-up was again predicted by the TAC_{urea}.

The second best outcome predictor was the *protein catabolic rate* (PCR),[11,38,39] equivalent to the dietary protein intake for dialysis patients in a steady state.[40] In a subsequent mechanistic analysis of the data from the NCDS, however, it was argued that this statistical association was a consequence of the protocol design (i.e., the PCR was not an independent variable).[41] This lack of independence is most evident when one appreciates that to achieve a predetermined TAC_{urea}, the amount of hemodialysis prescribed must be a function of the PCR. Thus, a higher PCR requires a greater amount of dialysis to achieve the same TAC_{urea}, and vice versa. Hence, any statistical correlation between TAC_{urea} and morbidity will be mirrored similarly by PCR. The design of the NCDS did not set PCR as a study variable. For all study groups, the PCR was permitted to fluctuate between the ranges of 0.8 and 1.4 g/kg/day (an inadequate to an excessive dietary protein intake).

It is apparent from the NCDS results that urea is an appropriate surrogate low molecular-weight solute marker and that the level of its removal predicts patient outcomes. However, several design limitations compromised the study's applicability to the current ESRD patient population and prevalent treatment practices. For example, the NCDS excluded older patients (>60 years of age) and diabetic patients; these patient profiles would exclude the preponderance of current Americans with ESRD.[3,42] Furthermore, participants in the NCDS were treated exclusively with cellulosic hemodialysis membranes that were not reused, so generalization to other increasingly prevalent biocompatible membrane materials[43] may not be appropriate. The follow-up period for the NCDS was 48 weeks or less and therefore did not adequately address more fundamental long-term outcomes, such as mortality. Despite these limitations, the NCDS is the foundation for all subsequent analyses linking hemodialysis adequacy to patient morbidity and mortality and to the use of urea as a surrogate low molecular-weight uremic toxin in the measurement of hemodialysis adequacy.

PRINCIPLES AND METHODS FOR QUANTIFYING THE DOSE OF SMALL SOLUTE REMOVAL DURING HEMODIALYSIS

Many putative uremic toxins are products from protein metabolism.[44] Because it is impossible to measure the large number of water-soluble uremic toxins in routine practice, a derivative of protein catabolism—urea—has emerged as the most popular marker for quantifying the dose of small solute removal. A small and readily dialyzed molecule, urea constitutes 90% of waste nitrogen accumulated in the interdialytic interval.[40] Its measurement is simple, inexpensive, and universally available. Also, the transport properties of urea between body compartments are well studied and thus fairly well understood.[45,46] Most important, its utility as a surrogate for hemodialysis treatment dose and outcomes has been validated, not the least by the NCDS,[11] but also subsequently by other reports.[13–18, 47]

As a result of the mechanistic analysis of the NCDS data, urea Kt/V is the most widely accepted measurement of the dose of small solute removal.[40,41] Indeed, it is often simply called the dose of dialysis, even though it only quantifies the amount of small solute clearance or removal. Although this construct for evaluating the dose of small solute removal enjoys almost universal acceptance, it should be noted that the mechanistic analysis of the NCDS data was an "as treated" analysis not the "intent to treat" analysis that is now universally applied to randomized clinical trials. This expression of the dose of small solute removal can be described as the total cleared volume of urea (Kt) normalized by its distribution volume (V), which is approximately total body water. In turn, K is the dialyzer clearance of urea and is a function of the mass transfer-area coefficient (K_oA) of urea and blood and dialysate flow rates (Q_b and Q_d, respectively). K is reported in L/min, t (hemodialysis treatment time) in minutes, and V in liters. Alternatively, noting that Kt/V is equal to $(Kt \times [urea]_{mean}) / (V \times [urea]_{mean})$, Kt/V approximately expresses the total mass of urea removed during hemodialysis ($Kt \times [urea]_{mean}$) normalized by the mean total amount of urea in the body ($V \times [urea]_{mean}$).

The clinical application of mathematical terms (such as Kt/V), to describe the removal of urea during hemodialysis, is called *urea kinetic modeling*. Nearly all solute kinetic models that apply to hemodialysis are based on the *law of conservation of mass*, which means that the accumulation of any substance in the system is equal to the difference between the input and output. Hence, given adequate knowledge of its rate of accumulation, metabolism, and excretion from the body, virtually any substance can be kinetically modeled. Finally, the accuracy of the model is only as good as the assumptions made to produce the model.

Adapting these principles to urea, we have:

> systemic mass   = input/urea mass generated −
>   accumulation   output/urea mass cleared
>   of urea

expressed in the form of a differential equation:

$$d(V \times C)/dt = G - (K + K_r) \times C \tag{1}$$

where the change in urea mass in the body with time ($d[V \times C] / dt$) is the result of the difference between net urea generation (G)

and total body urea mass cleared by the dialyzer (K) and residual renal function (K_r). Here, C denotes the concentration of urea, and V denotes the volume of distribution of urea.[40]

For most oligoanuric patients with ESRD, the value of such terms changes during and between dialysis treatments. From this simple concept, the single-pool, variable-volume model for urea kinetics has been derived and is the one most often in clinical use. This model assumes that:

1. Urea accumulates in and is removed from a single pool or compartment.
2. This single urea compartment expands in size between hemodialysis treatments (secondary to fluid retention) and diminishes in size with ultrafiltration during hemodialysis.

Formal Urea Kinetic Modeling

Advantages

When rigorously performed, formal urea kinetic modeling is a reproducible, quantitative method for measuring urea removal during hemodialysis. It has several advantages for assessing the adequacy of hemodialysis over alternative methods to measure the delivered dose of hemodialysis. *Assuming a single urea pool of variable-volume, formal urea kinetic modeling is the recommended principle method for measuring hemodialysis dose.* The strengths of formal urea kinetic modeling are that it:

- Can be used to prescribe individual hemodialysis treatment
- Checks for errors in dosage
- Can approximately take into account residual renal function
- Permits calculation of the *normalized protein catabolic rate* (nPCR)

Hemodialysis Prescription

Formal urea kinetic modeling can be utilized as a tool to prescribe individualized hemodialysis treatments to achieve the desired dose of small solute removal during hemodialysis (Kt/V) based on patient-specific parameters, such as (1) body size, (2) residual renal function, and (3) nPCR. To develop a hemodialysis prescription, it is necessary to obtain a dialyzer's urea clearance (K) for a variety of blood and dialysate flows in blood/water. To provide this information, the computational software for urea kinetic modeling uses the manufacturer's K to extrapolate a K_oA value for that dialyzer, which can then be used to calculate urea clearance at different blood and dialysate flow rates.

Ideally, the urea clearance is initially calculated based on the volume from which urea is removed and into which urea is generated as a function nPCR. Further, with computational software, formal urea kinetic modeling calculates the volume of distribution of urea by iteration of two formulas that share common terms. The kinetic determination of V is based on the assumption of a single pool of urea that is coextensive with total body water and that expands during the interdialytic interval from fluid retention and contracts during hemodialysis by ultrafiltration. Assuming a thrice-weekly hemodialysis schedule, the computational software iterates the following two formulas, having shared terms, until unique values are found for Vt and G to satisfy both expressions.

$$Vt = (Qf \times t)/[((C0 - G/(K + Kr - Qf))/(Ct - G/(K + Kr - Qf)))^{Qf/(K+Kr-Qf)} - 1] \qquad (2)$$

$$G = [(Kr + \alpha)[C0 - Ct(1 + \alpha\theta/Vt) - (Kr + \alpha)/\alpha)]/[1 - (1 + \alpha\theta/Vt)^{-(Kr + \alpha)/\alpha}] \qquad (3)$$

In these equations, Vt is the end dialysis volume; Qf is the rate of volume contraction during dialysis that is calculated from total weight loss during dialysis divided by the length of dialysis, t; G is the interdialytic urea generation rate; K and Kr are the dialyzer and renal urea clearances, respectively; and Ct and C0 are the BUN concentrations at the end and beginning of a dialysis treatment. (Note that C0 in equation 2 is the pre-dialysis BUN concentration from the first hemodialysis session, and C0 in equation 3 is the pre-dialysis BUN concentration from the second hemodialysis session.) Further, α is the rate of interdialytic volume expansion and is calculated by the total interdialytic weight gain divided by the length of the interdialytic interval, θ.[40] With K and V known, the treatment time can be determined easily to achieve the desired Kt/V. Formal urea kinetic modeling supports the derivation of various treatment time and blood flow combinations to achieve a target Kt/V. Thus, the use of formal urea kinetic modeling can guide the hemodialysis care team on which specific parameters of the prescription to modify to achieve the desired hemodialysis dose.

Checking of Dosage Errors

Formal urea kinetic modeling provides a means to check for errors in the delivered dose of hemodialysis, thus offering a necessary quality control mechanism. Formal urea kinetic modeling requires the measurement of pre-dialysis and post-dialysis BUN concentrations, delivered hemodialysis treatment time, and dialyzer clearance of urea (at the blood and dialysate flow rates used). The computer software assumes that all input data are accurate and uses these values to calculate the volume of distribution of urea. In addition, most programs also calculate a volume of distribution based on anthropometric formulas.[48–50] The anthropometric volume of distribution of urea may be calculated by one of several formulas derived from gender-specific estimates of total body water (TBW) in healthy subjects. The most common of these anthropometric formulas, the Watson formula,[49] is shown below:

Males: TBW = 2.447 − (0.09156 × age) + (0.1074 × height) + (0.3362 × weight)

Females: TBW = −2.097 + (0.1069 × height) + 0.2466 × weight   (4)

Because this formula was derived from analyses performed in healthy individuals, their general applicability to patients with ESRD has been questioned. Based on measurements of TBW using single frequency bioelectric impedance (BEI) in ESRD patients, a population-specific equation for calculating total body water was more recently derived by Chertow and associates.[50] Note that the Chertow formula calculates a pre-dialysis, not a post-dialysis value of total body water; thus, it requires a correction before comparison with the other formulas.

All previous anthropometric formulas were based on measurements of TBW using either isotope markers or BEI, and only the Chertow formula was derived in ESRD patients. Recent work by Daugirdas and associates[51] has evaluated the modeled urea distribution volume derived from urea kinetic modeling in a large sample of patients in the HEMO Study. Calculated urea distribution volumes in that study were

substantially (15%–20%) lower than the above-referenced anthropometric estimates of TBW. The reasons for these discrepancies are unknown, but these calculated results suggest that the use of anthropometric formulas for predicting TBW may substantially overestimate the urea distribution volume. These authors have also proposed methods to estimate the urea distribution volume from anthropometric formulas for TBW. For example, the modeled urea distribution volume (Vm) can be calculated from the TBW predicted by the Watson formula (Watson V) by the following formula:

$$Vm = (\text{Watson V}) \times (1.033 \text{ if diabetic}) \times (0.998 \times [\text{age} - 50] \text{ if male}) \times (0.985 \times [\text{age} - 50] \text{ if female}) \times (1.033 \text{ if female}) \times (1.043 \text{ if African American}) \quad (5)$$

Additional equations for predicting the modeled urea distribution volume from the Hume-Weyers and Chertow formulas can also be derived from this recently published work. Although there are no available data to suggest that such modified anthropometric formulas for urea distribution volume are superior to unmodified anthropometric formulas when prescribing hemodialysis, it would seem more valid to use these new modified formulas because they were derived directly from modeled urea distribution volume not from TBW. Only additional studies will permit evaluation of the advantages and disadvantages of these modified formulas.

By comparison of the V derived from formal urea kinetic modeling and that derived from anthropometric data, possible errors related to the hemodialysis procedure may be detected. A discrepancy between these two values should alert the dialysis care team to unappreciated errors in dialysis delivery (Table 20–2). When the kinetically derived V is larger than the anthropometric V, the delivered dose of hemodialysis would be less than the prescribed dose. Alternatively, when the kinetically derived V is less than the expected anthropometric V (used for the initial hemodialysis prescription), the Kt/V may seem inappropriately high. If this erroneous Kt/V is interpreted without consideration of the urea distribution volume, a reduction in the dose of hemodialysis may appear appropriate. However, this reduction in dialysis dose may reduce the delivered hemodialysis dose to an unsafe level and thus compromise the patient's well-being; for example, the hemodialysis dose might be appropriate, but an unappreciated error occurs in the calculation of V.

Because of the enhanced rigor in ascertaining that the delivered dose of hemodialysis is correct and the greater ease with which deficiencies are detected, formal urea kinetic modeling provides the greatest support for continuous quality improvement efforts in the delivery of hemodialysis. Optimal quality improvement efforts require that the processes of care affecting patient outcome be routinely measured, individual deficiencies defined, and corrective steps implemented. Furthermore, formal urea kinetic modeling facilitates the identification of the components in the hemodialysis delivery that were problematic, if the delivered dose has not mirrored the prescribed dose (Table 20–3).

Residual Renal Function

Formal urea kinetic modeling can account for the contribution of residual renal function to the sum total of the delivered hemodialysis dose. A minority of ESRD patients has significant residual renal function (Kr), but if this remains unac-

Table 20–2 Reasons for Discrepancies Between the Kinetically Derived and Anthropometric Distribution Volume (V)

Kinetically Derived V Larger Than Anthropometric V
- Low blood flow from the angioaccess
- Inadequate dialyzer performance
- Dialysate flows less than prescribed
- Dialysis machine programmed incorrectly
- Premature completion of treatment
- Pre-dialysis BUN sample drawn after initiation of hemodialysis

Kinetically Derived V Smaller Than Anthropometric V
- Post-dialysis BUN sample drawn from the venous blood line
- Post-dialysis BUN sample drawn in the setting of significant fistula recirculation
- Post-dialysis BUN sample drawn following a very efficient hemodialysis in a patient with a small V (high K/V)
- Post-dialysis BUN sample inadvertently diluted with saline

BUN, blood urea nitrogen.

counted, the actual total urea clearance and the nPCR will be underestimated. Because of the short duration, the effect of residual renal function on total urea clearance during hemodialysis will be small; however, in the relatively long interdialytic period, residual renal function will significantly lower the pre-dialysis BUN concentration.

Graphically, when Kr is zero, the interdialytic rise in BUN concentration is linear. If Kr is greater than 0, the rise in BUN concentration will be more shallow and curvilinear, as a result of continuous renal excretion. Thus, when Kr is greater than 0, less hemodialysis is required to achieve the same pre-dialysis BUN level as when Kr equals 0. The quantitative relationship that relates dialysis dose with and without residual renal function can be defined as:

$$kKr = Kt - K't \quad (6)$$

where K and K′ are the dialyzer urea clearances in the absence and presence of residual renal clearance, respectively, and t is the treatment time. Here, k relates Kr to the difference between K and K′ or the decrease in dialysis dose that is possible in the presence of residual renal function to achieve the same predialysis BUN. Therefore, the relationship between the total dialysis dose (KT), the dose provided by the dialyzer (Kt), and the contribution residual renal clearance (kKr), are expressed by:

$$KT/Vt = Kt/Vt + kKr/Vt \quad (7)$$

Since k is a coefficient, not a constant, its value depends on both Kt and Kr; thus, these equations can be solved using only computational software for formal urea kinetic modeling.[40]

Calculation of Normalized Protein Catabolic Rate

Formal urea kinetic modeling permits calculation of PCR and nPCR. The PCR has been shown to be linearly dependent on both the urea generation rate (G) and its distribution volume (Vt):

$$PCR = 9.35G + 0.29Vt \quad (8)$$

Table 20–3 Reasons for Underdelivery of Prescribed Dose of Hemodialysis

Compromised Urea Clearance
- Access recirculation
- Inadequate blood flow from the vascular access
- Inaccurate estimation of dialyzer performance
- Inadequate dialyzer reprocessing
- Dialyzer clotting during dialysis
- Blood pump/dialysate flow calibration errors
- Errors in prescribed blood and dialysate flow rates due to variability in blood pump tubing
- Dialysate flow rate that is inappropriately set too low
- Dialysate flow miscalibration
- Dialyzer leaks

Reductions in Treatment Time
- Inaccurate assessment of effective dialysis time using wristwatches
- Incorrect assumption of continuous treatment time because of failure to account for interruptions
- Premature discontinuation of hemodialysis for staff or unit convenience
- Premature discontinuation of hemodialysis to honor patient request or adherence
- Delay in starting dialysis session due to patient tardiness
- Wrong patient taken off dialysis
- Time on dialysis calculated incorrectly
- Time read incorrectly for initiation or completion of hemodialysis
- Clerical deficiencies

Laboratory or Blood Sampling Errors*
- Dilution of pre-dialysis BUN blood sample with saline
- Pre-dialysis BUN blood sample drawn after the start of dialysis
- Post-dialysis BUN blood sample drawn before the end of dialysis
- Laboratory error due to calibration or equipment problems
- Post-dialysis BUN blood sample drawn more than 5 minutes after dialysis completed

*Apparent underdelivery because of erroneous measurements.

Because urea distribution volumes vary between 30% and 65% of body weight, it is improper to index the PCR simply by dividing PCR by the patient's body weight. Rather, it is necessary to relate PCR to the normalized body weight (nBWT). If we presume that the average volume of urea distribution is 58% of body weight, the patient's weight is converted to an nBWT by the following:

$$nBWt = Vt/0.58 \qquad (9)$$

and normalized protein catabolic rate (nPCR) is thus expressed as

$$nPCR = PCR/(Vt/0.58) \qquad (10)$$

In patients who are not markedly catabolic or anabolic, the net protein catabolism correlates closely with dietary protein intake.[52–55] Because dietary records and histories are often inaccurate, PCR (calculated as part of formal urea kinetic modeling) provides a more reliable estimate of dietary protein intake. Hence, use of the nPCR enables the dialysis care team to perform longitudinal analysis of the patient's nutritional status and to more soundly guide dietary counseling about protein intake.

Although the NCDS showed that a high nPCR (presumably reflective of a better dietary protein intake) was associated with lower morbidity or lesser likelihood of treatment failure, the design of the study was not ideal to prove conclusively that nPCR was an independent risk factor.[41] However, several subsequent reports have statistically linked laboratory surrogates of nutrition to outcomes in chronic hemodialysis patients.[13,17,47,56,57] For example, a low serum albumin concentration (<3.5 g/dL), a laboratory surrogate of visceral malnutrition, was associated with a relative risk of death of 1.83 and 2.07 for diabetic and nondiabetic ESRD patients, respectively, although this difference was less when adjusted for Kt/V.[58]

In an analysis of 13,473 ESRD patients, the serum albumin concentration was 21 times more powerful a predictor of death than was the dose of hemodialysis. Furthermore, the serum albumin concentration was an independent risk factor, apart from the dose of hemodialysis.[47] This finding is provocative because the serum albumin concentration has been linked to the adequacy of hemodialysis. Although not uniformly observed,[47] a highly significant, positive correlation between the serum albumin concentration and the dose of hemodialysis (Kt/V) has been observed.[56] Certainly, patients who receive inadequate dialysis have a depressed appetite and a diminished protein-caloric intake. Thus, maintaining an adequate dose of hemodialysis may improve nutrition and patient survival.

Disadvantages

The modest disadvantages of formal urea kinetic modeling are logistical. The complexity of the calculations requires the use of computational devices and software. The cost of computer devices and software may not be much, but it remains a consideration for some smaller hemodialysis units. Physical parameters, such as the K and V, are burdensome to measure and monitor, and the actual treatment time can be difficult to determine. In addition, the time required for the dialysis unit staff to accurately collect and process all patient data to support these calculations may be significant in larger hemodialysis centers. Despite these relative limitations, both the Renal Physicians Association (RPA)[54] and the National Kidney Foundation's Dialysis Outcomes Quality Initiative (DOQI)[55] evidence-based clinical practice guidelines agreed that formal urea kinetic modeling is "the most rigorous method for prescribing dialysis treatment and evaluating the consistency with which the prescribed treatment is delivered to the patient."[54]

Alternate Methods of Quantification

Some reports have suggested that only one alternative method of calculating Kt/V (Kt/V *natural logarithm formula*[59]) and one other measurement of the delivered dialysis dose (*urea reduction ratio* [URR][47,60]) should be considered for routine use in clinical dialytic practice.[55]

Kt/V Natural Logarithm Formula

The second-generation logarithm formula,[59] which was proposed based on the variable-volume single-pool urea kinetic

model, accounts for urea removed by both diffusive and convective clearance, the latter secondary to ultrafiltration.[55] Urea removal accomplished by convective transport is not associated with a change in the post-dialysis to pre-dialysis BUN ratio. Over a wide range of single-pool, variable volume Kt/V values derived by formal urea kinetic modeling (range 0.7 to 2.1), the second-generation logarithm formula for calculating Kt/V is accurate.[59,61,62] The logarithm formula for calculating Kt/V is:

$$Kt/V = -\ln(R - 0.008 \times t) + (4 - 3.5 \times R) \times UF/W \quad \textbf{(11)}$$

in which ln denotes the natural logarithm, R the post-dialysis to pre-dialysis BUN ratio, t the dialysis session length in hours, UF the ultrafiltration volume in liters, and W the patient's post-dialysis weight in kilograms.

From the aforementioned criteria of accuracy and completeness, the second-generation logarithm formula for calculating Kt/V is the best alternative for dialysis care teams to use, if they cannot perform formal urea kinetic modeling. Although this simplified formula is convenient, its use alone deprives the dialysis care team of the error check function for the delivered hemodialysis dose in contrast to formal urea kinetic modeling. The logarithm calculation of Kt/V does not permit the rigorous, preemptive quantitative analysis of the hemodialysis prescriptions possible with formal urea kinetic modeling. Furthermore, this formula does not allow for calculation of the nPCR. However, an approximation of the nPCR can be derived from a normogram that uses patient-specific parameters and the Kt/V natural logarithm formula.[63]

Urea Reduction Ratio

The URR is calculated simply from the fractional post-dialysis BUN concentration, which equals C_t/C_0, where C_t is the post-dialysis BUN and C_0 the pre-dialysis BUN,[47,60] as

$$URR\ (\%) = 100 \times (1 - C_t/C_0) \quad \textbf{(12)}$$

URR represents the precent of the total urea mass, which is removed from the body during a single hemodialysis treatment, assuming there is no change in urea distribution volume. It can be appreciated that this is a remarkably easy measurement of the dose of hemodialysis. More important, the utility of URR as a measure that correlates with patient mortality has been validated in several clinical studies using different patient databases.[19,47] Therefore, URR is no better or worse than Kt/V in defining mortality risks for hemodialysis patients in epidemiologic studies.

Despite its ease of use, there are limitations to URR as a measure of hemodialysis adequacy. In contrast to formal urea kinetic modeling or the Kt/V natural logarithm formula, URR does not account for the contribution of ultrafiltration to the final delivered dose of hemodialysis.[64,65] As described earlier, although urea is removed with the ultrafiltrate, no change in the plasma concentration occurs. The failure to account for this additional urea removal limits the accuracy of the estimate of dialytic dose, depending on the volume of ultrafiltrate formed.[55] For example, a patient with a large ultrafiltration requirement has a much higher dialytic dose when measured by formal urea kinetic modeling or the natural logarithm formula compared with the same patient with no ultrafiltration requirement. However, the URR will be the same in both these circumstances, if all other parameters for the hemodialysis prescription are equal.

This discrepancy between the dose of small solute removal during hemodialysis delivered in the presence and absence of ultrafiltration and its relationship to URR is illustrated in Figure 20–1. If we assume a 3-hour dialysis session, no residual renal function, and a volume of distribution of urea of 58% body weight, the Kt/V derived using formal urea kinetic modeling is contrasted with the URR.[64] A URR of 65% may correspond to a single-pool Kt/V of as low as 1.1 in the absence of ultrafiltration or can be as high as approximately 1.35 when ultrafiltration of 10% body weight occurs. Furthermore, because the relation between URR and Kt/V is curvilinear, modest decreases in the URR can result in substantial declines in Kt/V, especially in the target range of URR of 65% or higher.

When the URR alone is used, errors in the delivered dose of hemodialysis may be particularly difficult to ascertain. This limitation is a consequence of the inability of URR to support
Figure 20–1 Impact of urea clearance secondary to ultrafiltration on Kt/V values. The family of curves is based on the assumption of a 3-hour hemodialysis treatment and the absence of residual renal function. ΔWt is the volume ultrafiltered in liters divided by the patient's estimated dry weight in liters as indicated by the numbers labeling this figure. The greater the ΔWt, the higher the Kt/V for any given urea reduction ratio (URR) value. (From National Kidney Foundation: K/DOQI Clinical Practice Guidelines for Hemodialysis Adequacy, 2000. Am J Kidney Dis 2001; 37[suppl 1]:S7-S64.)

the calculation of V for comparison with anthropometric-derived values. In addition, as noted for the Kt/V calculated by the natural logarithm formula, achieving a target delivered dose of hemodialysis is an empirical exercise involving modification of the various components of the treatment prescription. Similarly, the URR does not support calculations of the nPCR and effectively ignores the contribution of residual renal function to urea clearance. Thus, although the URR is a useful tool to measure the delivered dose of hemodialysis for statistical outcome analyses,[19,47] it lacks sufficient accuracy and detail to routinely provide insight into problems with the dialysis prescription.

Other Methods for Dose Calculation

A variety of alternatives to the Kt/V natural logarithm formula and URR using pre-dialysis and post-dialysis urea concentration has been previously proposed[66–68]; however, there are no demonstrable advantages for using these alternative formulas, and they should be avoided.

The clearance of urea as a surrogate for the clearance of small molecules during hemodialysis can also be quantified by collection of the dialysate.[69] Dialysate-based urea kinetics has been considered by some to be the "gold standard" for dose quantification[69,70]; however, this contention has recently been questioned.[71] The popularity of blood side measurement stems largely from the historical practice of measuring blood levels of different solutes and substances to detect and quantify disease state. Because the current measures of hemodialysis dose are in essence solute removal, quantification of solute removed in the dialysate could potentially provide for a better measure of the effectiveness of treatment. There are several advantages with dialysate side measurements. Direct dialysate quantification bypasses the problem of solute disequilibrium, which occurs at various time points during and after hemodialysis (the double-pool model is discussed later). It also measures patient clearance directly not dialyzer clearance (K). There are several methods by which quantification of solute removed in the dialysate can be made. Either total or fractional dialysate collection techniques[72,73] have previously been proposed, such that the total mass of urea removed can then be calculated. These methods have yet to be used extensively during routine therapy. The advent and application of built-in, online urea sensors in hemodialysis machines permits the automation of dialysate urea quantification and makes this method more feasible than dialysate sampling techniques.[74] Currently available urea sensors are, however, expensive.

Another online measure of clearance utilizes a conductivity probe and does not require a urea sensor. This probe can determine the effective ionic dialysance (D) and permits the calculation of Kt/V at each dialysis session without blood or dialysate sampling at a very low cost.[75–79] Online assessment with this method has been tested against formal urea kinetic, using a 30-minute post-dialysis BUN sample and the *Daugirdas equilibrated Kt/V formula* (see later).[76] In this study, conductivity-derived measurements were found to be accurate and fairly precise, and they compared well with the method of Daugirdas. Hence, with the availability of online assessment that is both clinically useful and affordable, dialysis dose can be measured as often as needed, and immediate remedial steps can be taken to ensure adequate dosing.

Urea Rebound Double-Pool Effects and Recirculation

Physiology of the Double-Pool Model

As described earlier, the simplest model of urea distribution and concentration changes in the anuric hemodialysis patient is the single-pool or "single-compartment" model, which assumes that:

1. Urea is distributed uniformly in a single compartment of volume approximately equal to total body water.
2. The compartment will expand and contract uniformly during and between hemodialysis sessions.

This elementary model yields the single-pool Kt/V, which has proved clinically useful in population studies and has received wide clinical acceptance. However, the actual anatomic distribution of urea consists of plasma, erythrocytes, and interstitial and intracellular water.

Functionally, transfer between these compartments behaves as a diffusive process and can be described by the product of a volumetric mass transfer coefficient and the difference in concentration between the compartments.[40] However, this model omits another physiologic consideration for urea kinetics during and between hemodialysis treatments—the variable distribution of blood flow to various vascular beds and organs. For example, in the anephric patient, approximately 80% of cardiac output is distributed to visceral organs (liver, intestine, heart, and brain), which contain only 30% of TBW. In contrast, only 20% of the cardiac output is distributed to muscle, bone, and skin (primarily muscle), which account for 70% of TBW.[80,81]

During hemodialysis, the clearance of solutes (such as urea) is dependent on dialyzer clearance and the rate at which solutes can be conveyed from all body compartments into the dialyzer. The rapidity with which urea can be transferred from the plasma water compartment into the dialysate can easily exceed its rate of transfer from other compartments into plasma water, thereby giving rise functionally to multiple compartments. This is a fundamental biophysical and practical basis for the double-pool urea kinetic model, which is a more accurate and rigorous description of urea kinetics during hemodialysis.

Specifically, one level of resistance of urea movement is from the intracellular compartment to the extracellular compartment, which is estimated to be approximately 600 to 800 mL/min.[82] This relative resistance to urea movement from the cells across the interstitium and into the blood compartment effectively renders the distribution of urea into at least two pools. This biophysical reality obviously undermines a key assumption made in the formulation of the single-pool model.[83] Perhaps of greater importance is the effect of differential organ perfusion that contributes to this "disequilibrium" of urea removal. Because of the preferential removal of urea from well-perfused, but relatively urea-depleted vascular beds during the course of hemodialysis, no single-pool, variable-volume model for urea kinetics accounts for the different rates of urea transfer between these compartments.

This combination of effects (diffusive resistance and flow-volume disequilibrium) is commonly described by the term *double-pool effects*. As a consequence, after completion of a hemodialysis session, release of the sequestered urea begins and continues for 30 to 60 minutes (post-dialysis urea rebound). The resistance

of urea transfer and variable organ perfusion are thought to be the major components of post-dialysis urea rebound.[84–88] The post-dialysis BUN concentrations measured before and after the occurrence of urea rebound vary significantly, such that a lower BUN concentration is observed before rebound than after (Figure 20–2). Thus, the effective delivered dose of dialysis will be overestimated, if this sequestered urea pool is large and not taken into consideration.

Early studies have suggested that the extent of urea rebound varies greatly among patients and is influenced by such variables as the size and the efficiency of the dialyzer. In one study, the mean amount of urea rebound, measured as the percent increase in post-dialysis BUN concentration immediately after dialysis versus 30 minutes post-dialysis, was 170%.[87] In some patients, however, the extent of urea rebound was as great as 45%.[86] The use of dialyzers with high K (efficient, high-flux dialyzers), especially in a patient with a small V, increases the risk of significant double-pool effects.[81,87,89] The extent of post-dialysis urea rebound has been shown by Daugirdas and Schneditz[81] to be primarily a function of K/V. Therefore, the degree of rebound is large in ESRD patients who have a low urea distribution volume, have severely compromised cardiac output, or have suffered intradialytic hypotension.[81,90] On average, the equilibrated Kt/V (the Kt/V calculated using the 30 minutes post-dialysis BUN sample) is approximately 0.2 units less than the single-pool Kt/V.[81,87,91] For most patients, urea rebound is almost complete 15 minutes after discontinuation of hemodialysis; however, for a minority, up to 60 minutes may be required.

Because of the inability to routinely predict which patients will experience significant urea rebound, and in view of the potential deleterious impact of urea rebound on the delivered hemodialysis dose, the double-pool or equilibrated urea kinetic model seems to offer a better estimate of the true dose of hemodialysis. Although the equilibrated model better quantifies intradialytic urea removal, thus resulting in a more

precise Kt/V and nPCR,[86,92] the need to obtain a 30- to 60-minute post-dialysis BUN sample makes it impractical in routine clinical practice. To overcome this limitation, several investigators have proposed different formulas to estimate the equilibrated Kt/V (Kt/V_{eq}) from pre-dialysis and immediate (0–20 seconds delayed) post-dialysis blood samples. Formulas have been derived to correct for post-dialysis urea rebound by three independent groups: Smye and associates,[85] Tattersal and associates[93] and Daugirdas and Schneditz.[89] Practical predictions of post-dialysis urea rebound using these formulas are approximately equivalent for thrice-weekly hemodialysis.[94] The Daugirdas-Schneditz rate equation has been verified in small scale studies[70] and in analyses from the pilot phase of the HEMO Study[95]; these are actually two separate formulas, depending on whether the angioaccess is of arterial or venous origin:

$$\text{arterial } Kt/V_{eq} = \text{art } Kt/V_{sp} - (0.6 \times [\text{art } Kt/V_{sp} \div t]) + 0.03 \quad \textbf{(13)}$$

$$\text{venous } Kt/V_{eq} = \text{ven } Kt/V_{sp} - (0.4 \times [\text{ven } Kt/V_{sp} \div t]) + 0.02 \quad \textbf{(14)}$$

where Kt/V_{sp} is the value of calculated Kt/V from single-pool urea kinetic modeling and the units of the $Kt/V_{sp} \div t$ terms are hours^{-1}. These equations are simple to apply during routine hemodialysis because Kt/V_{eq} can be calculated from the previously mentioned equations and single-pool urea kinetic modeling parameters.

The above two formulas are based on the assumption that, if all other variables in the hemodialysis prescription are equal, the urea rebound from a venovenous access is less than with an arteriovenous access.[63,81] These differences are because cardiopulmonary recirculation (see later) is lessened with venovenous sampling, hence, the two formulas for Kt/V_{eq} calculation depend on the blood sampling site.

Recent results from the HEMO Study have verified that the rate of hemodialysis (i.e., $Kt/V_{sp} \div t$) is the single most important predictor of the magnitude of post-dialysis urea
Figure 20–2 Biophysical and kinetic segregation of the components of urea rebound. After the completion of hemodialysis, the blood urea nitrogen (BUN) concentration increases. The increment from point A → B is secondary to access recirculation; from point B → C, secondary to cardiopulmonary recirculation; and point C → D, secondary to flow-volume disequilibrium and/or diffusive impedance of urea (undefined disequilibrium). (From National Kidney Foundation: K/DOQI Clinical Practice Guidelines for Hemodialysis Adequacy, 2000. Am J Kidney Dis 2001; 37[suppl 1]:S7-S64.)

rebound.[96] These results suggest, however, that the coefficients of the Daugirdas-Schneditz rate equation described previously may not always be the most accurate in predicting Kt/V_{eq}. Moreover, this study showed that the optimal coefficients to use in the Daugirdas-Schneditz rate equation depend on when the immediate post-dialysis blood sample is obtained. Based on their studies, these investigators suggested the following equations for general use when the post-dialysis blood sample was obtained 20 seconds after stopping the blood flow rate:

$$\text{arterial } Kt/V_{eq} = \text{art } Kt/V_{sp} - 0.39 \times (\text{art } Kt/V_{sp} \div t) \quad \textbf{(15)}$$

$$\text{venous } Kt/V_{eq} = \text{ven } Kt/V_{sp} - 0.22 \times (\text{ven } Kt/V_{sp} \div t) \quad \textbf{(16)}$$

These equations are potentially important to use in routine clinical practice because they were similar to those used to interpret the outcome results from the HEMO Study (see later).

Although it is increasingly recognized that conversion to an equilibrated model can enhance the accuracy of the measurement of the delivered hemodialysis dose, routine substitution of Kt/V_{eq} for Kt/V_{sp} may be problematic and is not recommended[55] because of the:

1. Impracticality of obtaining a 30- to 60-minute BUN sample after completion of hemodialysis.
2. Uncertainty about the longitudinal validity of the aforementioned formulas for estimation of equilibrated Kt/V for an individual patient.
3. Absence of studies characterizing the dose-response relationship between Kt/V_{eq} and patient outcomes.

Furthermore, it has been proposed that rigorous monitoring of the Kt/V_{sp} and application of the hemodialysis dose recommendations from evidence-based practice guidelines, which are, in turn, derived from appropriate patient outcome studies using single-pool models of urea kinetics,[54,55] ensure patient safety equally as well as the use of double-pool models.[55]

Recirculation

A biophysical variable potentially confounding measurements of the delivered dose of solute removal during hemodialysis is the occurrence of recirculation. During hemodialysis, some of the blood that enters the dialyzer inlet may have flowed from the outlet without first passing through the peripheral capillaries. This flow of previously dialyzed blood from the dialyzer outlet to the inlet is termed "recirculation"[88,97,98]; if it is present, it is a significant contributing factor in urea rebound. It is intellectually useful to consider urea rebound as two temporal phases, an early and a late phase before and after 3 minutes post-dialysis, respectively. In turn, early urea rebound may be segregated into two components, both occurring as a consequence of different types of recirculation. The first component, secondary to blood recirculation within the angioaccess, is termed "access recirculation." The second component of early urea rebound is a consequence of "cardiopulmonary recirculation."[98,99]

Access recirculation occurs when a proportion of the blood returning to the patient through the venous needle or port is immediately drawn back into the arterial needle or port and dialyzed again. Access recirculation commonly occurs when (1) the arterial needle is incorrectly placed downstream of the venous needle, (2) the venous limb of the angioaccess is used for the arterial flow into the dialyzer and vice versa, or (3) the blood pump speed exceeds the flow rate through the fistula (Figure 20–3).[98] The last is usually a result of a critical stenosis in the angioaccess. Without a stenosis, fistula flow rates well exceed 700 mL/min and are unlikely to be superseded by the extracorporeal blood flow rate (Q_b).

Access recirculation begins to resolve immediately upon the completion of hemodialysis, and its effects are completely abolished in a very short time period (10–20 seconds). Therefore, in the presence of access recirculation, a post-dialysis BUN sample obtained either without flushing recirculated blood from the arterial line or within the first 10 to 20 seconds post-hemodialysis, results in an erroneously low BUN concentration, an excessively large Kt/V, URR, and nPCR.

The second component of early urea rebound, *cardiopulmonary recirculation*, is inevitable when an arteriovenous angioaccess is used in hemodialysis.[99] Cardiopulmonary recirculation arises because of the routing of just-dialyzed blood through the veins to the heart and the pulmonary circuit and back to the angioaccess without the passage of this blood through any urea-rich peripheral tissues.[100] Like access recirculation, cardiopulmonary recirculation causes post-dialysis urea rebound that begins approximately 20 seconds after the hemodialysis treatment, and approximately 2 to 3 minutes is required for its dissipation. Similar to access recirculation, improper timing for sampling of the blood for measurement of the post-dialysis BUN concentration causes erroneous results from urea kinetic modeling.[55,101]

Blood Sampling

To calculate Kt/V, using formal urea kinetic modeling requires accurate measures of: pre-dialysis and post-dialysis BUN concentration drawn at the first dialysis treatment of the week, and the pre-dialysis BUN concentration at the following treatment in a thrice-weekly hemodialysis schedule. Urea kinetic modeling, based on two BUN samples obtained on the midweek pre-dialysis and post-dialysis BUN, has been described and validated for accuracy in comparison to classic three-sample urea kinetic modeling.[102]

The accuracy of the calculated Kt/V or URR depends on proper blood sampling techniques for the pre-dialysis and post-dialysis BUN concentrations.[101] These sampling techniques must control for (1) the site of the blood obtained, (2) needle or catheter preparation, (3) blood and dialysate flow rates, (4) ultrafiltration rate, and (5) timing of the blood sampling with respect to the initiation and termination of the hemodialysis treatment.[103]

The ideal and accurate measurement of the Kt/V, URR, and nPCR requires:

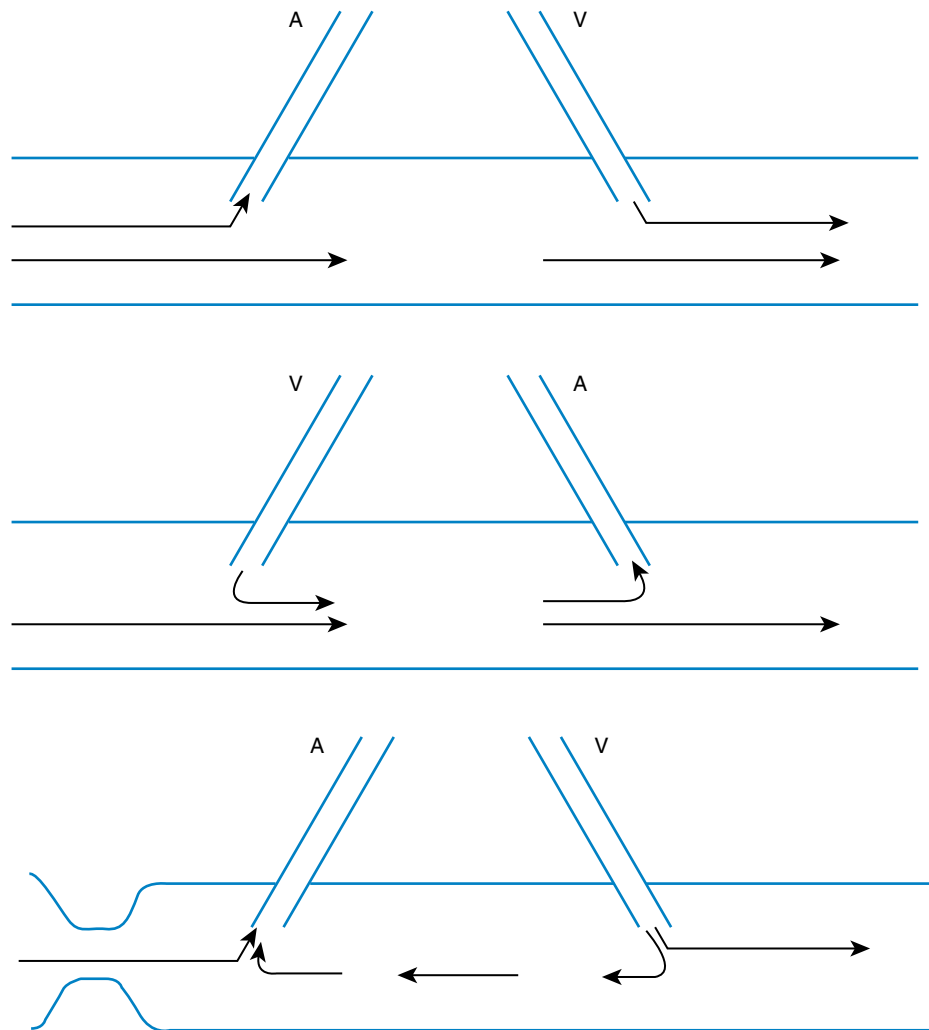
- Pre-dialysis BUN concentration be measured before hemodialysis begins and be obtained without dilution of the blood sample[103]
- Post-dialysis BUN concentration be measured after hemodialysis ends and angioaccess recirculation has resolved[104,105]
- Accurate laboratory processing of BUN samples
- Pre-dialysis and post-dialysis weights at the time of the first dialysis treatment of the week


Figure 20–3 Schematic representation of angioaccess recirculation. A and V refer to the arterial and venous paths of blood flow, respectively. *Uppermost panel*, the ideal situation of no access recirculation. *Middle panel*, access recirculation secondary to reversal of the needle placement, so that the blood path is from the venous limb to the arterial limb of the access. *Lower panel*, access recirculation secondary to stenosis of the arterial limb of the access with resultant blood flow that is inadequate to meet the pump speed. (Modified from Tattersall JE, Chamney P, Aldridge C, Greenwood RN: Recirculation and the postdialysis rebound. Nephrol Dial Transplant 1996; 11[suppl 2]:75-80.)

- Actual treatment time (delivered time, not the prescribed time)

The effective clearance of the dialyzer, as calculated from the hemodialysis unit (not the *in vitro* value provided by the manufacturer, which often overestimates the true in vivo value in plasma water).[106]

To calculate the URR requires pre-dialysis and post-dialysis BUN concentrations drawn at the same hemodialysis session. To calculate Kt/V using the simplified Daugirdas formula requires:

- Pre-dialysis and post-dialysis BUN concentration drawn at the same hemodialysis session
- Actual treatment time (delivered time)
- Patient's pre-dialysis and post-dialysis weights

Pre-Dialysis Blood Sampling Procedures

The pre-dialysis BUN must be obtained before dialysis begins to prevent this sample from being affected by the hemodialysis process. Sample dilution by heparin or saline must be avoided, or the pre-dialysis BUN sample will register an artificially low concentration. A recent, evidence-based clinical practice guideline described the best clinical practice for blood sampling. The sampling technique is one utilizing a fistula or graft as follows[55]:

1. Obtain the blood specimen from the arterial needle prior to connecting the arterial blood tubing or flushing the needle. Ensure that no saline or heparin is in the arterial needle.
2. Do not draw sample if the hemodialysis treatment has commenced.

The following sampling technique is recommended when one is utilizing a venous catheter[55]:

1. Withdraw any heparin or saline from the arterial port to prevent dilution of sample.
2. Using sterile technique, withdraw 10 mL of blood from the arterial port of the catheter. Do not discard this specimen, if reinfusion is intended.
3. Connect a new syringe or collection device, and draw the sample for BUN measurement.
4. Optional: Reinfuse the 10 mL of blood withdrawn earlier. Initiate hemodialysis, according to the dialysis unit's protocol.

Post-Dialysis Blood Sampling Procedures

The timing of the acquisition of the post-dialysis sample is especially crucial.[101,103] Immediately upon completion of the hemodialysis treatment, if access recirculation is present, some recirculated blood will be present in the angioaccess. If post-dialysis blood sampling is performed in the presence of recirculated blood, it will dilute the blood sample and give a falsely reduced BUN concentration. This results in an overestimation of the delivered dose of hemodialysis and the nPCR. Subsequently, cardiopulmonary recirculation and the double-pool effects take place to complete the post-dialysis urea rebound.

As described earlier, although the most accurate method to account for these biophysical effects is to wait 30 minutes after completion of dialysis, few patients agree to waiting. An alternative, clinically applicable method that best supports the use of formal urea kinetic modeling is the "slow flow/stop pump sampling technique."[55]

The sampling technique for the post-dialysis BUN concentration is as follows:

I. At the completion of hemodialysis, turn off the dialysate flow (to terminate the hemodialysis process) and decrease the ultrafiltration rate to 50 mL/hr (or to the lowest transmembrane pressure setting).

II. Decrease the blood flow rate to 50 to 100 mL/min for 15 (10–20) seconds. This step is performed to fill the arterial needle and blood tubing with nonrecirculated blood (i.e., to avoid the effect of access recirculation that may be present).

III. Proceed with either of two techniques:

    A. *Slow flow technique*

        1. Immediately draw the blood sample for measurement of the postdialysis BUN concentration from the arterial needle or port.
        2. Stop the blood pump, and complete the patient disconnection procedure according to dialysis unit protocol.

    B. *Stop pump technique*

        1. After running the blood flow rate at 50 to 100 mL/min for 15 seconds to flush any recirculated blood from the angioaccess, stop the pump immediately.
        2. Clamp the arterial line and venous blood lines, and clamp the arterial needle tubing.

3. Take blood sample from the arterial port or the arterial needle tubing after disconnecting from the arterial blood line.
4. After blood is returned to the patient, continue the disconnection procedure according to dialysis unit protocol. Uniformity of blood sampling methods has several advantages:
    a. As technical variability in blood sampling is minimized, the delivered doses of small solute removal during hemodialysis reported are comparable. Alternatively, a similar dose reported by dialysis centers using different blood sampling methods may have varied "actual" dialysis doses and are not comparable.[101]
    b. The single-pool urea kinetic model mandates that the post-dialysis BUN sample be measured without the effects of access recirculation and before significant urea rebound has occurred. The precise timing of the method of blood sampling advocated by the DOQI Hemodialysis Adequacy Work Group meets this requirement.[55]
    c. The recommended formulas for converting the single-pool Kt/V to a double-pool or equilibrated Kt/V value require that the post-dialysis BUN sample be obtained before urea rebound is completed.[95] Therefore, the reproducibility and accuracy of these blood sampling techniques outweigh the potential operational difficulties that may be encountered.

An alternative, widespread method of post-dialysis BUN sampling is the *blood reinfusion technique*,[55] which involves blood sampling after the patient's blood has been completely reinfused. Its relative simplicity has made it a popular technique, with a lower likelihood of operational errors. (The slow flow/stop pump techniques are more demanding technically.)

For blood sampling by the blood reinfusion technique:

1. Using a minimum volume of saline, return the patient's blood until the system is clear. Minimize the amount of saline used so that the post-dialysis BUN concentration is not decreased because of systemic dilution from administered saline. This is a particular concern for patients with a small V. Tapping the dialyzer during blood return, or pinching the lines and releasing to flush the tubing, may permit the use of less saline.
2. Clamp the blood and needle lines. Completely disconnect the patient from the extracorporeal circuit, per the dialysis unit protocol.
3. Using aseptic technique, attach a 10-mL syringe to the arterial needle tubing.
4. Unclamp arterial needle tubing or catheter. Withdraw and reinfuse 5 to 7 mL of blood several times to clear any remaining saline that might dilute the sample.
5. Clamp the arterial needle tubing or catheter after the line is filled with blood.
6. Utilizing a sterile technique, detach the syringe and set it aside.
7. Attach a multiple-sample Luer adapter or a second syringe to the Vacutainer needle holder. Attach whichever of these

devices is used to the end of the arterial fistula needle or catheter. Push the tube onto the holder.

8. Open the clamp on arterial needle tubing or catheter line to collect the post-dialysis BUN sample. Clamp the line when the tube is full. Remove the adapter and needle holder or syringe.
9. Clamp the blood line, and complete the termination procedure per dialysis unit protocol.

It is critical that the dialysis care team appreciate that the doses of hemodialysis measured by this blood sampling method will be systematically lower than those obtained using the slow flow/stop pump sampling techniques, even when the actual delivered dose of hemodialysis is the same.[107] Because variable amounts of urea rebound will have occurred owing to differences in the timing of blood reinfusion and sampling, the measured dialysis dose with the slow flow/stop pump sampling technique will be higher than that with the reinfusion sampling technique. Therefore, continuous quality improvement initiatives, which contrast the delivered dose of hemodialysis and nPCR between patients and facilities as clinical performance measurements, must not trivialize the potential for apparent differences arising from the blood sampling method alone.[101]

Uniformity of Dose Quantification and Blood Sampling

As implied from the earlier discussions, the method of drawing the pre-dialysis and especially post-dialysis BUN samples can affect the results of the Kt/V or URR measurement independent of the hemodialysis dose. A survey of 202 units across North America estimates that 5% of the centers have errors in their pre-dialysis sampling method, and up to 40% of the units surveyed have potential faults in their post-dialysis sampling method.[108] Adoption of the same method of hemodialysis dose quantification (either Kt/V or URR) for all patients in a given facility can enhance consistency and enable meaningful comparison of data for a given patient over time, between different patients in the same center, and among different hemodialysis facilities.[101]

In the absence of such uniformity in measurement, longitudinal comparisons of delivered doses of small solute removal during hemodialysis cannot be made. However, the adoption of one method of hemodialysis dose quantification does not preclude the use of another method as a supplementary measurement for some or all patients. Nevertheless, the dialysis facility must adopt a single, consistent, and comparable measurement of the dose of hemodialysis. For example, if a center uses URR as the principal measurement of the delivered dose of hemodialysis, this can be supplemented episodically by the more precise measure of Kt/V derived from formal urea kinetic modeling. Similarly, a dialysis facility that uses single-pool Kt/V can supplement this with a measurement of the equilibrated Kt/V.

Frequency of Dose Measurement

Numerous outcome studies have correlated the dose of small solute removal with patient morbidity and mortality.[11,14–16,18,19,47] It is clear that the outcome of the ESRD population receiving hemodialysis can be improved with a selected minimum dose of small solute removal during hemodialysis. As such, the dose of small solute removal during hemodialysis must be measured on a regular basis to ensure dialysis adequacy. Clinical signs and symptoms alone are not reliable indicators of hemodialysis adequacy.

The evidence suggests that measurement of hemodialysis dose should be performed monthly. This recommendation is based on the observation that most hemodialysis outcome studies have relied on monthly measurements.[11,14,19,47] Measurements performed less frequently may compromise the timeliness with which deficiencies in the delivered hemodialysis dose are detected and hence may delay implementation of corrective steps. Because most dialysis facilities schedule their patients to undergo monthly blood-based biochemical evaluations with monthly reporting of the institutional results, monthly measurement of the delivered hemodialysis dose is pragmatic.

The frequency of small solute dose measurements should be increased if:

1. Patients are noncompliant (i.e., if they often miss treatment or sign off prematurely).
2. Problems are noted in the delivery of hemodialysis (i.e., poor blood flow, treatment interruptions, clotting of the dialyzer).
3. The delivered dose varies widely in the absence of prescription changes.
4. The hemodialysis prescription has been modified.

When the use of online (real-time) measurement of dialysis dose becomes available extensively, dose of dialysis can be ascertained for every treatment and correction can be made immediately.

DEFINING AND DELIVERING AN ADEQUATE DOSE OF HEMODIALYSIS

Guideline Recommendations

In 1993, the Renal Physicians Association (RPA) released the first evidence-based, clinical practice guidelines on the adequacy of hemodialysis.[54] This document defined adequate hemodialysis as the "recommended quantity of hemodialysis delivered which is required for adequate treatment of ESRD such that patients receive full benefit of hemodialysis therapy." At the time of its release, the only randomized, prospective controlled trial that provided evidence for the required dose of hemodialysis was the NCDS.[11] As detailed earlier, reanalysis of the primary data from this trial showed that single-pool Kt/V values below 0.8 were associated with a relatively high rate of morbidity, whereas Kt/V values between 1.0 and 1.2 were associated with a relatively lower rate of morbidity.[41]

Extrapolating from the NCDS to current dialysis practice is problematic because of major differences in patient mix and dialysis practice since the performance of the trial. Because of the paucity of definitive literature at the time of the RPA's Clinical Guidelines on Adequacy of Hemodialysis, a supplementary clinical decision analysis was performed using available data.[107] The initial analysis used a probabilistic model to assess how variables in the dialysis prescription affect a patient's *quality-adjusted life expectancy* (QALE). In a complementary analysis, lifetime costs and QALE were modeled

to determine the "marginal cost-effectiveness of the components of the dialysis prescription."[109]

On the basis of these analyses, the RPA recommended that, "the delivered dose Kt/V should be at least 1.2." In the analysis by Hornberger[107] the QALE continued to increase to a tested Kt/V level of 2.0; at Kt/V values of 1.4 and greater, a rapid increase in cost was noted secondary to the increased costs of the delivery of hemodialysis, which offset the savings achieved by fewer hospitalizations. Thus, the RPA made a final recommendation that balanced the patient's QALE with marginal cost-effectiveness of the dialysis dose.

Since the publication of the RPA's Clinical Practice Guideline, several reports have suggested greater mortality benefit associated with a higher minimum dose of hemodialysis.[15,16,18,19,110] However, most of these reports were observational, retrospective analyses from self-selected dialysis centers. Some of the limitations include the following:

1. Comparison of patient outcomes to uncontrolled historical standards[18,110]
2. Lack of randomization[15,19]
3. Lack of standardization in the blood sampling method[15,19]
4. Use of relatively broad categories of Kt/V or URR for analysis[15,19,47]
5. Major differences in clinical practice and patient behaviors in other countries compared with those in the United States[110]

For example, Hakim and associates[16] performed a prospective study to increase the Kt/V of 130 patients from 0.8 to 1.3 over a 4-year period (1988 to 1991). Concurrent with this increase, they reported a reduction in gross annual mortality from 22.8% in 1988 to 9.1% in 1991. The standardized mortality rate and the hospitalization rate were also reduced. However, this was not a randomized controlled trial, and several factors during the course of the study period varied simultaneously with the dose of hemodialysis. The study did not define dose, because the only comparisons made were between Kt/V of 0.8 (known to be inadequate since the NCDS) and 1.3 (which is above the minimum set by the RPA's Clinical Practice Guidelines). Furthermore, not all study results suggest an improved survival with delivered hemodialysis doses higher than Kt/V of 1.2 or URR of 65%.[19,47] A retrospective analysis of data from the USRDS, which used both single-pool (sp) and double-pool (dp) urea kinetic models, found no improvement in survival for a categoric Kt/V_{sp} of 1.2 to 1.4 or a Kt/V_{dp} of 1.0 to 1.2.[111]

From a literature review in this area of hemodialysis care since the publication of the RPA's Clinical Practice Guidelines, the DOQI Hemodialysis Adequacy Work Group[55] recommended the following:

1. In the absence of definite and consistent evidence, the minimum dose of delivered hemodialysis, as recommended, should remain unchanged.
2. The present literature does not support the definition of an optimal dose of hemodialysis.[55] Specifically, "the dialysis care team should deliver a Kt/V of at least 1.2 (single-pool, variable-volume) for both adult and pediatric hemodialysis patients. For those using the URR, the delivered dose should be equivalent to a Kt/V of 1.2, that is, an average URR of 65%. URR can vary substantially as a function of fluid removal, however."[55]

In determining the minimum dose of hemodialysis, as measured by the URR, we note that the relationship between URR and Kt/V is greatly affected by the extent of the ultrafiltration.[64,65] Thus, the required URR to achieve the minimum adequate Kt/V of 1.2 can vary substantially as a function of fluid removal (see Figure 20–1).

It is clear that many ESRD patients do not receive their prescribed dose of hemodialysis. Some studies have suggested that only 50% of the ESRD patients in the United States actually received their prescribed hemodialysis dose.[14,19,112] As discussed later, URR cannot be prescriptive, but it does offer a valid single point in time analysis of the delivered dose of hemodialysis. A representative national survey of 6000 ESRD patients revealed that in 1995 only 59% of the patients surveyed received a URR of 65% or higher. A variety of factors may compromise the delivery of the prescribed dose.[14,112–115] These factors may be categorized into those that (1) compromise urea clearance, (2) reduce the hemodialysis treatment time, or (3) result in errors in blood sampling. Again, these problems in the delivered dose of hemodialysis result in a discrepancy between the V derived from urea kinetic modeling and the V derived from anthropometric values (see Tables 20–2 and 20–3). A continuous quality improvement initiative that uses formal urea kinetic modeling can readily detect these problems in the delivered hemodialysis dose.

To prevent the delivered dose of hemodialysis from declining to values below the recommended minimum dose, practitioners should prescribe doses of dialysis that are above these minimum values. In the HEMO Study, in which rigorous implementation and measurements of the hemodialysis prescription were executed, the 90% confidence interval for the single-pool Kt/V of 1.3 is 0.1 unit (personal communication, T. Greene, 1995). As such, the DOQI Hemodialysis Adequacy Work Group[55] suggests that *the prescribed minimum Kt/V should be 1.3.* For the URR, the HEMO Study observed a 90% confidence interval of 4% (Greene, 1995). Therefore, *for those using URR, a minimum target URR of 70% should be set.*[55]

To achieve a desired Kt/V, K and V can be derived by various means and the treatment time, t, then determined. As such, Kt/V is prescriptive but URR is not. In contrast to the Kt/V, means to increase the URR are subject to the preferences of the dialysis physician and are executed by trial and error. Specifically, an arbitrary estimate of the blood or dialysate flow rates, or the duration of treatment needed to achieve the target URR, is prescribed and a follow-up URR is obtained. However, when a series of normograms is used, the URR can be correlated to an extrapolated Kt/V, and this value is used to guide modification of the appropriate components of the hemodialysis prescription.[63]

Patients with Diabetes Mellitus

Collins and associates[15] suggested that diabetic patients with ESRD may experience an approximate 40% reduction in their odds of risk of death, if the minimum delivered single-pool Kt/V is increased from 1.0 to 1.2 to 1.4 or greater. However, this finding has not been observed uniformly in other studies of diabetic patients with ESRD.[19,111] Therefore, this discrepancy makes it difficult to routinely recommend a higher minimum dose of hemodialysis for diabetic patients.

Race and Gender

Several observational analyses have reported that although African-Americans with ESRD often receive less than the minimum appropriate dose of hemodialysis (as recommended by the RPA and DOQI),[116,117] they have an improved survival rate compared with whites.[47,117] Despite knowledge of the cause of death, the basis of the improved survival for African-Americans is unclear. Potential explanations include:

1. The selection of healthier African-Americans for maintenance dialysis
2. Misdiagnosis or misclassification of the cause of ESRD among African-Americans
3. Improved nutrition among African-Americans
4. African-Americans have better quality of life on dialysis and thus adopt fewer deleterious health-related behaviors
5. Relatively less susceptibility to the deleterious effects of inadequate hemodialysis[117]

It is important to realize that all previous analyses of the relationship between the dose of hemodialysis and patients' mortality risk were derived by statistically aggregating all patient subgroups (race, gender, diabetes), on the assumption that their sensitivity is equivalent. Using a database of 18,144 representative ESRD patients (from Fresenius Medical Care), the analysis suggests that the previous clinical assumption of no difference in the odds of risk of death among different racial groups and genders by URR is incorrect.[19,47,118] White patients, particularly white females, are much more affected by the mortal risk of lower URR values than African-Americans (Figure 20–4). This differential racial sensitivity to lower hemodialysis doses, as measured by the URR, is not explained by differences in patients' ages. It may not be a case of differential sensitivity to dialysis dose, but, simply, that URR is inadequate as a measure of hemodialysis dose. African-Americans were observed to have greater weight and TBW and higher serum albumin and serum creatinine levels.

The TBW is related to both URR and nutrition because TBW is calculated using patient weight and not directly measured. A change in TBW causes the two predictors (URR and nutrition) to bring about changes in contrasting direction.

The nutrition-derived effect of urea distribution volume may supersede its mortality impact by way of URR. These findings underscore the limitation of URR and Kt/V because measures of the adequacy of hemodialysis suggest that quality assurance efforts in this domain of care must be dynamic and reiterative to reflect the rapidly evolving knowledge base in dialysis care. However, there is no evidence that African-Americans should receive less dialysis than Caucasians.

Twice-Weekly Hemodialysis

Twice-weekly hemodialysis is usually inadequate, unless there is a significant amount of residual renal function, that is, a glomerular filtration rate (GFR) of 5 mL/min or greater. Because residual renal function declines with time, the presence of a significant amount of residual renal function at the initiation of maintenance hemodialysis mandates serial monitoring of renal function, if the patient is undergoing twice-weekly hemodialysis. Such diligence can guide the appropriate addition of a third-weekly hemodialysis treatment, if renal function declines further. Unless the patient's residual renal function can be monitored serially and regularly, patients should start a thrice-weekly hemodialysis schedule from the onset.[55]

Are the Current Measures Appropriate Predictors of Survival?

The clearance of urea normalized to the volume of distribution of urea (Kt/V) and the URR are the current standards upon which clinical guidelines and regulation on hemodialysis adequacy in the United States are based. As stated earlier, any clinically meaningful measure of the dose of dialysis must be relevant to patient outcome. The urea kinetic concepts of Kt/V and URR have been correlated variously to morbidity and mortality outcomes in past years (Table 20–3). It does appear that these mathematical constructs are useful and relevant to patient outcome.*

However, recent reports suggest clinical problems and paradoxes when medical outcome is considered in terms of Kt/V or URR. First, Kopple and associates[121] reported progressive deterioration of survival among patients grouped by weight-for-height percentile. URR decreased progressively with increasing weight-for-height percentile, so that the lightest patients had both the highest URR and death risk. Taken by themselves, one may conclude from these data that higher clearance (as measured by URR) leads to undernutrition and increased risk of death.

A second report by Chertow and associates[122] described increasing mortality risk when URR was above 70%, producing a reverse J curve to the URR death risk profile. He then measured TBW (by bioelectric impedence) and adjusted URR for TBW and showed improved survival across the entire range of TBW adjusted URR.[122] Low TBW (giving rise to a high unadjusted URR) reflected low lean body mass and poor nutritional status, thus contributing to greater risk of death. The reverse J curve profile has also been reported in the past, although no satisfactory answers availed at the time that it was published. Patients with a URR above 70% (urea ratio, 3.4) and Kt/V above 1.25 were associated with higher mortality risk.[119,123]

The mortality risk of low URR appears to affect African-Americans and males less significantly.[118] As is known, African-Americans and males have higher body mass, suggesting that the effect of URR on survival is altered by body mass. Serum concentration of creatinine is favorably associated with survival in dialysis patients, and African-Americans and males tend to have higher levels. Statistical adjustment for differences in serum creatinine concentration negates the survival advantage of African-Americans receiving hemodialysis.

Using data from a USRDS special study (of 8591 patients), Wolfe and associates[124] reported their findings on the relationship between dose of hemodialysis (Kt/V), body size, and mortality. Kt/V and body size measure were both independently and significantly related to mortality after adjustment for patient characteristics and comorbid conditions.[124] It was concluded that Kt/V (as a measure of dialysis dose) and body size (as proxy for nutrition) are clinically important predictors of mortality.

*References 11,15,16,18,19,47,118–120.

Figure 20–4 Age-adjusted death probability for patients with end-stage renal disease as a function of urea reduction ratio (URR). *Key:* Top curve, white females; second *(solid)* curve, white males; third *(dotted)* curve, black males; bottom curve, black females. The URR is expressed as a second-order variable.[118] Again, white females and males exhibited a greater sensitivity to the mortal effects of URR values less than those recommended by the Renal Physicians Association (RPA) and Dialysis Outcomes Quality Initiative (DOQI) Clinical Practice Guidelines on hemodialysis adequacy.
These observations suggest that the present urea kinetic construct for dialysis dose, Kt/V or URR, whereby one measure (the urea clearance product, K × t) is divided by another (V, a proxy of lean body mass and nutrition) may be flawed. Increasing V diminishes Kt/V, generally associated with higher mortality risk, but a larger V by itself is associated with better nutritional status and, hence, better outcome (lower mortality risk).

Lowrie and associates,[125] analyzing data from more than 17,000 patients using the Fresenius Medical Care database, demonstrated improving death odds with increasing Kt alone (not corrected for V). Similar favorable findings were noted with increasing body size (measured here as BSA, TBW, body weight, and body mass index) whether adjusted or not for Kt. Patients with smaller body size needed higher Kt/V to achieve the same level of risk. Thus, dividing Kt by V failed to "normalize" treatment across all classes of body size as it was intended to; instead, it accentuated the differences. Additional analyses by these same investigators have confirmed and extended these concepts, using an even larger database.[126]

The fundamental premise that V is assumed to be an inert receptacle for urea is not true—the reason why the seemingly contradictory rise in mortality risk as Kt/V or URR is very high. Some patients with small body size have both higher mortality and URR or Kt/V (i.e., lower body mass permits higher URR but contributes to greater mortality). This paradox can be resolved, if we disaggregate Kt/V into two separate measures of outcome: (1) dialysis exposure and (2) body mass. Indexing treatment to body size gives rise to confusing discrepancies of patient outcome. The Lowrie[125] report suggested that Kt may be a better outcome predictor, and the minimum clearance (Kt) threshold is 40 to 45 L per treatment for female patients and 45 to 50 L per treatment for male patients. This was inferred from retrospective data, and the possibility that higher values may yield incremental benefit must be considered. The consideration of Kt as a dose parameter for evaluating dialysis adequacy has both scientific

and clinical merit; recent work confirms its comparability to Kt/V in epidemiologic studies.[127]

PRINCIPLES AND METHODS FOR QUANTIFYING THE DOSE OF MIDDLE MOLECULE REMOVAL DURING HEMODIALYSIS

Duration of Treatment

It has been suggested that the duration of the hemodialysis session is an independent measure of hemodialysis adequacy, separate from either Kt/V or URR. The proponents of dialysis duration as a unique measure of hemodialysis adequacy propose that extending the length of hemodialysis disproportionately increases the clearance of uremic toxins for which urea is not a good surrogate (e.g., middle molecules). Because of their size, middle molecules are less dependent on diffusive clearance than urea, if a conventional low-flux dialyzer is used. Acknowledging that urea is only a marker solute for uremic toxins, treatment time becomes a crude surrogate for the clearance of these molecules. Therefore, a longer duration for hemodialysis may enhance patient survival[13,128,129] and, thus, offer an alternative measure not accounted for by urea-based kinetic modeling alone.

A second potential advantage of longer hemodialysis sessions is the greater ease of establishing intravascular euvolemia. If the estimated dry weight is defined as the post-dialysis weight that correlates with intravascular euvolemia, routinely achieving this weight may reduce the risk of cardiovascular complications, especially from hypervolemia and hypertension.[129,130] Both the ultrafiltration volume and the rate of ultrafiltration greatly affect blood pressure,[131,132] such that large ultrafiltration volumes or rapid ultrafiltration can result in hypotension, cramps, or both. These symptoms are a frequent cause of the premature discontinuation of hemodialysis,[112,114,133] which, in turn,

may lead patients to finish the treatment without achieving their true estimated dry weight. With a typical interdialytic weight gain, the cycle is repeated at the next dialysis, such that the patient is chronically hypervolemic. This cycle may be further exaggerated by the physiologically incorrect clinical practice of routinely relying on hypotension or cramps to define estimated dry weight.[134–138]

All of these events may be confounded further by the deleterious effect of antihypertensive medications on the patient's intradialytic blood pressure.[139] Because some investigators have reported improved patient survival in the setting of greatly improved blood pressure control associated with increased dialysis treatment times,[129] it has been suggested that this is a causal relationship. Therefore, extending the duration of hemodialysis sessions has been advocated as a means of minimizing intradialytic hypotension and cramps, thus improving the likelihood of achieving the patient's dry weight.[55]

Despite these clinically sound arguments, there are no clinical outcomes data to support a minimum time for hemodialysis treatment. The few studies that have attempted to statistically examine this issue are compromised by reliance on the prescribed instead of the delivered dialysis time.[11,47] Held and associates[19] reported that prescribed treatment time was not statistically significant in explaining mortality when adjusted for dose of dialysis. A similar conclusion was published in an earlier study.[123] When dose of dialysis was maintained, hemodialysis time did not affect survival. Further studies are needed to ascertain whether actual delivered treatment time is a predictor of mortality. As described previously, however, the accuracy of the single-pool, variable-volume model of urea kinetics becomes increasingly compromised with shorter dialysis times, so that the delivered dose of hemodialysis becomes increasingly overestimated.[55] Therefore, some groups have recommended that irrespective of the delivered dose of hemodialysis, the dialysis time should not be shortened to less than 2.5 hours,[15] especially if single-pool urea kinetic modeling is used.

Calculation of Beta-2-Microglobulin Clearances

An alternative method for evaluating middle molecule removal during hemodialysis is by direct evaluation of the clearance of a given marker solute in the middle molecular weight range. The middle molecule that has historically been used as a marker is vitamin B_{12}, and calculated in vitro dialyzer clearances of vitamin B_{12} are an independent predictor survival among chronic hemodialysis patients.[140] Dialyzer clearances for this solute, however, can be accurately evaluated *in vitro* only; thus, determination of vitamin B_{12} clearance as an in vivo marker of middle molecule clearance is problematic because of its extensive binding to plasma proteins. The causative role of β_2-microglobulin in the pathogenesis of dialysis-related amyloidosis[31] and its ready measurement in the plasma of ESRD patients have resulted in the common use of β_2-microglobulin as a marker solute for evaluating the clearance of middle molecules.

Kinetic modeling of β_2-microglobulin during hemodialysis follows the same general principles as those described previously for urea. When modeling β_2-microglobulin, however, different simplifying assumptions are required. Assuming a single compartment model,[141] the following assumptions are reasonable:

1. β_2-microglobulin is uniformly distributed in a single compartment that approximates extracellular fluid volume. This assumption neglects post-dialysis rebound of β_2-microglobulin.
2. Fluid removed during hemodialysis treatment originates entirely from the extracellular fluid space.
3. The amount of β_2-microglobulin generated intradialytically can be neglected.
4. There is no residual renal nor extrarenal clearance of β_2-microglobulin.

Based on these assumptions, equation (1) can be integrated over the intradialytic period. From that solution, the following equation was derived to calculated mean dialyzer clearance of β_2-microglobulin (K_{b2m}) during the hemodialysis session from pre-dialysis and post-dialysis concentrations, C(0) and C(t), respectively:

$$K_{b2m} = Qf \, (1 - \ln \, (C(t)/C(0))/\ln \, [1 + Qf \times t/V \, [t]]) \quad \textbf{(17)}$$

where Qf is the ultrafiltration rate determined as the difference between the pre-dialysis and post-dialysis body weights divided by t, the treatment time, and V(t) is an estimate of extracellular fluid volume post-dialysis. Equation (17) was used to evaluate dialyzer clearances of β_2-microglobulin to define the flux intervention in the HEMO Study and to examine the effect of reuse on dialyzer clearances of β_2-microglobulin.[142] Although valuable for certain purposes, the estimates of dialyzer clearance provided by equation (17) are likely inaccurate because this model neglects post-dialysis rebound of β_2-microglobulin.[143] Further work is needed to provide practical equations for calculating dialyzer clearances of β_2-microglobulin, which account for post-dialysis rebound.

RESULTS FROM THE HEMO STUDY

The HEMO Study was a prospective, randomized, multicenter clinical trial designed to study the effects of the dose of small solute removal (defined in this trial as "dialysis dose") and membrane flux on hemodialysis patient morbidity and mortality. Patients were randomized using a 2×2 factorial design to a target eKt/V of either 1.05 of 1.45 and to the use of either low-flux or high-flux membranes. Entry criteria included a thrice-weekly treatment regimen, age 18 to 80 years, residual renal urea clearance less than 1.5 mL/min/35 L of urea volume, and anticipated ability to achieve a target eKt/V of 1.45 during a 4.5-hour hemodialysis session. Between 1995 and 2001, 1846 patients were randomized in 72 dialysis units affiliated with 15 clinical centers in the United States. More details on the study design and implementation have been reported elsewhere.[144,145] The primary outcome was patient death from any cause. Several secondary outcomes were also evaluated.

Randomized patients were, in general, similar to national data from the United States. There was a slight predominance of women, 63% African-Americans, and 45% of the patients were diabetic. Table 20–4 shows selected treatment characteristics during the follow-up period of study for each intervention group. Duration of treatment, blood flow rate, and all parameters related to urea clearance or removal were greater

Table 20–4 Characteristics of Treatments During HEMO Study Follow-Up (Values are Mean ± SD)

Treatment Variable	Standard Dose Group	High-Dose Group	Low-Flux Group	High-Flux Group
Duration of dialysis (min)	190 ± 23	219 ± 23	206 ± 28	203 ± 27
Blood flow rate (mL/min)	311 ± 51	375 ± 32	344 ± 53	341 ± 54
Urea clearance (mL/min)	218 ± 25	251 ± 18	233 ± 27	236 ± 28
spKt/V	1.32 ± 0.09	1.71 ± 0.11	1.51 ± 0.22	1.52 ± 0.22
eKt/V	1.16 ± 0.08	1.53 ± 0.09	1.34 ± 0.21	1.34 ± 0.21
Urea reduction ratio (%)	66.3 ± 2.5	75.2 ± 2.5	70.6 ± 5.1	70.9 ± 5.1
β_2-microglobulin clearance (mL/min)	18.9 ± 19.0	18.3 ± 16.8	3.4 ± 7.2	33.8 ± 11.4

in the high dose than in the standard dose group. Dialyzer clearance of β_2-microglobulin was higher in the high-flux than in the low-flux group. There were no differences in urea clearance parameters in the flux groups or β_2-microglobulin clearances in the dose groups.

Table 20–5 shows the primary analyses of mortality.[145] Patient mortality was lower for younger patients, females than males, African-Americans than all other races, nondiabetics than diabetics, patients who had been treated for shorter periods before the enrollment into the study, patients with higher serum albumin levels, and patients with lower comorbidity (ICED) scores. These results were similar to those expected from prior studies. In contrast, neither the dose intervention nor the flux intervention had a significant effect on all-cause mortality. Kaplan-Meier survival curves for the dose and flux interventions are shown in Figures 20–5 and 20–6, respectively. The 95% confidence intervals were relatively large, suggesting that either intervention may have had an effect on mortality, but the size of the effect was too small to be detected in a trial of this size. Of interest, however, the effect of the flux intervention on two main secondary outcomes, death due to cardiac causes and first hospitalization or death due to cardiac causes, showed a statistically significant reduction in risk of 20% ($P = .04$) and 13% ($P = .05$), respectively.[145,146]

The results for interactions of the treatment interventions with seven of the prespecified baseline characteristics are

Table 20–5 Primary Cox Regression Analysis of All-Cause Mortality in the HEMO Study

Predictor Variable	Relative Risk of Death (95% CI)	P Value
High dose	0.96 (0.84-1.10)	.53
High flux membrane	0.92 (0.81-1.05)	.23
Age (per 10-year increase)	1.41 (1.33-1.50	<.001
Female gender	0.85 (0.73-0.98)	.02
Black race	0.77 (0.55-0.91)	.002
Diabetes	1.29 (1.11-1.50)	.001
Pre-study years on dialysis (per 1-year increase)	1.04 (1.02-1.06)	<.001
Baseline ICED score (per 1-unit increase)	1.37 (1.25-1.50)	<.001
Baseline serum albumin (per 0.5 g/dL increase)	0.51 (0.43-0.62)	<.001

shown in Tables 20–6 and 20–7 for the dose and flux interventions on the primary outcome, respectively. The interaction of the dose intervention with gender was significant ($P = .014$), only before considering the Bonferroni correction for multiple comparisons, however. Women randomized to the high dose group had a lower mortality rate than women randomized to the standard dose group (relative risk or RR = 0.81, $P = .02$), whereas men randomized to the high dose group had a nonsignificant trend for a higher mortality rate than men randomized to the standard dose group (RR = 1.16, $P = .16$). Although mean body sizes were different between men than women, the RR of mortality for the high vs. standard dose groups remained lower in women than in men after adjustment for the modeled urea volume or with other size parameters, including body weight and body-mass index. The interaction of the dose intervention with race was of borderline significance ($P = .06$); thus, race will need further consideration in additional analyses. Indeed, it appeared that the effect of gender was predominantly driven by the greater response to the higher dose in non–African-American females than in African-American females. Further details of these analyses have been recently reported.[147] No other interaction within the dose intervention for the primary outcome (all-cause mortality) was significant. It is important to emphasize that there was no interaction of dose with age, diabetes, or comorbidity, as suggested in certain previous studies.[15]

The interaction of the flux intervention and pre-study years on dialysis was statistically significant ($P = .005$), even after considering the Bonferroni correction for multiple comparisons. Thus, patients who had been previously treated for more than 3.7 years and were randomized to the high-flux group had a lower mortality rate than such patients randomized to the low-flux group (RR = 0.68, $P = .001$). In contrast, in patients who had been previously treated for less than 3.7 years and were randomized to high-flux hemodialysis had a nonsignificant trend for a higher mortality rate than those randomized to the low-flux hemodialysis (RR = 1.05, $P = .55$). Further analyses of these data did not find a difference in the effect of high-flux hemodialysis on mortality between patients with less than 0.24 mL/min versus greater than 0.24 mL/min of residual renal clearance. It should be noted, however, that more than half of the patients entering the HEMO Study had no residual renal clearance.[145] Thus, it does not follow that these outcomes can be explained by differences in residual renal clearances. Finally, it should be pointed out that the effect of

Figure 20–5 Kaplan-Meier survival curves for the dose intervention in the HEMO Study. The curves are adjusted for the prespecified baseline factors. Mortality in the high-dose group was 4% lower (P = .53) than that in the standard dose group.

No. at risk

Standard dose	854	759	630	524	451	382	315	253	197	149
High dose	857	753	637	538	470	399	327	266	219	166
Figure 20–6 Kaplan-Meier survival curves for the flux intervention in the HEMO Study. The curves are adjusted for the prespecified baseline factors. Mortality in the high-flux group was 8% lower (P = .23) than that in the low-flux group.

No. at risk

Low flux	851	750	632	525	446	383	307	250	203	149
High flux	860	761	635	537	473	399	335	269	212	160

high flux hemodialysis on patient mortality was considerably weakened when the years on dialysis during the follow-up phase were combined with the pre-study years of dialysis in those analyses. Further details of these analyses have been recently reported.[146] No other interaction with the flux intervention in the primary analysis was statistically significant.

FUTURE TRENDS

The findings from the HEMO Study that increasing the dose of small solute removal or the use of high-flux membranes during thrice-weekly hemodialysis therapy is unlikely to produce improved patient outcomes provides numerous challenges to the dialysis community. Two of these major challenges, discussed later, are: (1) the effect of the HEMO Study results on current treatment guidelines and (2) the importance of using and developing new markers for assessing hemodialysis adequacy for treatment schedules other than thrice weekly.

Although it is not the purpose of this review to propose new treatment recommendations, a major challenge to the dialysis community is whether current practice guidelines for hemodialysis should be altered, based on the results from the HEMO Study. One could argue that there is justification for keeping these guidelines unaltered, based on the primary

outcome of that study. If, however, one considers the possibility that the study was underpowered to perform analyses on various subgroups of patients, then it may be appropriate to revisit several aspects of the guidelines.

Let us examine a few such considerations. The K/DOQI 2000 Guidelines recommend that spKt/V be used to guide the dose of small solute removal. Because the HEMO Study used eKt/V dosing parameter to guide therapy, however, one could argue that eKt/V should be used to monitor therapy. This is not necessarily the case, as illustrated in Tables 20–8 and 20–9. Table 20–8 compares the relationship between spKt/V and eKt/V for the standard dose group in the HEMO Study, using the new rate equation developed in that study, as described previously.[96] Remember that mean achieved spKt/V and eK/V values in the standard dose group were 1.32 and 1.16, respectively (Table 20–4). If a target value for spKt/V is chosen as 1.32, for example, then only some of the patients would receive an eKt/V of 1.16 or greater, depending on treatment time. On the contrary, if instead a target spKt/V of 1.4 is chosen, then virtually all patients treated for greater than 2.5 hours would achieve an eKt/V of 1.16 or greater. Thus, an alternative strategy for achieving at least an eKt/V of 1.16 is to deliver a spKt/V of 1.4, unless treatment time is less than 2.5 hours. Since 2.5 hours was the minimum allowed during the HEMO Study, this would seem to also be an acceptable approach for achieving a minimum delivered dose of small solute removal. Indeed, this dose target for small solute removal is equivalent to that recommended by the European Best Practice Guidelines for Hemodialysis.[148] Similar considerations suggest that a spKt/V of 1.8 could be used to deliver a dose of small solute removal equivalent to that in the high dose group of the HEMO Study (Table 20–9).

Considering recent evidence discussed earlier regarding the effect of body size, gender, and membrane flux on patient outcome, one can also argue that patients of low body weight (or body mass index) and females should be treated with a dose of small solute removal higher than that delivered to the standard dose group of the HEMO Study. Since the evidence for these effects are only suggestive from a statistical perspective, it can be argued that the data do not support such a recommendation. To err on the conservative side, however, that is, to do no harm to the patient, delivering a higher dose to such

Table 20–6 Effects of Seven Prespecified Baseline Factors on the Response to High Dose (All-Cause Mortality)

1.80	4.0	1.58
1.80	4.5	1.60

patients would appear prudent. Similar reasoning holds when considering whether to employ high-flux hemodialysis. The data in this case are stronger and appear to support the use of high-flux hemodialysis therapy, especially for patients who have been treated for some time on hemodialysis. Others have even suggested that these data support the use of even higher-flux membranes or the use of adsorption devices to remove other middle molecules. These suggestions require further study.

The HEMO Study has expanded the definition of hemodialysis adequacy as described by the K/DOQI Guidelines to include the consideration of the dose of middle molecule removal. As other treatment schedules for hemodialysis, such as short daily and nocturnal, are increasingly being considered, one must question whether treatment adequacy can be defined only by considering the dose of small solute and middle molecule removal. The previous discussion regarding the EUTox categorizations of uremic toxins suggests that consideration of protein-bound uremic toxins may also be necessary in such definitions. Indeed, recent work suggests that clearances of protein-bound solutes are greater during daily hemodialysis than during thrice-weekly hemodialysis.[149] Alternatively, the use of other dose parameters, such as the standard urea Kt/V parameter defined by Gotch[150] and its relationship to protein-bound uremic toxin removal, are of high interest. The definition of treatment adequacy for dialysis patients remains the most significant challenge to the dialysis community, as long as dialysis remains far less efficient than the native kidneys.

Nosocomial Infections in Hemodialysis Units

Jerome Tokars, M.D., M.P.H. • Miriam J. Alter, Ph.D. • Matthew J. Arduino, M.S., Dr.P.H. • Martin S. Favero, Ph.D.

Of the patients with end-stage renal disease (ESRD) treated by maintenance hemodialysis in the United States, 91% are on hemodialysis.[1] Chronic hemodialysis patients are at high risk for infection because the process of hemodialysis requires vascular access for prolonged periods. In an environment where multiple patients receive dialysis concurrently, repeated opportunities exist for person-to-person transmission of infectious agents, directly or indirectly via contaminated devices, equipment and supplies, environmental surfaces, or hands of personnel. Furthermore, hemodialysis patients are immunosuppressed, which increases their susceptibility to infection, and they require frequent hospitalizations and surgery, which increases their opportunities for exposure to nosocomial infections. This chapter describes (1) the major infectious diseases that can be acquired in the dialysis center setting, (2) the important epidemiologic and environmental microbiologic considerations, and (3) infection control strategies.

CONTAMINANTS IN HEMODIALYSIS SYSTEMS

Gram-negative water bacteria are commonly found in water supplies used for hemodialysis. Under certain circumstances, these microorganisms can persist and multiply in aqueous environments associated with hemodialysis equipment. These bacteria can adhere to surfaces and form biofilms (glycocalyces), which are virtually impossible to eradicate.[2–4] Control strategies are designed to not eradicate bacteria but to reduce their concentration to relatively low levels and to prevent their regrowth.

Although certain genera of gram-negative water bacteria (e.g., *Achromobacter, Acinetobacter, Alcaligenes, Aeromonas, Burkholderia, Flavobacterium, Pseudomonas, Ralstonia, Serratia,* and *Xanthomonas*) are most commonly encountered, virtually any bacterium that can grow in water can be a problem in a hemodialysis unit. Several species of nontuberculous mycobacteria may also contaminate water treatment systems, including *Mycobacterium chelonae, M. abscessus, M. fortuitum, M. gordonae, M. mucogenicum* (formerly *MCLO*), *M. scrofulaceum, M. kansaii, M. avium,* and *M. intracellulare*; these microorganisms do not contain bacterial endotoxin but are comparatively resistant to chemical germicides.[5–7]

Gram-negative water bacteria can multiply even in water containing relatively small amounts of organic matter, such as water treated by distillation, softening, deionization, or reverse osmosis, reaching levels of 10^5 to 10^7 microorganisms/mL[8]; these levels are not associated with visible turbidity. When treated water is mixed with dialysis concentrate, the resulting dialysis fluid is a balanced salt solution and growth medium almost as rich in nutrients as conventional nutrient broth.[8,9] Gram-negative water bacteria growing in dialysis fluids can reach levels of 10^8 to 10^9 microorganisms/mL, which produce visible turbidity.

Bacterial growth in water used for hemodialysis depends on the types of water treatment system used, dialysate distribution systems, dialysis machine type, and method of disinfection[5,6,10] (Table 21–1). Each component is discussed separately.

Water Supply

Municipal water may be derived from either surface or ground waters, both of which may be contaminated with bacteria and endotoxin (Table 21–1). Endotoxin is particularly likely to be present in surface waters, is not substantially removed by conventional municipal water treatment processes, and may cause pyrogenic reactions.[11] Disinfectants such as chlorine and combined chlorine (monochloramine) reduce the numbers of but do not eliminate bacteria in municipal water.

Water Treatment Systems

Water used for the production of dialysis fluid must be treated to remove chemical and microbial contaminants. The Association for the Advancement of Medical Instrumentation (AAMI) has published guidelines for the chemical and bacteriologic quality of water used to prepare dialysis fluid (Table 21–2)[12] Some components of the water treatment system may allow amplification of water bacteria. For example, ion exchangers such as water softeners and deionizers do not remove endotoxins or bacteria and provide sites for significant bacterial multiplication.[13] Granular activated carbon adsorption media (i.e., carbon filters) are used to remove certain organic chemicals and available chlorine from water, but they also significantly increase the level of water bacteria and do not remove bacterial endotoxins.

A variety of filters are marketed to control bacterial contamination in water and dialysis fluids. Most are inadequate, especially if they are not routinely disinfected or changed frequently. Particulate filters, commonly called prefilters, operate by depth filtration and do not remove bacteria or bacterial endotoxins. These filters can become colonized with gram-negative water bacteria, resulting in higher levels of bacteria and endotoxin in the filter effluent. Absolute filters, including the membrane types, temporarily remove bacteria from passing water. However, some of these filters tend to clog, and gram-negative water bacteria can "grow through" the filter

Table 21–1 Factors Influencing Microbial Contamination in Hemodialysis Systems

Factors	Comments
Water supply	
Source of community water	
Groundwater	Contains endotoxin and bacteria
Surface water	Contains high levels of endotoxin and bacteria
Water treatment at dialysis center	
None	Not recommended
Filtration	
Prefilter	Particulate filter to protect equipment; does not remove microorganisms
Absolute filter (depth or membrane)	Removes bacteria but, unless changed frequently or disinfected, bacteria will accumulate and grow through filter; acts as significant reservoir of bacteria and endotoxin
Activated carbon filter	Removes organics and available chlorine or chloramine; significant reservoir of water bacteria and endotoxin
Water treatment devices	
Ion-exchange softener, deionization	Softeners and deionizers are significant reservoirs of bacteria and neither remove endotoxin
Reverse osmosis	Removes bacteria and endotoxin, but must be disinfected; operates at high water pressure
Ultraviolet light	Kills some bacteria, but there is no residual, and ultraviolet-resistant bacteria can develop
Ultrafilter	Removes bacteria and endotoxin; operates on normal line pressure; can be positioned distal to deionizer; must be disinfected
Water and dialysate distribution system	
Distribution pipes	
Size	Oversized diameter and length decrease fluid flow and increase bacteria reservoir for both treated water and centrally prepared dialysate
Construction	Rough joints, dead ends, and unused branches can act as bacterial reservoirs
Elevation	Outlet taps should be located at highest elevation to prevent loss of disinfectant
Storage tanks	Undesirable because they act as reservoir of water bacteria; if present, must be routinely scrubbed and disinfected
Dialysis machines	
Single-pass	Disinfectant should have contact with all parts of machine that are exposed to water or dialysis fluid
Recirculating single-pass, or recirculating (batch)	Recirculating pumps and machine design allow for massive contamination levels if not properly disinfected. Overnight chemical germicide treatment recommended.

Table 21–2 Association for the Advancement of Medical Instrumentation (AAMI) Microbiologic and Endotoxin Standards for Dialysis Fluids

Type of Hemodialysis Fluid	Maximum Contaminant Level Total Heterotrophs (CFU/mL)	Maximum Contaminant Level Endotoxin (EU/mL)
Water used to prepare dialysate, rinse dialyzers, or prepare dialyzer disinfectant	200	2
Conventional dialysate	2000/200*	No standard/2[†]
Ultrapure dialysate	0.1	0.03
Dialysate for infusion	ND[‡]	0.03

*2000 is the current standard; 200 is the proposed standard.
[†]There is no current standard for endotoxin; 2 is the proposed standard.
[‡]Not detectable by routine methods—limit is 1 CFU/1000 L.

matrix and colonize the downstream surface of the filters within a few days. Further, absolute filters do not reduce levels of endotoxin in the effluent water. These types of filters should be changed regularly in accordance with the manufacturer's directions and disinfected in the same manner and at the same time as the dialysis system.

Ultraviolet irradiation is sometimes used to reduce bacterial contamination in water, but this approach is not recommended.[8] Certain populations of gram-negative water bacteria are far more resistant to and may survive ultraviolet radiation. In recirculating dialysis systems, repeated exposures to ultraviolet radiation are used to ensure adequate disinfection; however, this approach allows progressive removal of sensitive microorganisms and multiplication of ultraviolet-resistant microorganisms. In addition, bacterial endotoxins are not affected.

Reverse osmosis is an effective water treatment modality that is used in 97% of U.S. hemodialysis units.[14] Reverse osmosis possesses the singular advantage of being able to remove both bacterial endotoxins and bacteria from supply water. However, low numbers of gram-negative and nontuberculous mycobacteria water bacteria can either penetrate this barrier or, by other means, colonize the downstream portion of the reverse osmosis unit. Consequently, reverse osmosis systems must be disinfected routinely.

We recommend a water treatment system that produces chemically adequate water while avoiding high levels of microbial contamination. The components in the following sequence are well suited for treatment of hard water[15]: (1) a set of prefilters, (2) a softener, (3) carbon adsorption tanks (at least two in series are recommended), (4) a particulate filter, (5) a reverse osmosis unit, (6) a deionization unit, and (7) an ultrafilter. As the water passes through these components, it becomes progressively more pure chemically, but the level of bacterial contamination increases. Therefore, an ultrafilter is included as the final component to remove bacteria and bacterial endotoxin. The ultrafilter contains membranes similar to those in a reverse osmosis unit but is operated at ordinary waterline pressure. Additional source water treatment devices may be added to this system, depending on the chemical quality of the municipal water. If this system is adequately disinfected, the microbial content of water should be well within the recommended guidelines.

Distribution Systems

Water that has passed through the water treatment system (product water) may be distributed to individual dialysis machines where it is combined with dialysate concentrate. Alternately, it may be combined with concentrate in a central location and the resulting dialysis fluid supplied to individual machines. Plastic pipes (usually polyvinyl chloride) are used to distribute water or dialysis fluid to dialysis machines. The use of pipes with a diameter larger than necessary slows the fluid velocity and increases the wetted surface area available for microbial colonization. Increased surface area also results from using pipes that are longer than needed. Gram-negative bacteria in fluids remaining in pipes overnight can multiply rapidly and colonize the wetted surfaces of the pipes, producing bacterial populations and endotoxin in quantities proportional to the volume and surface area. Such colonization results in the formation of a protective biofilm,

which is difficult to remove and protects the bacteria from disinfection.[16]

Routine disinfection of the water or dialysate distribution system should be performed at least weekly.[17] However, the AAMI Standards and recommendations, which are consensus documents, do not specify a schedule for disinfection other than suggest that routine disinfection should be conducted. In many instances, microbiologic monitoring can be used to determine frequency of disinfection of the water distribution system.[18,19]

To prevent disinfectant from draining from pipes by gravity before contact time is adequate, distribution systems should be designed with all outlet taps at equal elevation and at the highest point of the system. Furthermore, the system should be free of rough joints, dead-end pipes, and unused branches and taps. Fluid trapped in such stagnant areas can serve as a reservoir for bacteria that are later inoculated into the distribution system.[20]

Storage tanks greatly increase the volume of fluid and surface area of the distribution system. If used, they should be drained frequently, cleaned (including scrubbing of the sides of the tank to remove bacterial biofilm), and disinfected. Also, an ultrafilter distal to the storage tank is recommended.

Hemodialysis Machines

In the 1970s, most dialysis machines were of the recirculating or recirculating single-pass type; their design contributed to relatively high levels of gram-negative bacterial contamination in dialysis fluid. Currently, virtually all centers in the United States use single-pass hemodialysis machines. Single-pass machines tend to respond to adequate cleaning and disinfection procedures and, in general, have lower levels of bacterial contamination in their dialysis fluid than do recirculating machines. Levels of contamination in single-pass machines depend primarily on the bacteriologic quality of the incoming water and on the method of machine disinfection.[8,21]

A frequent error in disinfecting single-pass systems is introduction of the disinfectant in the same manner and through the same port as the dialysate concentrate. By so doing, the pipes and tubing carrying incoming water or dialysate are not disinfected and may act as a reservoir for bacteria. To ensure adequate disinfection of a single-pass machine, the disinfectant must reach all parts of the system's fluid pathways.

Disinfection of Hemodialysis Systems

Routine disinfection of isolated components of a dialysis system frequently produces inadequate results. Consequently, the total dialysis system (water treatment system, distribution system, and dialysis machine) should be included in the disinfection procedure.

Chlorine-based disinfectants, such as sodium hypochlorite solutions, are convenient and effective in most parts of the dialysis system when used at the manufacturer's recommended concentration. Also, the test for residual available chlorine to confirm adequate rinsing is simple and sensitive. However, because chlorine is corrosive, it is usually rinsed from the system after a short (20–30 min) exposure time. The rinse water invariably contains gram-negative water bacteria that can multiply to significant levels, if the system is permitted to stand

overnight. Therefore, chlorine disinfectants are best used just before the start-up of the dialysis system rather than at the end of the day. In centers dialyzing patients in multiple shifts, it may be reasonable to disinfect with sodium hypochlorite between shifts (this may not be necessary with some single-pass machines, if the levels of bacterial contamination are within AAMI limits) and with another disinfectant (formaldehyde, peroxyacetic acid, or glutaraldehyde) at the end of the day.

Aqueous formaldehyde, peroxyacetic acid, or glutaraldehyde solutions produce good disinfection results.[22,23] These products are not as corrosive as hypochlorite solutions and can be allowed to remain in the dialysis system for long periods when the system is not operational, thereby preventing regrowth of bacteria. Formaldehyde has good penetrating characteristics but is considered an environmental hazard and potential carcinogen and has irritating qualities that may be objectionable to staff members.[24] The U.S. Environmental Protection Agency (EPA) has reduced the allowable amount of formaldehyde that can be discharged into the wastewater stream, which has reduced the use of this disinfectant in the dialysis community. Commercial tests (e.g., Formalert, Organon Teknika, Durham, NC) are available and can detect residual formaldehyde in water at concentrations as low as 1 part per million. Peroxyacetic acid and glutaraldehyde are commercially available and are designed for use with dialysis machines; both are good germicides when used according to the manufacturer's recommendations.

Some dialysis systems use hot-water disinfection for the control of microbial contamination. In this type of system, water heated to greater than 80°C (176°F) is passed through all proportioning, distribution, and patient-monitoring devices at the end of the day. These systems are excellent for controlling bacterial contamination.

Monitoring of Water and Dialysis Fluid

Microbiologic and endotoxin standards for water and dialysis fluids (Table 21–2)[3,12,25–27] were originally based on the results of culture assays performed during epidemiologic investigations and should be used as broad guidelines rather than absolute standards. These standards are in the process of being revised based on new data on the effects of the microbial quality of hemodialysis fluids on chronic inflammatory response syndrome and anemia management in dialysis patients.[28–32]

Water samples should be collected from a source as close as possible to where water enters the dialysate concentrate-proportioning unit. Water samples should be collected at least monthly and repeated when bacteriologic counts exceed 200 colony forming units per milliliter (CFU/mL) and/or endotoxin activity exceeds 2 EU/mL (Table 21–2) or when changes have been made in the disinfection procedure, the water treatment system, or the water distribution system. Dialysis fluid samples should be collected during or at the termination of dialysis from a source close to where the dialysis fluid either enters or leaves the dialyzer. Dialysis fluid samples should also be collected at least once monthly and repeated when the recommended levels for microbial or endotoxin contamination are exceeded (Table 21–2), when pyrogenic reactions are suspected, or when changes are made in the water treatment system or disinfection protocol. If centers reprocess dialyzers for reuse on the same patient, water used to rinse dialyzers and

prepare dialyzer disinfectants should also be assayed at least monthly.

Specimens should be assayed within 30 minutes or refrigerated at 4°C and assayed within 24 hours of collection. Conventional laboratory procedures such as the pour plate, spread plate, or membrane filter technique can be used. Calibrated loops should not be used because they sample a small volume and are inaccurate. Although standard methods agar, blood agar, and trypticase soy agar were once considered equivalent, it has since been shown that a portion of the gram-negative bacterial flora of bicarbonate dialysis fluid and water have special growth requirements. Microorganisms found in bicarbonate dialysis fluid require a small amount of sodium chloride, and those found in processed water may require a nutrient poor medium. Consequently, to cover both conditions needed, trypticase soy agar is the currently recommended medium; however, one may also use standard plate count, standard methods, or soybean-casein digest agars along with commercially available samplers. Blood agar should not be used for this purpose. The assay should be quantitative, not qualitative, and a standard technique for enumeration should be used. Colonies should be counted with the aide of a magnifying device after 48 hours of incubation at 35° to 37°C.[3,12,25–27,33] Total viable counts (standard plate counts) are the objective of the assays.

In an outbreak investigation, the assay may need to be both qualitative and quantitative; also, detection of nontuberculous mycobacteria in water may be desirable. In such instances, plates should be incubated for 5 to 14 days.

DIALYSIS-ASSOCIATED PYROGENIC REACTIONS

Gram-negative bacterial contamination of dialysis water or components can cause pyrogenic reactions. Pyrogenic reactions are defined as objective chills (visible rigors) or fever (oral temperature 37.8°C [100°F] or higher) or both in a patient who was afebrile (oral temperature up to 37.0°C [98.6°F]) and had no signs or symptoms of infection before the dialysis treatment.[24] Depending on the type of dialysis system and level of contamination, fever and chills may start 1 to 5 hours after dialysis is initiated. Other symptoms may include hypotension, headache, myalgia, nausea, and vomiting. Pyrogenic reactions can occur with or without bacteremia; because presenting signs and symptoms may not be different in these two instances, blood cultures are necessary.

During the 1990s, an annual average of 20% of the hemodialysis centers in the United States reported at least one pyrogenic reaction in the absence of septicemia in patients undergoing dialysis.[14] Pyrogenic reactions without bacteremia can result from either the passage of bacterial endotoxin (lipopolysaccharide) in the dialysis fluid across the dialyzer membrane[34,35] or the transmembrane stimulation of cytokine production in the patient's blood by endotoxins in the dialysis fluid.[36,37] In other instances, endotoxins can enter the bloodstream directly with fluids that are contaminated with gram-negative bacteria.[38,39] The signs and symptoms of pyrogenic reactions without bacteremia generally abate within a few hours after dialysis has been stopped. If gram-negative bacterial sepsis is associated, fever and chills may persist, and hypotension is more refractory to therapy.[11,38]

When a pyrogenic reaction occurs, the following steps are recommended: (1) a careful physical examination to rule out other causes of chills and fever (e.g., pneumonia, vascular access infection, urinary tract infection); (2) blood cultures, other diagnostic tests (e.g., chest radiograph), and cultures as clinically indicated; (3) collection of dialysis fluid from the dialyzer (downstream side) for quantitative and qualitative bacteriologic assays; and (4) recording of the incident in a log or other permanent record. Determining the cause of these episodes is important because they may be the first indication of a remediable problem.

The higher the level of bacteria and endotoxin in dialysis fluid, the higher the probability that they will pass through the dialysis membrane or stimulate cytokine production. In an outbreak of febrile reactions among patients undergoing dialysis, the attack rates were directly proportional to the level of bacterial contamination in the dialysis fluid.[8] Prospective studies also demonstrated a lower pyrogenic reaction rate among patients when they underwent dialysis with dialysis fluid that had been filtered and from which most bacteria had been removed, compared with patients who underwent dialysis with dialysis fluid that was highly contaminated (mean 19,000 CFU/mL).[40–42]

Among seven outbreaks of bacteremia and pyrogenic reactions not related to dialyzer reuse investigated by the Centers of Disease Control (CDC), inadequate disinfection of the water distribution or storage system was implicated in three (Table 21–3). The most recent outbreaks occurred at centers using dialysis machines having a port to dispose of dialyzer priming fluid (waste handling option).[43,44] One-way valves in the waste handling option had not been maintained, checked for competency, or disinfected as recommended, allowing backflow from the drain and contamination of the port.

Hemodialyzer Reuse

Since 1976, the percentage of chronic dialysis centers in the United States that reported reuse of disposable hollow-fiber dialyzers has increased steadily[44]; the largest increase (126%) occurred during 1976 to 1982, from 18% to 43%, and the highest percentage (82%) was reported in 1997. In 2001, reuse of dialyzers was reported by 76% of centers (CDC, unpublished data).

In 1986, the AAMI's guidelines for reusing hemodialyzers[45] were adopted by the U.S. Public Health Service (USPHS) and later became the Centers for Medicare and Medicaid Services (CMS) regulations. In general, dialyzer reuse appears to be safe if performed according to strict and established protocols. Dialyzer reuse has not been associated with transmission of hepatitis B virus (HBV) or hepatitis C virus (HCV) infection but has been associated with pyrogenic reactions[46] (Table 21–3). These adverse events may be the result of the use of incorrect concentrations of chemical germicides or the failure to maintain standards for water quality. Manual reprocessing of dialyzers that does not include a test for membrane integrity, such as the air-pressure leak test, may fail to detect membrane defects and may be a cause of pyrogenic reactions.[46]

Some procedures used to reprocess hemodialyzers generally constitute high-level disinfection rather than sterilization.[3,47] There are several liquid germicides commonly used for high-level disinfection of dialyzers. Formaldehyde is a chemical solution obtained from chemical supply houses and is not formulated specifically for dialyzer disinfection. There are chemical germicides specifically formulated for this purpose (e.g., peracetic acid and glutaraldehyde-based products) that are approved by the U.S. Food and Drug Administration (FDA) as sterilants for reprocessing hemodialyzers. In 2001, a peracetic acid formulation was used by 62% of centers that reused dialyzers, formaldehyde by 29%, and glutaraldehyde by 5%; 4% of centers used a heat process (CDC, unpublished data).

In 1983, most centers in the United States used 2% aqueous formaldehyde with a contact time of approximately 36 hours for high-level disinfection of disposable dialyzers.[48] In 1982, a center using this regimen experienced an outbreak of infections caused by nontuberculous mycobacteria.[5] It subsequently was shown that the 2% formaldehyde regimen was not effective against nontuberculous mycobacteria. Rather, a regimen of 4% formaldehyde with a minimum contact time of 24 hours is required to inactivate high numbers of these microorganisms and is recommended as a minimum solution for disinfection of dialyzers.[3,46,47] A similar outbreak of systemic mycobacterial infections in five dialysis patients, resulting in two deaths, occurred when high-flux dialyzers were contaminated with mycobacteria during manual reprocessing and were then disinfected with a commercial dialyzer disinfectant prepared at a concentration that did not ensure complete inactivation of mycobacteria.[7] These two outbreaks of infection in dialysis patients emphasize the need to use dialyzer disinfectants at concentrations that are effective against the more chemically resistant microorganisms, such as mycobacteria.

Outbreaks of pyrogenic reactions have often resulted from reprocessing dialyzers with water that did not meet AAMI standards (Table 21–3). In most instances, the water used to rinse dialyzers or to prepare dialyzer disinfectants exceeded allowable AAMI microbial or endotoxin standards because the water distribution system was not disinfected frequently, the disinfectant was improperly prepared, or routine microbiologic assays were improperly performed.

High-Flux Dialysis and Bicarbonate Dialysate

High-flux dialysis uses dialyzer membranes with hydraulic permeabilities 5 to 10 times greater than those of conventional dialyzer membranes. There is concern that bacteria or endotoxin in the dialysate may penetrate these highly permeable high-flux dialyzer membranes.

Another concern is that high-flux dialysis requires the use of bicarbonate rather than acetate dialysate. Acetate dialysate is prepared from a single concentrate with a high salt molarity (4.8 M) that cannot support the growth of most bacteria. Bicarbonate dialysate, however, must be prepared from two concentrates, an acid concentrate with a pH of 2.8 that is not conducive to bacterial growth and a bicarbonate concentrate with a relatively neutral pH and a salt molarity of 1.2 M. Because the bicarbonate concentration will support rapid bacterial growth,[49] its use can increase bacterial and endotoxin concentrations in the dialysate and theoretically may contribute to an increase in pyrogenic reactions, especially when it is used during high-flux dialysis.

Some of this concern appeared justified by the results of surveillance data during the 1990s that showed a significant

Table 21–3 Outbreaks of Dialysis-Associated Illnesses Investigated by the Centers for Disease Control and Prevention

Description (Reference)	Cause(s) of Outbreak	Corrective Measure(s) Recommended
Bacteremia, Fungemia, or Pyrogenic Reactions Not Related to Dialyzer Reuse		
Pyrogenic reactions in 49 patients[11]	Untreated city water contained high levels of endotoxin	Install reverse osmosis system
Pyrogenic reactions in 45 patients[20]	Inadequate disinfection of fluid distribution system	Increase disinfection frequency and germicide contact time
Pyrogenic reactions in 14 patients; 2 bacteremias; 1 death[4]	Reverse osmosis water storage tank contaminated with bacteria	Remove or properly disinfect and maintain storage tank
Pyrogenic reactions in 6 patients; 7 bacteremias[149]	Inadequate disinfection of water distribution system and dialysis machines; improper microbial assay procedure	Use correct microbial assay procedure; disinfect water distribution system and dialysis machines according to manufacturer's recommendations
Bacteremia in 35 patients with central vein catheters[150]	Central vein catheters used as primary access; median duration of infected catheters was 311 days; improper aseptic techniques	Use central vein catheters only when necessary; use appropriate aseptic techniques when inserting and performing catheter care
3 pyrogenic reactions and 10 bacteremias in patients treated on machines with a port for disposal of dialyzer priming fluid (waste handling option or WHO)[151]	Incompetent valve allowing backflow from drain to the WHO; bacterial contamination of the WHO	Routine maintenance, disinfection, and check for valve competency of the WHO
Bacteremia in 10 patients treated on machines with a port for disposal of dialyzer prime[152]	Incompetent valve allowing backflow from drain to the WHO; bacterial contamination of the WHO	Routine maintenance, disinfection, and check for valve competency of the WHO
Outbreak of pyrogenic reactions and gram-negative bacteremia in 11 patients (4 with bacteremia)[17]	Water distribution system and machines were not routinely disinfected or according to manufacturer's instructions. Water and dialysate samples were cultured using calibrated loop and blood agar plates—results were always recorded as no growth	Disinfect machines according to manufacturer's instructions; include water distribution system in the weekly disinfection of the RO system.
Phialemonium curvatum access infections in 4 hemodialysis patients; 2 of these patients died of systemic disease. (CDC, unpublished data)	Observations at the facility noted some irregularities in site prep for needle insertion. All affected patients have synthetic grafts. One environmental culture was positive for *P. curvatum* (condensate pan of HVAC serving the dialysis facility)	Review infection control practices; clean and disinfect HVAC system where water accumulates. Perform surveillance on all patients.
Bacteremia/Pyrogenic Reactions Related to Dialyzer Reuse		
Mycobacterial infections in 27 patients[5]	Inadequate concentration of dialyzer disinfectant	Increase formaldehyde dialyzer disinfectant concentration to 4%
Mycobacterial infection in 5 high-flux dialysis patients; 2 deaths[7]	Inadequate concentration of dialyzer disinfectant	Use higher disinfectant concentration and more frequent disinfection of water treatment system
Bacteremia and pyrogenic reactions in 6 patients[153]	Dialyzer disinfectant diluted to improper concentration	Use disinfectant at recommended dilution and verify concentration
Bacteremia in 6 patients (CDC unpublished data)	Inadequate concentration of dialyzer disinfectant; water used for reuse did not meet AAMI standards	Use AAMI quality of water; ensure proper germicide concentration in dialyzer
Bacteremia and pyrogenic reactions in 6 patients[154]	Inadequate mixing of dialyzer disinfectant	Thoroughly mix disinfectant and verify proper concentration
Bacteremia in 33 patients at two dialysis centers[39,155]	Dialyzer disinfectant created holes in dialyzer membrane	Change disinfectant (removed from marketplace by manufacturer)

Description (Reference)	Cause(s) of Outbreak	Corrective Measure(s) Recommended
Bacteremia/Pyrogenic Reactions Related to Dialyzer Reuse—cont'd		
Bacteremia in 6 patients; all blood isolates had similar plasmid profiles[156]	Dialyzers contaminated during removal and cleaning of headers with gauze; staff not routinely changing gloves; dialyzers not processed for several hours after disassembly and cleaning	Do not use gauze or similar material to remove clots from header; change gloves frequently; process dialyzers immediately after rinsing and cleaning
Pyrogenic reactions in 3 high-flux dialysis patients[157]	Dialyzer reprocessed with two disinfectants; water used for reuse did not meet AAMI standards	Do not disinfect dialyzers with multiple germicides; more frequent disinfection of water system
Pyrogenic reactions in 14 high-flux dialysis patients; 1 death[158]	Dialyzers rinsed with city water; water for reuse did not meet AAMI standards	Do not rinse or clean dialyzers with city water; disinfect water treatment system more frequently
Pyrogenic reactions in 18 patients[51]	Dialyzers rinsed with city water containing high levels of endotoxin; water used for reuse did not meet AAMI standards	Do not rinse or clean dialyzers with city water; disinfect water treatment system more frequently
Pyrogenic reactions in 22 patients[159]	Water for reuse did not meet AAMI standards; improper microbial assay technique	Use correct microbial assay procedure; disinfect water distribution system
Transmission of Viral Agents		
26 patients seroconverted to HBsAg positive during a 10-month period[160]	Leakage of coil dialyzer membranes and use of recirculating bath dialysis machines	Separation of HBsAg-positive patients and equipment from other patients
19 patients and 1 staff seroconverted to HBsAg positive during a 14-month period[96]	No specific cause determined; false-positive HBsAg results caused some susceptible patients to be dialyzed with infected patients	Laboratory confirmation of HBsAg-positive results; strict adherence to glove use and use of separate equipment
24 patients and 6 staff seroconverted to HBsAg positive during a 10-month period[91]	Staff not wearing gloves; surfaces not properly disinfected; improper handling of needles/sharps resulting in many staff needlesticks	Separation of HBsAg-positive patients and equipment from other patients; proper precautions by staff (e.g., gloves; handling of needles/sharps)
13 patients and 1 staff seroconverted to HBsAg positive during a 1-month period[95]	Extrinsic contamination of intravenous medication being prepared adjacent to area where blood work was handled	Separate medication preparation area and blood processing for diagnostic tests
10 patients seroconverted to HBsAg positive in 1 month[161]	Extrinsic contamination of multidose medication vial shared by HBsAg-positive and HBsAg-susceptible patients	No sharing of supplies, equipment, and medications between patients
8 patients seroconverted to HBsAg positive during a 5-month period (CDC, unpublished data)	Sporadic screening for HBsAg; HBsAg carriers not separated; major bleeding incident with environmental contamination	Monthly screening of patients for HBsAg; separation of positive patients with dedicated equipment and staff; vaccination of all susceptibles
7 patients seroconverted to HBsAg positive during a 3-month period[92]	Same staff caring for HBsAg-positive and HBsAg-negative patients	Separation of HBsAg-positive patients from other patients; same staff should not care for HBsAg-positive and HBsAg-negative patients on same shift
8 patients seroconverted to HBsAg-positive during 1 month[148]	Not consistently using pressure transducer filters; same members staff cared for HBsAg-positive and -negative patients on same shift	Use pressure transducer filters and replace after each use; same staff members should not care for HBsAg-positive and HBsAg-negative patients on same shift

Table 21–3 Outbreaks of Dialysis-Associated Illnesses Investigated by the Centers for Disease Control and Prevention—cont'd

Description (Reference)	Cause(s) of Outbreak	Corrective Measure(s) Recommended
Transmission of Viral Agents		
14 patients seroconverted to HBsAg positive during a 6-week period[93]	Failure to review results of admission and monthly HBsAg testing; inconsistent handwashing and use of gloves; adjacent clean and contaminated areas; <20% of patients vaccinated	Proper infection control precautions for dialysis units; routine review of serologic testing; hepatitis B vaccination of all patients
7 patients seroconverted to HBsAg positive during a 2-month period[93]	Same staff members cared for HBsAg-positive and HBsAg-negative patients on same shift; common medication and supply carts were moved between stations, and multidose vials were shared. No patients were vaccinated.	Dedicated staff for HBsAg-positive patients; no sharing of medication or supplies between any patients; centralized medication and supply areas; hepatitis B vaccination of all patients
4 patients seroconverted to HbsAg positive during a 3-month period[93]	Transmission appeared to occur during hospitalization at an acute care facility	Hepatitis B vaccination of all patients
11 patients seroconverted to HbsAg positive during a 3-month period[93]	Staff, equipment, and supplies were shared between HBsAg-positive and HBsAg-negative patients. No patients were vaccinated.	Dedicated staff for HbsAg-positive patients; no sharing of medication or supplies between any patients; hepatitis B vaccination of all patients.
2 patients seroconverted to HbsAg positive during a 4-month period[101]	Same staff members cared for HBsAg-positive and HBsAg-negative patients; no patients were vaccinated.	Dedicated staff for HbsAg-positive patients; hepatitis B vaccination of all patients.
36 patients with liver enzyme elevations consistent with non-A, non-B hepatitis[162]	Environmental contamination with blood	Monthly liver enzyme screening; proper precautions (i.e., use of gloves) by staff
35 patients with liver enzyme elevations consistent with non-A, non-B hepatitis during a 22-month period; 82% of probable cases were anti-HCV positive[163]	Inconsistent use of infection control precautions, especially handwashing and glove use	Strict compliance to aseptic technique and dialysis center precautions
HCV infection developed in 7/41 (17.1%) patients; shift specific attack rates of 29%–36%[164]	Multidose vials left on top of machine and used by multiple patients; routine cleaning and disinfection of surfaces and equipment between patients not routinely done; arterial line for draining prime waste draped into bucket that was not routinely cleaned between patients	Strict compliance with infection control precautions recommended for all dialysis patients; routine HCV testing
HCV infection developed in 5/75 (6.6%) patients[165]	Sharing of equipment and supplies between chronically infected and susceptible patients; gloves not routinely used; clean and contaminated areas not separated	Strict compliance with infection control precautions recommended for all dialysis patients
HCV infection developed in 3/23 (13%) patients[166]	Supply carts moved between stations and contained both clean supplies and blood-contaminated items. Medications prepared in same area used for disposal of used injection equipment	Strict compliance with infection control precautions recommended for all dialysis patients

association between use of high-flux dialysis and reporting of pyrogenic reactions among patients during dialysis.[50] However, a prospective study of pyrogenic reactions in patients receiving more than 27,000 conventional, high-efficiency, or high-flux dialysis treatments with a bicarbonate dialysate containing high concentrations of bacteria and endotoxin found no association between pyrogenic reactions and the type of dialysis treatment.[51] Although there seem to be conflicting data on the relationship between high-flux dialysis and pyrogenic reactions, centers providing high-flux dialysis should ensure that dialysate meets AAMI microbial standards (Table 21–2).

OTHER BACTERIAL INFECTIONS

The annual mortality rate among hemodialysis patients is 23%, and infections are the second most common cause, accounting for 14% of deaths.[1] Septicemia (11% of all deaths) is the most common infectious cause of mortality. In studies published during 1997 to 2000 that evaluated rates of bacterial infections in hemodialysis outpatients, bacteremia occurred in 0.6% to 1.7% of patients per month and vascular access infections (with or without bacteremia) in 1.3% to 7.2% of patients per month.[52–60] A review of four studies published during 2002 estimated that 1.8% of hemodialysis patients have vascular access associated bacteremia each month, amounting to 50,000 cases nationally per year.[61]

Because of the importance of bacterial infections in hemodialysis patients, the CDC initiated an ongoing surveillance project in 1999.[62] All U.S. hemodialysis centers treating outpatients are eligible to enroll. Only bacterial infections associated with hospital admission or intravenous antimicrobial receipt are counted; since infections treated with outpatient oral antimicrobials are excluded, this system likely detects only the more severe infections. During 1999 to 2001, 109 centers reported data. Rates of infection per 100 patient months were 3.2 for all vascular access infections (including access infections both with and without bacteremia), 1.8 for vascular-access associated bacteremia, 1.3 for wound infections not related to the vascular access, 0.8 for pneumonias, and 0.3 for urinary tract infections. Among patients with fistulas or grafts, wounds were the most common site of infection. Among patients with hemodialysis catheters, infections of the vascular access site were most common.

In a study of 27 French hemodialysis centers, 28% of 230 infections in hemodialysis patients involved the vascular access, whereas 25% involved the lung, 23% the urinary tract, 9% the skin and soft tissues, and 15% other or unknown sites.[58] Thirty-three percent of infections involved either the vascular access site or were bacteremias of unknown origin, many of which might have been caused by occult access infections. Thus, the vascular access site was the most common site for infection but accounted for only one-third of infections.

Bacterial pathogens causing infection can be either exogenous (i.e., acquired from contaminated dialysis fluids or equipment) or endogenous (i.e., caused by invasion of bacteria present in or on the patient). Exogenous pathogens have caused numerous outbreaks, most of which resulted from inadequate dialyzer reprocessing procedures (e.g., contaminated water or inadequate disinfectant) or inadequate treatment of municipal water for use in dialysis. During 1995

to 1997, four outbreaks were traced to contamination of the waste drain port on one type of dialysis machine.[43] Recommendations to prevent such outbreaks are published elsewhere.[63]

Contaminated medication vials are also a potential source of bacterial infection for patients. In 1999, an outbreak of Serratia liquefaciens bloodstream infections and pyrogenic reactions among hemodialysis patients was traced to contamination of vials of erythropoietin. These vials, which were intended for single use, were contaminated by repeated puncture to obtain additional doses and by pooling of residual medication into a common vial.[64]

Vascular Access Infections

Access site infections are particularly important because they can cause disseminated bacteremia or loss of the vascular access. Local signs of vascular access infection include erythema, warmth, induration, swelling, tenderness, breakdown of skin, loculated fluid, or purulent exudates.[53,56,62,65] In the CDC surveillance project, rates of access-associated bacteremia per 100 patient months were 1.8 overall and varied by access type: 0.25 for fistulas, 0.53 for grafts, 4.8 for permanent (tunneled, cuffed) catheters, and 8.7 for temporary (nontunneled, noncuffed) catheters.[62]

Vascular access infections are caused (in descending order of frequency) by Staphylococcus aureus (32%–53% of cases), coagulase-negative staphylococci (CNS; 20%–32%), gram-negative bacilli (10%–18%), nonstaphylococcal gram-positive cocci (including enterococci; 10%–12%), and fungi (< 1%).[62] The proportion of infections caused by S. aureus is higher among patients with fistulas or grafts, and the proportion caused by CNS is higher among patients dialyzed through catheters.

The primary risk factor for access infection is access type, with catheters having the highest risk for infection; grafts intermediate; and native arteriovenous (AV) fistulas the lowest.[55,62,66] Other potential risk factors for vascular access infections include: (1) location of the access in the lower extremity; (2) recent access surgery; (3) trauma, hematoma, dermatitis, or scratching over the access site; (4) poor patient hygiene; (5) poor needle insertion technique; (6) older age; (7) diabetes; (8) immunosuppression; and (9) iron overload.[53,56,67–69]

Based on the relative risk of both infectious and noninfectious complications, it is recommended that native arteriovenous fistulas be used more commonly and hemodialysis catheters less commonly; a goal of no more than 10% of patients maintained with permanent catheter-based hemodialysis treatments is recommended.[53,56,67–70] To minimize infectious complications, patients should be referred early for creation of an implanted access, thereby decreasing the time dialyzed through a temporary catheter. Additionally, permanent catheters should be used only in patients for whom implanted access is impossible. During 1995 to 2001, the percentage of patients dialyzed through fistulas increased from 22% to 30%, with most of the increase occurring since 1999.[44] (CDC, unpublished data). During the same period, use of grafts decreased from 65% to 44% of patients, and use of catheters increased from 13% to 25%; however, the rate of increase in catheter use appears to be slowing.

Recommendations for preventing vascular access infections have been developed by the National Kidney Foundation[70]

and the CDC[71] and recently summarized.[72] Selected recommendations for preventing hemodialysis-catheter associated infection include: (1) not using antimicrobial prophylaxis before insertion or during the use of the catheter; (2) not routinely replacing the catheter; (3) using sterile technique (cap, mask, sterile gown, large sterile drapes, and gloves) during catheter insertion; (4) limiting use of noncuffed catheters to 3 to 4 weeks; (5) using the catheter solely for hemodialysis unless there is no alternative; (6) restricting catheter manipulation and dressing changes to trained personnel; (7) replacing catheter-site dressing at each dialysis treatment or if damp, loose, or soiled; (8) disinfecting skin before catheter insertion and dressing changes (a 2% chlorhexidine-based preparation is preferred); and (9) ensuring that catheter-site care is compatible with the catheter material.

In hemodialysis patients, the Infectious Diseases Society of America has recommended treatment with nasal mupirocin in documented *S. aureus* carriers who have a catheter-related bloodstream infection with *S. aureus* and continue to need the hemodialysis catheter.[73] Otherwise, the routine use of nasal mupirocin in patients with hemodialysis catheters is not recommended by either CDC or the National Kidney Foundation.[70,71]

Antimicrobial Resistant Bacteria

Hemodialysis patients have been in the forefront of the epidemic of antimicrobial resistance, especially vancomycin resistance. One of the earliest reports of vancomycin-resistant enterococci (VRE) was from a renal unit in London, England, in 1988.[74] The prevalence of VRE stool colonization among dialysis patients has varied from 2.4% at three centers in Indianapolis, IN,[75] to 9.5% at a university hospital in Baltimore, MD.[76] In one center with a prevalence of 9%, three patients developed VRE infections in 1 year.[77] Among enterococci causing bloodstream infections in hemodialysis patients, 0% to 5% have been reported to be resistant to vancomycin.[62,78,79]

Vancomycin resistance in staphylococci has also been reported in dialysis patients. Five of the first six U.S. patients identified with vancomycin intermediate-resistant *S. aureus* infections required dialysis.[80] Additionally, the first patient found to be infected with a fully vancomycin resistant *S. aureus* strain was a chronic hemodialysis patient; vancomycin-resistant *S. aureus* was isolated from a foot wound and temporary catheter exit site.[81]

For certain patients, including those infected or colonized with Methicillin-resistant *Staphylococcus aureus* (MRSA) or VRE, contact precautions are used in the inpatient hospital setting. However, contact precautions are not recommended in hemodialysis units for patients infected or colonized with pathogenic bacteria for several reasons. First, although contact transmission of pathogenic bacteria is well-documented in hospitals, similar transmission has not been well-documented in hemodialysis centers. Transmission might not be apparent in dialysis centers, possibly because it occurs less frequently than in acute-care hospitals or results in undetected colonization rather than overt infection. Also, because dialysis patients are frequently hospitalized, determining whether transmission occurred in the inpatient or outpatient setting is difficult. Second, contamination of the patient's skin, bedclothes, and environmental surfaces with pathogenic bacteria is likely to be more common in hospital settings (where patients spend 24 hours a day) than in outpatient hemodialysis centers (where patients spend approximately 10 hours a week). Third, the routine use of infection control practices recommended for hemodialysis units, which are more stringent than the *standard precautions* routinely used in hospitals, should prevent transmission by the contact route.

HEPATITIS B VIRUS

HBV is the microbe that is most efficiently transmitted in the dialysis setting. Recommendations for the control of hepatitis B in hemodialysis centers were first published in 1977[82] and, by 1980, their widespread implementation was associated with a sharp reduction in incidence of HBV infection among both patients and staff members.[83] In 1982, hepatitis B vaccination was recommended for all susceptible patients and staff members.[84] However, outbreaks of both HBV and HCV infections continue to occur among chronic hemodialysis patients. Hepatitis A and E viruses, which are spread by the fecal-oral route and rarely by blood, have not been associated with hemodialysis.

Epidemiology

During the early 1970s, HBV infection was endemic in dialysis units and outbreaks were common. Subsequently, the incidence and prevalence of HBV infection among chronic hemodialysis patients in the United States have dramatically declined, and, by 2001, was 0.05% and 0.9%, respectively.[85] (CDC, unpublished data, 2001) Only 2.9% of all centers reported patients with newly acquired infections, however, 26.5% of centers provided dialysis to one or more chronically infected patients (CDC, unpublished data, 2001).

The chronically infected person is central to the epidemiology of HBV transmission. HBV is transmitted by percutaneous (i.e., puncture through the skin) or permucosal (i.e., direct contact with mucous membranes) exposure to infectious blood or to body fluids that contain blood. All HBsAg positive persons are infectious, but those who are also positive for hepatitis B e antigen (HBeAg) circulate HBV at high titers in their blood (10^{8-9} virions/mL).[86,87] With virus titers this high in blood, body fluids containing serum or blood can also contain high levels of HBV and are potentially infectious. Furthermore, HBV at titers of 10^{2-3} virions/mL can be present on environmental surfaces in the absence of any visible blood and still cause transmission.[86,88,89]

HBV is relatively stable in the environment and remains viable for at least 7 days on environmental surfaces at room temperature.[86,88,89] HBsAg has been detected in dialysis centers on clamps, scissors, dialysis machine control knobs, and doorknobs.[90] Thus, blood-contaminated surfaces that are not routinely cleaned and disinfected represent a reservoir for HBV transmission. Dialysis staff members can transfer virus to patients from contaminated surfaces by their hands or gloves or through use of contaminated equipment and supplies.

Most HBV infection outbreaks among hemodialysis patients (Table 21–3) were caused by cross-contamination to patients via (1) environmental surfaces, supplies (e.g., hemostats, clamps), or equipment that were not routinely disinfected after each use; (2) multiple dose medication vials and

intravenous solutions that were not used exclusively for one patient; (3) medications for injection that were prepared in areas adjacent to areas where blood samples were handled; and (4) staff members who simultaneously cared for both HBV-infected and susceptible patients.[91–96] Once the factors that promote HBV transmission among hemodialysis patients were identified, recommendations for control were published in 1977.[82] These recommendations included: (1) serologic surveillance of patients (and staff members) for HBV infection, including monthly testing of all susceptible patients for HBsAg; (2) isolation of HBsAg-positive patients in a separate room; (3) assignment of staff members to HBsAg-positive patients and not to HBV-susceptible patients during the same shift; (4) assignment of dialysis equipment to HBsAg-positive patients that is not shared by HBV-susceptible patients; (5) assignment of a supply tray to each patient (regardless of serologic status); (6) cleaning and disinfection of nondisposable items (e.g., clamps, scissors) before use on another patient; (7) glove use whenever any patient or hemodialysis equipment is touched and glove changes between each patient (and station); and (8) routine cleaning and disinfection of equipment and environmental surfaces.

The segregation of HBsAg-positive patients and their equipment from HBV-susceptible patients resulted in 70% to 80% reductions in incidence of HBV infection among hemodialysis patients.[97–99] The success of isolation practices in preventing transmission of HBV infection is linked to other infection control practices, including routine serologic surveillance and routine cleaning and disinfection. Frequent serologic testing for HBsAg detects patients recently infected with HBV quickly so isolation procedures can be implemented before cross-contamination can occur. Environmental control by routine cleaning and disinfection procedures reduces the opportunity for cross-contamination, either directly from environmental surfaces or indirectly by hands of personnel.

Despite the current low incidence of HBV infection among hemodialysis patients, outbreaks continue to occur in chronic hemodialysis centers. Investigations of these outbreaks have documented that HBV transmission resulted from failure to use recommended infection control practices, including: (1) failure to routinely screen patients for HBsAg or routinely review results of testing to identify infected patients; (2) assignment of staff members to the simultaneous care of infected and susceptible patients; and (3) sharing of supplies, particularly multiple dose medication vials, among patients.[93] In addition, few patients had received hepatitis B vaccine. National surveillance data have demonstrated that independent risk factors among chronic hemodialysis patients for acquiring HBV infection include the presence of more than one HBV-infected patient in the hemodialysis center who is not isolated, as well as a less than 50% hepatitis B vaccination rate among patients.[100]

HBV infection among chronic hemodialysis patients has also been associated with hemodialysis provided in the acute-care setting.[93,101] Transmission appeared to stem from chronically infected HBV patients who shared staff members, multiple dose medication vials, and other supplies and equipment with susceptible patients. These episodes were recognized when patients returned to their chronic hemodialysis units, and routine HBsAg testing was resumed. Transmission from HBV-infected chronic hemodialysis patients to patients undergoing hemodialysis for acute renal failure has not been documented, possibly because these patients are dialyzed for short durations and have limited exposure. However, such transmission could go unrecognized because acute renal failure patients are unlikely to be tested for HBV infection.

Other risk factors for acquiring HBV infection include injection drug use, sexual and household exposure to an HBV-infected contact, exposure to multiple sexual partners, male homosexual activity, and perinatal exposure. Dialysis patients should be educated about these other risks and, for those patients chronically infected with HBV, informed that their sexual partners and household contacts should be vaccinated against hepatitis B.[102]

Screening and Diagnostic Tests

Several well-defined antigen-antibody systems are associated with HBV infection, including HBsAg and antibody to HBsAg (anti-HBs); hepatitis B core antigen (HBcAg) and antibody to HBcAg (anti-HBc); and HBeAg and antibody to HBeAg (anti-HBe). Serologic assays are commercially available for all of these except HBcAg because no free HBcAg circulates in blood. One or more of these serologic markers are present during different phases of HBV infection (Table 21–4).[103] HBV infection can also be detected, using qualitative or quantitative tests for HBV DNA. These tests are not FDA-approved and are most commonly used for patients being managed with antiviral therapy.[97,98,104,105]

The presence of HBsAg is indicative of ongoing HBV infection and potential infectiousness. In newly infected persons, HBsAg is present in serum 30 to 60 days after exposure to HBV and persists for variable periods. Transient HBsAg positivity (lasting < 18 days) can be detected in some patients during vaccination.[106,107] Anti-HBc develops in all HBV infections, appearing at onset of symptoms or liver test abnormalities in acute HBV infection, rising rapidly to high levels, and persisting for life. Acute or recently acquired infection can be distinguished by presence of the immunoglobulin M (IgM) class of anti-HBc, which persists for approximately 6 months.

In persons who recover from HBV infection, HBsAg is eliminated from the blood, usually in 23 months, and anti-HBs develops during convalescence. The presence of anti-HBs indicates immunity from HBV infection. After recovery from natural infection, most persons will be positive for both anti-HBs and anti-HBc, whereas only anti-HBs develops in persons who are successfully vaccinated against hepatitis B. Persons who do not recover from HBV infection and become chronically infected remain positive for HBsAg (and anti-HBc), although a small proportion (0.3% per year) eventually clear HBsAg and might develop anti-HBs.[108]

In some persons, the only HBV serologic marker detected is anti-HBc (i.e., isolated anti-HBc). Among most asymptomatic persons in the United States tested for HBV infection, an average of 2% (range: < 0.1%–6%) test positive for isolated anti-HBc[109]; among injecting-drug users, however, the rate is 24%.[110] In general, the frequency of isolated anti-HBc is directly related to the frequency of previous HBV infection in the population and can have several explanations. This pattern can occur after HBV infection among persons who have recovered but whose anti-HBs levels have waned or among persons who failed to develop anti-HBs. Persons in the latter category include those who circulate HBsAg at levels not detectable by current commercial assays. However, HBV DNA

Table 21–4 Interpretation of Serologic Test Results for Hepatitis B Virus Infection

Serologic Markers				Interpretation
HBsAg*	Total Anti-HBc[†]	IgM[‡] Anti-HBc	Anti-HBs[§]	
−	−	−	−	Susceptible, never infected
+	−	−	−	Acute infection, early incubation[¶]
+	+	+	−	Acute infection
−	+	+	−	Acute resolving infection
−	+	−	+	Past infection, recovered and immune
+	+	−	−	Chronic infection
−	+	−	−	False positive (i.e., susceptible), past infection, or low-level chronic infection
−	−	−	+	Immune if titer is ≥ 10 mIU/mL

[†]Antibody to hepatitis B core antigen.
[‡]Immunoglobulin M.
[§]Antibody to hepatitis B surface antigen.
[¶]Transient HBsAg positivity (lasting ≤18 days) might be detected in some patients during vaccination.

has been detected in less than 10% of persons with isolated anti-HBc, and these persons are unlikely to be infectious to others except under unusual circumstances involving direct percutaneous exposure to large quantities of blood (e.g., transfusion).[111] In most persons with isolated anti-HBc, the result appears to be a false positive. Data from several studies have demonstrated that a primary anti-HBs response develops in most of these persons after a three-dose series of hepatitis B vaccine.[112,113] No data exist on response to vaccination among hemodialysis patients with this serologic pattern.

A third antigen, HBeAg, can be detected in serum of persons with acute or chronic HBV infection. The presence of HBeAg correlates with viral replication and high levels of virus (i.e., high infectivity). Anti-HBe correlates with the loss of replicating virus and with lower levels of virus. However, all HBsAg-positive persons should be considered potentially infectious, regardless of their HBeAg or anti-HBe status.

HEPATITIS C VIRUS

Epidemiology

Data are limited on current incidence and prevalence of HCV infection among chronic hemodialysis patients. In 2001, 62% of centers reported that they tested patients for antibody to HCV (anti-HCV) (CDC, unpublished data). In the centers that tested, the reported incidence was 0.29% and prevalence was 8.6% (range among ESRD networks, 5.7%–11.9%). Twelve percent of centers reported newly acquired HCV infections among patients. Higher incidence rates have been reported from cohort studies of hemodialysis patients in the United States (less than 1%–3%) and in Europe (3%–10%).[114–120] Higher prevalences (10%–36%) have also been reported from studies of patients in individual facilities.[114,121]

HCV is most efficiently transmitted by direct percutaneous exposure to infectious blood, and like HBV, the chronically infected person is central to the epidemiology of HCV transmission. Risk factors associated with HCV infection among hemodialysis patients include blood transfusions from unscreened donors and years on dialysis.[114,121] The number of years on dialysis is the major risk factor independently associated with higher rates of HCV infection. As the time patients spent on dialysis increased, their prevalence of HCV infection increased from an average of 12% for patients receiving dialysis less than 5 years to an average of 37% for patients receiving dialysis more than 5 years.[114,121–123]

These studies, as well as investigations of dialysis-associated outbreaks of hepatitis C, indicate that HCV transmission occurs most likely because of inadequate infection control practices. During 1999 to 2000, CDC investigated three outbreaks of HCV infection among patients in chronic hemodialysis centers (CDC, unpublished data, 1999 and 2000). In two of the outbreaks, multiple transmissions of HCV occurred during periods of 16 to 24 months (attack rates: 6.6%–17.5%), and seroconversions were associated with receiving dialysis immediately after a chronically infected patient. Multiple opportunities for cross-contamination among patients were observed, including: (1) equipment and supplies that were not disinfected between patient use; (2) use of common medication carts to prepare and distribute medications at patients' stations; (3) sharing of multiple dose medication vials, which were placed at patients' stations on top of hemodialysis machines; (4) contaminated priming buckets that were not routinely changed or cleaned and disinfected between patients; (5) machine surfaces that were not routinely cleaned and disinfected between patients; and (6) blood spills that were not cleaned up promptly. In the third outbreak, multiple new infections clustered at one point in time (attack rate: 27%), suggesting a common exposure event. Multiple opportunities for cross-contamination from chronically infected patients were also observed in this unit. In particular, supply carts were moved from one station to another and contained both clean supplies and blood-contaminated items, including small biohazard containers, sharps disposal boxes, and used vacutainers containing patients' blood.

Other risk factors for acquiring HCV infection include injection drug use, exposure to an HCV-infected sexual partner or household contact, multiple sexual partners, and perinatal exposure.[124,125] The efficiency of transmission in settings

involving sexual or household exposure to infected contacts is low, and the magnitude of risk and the circumstances under which these exposures result in transmission are not well defined.

Screening and Diagnostic Tests

FDA-licensed or approved anti-HCV screening test kits being used in the United States comprise three immunoassays: two enzyme immunoassays (EIA) and one enhanced chemiluminescence immunoassay (CIA).[126] FDA-licensed or approved supplemental tests include a serologic anti-HCV assay, the strip immunoblot assay (Chiron RIBA HCV 3.0 SIA, Chiron Corp., Emeryville, CA), and nucleic acid tests (NAT) for HCV RNA (including reverse transcriptase polymerase chain reaction [RT-PCR] amplification and transcription mediated amplification [TMA]).

Anti-HCV testing includes initial screening with an immunoassay. If the screening test is positive, an independent supplemental test with high specificity should be performed to verify the results. Among hemodialysis patients, the proportion of false-positive screening test results averages approximately 15%.[126] For this reason, not relying exclusively on anti-HCV screening-test–positive results to determine whether a person has been infected with HCV is critical. Table 21–5 describes the interpretation of HCV testing results for both screening and diagnosis.

For routine HCV testing of hemodialysis patients, the anti-HCV screening immunoassay is recommended and, if positive, supplemental anti-HCV testing using RIBA. RIBA is recommended rather than a NAT because it is a serologic assay and can be performed on the same serum or plasma sample collected for the screening anti-HCV assay. In addition, certain situations exist in which the HCV RNA result can be negative in persons with active HCV infection. As the titer of anti-HCV increases during acute infection, the titer of HCV RNA declines.[127] Thus, HCV RNA is not detectable in certain persons during the acute phase of their hepatitis C, but this finding can be transient and chronic infection can develop.[128] In addition, intermittent HCV RNA positivity has been observed among persons with chronic HCV infection.[129–131] Therefore, the significance of a single negative HCV RNA result is unknown, and the need for further investigation or follow-up is determined by verifying anti-HCV status. In addition, detection of HCV RNA requires that the serum or plasma sample be collected and handled in a manner suitable for NAT and that testing be performed in a laboratory with facilities established for this purpose (test MMWR). Although in rare instances, detection of HCV RNA might be the only evidence of HCV infection, a recent study conducted among almost 3000 hemodialysis patients in the United States found that only 0.07% were HCV RNA positive but anti-HCV negative (CDC, unpublished data).

Table 21–5 Interpretation of Test Results for Hepatitis C Virus Infection

Anti-HCV-Positive
- An anti-HCV-positive result is defined as anti-HCV screening-test-positive and recombinant immunoblot positive (RIBA) or nucleic acid test (NAT) positive; or anti-HCV screening-test-positive, NAT negative, RIBA positive.
  - An anti-HCV-positive result indicates past or current HCV infection.
  - An HCV RNA-positive result indicates current (active) infection, but the significance of a single HCV RNA negative result is unknown; it does not differentiate intermittent viremia from resolved infection.
  - All anti-HCV positive persons should receive counseling and undergo medical evaluation, including additional testing for the presence of virus and liver disease.
  - Anti-HCV testing generally does not need to be repeated, once a positive anti-HCV result has been confirmed.

Anti-HCV-Negative
- An anti-HCV negative result is defined as anti-HCV screening-test-negative*; or anti-HCV screening-test-positive, RIBA negative; or anti-HCV screening-test-positive, NAT negative, RIBA negative.
  - An anti-HCV negative person is considered uninfected.
  - No further evaluation or follow-up for HCV is required, unless recent infection is suspected or other evidence exists to indicate HCV infection (e.g., abnormal liver enzyme levels in immunocompromised persons or persons with no other etiology for their liver disease).

Anti-HCV-Indeterminate
- An indeterminate anti-HCV result is defined as anti-HCV screening-test-positive, RIBA indeterminate; or anti-HCV screening-test-positive, NAT negative, RIBA indeterminate.
  - An indeterminate anti-HCV result indicates that the HCV antibody status cannot be determined.
  - Can indicate a false positive anti-HCV screening test result, the most likely interpretation in those at low risk for HCV infection; such persons are HCV RNA negative.
  - Can occur as a transient finding in recently infected persons who are in the process of seroconversion; such persons usually are HCV RNA positive.
  - Can be a persistent finding in persons chronically infected with HCV; such persons are usually HCV RNA positive.
  - If NAT is not performed, another sample should be collected for repeat anti-HCV testing (≥1 month later).

Anti-HCV, antibody to hepatitis C virus.
*Interpretation of screening immunoassay test results based on criteria provided by the manufacturer.

HEPATITIS DELTA VIRUS

Delta hepatitis is caused by the hepatitis delta virus (HDV), a defective virus that causes infection only in persons with active HBV infection. The prevalence of HDV infection is low in the United States, with rates of less than 1% among HBsAg-positive persons in the general population and greater than 10% among HBsAg-positive persons with repeated percutaneous exposures (e.g., injecting-drug users, persons with hemophilia).[132] Areas of the world with high endemic rates of HDV infection include southern Italy, parts of Africa, and the Amazon Basin.

Few data exist on the prevalence of HDV infection among chronic hemodialysis patients, and only one transmission of HDV between such patients has been reported in the United States.[133] In this episode, transmission occurred from a patient who was chronically infected with HBV and HDV to an HBsAg-positive patient after a massive bleeding incident; both patients received dialysis at the same station.

HDV infection occurs either as a co-infection with HBV or as a superinfection in a person with chronic HBV infection. Co-infection usually resolves, but superinfection frequently results in chronic HDV infection and severe disease. High mortality rates are associated with both types of infection. A serologic test that measures total antibody to HDV is commercially available.

HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

During 1985 to 2001, the percentage of U.S. hemodialysis centers that reported providing chronic hemodialysis for patients with HIV infection increased from 11% to 37%, and the proportion of hemodialysis patients with known HIV infection increased from 0.3% to 1.5%[44] (CDC, unpublished data, 2001). HIV is transmitted by blood and other body fluids that contain blood. No patient-to-patient transmission of HIV has been reported in U.S. hemodialysis centers. However, such transmission has been reported in other countries; in one case, HIV transmission was attributed to mixing of reused access needles and inadequate disinfection of equipment.[134] HIV infection is usually diagnosed with assays that measure antibody to HIV, and a repeatedly positive EIA test should be confirmed by Western blot or another confirmatory test.

PREVENTING TRANSMISSION OF INFECTIONS AMONG CHRONIC HEMODIALYSIS PATIENTS

Preventing transmission among chronic hemodialysis patients of blood-borne viruses and pathogenic bacteria from both recognized and unrecognized sources of infection requires implementation of a comprehensive infection control program. The components of such a program include infection control practices specifically designed for the hemodialysis setting, including routine serologic testing and immunization, surveillance, and training and education. CDC has published recommendations describing these components in detail.[135]

The infection control practices recommended for hemodialysis units (Table 21–6) will reduce opportunities for patient-to-patient transmission of infectious agents, directly or indirectly via contaminated devices, equipment and supplies, environmental surfaces, or hands of personnel. These practices should be carried out routinely for all patients in the chronic hemodialysis setting because of the increased potential for blood contamination during hemodialysis and because many patients are colonized or infected with pathogenic bacteria.

Such practices include additional measures to prevent HBV transmission because of the high titer of HBV and its ability to survive on environmental surfaces (Table 21–6). It is the potential for environmentally mediated transmission of HBV, rather than internal contamination of dialysis machines, that is the focus of infection control strategies for preventing HBV transmission in dialysis centers. For patients at increased risk for transmission of pathogenic bacteria, including antimicrobial-resistant strains, additional precautions might also be necessary in some circumstances. Furthermore, surveillance for infections and other adverse events is required to monitor the effectiveness of infection control practices, as well as training and education of both staff members and patients to ensure that appropriate infection control behaviors and techniques are carried out.

In each chronic hemodialysis unit, policies and practices should be reviewed and updated to ensure that infection control practices recommended for hemodialysis units are implemented and rigorously followed. Intensive efforts must be made to educate new staff members and reeducate existing staff members regarding these practices. Readers should consult the CDC recommendations for details on these practices.[135] The following is a summary of selected issues.

Routine Testing

All chronic hemodialysis patients should be routinely tested for HBV and HCV infection and the results promptly reviewed so that potential episodes of transmission can be identified quickly and patients appropriately managed based on their testing results. Test results (positive and negative) must be communicated to other units or hospitals when patients are transferred for care. Routine testing for HDV or HIV infection for purposes of infection control is not recommended.

Before admission to the hemodialysis unit, the HBV serologic status (i.e., HBsAg, total anti-HBc, and anti-HBs) of all patients should be known. For patients transferred from another unit, test results should be obtained before the patients' transfer. If a patient's HBV serologic status is not known at the time of admission, testing should be completed within 7 days. The hemodialysis unit should ensure that the laboratory performing the testing for anti-HBs can define a 10 mIU/mL concentration to determine protective levels of antibody.

Routine HCV testing should include use of both a screening immunoassay to test for anti-HCV and supplemental or confirmatory testing with an additional, more specific assay. Use of NAT for HCV RNA as the primary test for routine screening is not recommended because few HCV infections will be identified in anti-HCV negative patients. However, if alanine aminotransferase (ALT) levels are persistently abnormal

Table 21–6 Recommended Infection Control Practices for Hemodialysis Units

Infection Control Precautions for All Patients

- Wear disposable gloves when caring for the patient or touching the patient's equipment at the dialysis station; remove gloves and wash hands between each patient or station.
- Items taken into dialysis station should either be disposed of, dedicated for use only on a single patient, or cleaned and disinfected before taken to a common clean area or used on another patient.
  - Nondisposable items that cannot be cleaned and disinfected (e.g., adhesive tape, cloth-covered blood pressure cuffs) should be dedicated for use only on a single patient.
  - Unused medications (including multiple dose vials containing diluents) or supplies (syringes, alcohol swabs, etc.) taken to the patient's station should be used only for that patient and should not be returned to a common clean area or used on other patients.
- When multiple dose medication vials are used (including vials containing diluents), prepare individual patient doses in a clean (centralized) area away from dialysis stations and deliver separately to each patient. Do not carry multiple dose medication vials from station to station.
- Do not use common medication carts to deliver medication to patients. Do not carry medication vials, syringes, alcohol swabs, or supplies in pockets. If trays are used to deliver medication to individual patients, they must be cleaned between patients.
- Clean areas should be clearly designated for the preparation handling and storage of medications and unused supplies and equipment. Clean areas should be clearly separated from contaminated areas where used supplies and equipment are handled. Do not handle and store medications or clean supplies in the same or an adjacent area to that where used equipment or blood samples are handled.
- Use external venous and arterial pressure transducer filters/protectors for each patient treatment to prevent blood contamination of the dialysis machines' pressure monitors. Change filters/protectors between each patient treatment, and do not reuse them. Internal transducer filters do not need to be changed routinely between patients.
- Clean and disinfect the dialysis station (chairs, beds, tables, machines, etc.) between patients.
  - Give special attention to cleaning control panels on the dialysis machines and other surfaces that are frequently touched and potentially contaminated with patients' blood.
  - Discard all fluid and clean and disinfect all surfaces and containers associated with the prime waste (including buckets attached to the machines).
- For dialyzers and blood tubing that will be reprocessed, cap dialyzer ports and clamp tubing. Place all used dialyzers and tubing in leak-proof containers for transport from station to reprocessing or disposal area.

Schedule for Routine Testing for Hepatitis B Virus (HBV) and Hepatitis C Virus (HCV) Infections

Patient Status	On Admission*	Monthly	Semi-Annual	Annual
All patients	HBsAg,[†] Anti-HBc (total)[†] Anti-HBs,[†] Anti-HCV, ALT[†]			
HBV susceptible, including nonresponders to vaccine		HBsAg		
Anti-HBs positive (=10 mIU/mL), anti-HBc negative				Anti-HBs
Anti-HBs and anti-HBc positive		No additional HBV testing needed		
Anti-HCV negative		ALT	Anti-HCV	

*Results of HBV testing should be known before the patient begins dialysis.
[†]HBsAg = hepatitis B surface antigen; Anti-HBc = antibody to hepatitis B core antigen; Anti-HBs = antibody to hepatitis B surface antigen; Anti-HCV = antibody to hepatitis C virus; ALT = alanine aminotransferase.

Hepatitis B Vaccination

- Vaccinate all susceptible patients against hepatitis B.
- Test for anti-HBs 1–2 months after last dose
  - If anti-HBs is <10 mIU/mL, consider patient susceptible, revaccinate with an additional three doses, and retest for anti-HBs.
  - If anti-HBs is >10 mIU/mL, consider immune, and retest annually.
    - Give booster dose of vaccine if anti-HBs declines to <10 mIU/mL and continue to retest annually

Management of HBsAg-Positive Patients

- Follow infection control practices for hemodialysis units for all patients.
- Dialyze HBsAg-positive patients in a separate room using separate machines, equipment, instruments, and supplies.
- Staff members caring for HBsAg-positive patients should not care for HBV susceptible patients at the same time (e.g., during the same shift or during patient changeover).

(From Centers for Disease Control and Prevention. Recommendations for preventing transmission of infections among chronic hemodialysis patients. MMWR Morb Mortal Wkly Rep 2001; 50[No.RR-5]:1–43.)

in anti-HCV negative patients in the absence of another etiology, testing for HCV RNA should be considered. Blood samples collected for NAT should not contain heparin, which interferes with the accurate performance of this assay.

Hepatitis B vaccination is an essential component of prevention in the hemodialysis setting. All susceptible patients and staff should receive hepatitis B vaccine. Susceptible patients who have not yet received hepatitis B vaccine, are in the process of being vaccinated, or have not adequately responded to vaccination should continue to be tested regularly for HBsAg. Detailed recommendations for vaccination and follow-up of hemodialysis patients have been published elsewhere.[135]

Management of Infected Patients

HBV

HBsAg-positive patients should undergo dialysis in a separate room designated only for HBsAg-positive patients. They should use separate machines, equipment, and supplies, and, most importantly, staff members should not care for both HBsAg-positive and susceptible patients on the same shift or at the same time. Dialyzers should not be reused on HBsAg-positive patients. Because HBV is efficiently transmitted through occupational exposure to blood, reprocessing dialyzers from HBsAg-positive patients might place HBV-susceptible staff members at increased risk for infection.

HBV chronically infected patients (i.e., those who are HBsAg positive, total anti-HBc positive, and IgM anti-HBc negative) are infectious to others and are at risk for chronic liver disease. They should be counseled regarding preventing transmission to others, their household and sexual partners should receive hepatitis B vaccine, and they should be evaluated (by consultation or referral, if appropriate) for the presence or development of chronic liver disease according to current medical practice guidelines. Persons with chronic liver disease should be vaccinated against hepatitis A, if susceptible.

HBV chronically infected patients do not require any routine follow-up testing for purposes of infection control. However, annual testing for HBsAg is reasonable to detect the small percentage of HBV-infected patients who might lose their HBsAg.

HCV

HCV transmission within the dialysis environment can be prevented by strict adherence to infection control precautions recommended for all hemodialysis patients (Table 21–6). Although isolation of HCV positive patients is not recommended, routine testing for ALT and anti-HCV is important for monitoring the potential for transmission within centers and ensuring that appropriate precautions are being properly and consistently used. Furthermore, HCV-positive patients can participate in dialyzer reuse programs. Unlike HBV, HCV is not transmitted efficiently through occupational exposures. Thus, reprocessing dialyzers from HCV-positive patients should not place staff members at increased risk for infection.

HCV-positive persons should be evaluated (by consultation or referral, if appropriate) for the presence or development of chronic liver disease according to current medical practice guidelines. They should also receive information concerning how they can prevent further harm to their liver and prevent transmitting HCV to others.[136,137] Persons with chronic liver disease should be vaccinated against hepatitis A, if susceptible.

HDV

Because HDV depends on an HBV-infected host for replication, prevention of HBV infection will prevent HDV infection in a person susceptible to HBV. Patients known to be infected with HDV should be isolated from all other dialysis patients, especially those who are HBsAg positive.

HIV

Infection control precautions recommended for all hemodialysis patients are sufficient to prevent HIV transmission between patients. HIV-infected patients do not have to be isolated from other patients or dialyzed separately on dedicated machines. In addition, they can participate in dialyzer reuse programs. Because HIV is not transmitted efficiently through occupational exposures, reprocessing dialyzers from HIV-positive patients should not place staff members at increased risk for infection.

Bacterial

Contact transmission can be prevented by hand hygiene,[138] glove use, and disinfection of environmental surfaces. Infection control precautions recommended for all hemodialysis patients are adequate to prevent transmission for most patients infected or colonized with pathogenic bacteria, including antimicrobial-resistant strains. However, additional precautions should be considered for treatment of patients who might be at increased risk for transmitting pathogenic bacteria. Such patients include those with either an infected skin wound with drainage that is not contained by dressings (the drainage does not have to be culture positive for MRSA or VRE or any specific pathogen) or fecal incontinence or diarrhea uncontrolled with personal hygiene measures. For these patients, consider using the following additional precautions[135]:

1. Staff members treating the patient should wear a separate gown over their usual clothing and remove the gown when finished caring for the patient.
2. Dialyze the patient at a station with as few adjacent stations as possible (e.g., at the end or corner of the unit).

Vancomycin is used commonly in dialysis patients, in part, because vancomycin can be conveniently administered to patients when they come in for hemodialysis treatments. Prudent antimicrobial use is an important component of the CDC recommendations for preventing the spread of vancomycin resistance.[139] This guideline states that vancomycin is *not* indicated for therapy (chosen for dosing convenience) of infections due to β-lactam-sensitive gram-positive microorganisms in patients with renal failure. Depending on the situation, alternative antimicrobials (e.g., cephalosporins) with dosing intervals greater than 48 hours, which would allow post-dialytic dosing, could be used. Recent studies suggest that cefazolin given three times a week in the dialysis unit provides adequate blood levels and could be used to treat many infections in hemodialysis patients.[140,141]

Disinfection, Sterilization, and Environmental Hygiene

Good cleaning, disinfection, and sterilization procedures are important components of infection control in the hemodialysis center. The procedures do not differ from those recommended for other health care settings,[142,143] but the high potential for blood contamination makes the hemodialysis setting unique. Additionally, the need for routine aseptic access of the patient's vascular system makes the hemodialysis unit more akin to a surgical suite than to a standard hospital room. Medical items are categorized as critical (e.g., needles and catheters), which are introduced directly into the bloodstream or normally sterile areas of the body; semicritical (e.g., fiberoptic endoscopes), which come in contact with intact mucous membranes; and noncritical (e.g., blood pressure cuffs), which touch only intact skin.[138,142]

Cleaning and housekeeping in the dialysis center have two goals: to remove soil and waste on a regular basis, thereby preventing the accumulation of potentially infectious material, and to maintain an environment that is conducive to good patient care. Crowding of patients and overtaxing of staff members may increase the likelihood of microbial transmission. Adequate cleaning may be difficult if there are multiple wires, tubes, and hoses in a small area. There should be enough space to move completely around each patient's dialysis station without interfering with the neighboring stations. Where space is limited, elimination of unneeded items; orderly arrangement of required items; and removal of excess lengths of tubes, hoses, and wires from the floor can improve accessibility for cleaning. Because of the special requirements for cleaning in the dialysis center, staff should be specially trained in this task.

After each patient treatment, frequently touched environmental surfaces, including external surfaces of the dialysis machine, should be cleaned (with a good detergent) or disinfected (with a detergent germicide). It is the cleaning step that is important for interrupting the cross-contamination transmission routes. Antiseptics, such as formulations with povidone-iodine, hexachlorophene, or chlorhexidine, should not be used, because these are formulated for use on skin and are not designed for use on hard surfaces.

There is no evidence that medical waste is any more infectious than residential waste or has caused disease in the community.[144] Wastes from a hemodialysis center that are actually or potentially contaminated with blood should be considered infectious and handled accordingly. Eventually, these items of solid waste should be disposed of properly in an incinerator or sanitary landfill, depending on state or local laws.

Standard protocols for sterilization and disinfection are adequate for processing any items or devices contaminated with blood. Historically, there has been a tendency to use "overkill" strategies for instrument sterilization or disinfection and housekeeping protocols. This is not necessary. The floors in a dialysis center are routinely contaminated with blood, but the protocol for floor cleaning is the same as for floors in other health care settings. Usually, this involves the use of a good detergent-germicide; the formulation can contain a low- or intermediate-level disinfectant.

Blood-borne viruses, such as HBV and HIV, are inactivated by any standard sterilization systems such as standard steam autoclave cycles of 121°C (249.8°F) for 15 minutes, ethylene oxide gas,[142] and low-temperature hydrogen peroxide gas plasma.[145] Large blood spills should be cleaned to remove visible material, and then, the area should receive low- to intermediate-level disinfection after the directions of the germicide manufacturer.

Blood and other specimens, such as peritoneal fluid, from all patients should be handled with care. Peritoneal fluid can contain high levels of HBV and should be handled in the same manner as the patient's blood. Consequently, if the center performs peritoneal dialysis, the same criteria for separating HBsAg-positive patients who are undergoing hemodialysis apply to those undergoing peritoneal dialysis.

HBV has not been grown in tissue cultures, and without a viral assay system, studies on the precise resistance of this virus to various chemical germicides and heat have not been performed. However, the resistance of HBV to heat and chemical germicides may approach that of some other viruses and bacteria but certainly not that of the bacterial endospore or the tubercle bacillus. Further, studies have shown that HBV is not resistant to commonly used high-level and intermediate-level disinfectants.[146,147]

Blood contamination of venous pressure monitors has been implicated in HBV transmission.[148] Therefore, venous pressure transducer filters should be used; these filters should not be reused.

In single-pass artificial kidney machines, the internal fluid pathways are not subject to contamination with blood. Although the fluid pathways that exhaust dialysis fluid from the dialyzer may become contaminated with blood in the event of a dialyzer leak, it is unlikely that this blood contamination will reach a subsequent patient. Therefore, disinfection and rinsing procedures should be designed to control contamination with bacterial rather than blood-borne pathogens.

For dialysis machines that use a dialysate recirculating system (such as some ultrafiltration control machines and those that regenerate the dialysate), a blood leak in a dialyzer, especially a massive leak, can result in contamination of a number of surfaces that will contact the dialysis fluid of subsequent patients. However, the procedures that are normally practiced after each use—draining of the dialysis fluid, subsequent rinsing, and disinfection—will reduce the level of contamination to below infectious levels. In addition, an intact dialyzer membrane will not allow passage of bacteria or viruses. Consequently, if a blood leak does occur with either type of dialysis machine, the standard disinfection procedure used for machines in the dialysis center to control bacterial contamination will also prevent transmission of blood-borne pathogens.

Acute Complications Associated with Hemodialysis

Orfeas Liangos, M.D. • Brian J.G. Pereira, M.D., M.B.A. • Bertrand L. Jaber, M.D.

Since first successfully performed in 1945,[1] hemodialysis (HD) has become a routine procedure. However, despite significant improvements in HD equipment and improvement in patient monitoring, acute complications can still occur during the therapy. This chapter will review acute complications that are encountered during or are directly related to HD. The chronic complications of dialysis have been extensively reviewed elsewhere.[2,3]

DIALYSIS REACTIONS

Adverse reactions occurring during HD may be caused by the exposure of patient blood to surface components of the extracorporeal circuit including the dialyzer, tubing, as well as other compounds used in the manufacturing and sterilization processes. This interaction between the patient's blood and the extracorporeal system can lead to various adverse reactions that can range in severity from mild to life-threatening anaphylactic/anaphylactoid reactions (Table 22–1).[4]

LIFE-THREATENING ANAPHYLACTIC/ANAPHYLACTOID REACTIONS

Anaphylaxis is the result of an immunoglobulin E (IgE)-mediated acute allergic reaction in a sensitized patient, whereas anaphylactoid reactions result from the direct release of mediators by host cells. Symptoms typically develop within the first 5 minutes of dialysis initiation, although they may be delayed by up to 20 minutes. The severity can range from mild to life threatening and can encompass a burning or heat sensation throughout the body or at the access site, dyspnea, chest pressure or tightness, angioedema/laryngeal edema, acral or oral paresthesias, rhinorrhea, lacrimation, sneezing or coughing, flushing, pruritus, nausea/vomiting, abdominal cramps, and diarrhea. A history of atopy, elevated total serum IgE, eosinophilia, and the use of angiotensin converting enzyme (ACE) inhibitors as well as, but less frequently, angiotensin receptor blockers predispose the patient to such reactions.[5,6] The etiology of dialysis reactions (DR) is diverse and requires prompt investigation to help prevent further reactions.

Leachables

Allergy to Ethylene Oxide: "First Use Syndrome"

Ethylene oxide (ETO), the dialyzer manufacturer's gas sterilant, can cause DR by acting as a hapten through binding to albumin. Specific IgE antibodies against ETO conjugated to human serum albumin (HSA) have been detected using a radioallergosorbent test (RAST).[7] However, only two-thirds of patients with such reactions have circulating IgE antibodies against ETO-HSA, whereas one-third do not. Circulating levels of anti-ETO-HSA IgE antibodies can be detected in up to 10% of patients with no prior history of DR.[8] The potting compound used to anchor the hollow fibers in the dialyzer housing acts as a reservoir for ETO and may impede its washout from the dialyzer. ETO may still be detectable after long periods of thorough rinsing of the dialyzer.[9] Furthermore, delayed entry of ETO into the priming fluid has also been observed, and dialyzer reprocessing prior to first use has reduced the incidence of these reactions.[4] Testing for ETO-specific IgE antibodies may be helpful if an ETO allergy is suspected.[10] Once the diagnosis has been confirmed or is highly suspected, ETO-sterilized dialyzers should be replaced with gamma- or steam-sterilized dialyzers. A recent survey suggests that allergic reactions to ETO have become less frequent.[11]

Dialyzer's Reuse Reactions: "Reuse Syndromes"

Most residual ETO is washed out of the dialyzer during "first use" and with subsequent reprocessing. Thus, reuse reactions are more likely to be due to other agents, such as the germicides used for dialyzer reprocessing. Commonly used germicides include formaldehyde, glutaraldehyde, and peracetic acid/hydrogen peroxide. Formaldehyde is a known allergen, and life-threatening reactions have been observed in HD patients in whom the RAST to formaldehyde was positive.[6,12] Exposure may also result from residual formaldehyde after disinfection of the water supply system.[13]

Other Leachables

Isopropyl myristate used in the solution spinning process of hollow fiber fabrication, isocyanates found in the potting compound, and nonendotoxin LAL-reactive material believed to be cellulose in nature and found during rinsing of cellulose hollow-fiber dialyzers have also been suspected to cause DR.[4]

Membrane Bioincompatibility

Evidence to support the hypothesis that life-threatening reactions follow complement activation during dialysis with unsubstituted cellulose membranes has been disputed.[4] Indeed, although complement activation does occur during dialysis, it does not prove causality because severe anaphylaxis results in complement activation.[14] However, it is possible that

Table 22–1   Development, Management, and Prevention of Dialysis Reactions

Dialysis Reaction	Onset During Hemodialysis	Etiology	Course of Action	Prevention
Life-threatening anaphylactic/ anaphylactoid	5-20 minutes	Ethylene oxide (first-use dialyzer syndrome) Germicide (reuse dialyzer syndrome) AN69 dialyzer and ACE inhibitor interaction Renalin dialyzer reuse and ACE inhibitor interaction Medications (parenteral iron, heparin)	Stop hemodialysis Do not return blood to patient Epinephrine Corticosteroids Antihistamines	Rinse dialyzer before use Use gamma/steam sterilized dialyzer Discontinue dialyzer reuse Avoid AN69 dialyzer with ACE inhibitor Discontinue reuse with renalin Use test dose for parenteral iron
Non-life threatening	20-40 minutes	Complement activation	Continue hemodialysis	Use noncellulose dialyzer membrane
Pyrogen	Anytime	Endotoxin/bacterial contamination	Stop hemodialysis if hypotension present Blood cultures Antibiotics Antipyretics	Preventive strategies (Table 22–3)

secondary or concomitant release of complement fragments may amplify an IgE-mediated ETO reaction, for instance, by enhancing release of histamine or other mediators.[15]

Bradykinin-Mediated Reactions

Polyacrylonitrile (PAN) is a negatively charged synthetic membrane, which is composed of a copolymer of acrylonitrile and an aryl sulfonate.[16] In the 1990s, severe anaphylactoid reactions were reported in patients dialyzed with PAN membranes who were also taking ACE inhibitors.[17,18] Binding of Hageman factor (Factor XII) to a negatively charged membrane leads to formation of kallikrein from prekallikrein and the subsequent release of kinins (i.e., bradykinin) from kininogen. Although cuprophan and polymethyl methacrylate (PMMA) membranes display an ability to activate factor XII, PAN activates it to a greater extent.[19] Bradykinin, a molecule with a very short half-life, in turn, activates production of prostaglandin and histamine release, with subsequent vasodilatation and increased vascular permeability.[20] ACE inactivates bradykinin and, therefore, ACE inhibitors can prolong the biologic activities of bradykinin, which are highly calcium-dependent.[4]

Several anaphylactoid reactions have also been reported in patients dialyzed with bleach reprocessed polysulfone (PS) membranes and treated with ACE inhibitors.[21] These reactions ceased once the use of bleach was discontinued. Furthermore, a cluster of anaphylactoid reactions was observed in patients dialyzed with different membranes who were also taking ACE inhibitors.[22] Hydrogen peroxide/peracetic acid was the reprocessing agent used, and the reactions abated once reprocessing was discontinued, despite continued use of ACE inhibitors.[23]

Dialysate Factors

The use of acetate dialysate has been implicated in DR, and proposed mechanisms include interleukin 1 (IL-1) production by monocytes and prostaglandin/adenosine-mediated mechanisms.[4] Conversely, bicarbonate dialysate is highly susceptible to bacterial contamination, and bacterial products present in the dialysate can diffuse across both high-flux and low-flux membranes[24,25] (see "Bacterial Contamination"). Further, reprocessing of dialyzers, particularly with bleach, can increase the likelihood of reverse transfer of bacterial products from the dialysate to blood.[24] These bacterial products can induce cytokine release by monocytes and, consequently, pyrogen reactions (PR). Although PR during dialysis are reported with a high frequency in dialysis units that use high-flux or reprocessed dialyzers,[26] some authors suggest that they do not cause life-threatening reactions.[27]

Drug-Induced Reactions

Iron Dextran

Dextran, a mixture of synthetic glucose polymers has been associated with systemic reactions.[28] Anaphylactic reactions to iron dextran are due to this compound and occur in 0.6% to 1% of recipients.[4] The incidence of anaphylactic reactions is expected to rise, in view of the increasing need for parenteral iron therapy in erythropoietin-treated HD patients who suffer from absolute or functional iron deficiency.[29] The precise mechanisms responsible for dextran-induced anaphylactoid reactions are elusive, but there seems to be dose-dependent basophil histamine release that may

account for the cardiovascular collapse.[4] Due to this dose-related toxicity, iron dextran should always be initiated as a 0.5- to 1-mg test dose, with staff available to respond to reactions. If the test dose is uneventful, a course of therapy can then be given safely (i.e., 100-200 mg/dialysis session for 10 doses).[30] Intravenous iron gluconate or saccharate are alternatives for patients with severe iron deficiency anemia who are allergic to iron dextran.[31]

Heparin

Patients rarely exhibit hypersensitivity to heparin formulations but usually respond by substituting beef with pork heparin or vice versa.[4] Heparin reduces aldosterone secretion by a direct action on the adrenal gland, leading to hyperkalemia. It is not clear, however, whether this effect is due to heparin or its preservative chlorbutol.[32] The resultant hyperkalemia may be clinically-significant in patients with underlying chronic kidney disease.[33] However, this phenomenon has not been studied in the dialysis population, and heparin-associated complications are mainly related to bleeding (see "Hemorrhage") of thrombocytopenia (see "Hematologic Complications").

Desferrioxamine

Desferrioxamine therapy for aluminum or iron chelation can produce hypotension during dialysis or rare allergic reactions, gastrointestinal disturbances, loss of vision, auditory toxicity, bone pain, or exacerbation of aluminum encephalopathy.[34]

Treatment and Prevention

The treatment of severe anaphylactic and anaphylactoid reaction is similar and requires immediate cessation of HD without returning the extracorporeal blood to the patient's circulation. Antihistamines (H_1- and H_2-antagonists), epinephrine, corticosteroids, and respiratory support should be provided, if needed.[35] Specific preventive measures include rinsing the dialyzer immediately before first use, substituting ETO with gamma- or steam-sterilized dialyzers, and avoiding PAN membranes in patients on ACE inhibitors.

MILD REACTIONS

Mild reactions consisting of chest/back pain often occur 20 to 40 minutes after initiation of HD. They are not characterized by anaphylactic or allergic reactions, and dialysis can usually be continued. Symptoms usually abate after the 1st hour, suggesting a relation to the degree of complement activation.[36] Indeed, these reactions decrease with the use of substituted and reprocessed unsubstituted cellulose membranes, particularly when bleach has been omitted from the reuse procedure.[4] Some studies suggest that the incidence of chest/back pain parallels the degree of complement activation and increases with larger surface-area dialyzers.[4] However, a randomized crossover study comparing two similar size unsubstituted cellulose and PAN dialyzers showed no difference in these reactions between the two membranes, in spite of differences in complement activation.[37] Treatment with oxygen and analgesics is usually sufficient, and preventive measures include automated cleansing of new dialyzers or using non-cellulose membranes.

MICROBIAL CONTAMINATION

Naturally occurring water bacteria commonly found in HD water systems include gram-negative bacteria (GNB) such as Pseudomonas species and nontuberculous mycobacteria. GNB release endotoxin or lipopolysaccharide (LPS) and other bacterial products, and nontuberculous mycobacteria are highly resistant to germicides.[4] Several factors that are operative during dialysis place patients at risk for exposure to bacteria and/or bacterial products, including contaminated water or bicarbonate dialysate, improperly sterilized dialyzers, and cannulation of infected grafts or fistulas.

Bicarbonate-containing solutions are highly susceptible to bacterial contamination.[4] If stored for too long, sodium bicarbonate breaks down to sodium carbonate, which, along with glucose contained in the dialysate, constitute a growth medium for bacteria. When GNB reach excessively high concentrations in the dialysate, serious health risks to patients, including PR with or without bacteremia can result.[38] Indeed, outbreaks of clusters of infection in HD patients have been ascribed to bacterial contamination (Table 22–2). The passage of endotoxin from the dialysate into the blood can occur by diffusion or convection. The use of high-flux dialyzers, especially those reprocessed with bleach (which increases the permeability), increases the risk of passage of endotoxin, particularly lipid A (~2000 Da), the active moiety of LPS, from dialysate into blood. LPS interacts with plasma LPS Binding Protein (LBP) and mediates cytokine production by interacting with the monocyte CD14 receptor.[39] The subsequent release of pyrogenic cytokines, such as interleukin-1, and tumor necrosis factor produce a transient febrile reaction.

Reprocessing of dialyzers has become a common practice in the United States because of decreased cost, improved biocompatibility, and fewer patient symptoms.[4] However, despite general safety of the procedure, PR and bacteremia may supervene. Reprocessing involves rinsing, cleaning, testing, and sterilizing hollow-fiber dialyzers. PR due to reprocessing have been attributed to improper disinfection procedures, inadequate potency of the solution used to disinfect the dialyzer, and inadequate measures to disinfect the O-rings of dialyzers with removable headers.[4] In a survey by the Centers for Disease Control (CDC) and Prevention in the United States, the incidence of PR in the absence of septicemia was reported by 19% of U.S. dialysis centers.[26] Furthermore, the use of high-flux dialyzers (especially in conjunction with bicarbonate dialysate) and reprocessed dialyzers was associated with an increased incidence of PR.[26] Finally, intradialytic hypotension can also cause transient mesenteric ischemia that may be sufficient to damage the gastrointestinal mucosa and lead to bacterial and/or LPS translocation.[39]

Pyrogenic reactions should be entertained after septicemia has been ruled out. Careful examination of the dialysis access is warranted and blood cultures should be obtained. Treatment of PR includes antipyretics, empiric broad-spectrum antibiotics, discontinuation of ultrafiltration whenever hypotension is present, and selective hospitalization. An outbreak of

Table 22–2   Reactions/Infections Related to Microbial Contamination of Dialysis Fluids

Causative Agents	Identifiable Sources of Contamination	Manifestations
Bacterial Products		
Lipopolysaccharide	Backfiltration from bicarbonate/glucose dialysate	PR without bacteremia

Rhodotorula glutinis	Drain of hemodialysis machines	Unknown

PR, pyrogen reaction.

bacteremia among several patients, involving a similar organism should prompt thorough search for bacterial contaminants of the dialysis equipment.

Strategies for the prevention of PR are summarized in Table 22–3 and start with strict adherence to the Association for the Advancement of Medical Instrumentation (AAMI) standards. In an era of high-flux dialysis and reuse, some authors believe that these recommendations are too liberal and that sterile, pyrogen-free dialysis fluids be used.[40] Although this approach may offer clear advantages to patients, skepticism with regards to cost remains an unresolved issue, and data to support its benefit are currently lacking.

BLOODLINE TOXICITY

Particle Spallation

Bloodline components may enter the circulation by spallation, which is the release of silicone (not used in the United States) or polyvinyl chloride (PVC) particles, induced by the roller pump.[41,42] Studies of the bioengineering aspects of spallation indicate that the origin of these particles is from cracks in the pump insert material near the point of flexing caused by the repeated compression/relaxation of the tubing by the rollers.[42] With current high-flux technology demanding high pump speed performances, spallation is more likely to occur. Quantitative studies indicate that the majority of particles released are less than 5μm in diameter and that the greatest release of particles occurs during the 1st hour of pumping.[43] Even though silicone has been largely replaced by PVC, the problem of spallation persists.[43] Loading of

animals with PVC or silicone particles induces IL-1 and prostanoid secretion by macrophages,[44,45] and ascribed clinicopathologic effects include hepatomegaly, granulomatous hepatitis and hypersplenism.[42] Silicon-related toxicity with plasma levels greater than 2 mg/L has been described in two dialysis patients.[46] Although it was not thought to be related to dialysis-related contamination, the syndrome was characterized by perforating folliculitis and aberrant hair growth.[46] Future bioengineering advances aimed at improving bloodline biocompatibility are warranted, including newer design of roller and pump segments and internal coating of PVC tubing.

Leachables

The flexibility of PVC is achieved by the addition of a plasticizer, di(2-ethylhexyl) phthalates (DEHP).[47] Phthalates are physically linked but not bound to PVC and hence may leach from the tubing matrix into the circulation. DEHP has been recovered from plasma and erythrocytes that were stored in plastic tubes.[42] Although there is no clear evidence to confirm its toxicity, DEHP can bind to plasma lipids and lipoproteins, and significant tissue levels have been recovered at autopsy.[42] Furthermore, a hepatitis-like syndrome and necrotizing dermatitis have been reported in association with PVC exposure.[42] In the dermatologic literature, contact dermatitis due to DEHP exposure has been described.[48]

Leachability studies of a newer plasticizer, trimellitate from blood tubing demonstrate a lower release when compared to DEHP.[49] Of note, the AAMI standards do not enforce leachability and spallation study requirements from manufacturers of bloodline tubing and dialysis equipment.

*A minimum of 11- or 24-hour exposure to peracetic acid or formaldehyde is required, respectively.
†These germicides are all equivalent or superior to 4% formaldehyde.

CARDIOVASCULAR COMPLICATIONS

Hypotension

Intradialytic hypotension requiring medical intervention occurs in 10% to 30% of treatments.[50] Although it may be frequently asymptomatic, it can also be accompanied by a severe compromise of vital organ perfusion resulting in loss of consciousness, seizures, and even death. Associated vomiting may be complicated by aspiration.

The pathogenesis of intradialytic hypotension is multifactorial. Ultrafiltration rate, total volume of fluid removed, a reduced plasma refilling rate coupled with impaired compensatory physiologic responses to hypovolemia play a major role. An altered nitric oxide versus endothelin balance has recently been implied in the pathogenesis of dialysis induced hypotension.[51] Although an ultrafiltration rate of greater than 0.35 mL/kg/min will produce hypotension in most patients,[52] slower ultrafiltration rates, with up to a 20% decrease in plasma volume are generally well tolerated.[53] Failure of the normal compensatory responses to hypovolemia, which include central redistribution of the blood volume and increase in peripheral vascular resistance, are frequent mechanisms in hypotensive episodes. Patient-related factors include autonomic dysfunction (i.e., baroreflex impairment and alteration of heart rate responses), particularly in elderly and diabetic patients, use of anti-hypertensive medications, structural heart disease, cardiac arrhythmias, bacterial sepsis, hemorrhage, intradialytic venous pooling, increase in core body temperature, ingestion of food during dialysis and anemia. Dialysis associated L-carnitine deficiency may also contribute to intradialytic hypotension.[54] In addition, "sympathetic failure" due to a lack of appropriate rise in plasma norepinephrine levels during HD may be a manifestation of baroreflex dysfunction.[55] The decreased sensitivity of the renin-angiotensin, adrenergic, and arginine vasopressine systems could also contribute to inadequate vasoactive responses to HD-induced hypovolemia.[56]

Immediate management of intradialytic hypotension consists of restoration of vital organ perfusion by placing the patient in a Trendelenburg's position while preventing aspiration and augmentation of the circulating blood volume through infusion of isotonic normal saline, hypertonic agents, and reduction/cessation of ultrafiltration.

Cardiovascular instability and intradialytic hypotension can also be reduced with the use of bicarbonate dialysate, volumetric control of ultrafiltration, increased dialysate sodium

concentration, better assessment of patient's "dry weight" using bioelectric impedance or vena caval ultrasound, and the use of cooler temperature dialysis.[57] Sodium modeling also reduces hypotensive episodes.[58] The use of salt-poor albumin offers no advantage to normal saline but costs more. On-line blood volume monitoring techniques have been used to control intradialytic hypotensive episodes, but their effectiveness is controversial.[59,60] Other preventive strategies include (1) correction of anemia and hypoalbuminemia, (2) withdrawal of antihypertensive drugs before dialysis, (3) avoiding food before and during dialysis, (4) counseling patients regarding weight gain, (5) treatment of congestive heart failure and arrhythmias, and (6) search for other causes such as pericardial effusion. Finally, the pre-dialysis use of midodrine, a selective alpha$_1$-adrenergic receptor agonist, is effective and safe in reducing the severity and frequency of hypotensive episodes.[61] Other pharmacologic options include the use of L-carnitine and setraline.[62,63]

Hypertension

Intradialytic and immediate postdialytic hypertension also constitute an important risk factor for cardiovascular mortality, the leading cause of mortality in HD patients. Time-averaged blood pressure measurements correlate better with postdialysis than with predialysis blood pressure, and dialysis patients often fail to show the normal "nocturnal dip" in blood pressure.[64,65] In a recent study, elevated postdialysis pulse pressure was associated with a 12% increase in the hazard for death, whereas postdialysis systolic blood pressure was inversely related to mortality.[66]

Although volume control is still the mainstay of blood pressure management in dialysis patients, blood pressure control is not achieved despite fluid removal in up to 50% of patients.[67] Preexisting hypertension, volume depletion, hypokalemia-induced increased renin-angiotensin secretion,[68] hypercalcemia-induced increased inotropism and vascular tone,[69] and increased sympathetic tone during rapid ultrafiltration, especially among young patients with kidneys *in situ*,[70] have all been associated with volume-independent hypertension in HD.[71] The chronic administration of recombinant human erythropoietin (rHuEPO) has also been associated with hypertension. This effect may be mediated by rheologic mechanisms as well as humoral factors, such as elevation in resting and agonist-stimulated cytoplasmic calcium concentration, increased endothelin production, upregulation of tissue renin and angiotensinogen expression, and a possible change in vascular tissue prostaglandin production.[72]

If signs or symptoms of volume contraction are lacking, it is justified to reduce the dry weight by 0.5 kg, observe the clinical response, and reevaluate periodically. Increases in dialysis or ultrafiltration time and/or frequency may facilitate volume removal. Atrial natriuretic peptide measurements indicate that a substantial fraction of patients with dialysis-refractory hypertension are not at their "true dry weight."[73]

Changing the administration of rHuEPO from the intravenous to the subcutaneous route has been associated with improved blood pressure control in hypertensive dialysis patients.[74]

Cardiac Arrhythmias

Intradialytic atrial and ventricular arrhythmias are common in HD patients, and the etiology is often multifactorial. Frequently encountered underlying conditions include ischemic or hypertensive heart disease, left ventricular hypertrophy and/or dysfunction, uremic pericarditis, silent myocardial ischemia, and conduction system calcification.[75–78] In addition, acute and chronic alterations in fluid, electrolyte, and acid/base homeostasis, may enhance the arrhythmogenic properties of digitalis preparations, antiarrhythmic and other drugs,[76] or simply increase myocardial oxygen delivery or consumption, such as in intradialytic hypotension or volume overload, respectively.

Measures to prevent arrhythmias include the use of bicarbonate dialysate and careful attention to dialysate potassium and calcium levels. Use of zero potassium dialysate should be discouraged due to arrhythmogenic potential, and potassium modeling may be useful.[79] In patients on digitalis, intracellular potassium shifts during dialysis should be minimized. Serum digoxin levels should be regularly monitored and the need for the drug regularly reassessed. Dialysate calcium levels of 3.5 mEq/L have been associated with cardiac ectopy.[80] By contrast, a calcium dialysate of 2.5 mEq/L has been associated with a prolonged QT interval.[81] QT dispersion, a measure of the variation in QT interval length on a standard 12-lead electrocardiogram, appears to reflect on the inhomogeneity in ventricle repolarization and has been used to predict risk of malignant cardiac arrhythmia. In HD patients, QT dispersion correlates with left ventricular hypertrophy, and mass and has been shown to improve following kidney transplantation.[82,83]

Similar to the general population, HD patients who develop atrial fibrillation have an increased risk for thromboembolic complications and may benefit from anticoagulation.[84]

Sudden Death

Based on data from the United States Renal Data System, 42% of dialysis patient deaths were documented as sudden or cardiac in origin, with 22% of deaths related to cardiac arrests and arrhythmia.[85] An excess mortality (approximately 20% of all deaths occurring per week) was found on Mondays for patients dialyzing on Mondays, Wednesdays, and Fridays and similarly on Tuesdays for patients dialyzing on Tuesdays, Thursdays, and Saturdays. No excess mortality on a particular day of the week was found in patients on peritoneal dialysis. These observational studies suggest that the cause of death may be due to the discontinuous nature of HD.[85] Elevations of cardiac troponin T[86] and elevations of serum phosphate and calcium phosphate product[87] have also been associated with an increased risk of death in dialysis patients.

Patients who sustain a cardiac arrest in the dialysis facility tend to be older and are more likely to have diabetes mellitus and a dialysis catheter for vascular access. They also tend to have had a recent hospitalization and often experience a blood pressure drop prior to the cardiac arrest.[88] There has been particular interest in the occurrence of ventricular ectopic activity in HD patients and risk factors such as age, left ventricular hypertrophy or dysfunction, and electrolyte disturbances have been entertained. A clear relationship to cardiovascular outcomes, however, has not been shown to date.

Considering that a variety of psychotropic drugs have been linked to reports of iatrogenic prolongation of the QT interval, cardiac arrhythmia, and sudden death in the general population,[89] a thorough drug history is warranted when investigating sudden cardiac arrest. This is critical because

numerous psychotropic drugs that enter the market may not undergo thorough post-marketing pharmacokinetic studies in dialysis patients.

In the acute management of intradialytic cardiac arrest, other catastrophic intradialytic events need to be ruled out. The prompt recognition and treatment of life-threatening hyperkalemia and the identification and correction of technical errors, such as air embolism, unsafe dialysate composition, overheated dialysate, line disconnection, or sterilant in the dialyzer have to be sought and ruled out. Air in the dialysate, grossly hemolyzed blood, and hemorrhage due to line disconnection may be immediately detected. However, if no obvious cause is identifiable, blood should not be returned to the patient, particularly if the arrest occurred immediately upon initiation of dialysis. Complaints of burning at the access site prior to arrest might indicate an exposure to formaldehyde. If the event occurred during dialysis and a problem with dialysate composition is unlikely, blood may be returned to the patient, blood and dialysate samples should be immediately sent for electrolyte analysis, the dialyzer and bloodlines should be saved for later analysis, and the dialysis machine should be replaced until all of its safety features have been thoroughly evaluated for possible malfunction, which will be discussed later. The management of cardiopulmonary arrest during dialysis should follow the guidelines for cardiopulmonary resuscitation.

Dialysis-Associated Steal Syndrome (DASS)

While the construction of an arteriovenous fistula or graft for HD access frequently results in reduction of blood flow to the hand,[90] clinically significant or symptomatic ischemia is much more infrequent. Once it becomes symptomatic, however, it can lead to critical limb ischemia and amputation, particularly in patients with peripheral vascular disease and/or diabetes mellitus.[91–93] Fistulas or grafts are classified as small, if their diameter is less than 75% of the diameter of the feeding artery, and large, if they are greater than 75%. Blood flow in the artery located distal to a small fistula/graft remains orthodirectional, whereas larger fistulas/grafts cause retrograde flow in the distal artery, thus leading to a steal syndrome.[94] DASS has been reported in 1% and 6% of patients with radiocephalic fistulas and grafts, respectively.[95] Symptoms of numbness, pain, and weakness of the hand may appear or worsen during HD, and clinical findings include coolness of the distal arm, diminished pulses, acrocyanosis, and, rarely, gangrene. Symptomatic DASS should be differentiated from other causes of painful limbs, including dialysis-associated muscle cramps, coexistent polyneuropathy, and entrapment mononeuropathies, such as the carpal tunnel syndrome associated with dialysis-related amyloidosis. The syndrome of acute ischemic monomelic mononeuropathy following the creation of an arm access has been described,[92] and rapidly progressing acral gangrene may also be caused by calciphylaxis.[96]

The evaluation of a painful hand includes pulse oximetry,[97] plethysmography,[95] doppler flows, and arteriography.[92] The treatment of DASS depends on its clinical severity and the anatomy of the access. The simplest and most effective treatment is ligation of the venous outflow of the fistula/graft.[98] However, this procedure results in the elimination of a site for vascular access and the immediate need to construct another. Ipsilateral distal revascularization-interval ligation[91] is a surgical treatment that preserves vascular access patency and relieves clinical steal symptoms in about 90% of patients.[99] Narrowing or "banding" of the fistula/graft to reduce flow[100] can also be used. Intraoperative digital plethysmography[95] or duplex sonography[101] may be useful for an early diagnosis or for intraoperative guidance in the correction of DASS. Percutaneous luminal angioplasty or laser recanalization is reserved for patients with inflow or outflow arterial disease.[92,102]

A different DASS that may be of clinical significance was recently reported in dialysis patients with an arteriovenous fistula who received myocardial revascularization with an ipsilateral mammary artery bypass graft. These patients developed a significant reduction in coronary bypass blood flows and myocardial perfusion that was manifest during dialysis.[103]

NEUROLOGIC COMPLICATIONS

Muscle Cramps

Prolonged involuntary muscle contractions or cramps that occur late in HD and typically involve the legs are the most common acute neuromuscular complications observed during dialysis. They occur in 5% to 20% of treatments[104] and frequently lead to premature discontinuation of dialysis. Electromyography performed during HD demonstrates tonic muscle electrical activity, steadily increasing throughout dialysis in those who develop cramps, as opposed to a steady decline in those who do not.[105] Furthermore, a subset of patients have elevated predialysis serum creatine phosphokinase levels during periods of cramping.[106]

The pathogenesis of intradialytic cramps is unknown. Plasma volume contraction and progressive hypoosmolality induced by HD are the two most important predisposing factors.[107] Hypomagnesemia, L-carnitine, and vitamin C and E deficiencies have also been incriminated.

The acute management of cramps is directed at increasing the plasma osmolality. Parenteral infusion of 23.5% hypertonic saline (15–20 mL), 25% mannitol (50–100 mL), or 50% dextrose in water (25–50 mL) has been shown to be equally effective.[108] Dextrose in water is preferred because compared to the other agents, it neither causes flushing during infusion nor leads to increased thirst, interdialytic fluid intake and, therefore, fluid overload, but it may cause transient hyperglycemia. The use of midodrine may reduce cramps in patients with concomitant symptomatic intradialytic hypotension.[109]

Preventive measures include dietary counseling to reduce excessive interdialytic weight gains. In patients without clinical signs of fluid overload, it is reasonable to increase the dry weight by 0.5 kg and observe the clinical response. In those patients who do not respond to the above measures, 5 mg of enalapril twice weekly has been shown to be effective, presumably by inhibiting angiotensin II-mediated thirst.[110] Oral quinine sulfate (325 mg) at the initiation of HD has been shown to significantly reduce the incidence of muscle cramps.[111] However, quinine sulfate is currently not approved as an over-the-counter product for the prevention of cramps and is only available by prescription.[112] The association of quinine with the hemolytic uremic syndrome and the lack

of the U.S. Food and Drug Administration's (FDA) approval, however, should discourage its use. The use of sodium gradient HD is effective in minimizing intradialytic hypoosmolality and preventing hypotension. Different sodium modeling strategies, such as starting from a dialysate sodium concentration of 145 to 155 mEq/L and decreasing linearly exponentially or step-wise to 135 to 140 mEq/L,[107,113] have yielded similar clinical results.[114] The use of an intradialytic blood volume ultrafiltration feedback control system has been associated with a lower incidence of cramps.[115] Finally, stretching exercises during dialysis, targeting the affected muscle groups may be beneficial.[113] Both L-carnitine[116] as well as creatine monohydrate[117] are effective pharmacotherapies in decreasing the frequency of muscle cramps.

Headache

Both historic and contemporary data indicate that dialysis-associated headache is common and occurs in about 60% to 70% of patients.[118,119] The symptoms may resemble migraines, tension headaches, or a combination of both.

The etiology of dialysis headache is unknown. It may be a subtle manifestation of the dialysis disequilibrium syndrome (DDS) and, in the past, may have been related to the use of acetate dialysate. The incidence of headaches seems to be lower with reused than with new dialyzers, with longer than with shorter conventional dialysis treatments, with dialysate containing glucose than with a glucose-free dialysate, and in patients undergoing short daily hemodialysis.[120] Furthermore, headaches may be a manifestation of caffeine withdrawal, caused by an acute intradialytic drop in blood caffeine levels in heavy coffee drinkers.[113]

The treatment of dialysis headache consists of oral analgesics (acetaminophen). Preventive measures include a reduction in the blood flow rate during the early part of dialysis. Coffee ingestion during dialysis may also be beneficial.

Restless Legs Syndrome (RLS)

With 20% to 40% prevalence in patients with end-stage renal disease, restless legs syndrome (RLS) is much more common than in the general population (5%).[121] It has been associated with premature discontinuation of dialysis ("sign-offs").[122] RLS is characterized by deep paresthesias, drawing and crawling sensations in the calves and legs, occasionally bordering on pain at the same site, which occur exclusively during rest and inactive seated or recumbent wakefulness.[123] Movement of the legs yields prompt relief of the symptoms, thus RLS may be responsible for premature discontinuation of a dialysis treatment. Insomnia, anxiety, and mild depression are frequent accompanying symptoms, whereas neurologic and electromyographic testing is generally unremarkable. RLS has to be differentiated from peripheral neuropathy in which paresthesias are constant and not relieved by activity. The exact cause of RLS is unknown but uremic toxins have been implied in its etiology. RLS and insomnia are frequently encountered in severely uremic patients and are relieved within a few weeks of initiating dialysis therapy.[123] RLS symptoms also improve after kidney transplantation.[124] Iron deficiency anemia, vascular insufficiency, chronic lung disease, and caffeine abuse have all been implicated in the pathogenesis of this syndrome.[123]

Short acting benzodiazepines, opiates, and carbamazepine have all been reported to be effective therapies but have the potential for tolerance and abuse. A small randomized, controlled trial recently reported on the effectiveness of gabapentin 200 to 300 mg given after dialysis.[125] Levodopa/carbidopa has also been used with some success.[121] A nonpharmacologic approach with transcutaneous electric nerve stimulation is reserved for refractory cases, but experience is limited.[123] In a nondialysis population, pramipexole, a dopamine receptor agonist, has also been associated with good outcomes.[126]

Dialysis Disequilibrium Syndrome (DDS)

DDS still represents a clinical problem in patients with acute renal failure and end-stage renal disease (ESRD) initiating HD, particularly with use of large surface area, high-flux dialyzers and shorter dialysis time. Risk factors include young age, severe azotemia, low dialysate sodium concentration, and preexisting neurologic disorders, such as recent stroke, head trauma, subdural hematoma, or malignant hypertension.[127] Use of dialysis machines with volumetric control, bicarbonate dialysate, sodium modeling, and earlier initiation of renal replacement therapy has reduced the incidence of DDS.

Minor symptoms include restlessness, headache, nausea, vomiting, blurred vision, muscle twitching, disorientation, tremor, and hypertension. But major symptoms including obtundation, seizures, coma, cardiac arrhythmias, or death may occur. DDS usually occurs towards the end of dialysis and may be delayed by up to 24 hours. This syndrome is usually self-limited but full recovery may take several days. DDS is a clinical diagnosis, and electroencephalography (EEG) is usually nonspecific, whereas cerebral edema is a consistent finding on computerized tomographic scanning (CT-scan). The differential diagnosis includes intracranial hemorrhage, ischemic or hemorrhagic stroke, and Wernicke's encephalopathy.[128]

The pathogenesis of DDS, although not fully understood, is largely thought to be due to cerebral edema.[2] The classic hypothesis includes the development of a transient osmotic disequilibrium due to more rapid removal of urea from blood than from cerebrospinal fluid (CSF), leading to an osmotic disequilibrium and subsequent cerebral edema. An alternative hypothesis is the development of paradoxical CSF acidosis during HD, which is aborted by slower dialysis.[127] Other implemented factors include intracerebral accumulation of endogenous osmotic solutes such as inositol, glutamine, and glutamate.[2]

Preventive measures include shorter and more frequent dialysis using small surface area dialyzers, hypernatric dialysate, reduction in blood flow, and individual intradialytic sodium modeling. Continuous mannitol infusions during dialysis or the prophylactic use of anticonvulsants are not recommended.

Seizures

HD-associated seizures are typically generalized and easily controlled. They occur in less than 10% of chronically dialyzed patients and may be more frequent in acutely dialyzed patients.[129] Focal neurologic symptoms indicate a localized neurologic disease such as an intracranial hemorrhage and warrant further evaluation. Other causes for seizures include

DDS, uremic encephalopathy, acute aluminum intoxication, hypertensive encephalopathy, hypoglycemia, alcohol withdrawal, cerebral anoxia due to sustained intradialytic hypotension (i.e., from cardiac arrhythmias, hypersensitivity reaction, sepsis, or hemorrhage), hyperosmolality due to hypernatremia, hypocalcemia, use of epileptogenic drugs (i.e., theophylline, meperidine, β-lactams), and brain retention of contrast. Recombinant Human Erythropoietin (rHuEPO) therapy has also been implicated as a cause for seizures during dialysis, typically in patients with preexisting hypertension.

Treatment of established seizures requires cessation of dialysis, maintenance of airway patency, and investigation for metabolic abnormalities. Intravenous diazepam or clonazepam, and phenytoin may be required. Intravenous administration of 50% dextrose in water should be administered if hypoglycemia is suspected. In children with HD-associated seizures, the prophylactic use of diazepam appears to be more effective than phenobarbital.[130]

Acute Aluminum Neurotoxicity

Acute aluminum neurotoxicity may occur because of aluminum contamination of dialysate following administration of desferrioxamine resulting in higher aluminum levels. It may also follow the concomitant administration of oral aluminum-based phosphate binders and citrate compounds, which enhance aluminum absorption in the small intestine and increase solubility and uptake of aluminum by the central nervous system.[131] The acute onset of this syndrome comprises agitation, confusion, seizures, myoclonic jerks, coma, and death. Plasma aluminum levels are typically greater than 500 μg/L, and highly suggestive EEG findings include multifocal bursts of slow or delta wave activity and frequent spikes. The CT-scan is usually normal. Acute aluminum neurotoxicity of adult patients leads to death in most of the patients despite chelation therapy. The administration of low-dose (5 mg/kg) desferrioxamine 5 hours prior to the start of HD has been shown to be uneventful.[132]

The classical aluminum intoxication syndrome has a more chronic course characterized by "dialysis dementia," osteomalacia, microcytic anemia, and elevated plasma aluminum levels.

HEMATOLOGIC COMPLICATIONS

Leukopenia

Intradialytic leukopenia has been one of the earliest indices of membrane bioincompatibility. The onset is usually rapid and peaks at 10 to 15 minutes.[133,134] Neutrophils and other granulocytes are primarily affected. The leukocyte count usually returns to normal by the end of dialysis and may exceed the predialysis values. This rebound leukocytosis has been ascribed in part to demargination of leukocytes from the vascular wall as well as from a recruitment of neutrophils from the bone marrow following an increase in circulating levels of granulocyte colony-stimulating factor.[135] Although granulocytes are readily seen on the dialyzer membrane surface under microscopy,[136,137] the disappearance of these cells from the circulation is primarily due to sequestration in the pulmonary vasculature. Pulmonary leukosequestration has been demonstrated using radiolabeled cells in clinical studies.[138]

Binding of C5a to neutrophil cell-surface specific receptors is the primary underlying mechanism, and the degree of complement activation correlates closely with the degree of leukopenia.[139–141]

Intradialytic Hemolysis

Hemolysis associated with hemodialysis is rare (Table 22–4) and is most often caused by chemical contaminants, hypotonic or overheated dialysate,[142] or kink or manufacturing defects of the bloodline tubing.[142,143] Oxidative stress may also incease the RBC membrane fragility through lipid peroxidation, resulting in hemolysis.[144]

Whereas arterial limb negative pump pressures of less than −350 mmHg can cause mild hemolysis in a clinical setting,[145] in experimental studies, pressures as low as −720 mmHg failed to cause hemolysis.[146] The use of smaller gauge cannulas has been associated with significant hemolysis.[147] Other mechanical factors within the circuitry that may result in hemolysis include the varying geometry of the dialyzer inlet chamber.[148]

The most common chemical contaminants that cause hemolysis are chloramines, monochloramines, dichloramines, and trichloramines, which form when chlorine and ammonium are added to the municipal water supply as disinfectants.[149] These compounds can cause oxidative injury to RBC, resulting in methemoglobinemia and acute hemolysis.[150] Copper contamination leads to similar oxidative stress. Deionization and reverse osmosis do not effectively remove these contaminants. Adsorption through granular activated carbon[151] or neutralization of the dialysis fluid with ascorbic acid, a reducing compound, can prevent complications from chloramine.[150] The AAMI guidelines indicate a maximum chloramine content of 0.1 mg/L in dialysis water, compared with the 4 mg/L maximum concentration allowed in drinking water, according to the Environmental Protection Agency (EPA).[152]

Nitrate and nitrite intoxication can occur in home HD patients who use well water contaminated with urine from domesticated animals, resulting in methemoglobinemia and hemolysis.[153] The AAMI guidelines recommend a maximum nitrate concentration of 2 mg/L for dialysis water, compared with the 10 mg/L maximum concentration allowed in drinking water.[152]

The retention of formaldehyde and hydrogen peroxide during dialyzer reprocessing has been associated with hemolysis.[154,155] Formaldehyde is a potent reducing agent that impairs RBC metabolism by inhibiting glycolysis[154] and may act as a hapten that induces hemolysis by formaldehyde-induced anti-N-like cold agglutinins.[156]

Finally, drug-induced hemolysis, particularly in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, microangiopathic hemolytic anemia (e.g., quinine sulfate), hypophosphatemia, hypersplenism, and insufficient dialysis are rare causes that need to be considered.[150]

Patients with methemoglobinemia usually complain of nausea, vomiting, hypotension, and cyanosis, and oxygen therapy does not improve black-colored blood present in the extracorporeal circuit. Copper contamination should be suspected in the presence of skin flushing, abdominal pain, and/or diarrhea.

The diagnosis of acute hemolysis is self-evident when grossly translucent hemolyzed blood is observed in the

Table 22–4 Causes of Intradialytic Hemolysis

Mechanisms of Injury	Etiologies
Traumatic fragmentation	Dialyzer roller pump
	Excessive suction at arterial access site
	Single-needle dialysis
	High blood flow through a small needle
	Kinked dialysis catheter/tubing
	Right atrial subclavian catheter
Thermal	Overheated dialysate > 47°C
	Dialysate <35°C, activation of anti-N cold agglutinin (formaldehyde)
Osmolar	Hypoosmolar dialysate
	Hyperosmolar dialysate
Oxidative injury	Chloramines
	Nitrite/nitrate
	Copper
	Drugs (quinine sulfate)
Reducing injury	Formaldehyde
Interference with cellular thiols	Copper
Interference with iron uptake	Aluminum
Inhibition of RBC glycolysis	Formaldehyde
G6PD deficiency	Exacerbated by oxidants (quinine sulfate)
2,3-DPG deficiency	Hypophosphatemia
Drug-induced microangiopathy	Quinine sulfate

G6PD, Glucose-6-phosphate dehydrogenase; *2,3-DPG*, 2,3-diphosphoglycerate.

tubing. Evaluation should include reticulocyte count, haptoglobin, lactate dehydrogenase, blood smear for schistocytes or Heinz bodies, Coombs' test, and measurement of methemoglobin. Bone marrow examination may occasionally be indicated. More importantly, analysis of tap water for chloramines and metal contaminants and thorough analysis of the dialysis procedure for clues of increased blood turbulence and mechanical RBC injury are recommended.

Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) has increasingly been recognized as an important clinical problem in dialysis patients. Type-I HIT is characterized by the development of mild thrombocytopenia, where the platelet count rarely drops to less than 100,000/μL. Heparin can be usually continued and the thrombocytopenia resolves spontaneously. By contrast, type-II HIT results in more severe thrombocytopenia, is IgG-antibody mediated,[157] and is characterized by arterial and venous thromboses and dialysis circuit clotting[158] as well as a hemorrhagic propensity. The antibodies are directed against the complex of heparin and platelet factor IV.[159,160] Among chronic dialysis patients the prevalence of HIT is around 4%.[159,161]

The diagnosis of type-II HIT is complex and depends on multiple criteria, including the degree, rapidity and time of onset of thrombocytopenia, the presence of thrombosis, and resolution of the symptoms after cessation of heparin.[159,160] The presence of heparin antibodies only acts as an adjunct to the diagnosis.

The treatment of this syndrome includes complete withdrawal of all heparin products, including flush solutions and catheter locks, the use of heparinoids such as argatroban or danaparoid,[162] or direct thrombin inhibitors such as lepirudin, a biosynthetic hirudin analogue. Low molecular weight heparin is contraindicated. Lepirudin can be used as a 0.1 to 0.2 mg/kg IV bolus administered 5 minutes before starting HD, with an aPTT goal 1-hour into dialysis of 1.5 to 2.0 times normal.[163,164] Among patients with HIT who have indwelling dialysis catheters, at the end of dialysis, the venous and arterial ports of the catheter can be filled with lepirudin (1 mg/mL), according to the volumes indicated on the catheter.[165]

Transient thrombocytopenia may also result from blood-membrane interactions and reaches a nadir 1 hour after starting dialysis, with a platelet count declining to less than 100,000/mm^3.[140] Thrombocytopenia may also be secondary to other drugs used during dialysis such as vancomycin, quinine sulfate, or desferrioxamine.[166,167,168]

Hemorrhage

Bleeding complications are commonly related to anticoagulation. Heparin confounds the uremic bleeding tendency, which is due to platelet dysfunction, abnormal platelet-vessel wall interaction, alteration of blood rheology and platelet adhesion secondary to anemia, and abnormal production of nitric oxide.[169,170] An increased incidence of spontaneous bleeding episodes has been reported in HD patients, particularly bleeding at specific sites such as gastrointestinal arteriovenous malformation, colonic ulcera of the Dieulafoy-type, subdural hematoma, retroperitoneal bleeding, uremic hemopericardium, hemorrhagic pleural effusion, hemoptysis, subcapsular hepatic hematoma, ocular anterior chamber hemorrhage, and skin hemorrhages, including petechiasis, ecchymosis, and subungual splinter hemorrhages.[2,77,171–173] Rupture of native, cystically transformed kidneys with retroperitoneal hematoma formation has also been described.[174]

Despite its limitations, the bleeding time is the best indicator of hemorrhagic tendency in dialysis patients. Local treatment of the hemorrhage and treatment/reversal of uremic platelet dysfunction are both needed. Strategies to achieve improvement in platelet function include an increase in rHuEPO dose or RBC transfusions to achieve a hematocrit greater than 30% in order to improve rheologic platelets-vessel wall interactions, intravenous conjugated estrogens at 0.6 mg/kg/day for 5 consecutive days, intravenous/subcutaneous 1-deamino-8-D-arginine vasopressin (DDAVP) at 0.3 μg/kg over 15 to 30 minutes, and/or intravenous infusion of cryoprecipitate. For patients experiencing severe bleeding, particularly when related to anticoagulation, it is advisable to consider heparin-free dialysis, using normal saline flushes every 15 to 30 minutes with ultrafiltration adjustments,[175] regional heparin or citrate anticoagulation,[176] and heparin modeling or prostacyclin.[177] It is important to note that heparin free dialysis may cause a stimulation of the

coagulation system, increased fibrinogen consumption, and accelerated dialyzer hollow-fiber clotting.[178] The use of low-molecular weight heparin in HD has recently been proposed due to its convenient dosage regimen and lower impact on blood lipid levels, although bleeding complications are still possible.[179] Similarly, the use of lepirudin in dialysis patients with type-II HIT has also been associated with bleeding complications.[180]

In patients scheduled to undergo elective surgery or invasive procedures, it is recommended that aspirin be stopped a week earlier, the dose of anticoagulants be reduced to minimum and hematocrit maintained above 30%. In some cases, DDAVP and/or estrogens may also be required.

PULMONARY COMPLICATIONS

Hypoxemia

Transient hypoxemia during HD occurs in up to 90% of patients and is defined by a drop in arterial PaO_2 by 5 to 30 mm Hg, which reaches a nadir between 30 and 60 minutes, and returns to normal within 60 to 120 minutes following discontinuation of dialysis.[181] This mild reduction becomes clinically significant only when significant structural cardiopulmonary disease is present. The use of supplemental oxygen during dialysis improves arterial oxygen tension, but neither carbon dioxide tension nor breathing patterns are altered by this intervention.[182] Transient hypoxia is more common when dialyzers with high complement activating potential (unsubstituted cellulose) and acetate dialysate are used.[183,184] This may be mediated by complement activation following blood exposure to the free hydroxyl groups of cellulose membranes, with subsequent margination of leukocytes in the pulmonary vasculature.[2] Acetate dialysate may lead to loss of carbon dioxide in the dialyzer and, thus, result in hypocapnia and consequent compensatory hypoventilation. Use of bicarbonate dialysate (>35 mEq/L) may lead to hypoventilation and hypoxia by way of metabolic alkalosis.[2]

For diagnosing hypoxia during dialysis, arterial bloodline oxygen tension accurately correlates with systemic arterial blood and can conveniently be used in patients with an arteriovenous fistula or graft.[185]

Substituting acetate with bicarbonate dialysate at a concentration of less than 37 mEq/L, intradialytic oxygen supplementation, particularly in high risk patients, maintaining optimal hematocrit values to maximize blood's oxygen carrying capacity and sequential ultrafiltration followed by HD, particularly in patients with fluid overload can ameliorate dialysis-associated hypoxemia. In addition, the use of dialyzers with lower complement activating potential, such as synthetic, substituted cellulose, or reprocessed unsubstituted cellulose dialyzers could further reduce the likelihood of hypoxemia during HD. Finally, the use of cold dialysate may reduce intradialytic hypoxic episodes.[186]

TECHNICAL MALFUNCTIONS

Air Embolism

The incidence of air embolism, a potentially fatal complication, has decreased significantly due to improvements in dialysis machine safety monitors. The segment of the extracorporeal circuit that is most vulnerable to air entry is the pre-pump tubing segment, where significant subatmospheric pressures of up to 250 mm Hg can occur. Air can also originate from intravenous infusions circuits, especially with glass bottled intravenous solutions, air bubbles from the dialysate, and central venous catheters.[187] Furthermore, the use of high blood flow rates may allow rapid entry of large volumes of air despite small leaks.

Clinical manifestations depend on the volume of air introduced, the site of introduction, the patient's position, and the speed at which air is introduced.[188] The volume of air required to produce clinical manifestations varies due to above factors, and is partly dependent on preexisting cardiovascular or pulmonary disease. Microbubbles of air introduced at a slow rate dissolve in the blood and are better tolerated than macrobubbles. In the sitting position, air entry through a peripheral vein may bypass the heart and cause emboli into the cerebral circulation.[189] The acute onset of seizures and coma in the absence of precedent symptoms, such as chest pain or dyspnea, is highly suggestive of air embolism. If the patient is supine, air introduced through a central venous line will be trapped in the right ventricle where it forms foam, interfering with cardiac output and, if large enough, leads to obstructive shock. Dissemination of microemboli into the pulmonary vasculature occurs. In this event, dyspnea, dry cough, chest tightness, or respiratory arrest can also occur. Further passage of air across the pulmonary capillary bed can lead to embolization to a major cerebral or coronary artery. Foam may be visible in the extracorporeal tubing, and cardiac auscultation reveals a peculiar churning sound. In the Trendelenburg's position, air emboli migrate to the lower extremity venous circulation, resulting in ischemia, due to increased outflow resistance. Clinical manifestations include acrocyanosis, paresthesia and pain, and, unless peripheral vascular disease coexists, the outcome is usually favorable.

Once the diagnosis is suspected, the first step is to clamp the venous bloodline and stop the blood pump. For right heart air emboli, the patient is immediately placed in a recumbent position on the left side with the chest and head tilted downward. Cardiorespiratory support includes the administration of high-flow oxygen and endotracheal intubation and mechanical ventilation as needed. Aspiration of air from the ventricle by a percutaneously inserted needle or right atrial dialysis catheter can be attempted. If available, consideration should be given to hyperbaric oxygenation, where the patient undergoes decompression at a rate that allows the dissolved air to be expired through the lungs without coming out of solution.[190,191]

Preventive measures depend primarily on dialysis machines equipped with venous air bubble traps and foam detectors located just distal to the dialyzer and venous pressure monitor at the venous end. The detector is attached to a relay switch that simultaneously activates an alarm, shuts off the blood pump, and clamps the venous bloodline if air is detected. Therefore, dialysis should never be performed in the presence of an inoperative air detection alarm system. Glass bottles containing intravenous solutions should be avoided since they create vacuum effects that can permit air entry into the extracorporeal system. Further, dialysis catheters should be aspirated for blood return and flushed with saline prior to connection. Dialyzers rinsing with saline should fill up all

compartments and remove air bubbles. Finally, in order to remove dissolved air, heating and degassing of dialysis water, particularly in winter months, is accomplished by exposing heated water (34°–39°C) to high negative pressure during the purification process.[192]

Blood Loss

Blood loss during HD can result from malfunction of the dialysis circuitry or internal or external hemorrhage of the patient that is caused or worsened by anticoagulation given during dialysis. The latter has been discussed previously. Technical complications are arterial or venous needle disengagement, bloodline disconnection, femoral or central line dialysis catheter perforation or dislodgment, or rupture of a dialysis membrane with or without malfunction of the blood leak detector. Clinical findings include hypotension, loss of consciousness, and cardiac arrest, sometimes within minutes of starting HD.[193]

Blood loss can also occur following traumatic insertion of a dialysis catheter that results in a rapidly expanding, painful hematoma. Intrapericardial blood loss can lead to chest, shoulder, or neck pain[194]; back, flank, groin, or lower abdominal quadrant pain/distention can result from retroperitoneal bleeding.[195] Management of acute blood loss includes the immediate discontinuation of HD, pressure application for local hemostasis, hemodynamic support, oxygen administration, and blood transfusion may be needed for severe blood loss.

Incorrect Dialysate Composition

Incorrect dialysate composition occurs as a result of technical or human errors. There are two types of dialysate solution delivery systems. With central delivery, the solution used for the whole dialysis unit is produced by one machine by mixing liquid concentrate with purified water and offers the advantage of reduced equipment and labor cost. With the individual system, each dialysis machine proportions its own dialysate liquid concentrate with purified water, permitting the modification of dialysate composition for a given patient. Because the primary solutes constituting the dialysate are electrolytes, the degree of dialysate concentration will be reflected by its electrical conductivity. Therefore, proper proportioning of concentrate-to-water can be achieved by a meter, which continuously measures the conductivity of the dialysate solution as it is being fed to the dialyzer. Life-threatening electrolyte and acid-base abnormalities are avoidable if the conductivity alarm is functioning properly and the alarm limits are set correctly. However, in dialysis machines that are equipped with conductivity-controlled mixing systems, the system automatically changes the mixing ratio of the concentrates until the dialysate solution conductivity falls within the set limits. This may inadvertently lead to dialysate without any bicarbonate, with apparently acceptable conductivity. Therefore, if conductivity-controlled systems are used, it is safer to also check the dialysate pH prior to dialysis. Conductivity monitors can fail or can be improperly adjusted due to human error. However, it is important to add human monitoring of dialysate composition before every treatment, whenever a machine has been sterilized, moved about, and whenever a new concentrate is used. Furthermore, many nonstandardized solutions are available, some of which may be used with an inappropriate proportioning system. Therefore, it is essential that the supplies match the machine proportioning ratio for which they were prepared to obtain the appropriate final dialysate composition.

Dysnatremias

Since disturbances in renal water handling cannot occur in anephric dialysis patients, the etiology and management of dysnatremias is limited to factors related to dialysis and interdialytic fluid and electrolyte intake.

Hypernatremia

Hypernatremia can result from a faulty dialysate concentrate composition or an incorrect concentrate to water ratio, and dysfunction of conductivity monitors or alarms.[52] This results in water shifts from the intracellular to the extracellular fluid compartment and leads to cell shrinking. Symptoms include profound thirst, headache, nausea and vomiting, seizures, coma, and death.[171] Aggressive treatment is mandatory, because mortality from acute severe hypernatremia (Na > 160 mEq/L) is greater than 70%.[196] Management includes cessation of dialysis, hospitalization, and infusion of 5% dextrose in water and HD with a different dialysis machine, particularly if conductivity monitoring malfunction is suspected. The dialysate sodium level should be 2 mEq/L lower than the plasma, and isotonic saline should be concurrently infused. Dialysis against a dialysate sodium level that is 3 to 5 mEq/L lower than plasma may increase the risk of disequilibrium. Ultrafiltration with equal volume replacement with normal saline is another option.

Hyponatremia

Failure to add concentrate, inadequate concentrate/water ratio, and conductivity monitor or alarm malfunction can cause hyponatremia. Hyponatremia can also occur during the course of dialysis with a proportioning system, if the concentrate container runs dry and the conductivity set limits are inappropriate. Acute hypoosmolality causes hemolysis with hyperkalemia and hemodilution of all plasma constituents due to massive transfer of water from dialysate in the blood, leading to water intoxication.[197] Symptoms include restlessness, anxiety, pain in the vein injected with the hypotonic hemolyzed blood, chest pain, headache, nausea, and occasional severe abdominal/lumbar cramps.[171] Pallor, vomiting, and seizures may be observed. Treatment of dialysis-induced hypoosmolality consists of clamping the bloodlines and discarding the hemolyzed blood in the extracorporeal circuit. High-flow oxygen and cardiac monitoring because of hyperkalemia and potential myocardial injury are imperative.[171] Dialysis should be restarted without delay, with a new batch of dialysate, new dialyzer, and low dialysate potassium.[171] Anticonvulsants are indicated for seizures, and blood transfusions may be needed for severe anemia.

The susceptibility of dialysis patients to complications due to rapid correction of hyponatremia by dialysis against a high sodium dialysate is poorly understood. Transient urea disequilibrium has been implied as a protective factor against

cerebral water loss during rapid correction of extracellular osmolality during dialysis.[198] Even in the most acute symptomatic hyponatremic patient, a cautious approach is warranted, where a correction of sodium concentration by no more than 1 to 2 mEq/L/hr should be achieved.[199] Continuous renal replacement therapies have been used successfully for such a gradual correction of serum osmolality.[200]

Dyskalemias

Life-threatening hyperkalemia is not a common problem in dialysis patients and, if it occurs, is often caused by inadequate dialysis or dietary indiscretion. In healthy subjects, over 90% of the daily dietary potassium load is usually excreted by the kidneys. Anuric dialysis patients are able to excrete significant amounts of potassium via extrarenal potassium excretion, primarily in the colon. This mode of excretion depends on the stool volume and is minimal if constipation exists.[201] The use of fludrocortisone, a mineralocorticoid, has been proposed for enhancing colonic potassium secretion.[202] Despite a typically low dialysate potassium concentration of 1 to 3 mEq/L, potassium removal is limited due to its large distribution in the intracellular compartment of over 90% of total body potassium. A quantitative study of potassium removal over 4 hours of dialysis with a 1 mEq/L dialysate potassium concentration in hyperkalemic (serum potassium level 5–6 mEq/L) patients resulted in a mean potassium removal of 107 mEq per treatment. However, the serum levels rose back to over 5 mEq/L after reaching a nadir of 3.5 mEq/L.[203] The findings confirm our current understanding of the kinetics of potassium removal by dialysis, which does not follow single pool kinetics due to the delayed release of intracellular potassium. This underscores the relative inefficiency of a high serum to dialysate potassium gradient and illustrates why the use of potassium-free dialysate should be discouraged. The latter may precipitate cardiac arrhythmias, reduce dialysis efficiency through arteriolar vasoconstriction and small solute compartmentalization and limit correction of acidosis, by impairing bicarbonate diffusion into the blood compartment.[204–206] Potassium modeling and longer HD treatments have been suggested to avoid severe rebound.[207] Finally, with regards to the effects of packed RBC (PRBC) transfusion on potassium balance, various studies suggest that the potassium load per unit of PRBC transfused is 5 to 7 mEq for units stored 14 and 21 days, respectively,[208] and therefore, intradialytic PRBC transfusion should not be discouraged.

Severe hypokalemia induced by HD can occur despite the use of dialysate potassium concentration higher than serum.[209] This is due to rapid correction of acidosis that leads to intracellular shift of potassium. Overall, unless significant losses as a result of vomiting, diarrhea, or nasogastric suction are present, hypokalemia is not generally considered to be a problem in HD patients. Patients with marginal total body potassium stores (due to gastrointestinal losses) and metabolic acidosis, however, are prone to life-threatening hypokalemia during HD, where intradialytic potassium losses combined with intracellular shifts due to correction of acidosis may acutely precipitate life-threatening muscle weakness or cardiac arrhythmias, particularly in patients treated with digoxin.

Acid-Base Disturbances

HD patients have an alkali requirement of 240 mEq/treatment, taking into account daily acid generation and intradialytic losses of organic anions, which are bicarbonate precursors.[210] The physiology of acid-base disturbances in anephric patients on dialysis differs from that in subjects with functioning kidneys and is primarily governed by dialysis.

Metabolic Acidosis

A decrease in serum bicarbonate of greater than 4 mEq/L suggests the presence of a new metabolic acidosis.[210] Although acute intradialytic metabolic acidosis can occur due to improper mixing of concentrates or failure of pH monitors,[211] other causes that need to be ruled out include diabetic or alcoholic ketoacidosis, lactic acidosis, toxic ingestions, increased protein catabolism, progressive loss of residual renal function, and dilutional acidosis.[210,212] A transient acidosis during the 1st hour of acetate dialysis because of intradialytic bicarbonate losses that have not yet been compensated for by the metabolism of acetate by muscle mitochondria[213] has been described.

The patients typically present with acute onset of hyperventilation during HD. Severe metabolic acidosis is treated by correcting the underlying cause and administering HD with appropriate dialysate concentrate. Although dialysate bicarbonate levels of 35 to 38 mEq/L are adequate in most circumstances, excessive correction of severe metabolic acidosis (bicarbonate < 10 mEq/L) may lead to paradoxical acidification of the CSF and increased lactic acid formation by tissues.[213]

Metabolic Alkalosis

In anephric patients, elimination of excess base does not occur and the high concentration of bicarbonate in standard dialysate usually maintains the alkalosis. However, with acetate dialysis, net alkali loss will occur when plasma bicarbonate is greater than 26 to 28 mEq/L.[214] The presence of metabolic alkalosis is suggested by a rise in plasma bicarbonate by 4 to 5 mEq/L from its usual value.[214] A blood gas may be warranted to assess the respiratory response. The most common cause of metabolic alkalosis in HD patients is hydrochloric acid loss as a result of vomiting or nasogastric suction and is usually seen in the intensive care unit setting or endogenous and exogenous sources of added alkali. Such alkali or alkali precursors include sodium bicarbonate, calcium carbonate or acetate, citrate (blood products), lemon consumption, alkalinizing agents, lactate (Ringer's solution), acetate (TPN solutions), and connection of the bicarbonate concentrate to the wrong port.[214,215] The combination of sodium polystyrene sulfonate (Kayexalate) and aluminum hydroxide can lead to absorption of alkali that is normally neutralized in the small intestine.[216] Usually, removal of the alkali source is sufficient, and H_2-receptor antagonist or gastric H^+/K^+ ATPase inhibitors may be successful if gastric acid loss is present. If dialytic support is required for the rapid correction of this acid-base disorder, the dialysate composition may be altered by replacing alkali with chloride,[217] substituting bicarbonate with acetate dialysate,[218] using acid dialysate,[219] or using hydrochloric acid infusion during dialysis with citrate buffer.[220] Conventional bicarbonate dialysis or

dialysis using lower dialysate bicarbonate levels (25–30 mEq/L) is probably as effective.[221]

Severe metabolic alkalosis due to HD is rare and may be due to error in dialysate concentrates,[222] reversed connection of bicarbonate and acid concentrate containers to the entry ports of the dialysis machine[223] or malfunction of the pH monitor. Furthermore, severe metabolic alkalosis can occur with regional citrate HD[224] and following continuous renal replacement therapies in the setting of acute renal failure.[225,226]

Respiratory Alkalosis

Due to the lack of a renal compensatory response,[214] acute respiratory acid-base disorders are more likely to cause mixed acid-base disorders that may be severe and life threatening.

During HD, despite losses of carbon dioxide into the dialysate, respiratory alkalosis does not occur.[227] However, anxiety, stroke, sepsis, and hepatic failure or pregnancy may be precipitating factors for hyperventilation and result in respiratory alkalosis. A hyperventilation syndrome has been described in a patient on continuous ambulatory peritoneal dialysis (CAPD), which disappeared once the patient was switched over to HD.[228]

Respiratory Acidosis

The concomitance of respiratory acidosis and renal failure is common in the intensive care unit setting. REDY sorbent dialysis is a dialysate regenerating system, requiring only 6 L of dialysate compared to 120 L for a standard 4-hour dialysis treatment.[229] The system contains a sorbent cartridge that has three different layers that participate in the detoxification process. Although it offers some advantages over HD, REDY sorbent dialysis can cause acute hypercapnia.[230] Indeed, during dialysate regeneration, the breakdown of urea by urease that occurs in the second layer generates NH_4^+ and HCO_3^-. The third layer consisting of zirconium phosphate is a cation exchanger that exchanges Na^+ and H^+ for NH_4^+. Hence, carbonic acid is formed when HCO_3^- combines with H^+.

Carbon dioxide is then usually eliminated by the lungs. However, the excess of carbon dioxide may be limited in patients with underlying pulmonary disease, resulting in hypercapnia and a superimposed or worsening respiratory acidosis.[229]

Last, despite the theoretic possibility of a decrease in respiratory drive due to bicarbonate supplementation during dialysis, a study of intubated patients with ARF who were undergoing HD showed that the decrease in respiratory drive correlated with the ultrafiltration volume rather than with the reversal of the metabolic acidosis.[231]

Chemical Contaminants

The "hard water syndrome" used to occur when untreated tap water containing high levels of dissolved minerals was used for dialysate preparation. It manifests an hour after start of dialysis and symptoms include nausea, vomiting, hypertension, extreme weakness and lethargy (due to hypercalcemia), and warm sensation to the skin (due to hypermagnesemia).[232] Acute pancreatitis may be observed.[233] Currently, the water used for dialysate preparation is treated with deionization and reverse osmosis to control levels of divalent cations and remove trace elements that may be present. However, in some rural areas, the mineral content of the water is very high, and the hard water syndrome can occur during home HD despite seemingly adequate pretreatment of the water source.[234] The diagnosis is confirmed by establishing elevated dialysate water calcium and magnesium levels. Treatment is supportive and dialysis should be stopped and restarted with properly treated water.

Metal contaminants that induce acute hemolysis include copper, zinc, and aluminum (see "Intradialytic Hemolysis"). Intoxications with other metals such as lead and nickel may also occur.[171] Fluoride is a trace element that may accumulate in HD patients and deposit in bone.[235,236] Its contribution to renal osteodystrophy, however, is unclear.

When dialysate water purification is based on deionizing (DI) systems utilizing ion exchange resins, fluoride contamination of dialysate can occur once deionizing columns are exhausted. Acute fluoride poisoning may follow, manifesting primarily by gastrointestinal symptoms and life-threatening hyperkalemia due to potassium channel blockade, leading to significant extracellular potassium leakage.[237] A case of acute fluoride poisoning that occurred in a dialysis unit in Illinois in 1993 was reported to the CDC.[13] DI systems were used during unit remodeling when the incident occurred. Periodic testing of dialysis water supply for fluoride content, maintenance of and familiarity of the health care team with deionizing systems are necessary to prevent these events.

Temperature Monitor Malfunction

Heating of the dialysate assists in the degassing and improves the mixing of water with dialysate concentrate. The internal controls of the thermostat are set up by the manufacturer to limit the dialysate temperature to 33° to 39°C. Malfunction of the thermostat in the dialysis machine can result in the production of excessively cool or hot dialysate. Accidental use of cool dialysate is not dangerous and has beneficial hemodynamic effects, although it may cause shivering and/or hypothermia. Overheated dialysate, especially when temperatures above 51°C are reached, can cause immediate hemolysis and life-threatening hyperkalemia.[171] Lower temperatures of 47° to 51°C may cause up to a 48-hour delay in the onset of hemolysis.[238]

If the dialysate temperature rises to 51°C, dialysis must be stopped immediately and the blood in the system discarded. The patient should be monitored and treated for hyperkalemia and transfused as necessary. Dialysis may be resumed to treat hyperkalemia and to cool the patient by using a dialysate temperature of 34°C. To prevent this potentially catastrophic complication, visual and audible alarms are mandatory, as is a dialysate bypass for drainage, required with high-temperature alarms.

Milder thermal imbalances may be caused or worsened by ultrafiltration such that a reduction in blood volume has to be accompanied by relative cooling in order to achieve thermal energy homeostasis and avoid heat accumulation.[239]

MISCELLANEOUS COMPLICATIONS

Post-Dialysis Fatigue Syndrome

Common nonspecific symptoms of fatigue and malaise are observed in about 33% of patients.[193,240] The incidence of this

syndrome has decreased since glucose-free acetate-containing solutions were replaced by glucose/bicarbonate dialysate.[241] Reduced cardiac output, peripheral vascular disease, depression, poor conditioning, postdialysis hypokalemia or hypoglycemia, mild uremic encephalopathy, neuropathy, or myopathy and blood membrane interactions may be contributing factors. Randomized, double-blind, controlled studies failed to show improvement by exchange of cuprophane with PS membranes[242,243] but showed that high ultrafiltration rates and low dialysate sodium concentration predispose to postdialysis fatigue.[244] On-line predilution hemofiltration has been shown to be more effective than ultrapure high-flux HD.[245] Malaise has also been ascribed to carnitine deficiency, which is important for muscle metabolism, and L-carnitine supplementation has been shown to improve postdialysis well-being.[116]

Pruritus

Pruritus is a common finding among dialysis patients and often multifactorial and difficult to treat. Xerosis, hypercalcemia, and hyperphosphatemia (resulting in calcium phosphate crystal deposition in the skin), hyperparathyroidism, inadequate dialysis,[246] and female gender[247] are all risk factors for this vexing problem. Some, but not all, studies have observed elevated plasma histamine and serotonin levels and increased mast cell proliferation in the skin.[248] Use of antihistamine agents and 5-HT3 receptor antagonists do not affect these levels.[248] Two clinical trials failed to demonstrate any benefit from the use of ondansetron for pruritus in dialysis patients.[249,250]

In many cases, pruritus is more severe during or after dialysis and may be an allergic manifestation to heparin, ETO, formaldehyde, or acetate.[27] The exchange of formaldehyde as the germicide during reuse and the use of gamma-sterilized dialyzers, and switching over to bicarbonate dialysate has been associated with cessation of itching.[27] Anecdotal reports suggest a likelihood of itching with cuprophan and new dialyzers compared to substituted cellulose and reused dialyzers.[193] Eczematous reactions to antiseptic solutions used to clean the vascular access site, rubber glove components (thiuram), nickel in the puncture needles, epoxy of the glue at the tube-needle joint, or the collophane of glues used to maintain needles should be considered.[251]

Therapeutic strategies include the use of both emollients and antihistamine agents, oral activated charcoal, ultraviolet therapy and sunbathing, ketotifen (a mast cell stabilizer), rHuEPO therapy, topical capsaicin,[252,253] essential fatty acid replacement,[254] and short term use of daily oral naltrexone.[255] Finally, the dialysis prescription and adequacy should always be assessed.

Priapism

Priapism occurs either during or 2 to 7 hours following dialysis in about 0.5% of male patients[256] and is characterized by a painful erection that is unrelated to sexual activity. A causal relationship to an increase in blood viscosity due to heparin,[257,258] high hematocrit, rHuEPO[259] and androgen therapy[260,261] as well as dialysis-induced hypoxemia, hypovolemia due to excessive ultrafiltration, particularly in black males with sickle cell trait,[256] and the use of prazosin[262] have

all been implicated in the pathogenesis of this condition. Treatment includes immediate aspiration and irrigation of the corpora cavernosa.[263] Metaraminol has been used for irrigation in one report.[264] A dorsal penile block with 1% xylocaine without epinephrine and intravenous sedation can be given for pain control, but opiates are also effective. Surgical treatment consists of creating a shunt for drainage of the corpora cavernosa.[263] Permanent erectile dysfunction frequently results but can be treated with implantable cavernosal prostheses.[171]

Hearing and Visual Loss

The exact role of HD in hearing disturbances is unclear. Hearing loss in HD patients has been reported.[265,266] One study reported a hearing loss incidence of 41%, 15%, and 53% in the low, middle, and high frequency ranges, respectively.[267] In the same study, the low frequency hearing improved in 38% and worsened in 10% of patients after a single dialysis session.[267] Hearing impairment may improve following transplantation.[268] Advanced age, elevated plasma viscosity, and prior gentamicin administration are confounding factors of high frequency loss.[267] However, more recent investigations showed no acute change in audiometric parameters after HD but demonstrated a higher prevalence of hearing loss in patients with chronic kidney failure.[269,270] Acute hearing loss during HD may be due to bleeding in the inner ear as a consequence of heparinization or hair cell injury of the cochlea from edema (endolymphatic hydrops).[171] Finally, ototoxicity has been reported following desferrioxamine therapy,[271] isoniazid,[272] and amikacin.[273]

Visual loss is rare during HD and may be caused by central retinal vein occlusion,[274] precipitation of acute glaucoma,[275] ischemic optic neuropathy associated with intradialytic hypotension,[276,277] or Purtscher's-like retinopathy due to leukoembolization.[278] Desferrioxamine also causes ocular toxicity, and serial audiovisual monitoring may be required with chronic chelation therapy.[271]

Last, a recent outbreak of sudden onset of visual and hearing impairment 7 to 24 hours after a maintenance hemodialysis treatment in one center was caused by aged cellulose acetate dialyzers with patient exposure to cellulose acetate degradation products.[279]

Digoxin Toxicity

HD patients are particularly prone to complications associated with the use of digoxin (see "Cardiac Arrhythmias"). This compound has a narrow therapeutic window and, despite careful monitoring of drug levels, digoxin-induced arrhythmias can occur especially when coexistent with hypercalcemia, hypokalemia, and hypomagnesemia. A syndrome consisting of recurrent abdominal pain associated with use of digoxin can occur shortly after dialysis, particularly following marked ultrafiltration, and has been ascribed to digoxin-induced transient mesenteric ischemia.[276] Once digoxin intoxication has occurred, hemoperfusion with charcoal and antidigoxin antibodies are necessary for treatment due to inadequate clearance by dialysis. Adequate digoxin clearance of 145 mL/min has been achieved utilizing a commercially available β-2-microglobulin adsorption column (Lixelle, BM-01).[280]

Daily Hemodialysis

Andreas Pierratos, M.D., F.R.C.P.C. • Phil McFarlane, M.D., F.R.C.P.C. • Christopher Chan, M.D., F.R.C.P.C.

The quest for a solution to the problem of poor outcomes and low quality of life for patients with end-stage renal disease (ESRD) has led to an increased interest in daily hemodialysis.[1] Two distinct forms of daily dialysis have emerged (Figure 23–1). The first is characterized by frequent short treatments, with dialysis typically performed for 2 to 4 hours. The second is a nightly form, with treatments lasting 6 to 8 hours and performed while the patient sleeps. In both cases, treatments are performed five to seven times a week. Hybrid forms of varying frequency and length have also been used. In addition, some have chosen daily hemo(dia)filtration with an aim to increase middle molecule clearance.[2,3]

The term *quotidian* hemodialysis has been proposed to categorize any form of dialysis performed on a daily basis. The term *hemeral* has been suggested for the short daily form and *nocturnal* for the long overnight form. Other names in use include *short daily* hemodialysis and *daily (home) nocturnal* hemodialysis. Last, the term *intensive* hemodialysis has been proposed for any method whose length or frequency exceeds that of conventional hemodialysis.[4] Daily dialysis is not new; DePalma[5] first reported the benefits of short daily hemodialysis in 1969. Overnight dialysis at home was pioneered by Shaldon in 1968, with Uldall[6,7] reporting the use of daily home nocturnal hemodialysis in 1994. The number of publications in this area has increased in recent years, reflecting an increasing interest in these intensive dialysis techniques.[8] In the following chapter, we will discuss the available evidence suggesting that quotidian dialysis can improve outcomes in selected patients.

DIALYSIS TECHNIQUE

Although all hemodialysis machines can be used for quotidian hemodialysis, several new machines have been developed specifically for this purpose, and existing machines have been adapted for the specific needs of home hemodialysis.[2,9] Short daily hemodialysis can be done at an in-center facility or at home using high blood and dialysate flow to achieve maximal efficiency. Nocturnal hemodialysis thrice a week or every other night can be performed in-center or at home but quotidian nocturnal hemodialysis is typically not performed in-center.[10] For home treatments, the patient or a family member is trained in the technique. For quotidian nocturnal hemodialysis, blood flow is 200 to 300 mL/min, and dialysate flow is 100 to 300 mL/min. With this modality, a high dialysis dose can be delivered even through single needle systems. No data exist on how dialyzers should be selected for quotidian dialysis, with existing programs using low- and high-flux membranes and some programs using pediatric size dialyzers

in adult patients.[10] Dialyzer reprocessing has been used in quotidian programs, with delays in reprocessing of up to 1 week allowed in home programs.[11] The starting dialysate for short daily hemodialysis is similar to that used in conventional hemodialysis. Dialysate composition in quotidian nocturnal hemodialysis must be tailored for each patient, because the effect of intensive hemodialysis on calcium-phosphate balance and acid-base status can vary between individuals. The typical dialysate has a bicarbonate level of 28 to 35 mEq/L, calcium of 3.3 ± 0.2 mEq/L (1.6 ± 0.1 mmol/L), and phosphorus of 1.6 ± 0.9 mg/dL (0.5 ± 0.3 mmol/L). Dialysate calcium, if desired, can be adjusted through the addition of calcium chloride powder in the "acid" concentrate by the patient. Sodium phosphate can be added to either the acid or bicarbonate concentrate for patients requiring supplementation. In the absence of a commercially available preparation, oral Fleet Phospho-Soda or Fleet enema can be used. Heparin dose on both methods is similar to conventional hemodialysis. Water for dialysate is usually purified using reverse osmosis systems and carbon filters. Local water quality can require the use of deionizers, and some programs have chosen to use ultra-pure dialysate for quotidian dialysis.[12,13]

Live Remote Monitoring

Several centers have been remotely monitoring patients "live" while on home nocturnal hemodialysis through a telephone or an Internet connection, usually dependent on whether a call from the patient's home is a local phone call to the monitoring center.[14–16] Current technology allows for the monitoring of machine functions, such as alarms and pump speeds. Biologic monitoring (e.g., heart rate, blood pressure) will require further innovations. While some programs and patients have touted the extra safety associated with remote monitoring, other programs have many patients performing these techniques without remote monitoring systems, without complications to this point.

Dialysis Access

Access for quotidian dialysis has been established through central venous catheters and arteriovenous fistulas or grafts. Single needle systems have been used in some home nocturnal hemodialysis programs, decreasing the number of cannulations and providing improved safety in scenarios where a needle is inadvertently removed during a nocturnal dialysis treatment.[17] Many quotidian dialysis programs access arteriovenous fistulae through the buttonhole technique, where cannulation occurs at the same site each day, allowing for the development of a subcutaneous track that aids the accurate

placement of needles. Once a track has developed, noncutting needles are used at buttonhole sites, helping preserve the tracks, and improving patient comfort during cannulation.[18] Meticulous attention to hygiene is pivotal when the button-hole technique is utilized, with aseptic removal of scabs and cleansing of the site required prior to cannulation. Evidence of lower fistula complication rates on daily hemodialysis has been reported by Quintaliani and associates[19] and Woods and associates,[20] but no prospectively collected data has been published. The long-term use of central venous catheters has also been demonstrated but published data are again insufficient. Given our current understanding, an arteriovenous fistula is the preferred access for quotidian dialysis, with grafts or central venous catheters used in patients where a fistula is not feasible.

Safety

Controversy remains about when a partner is required for home hemodialysis modalities, and whether the partner needs to be trained in the technique. Most home programs do not require a partner for hemeral or nocturnal techniques. As patients are expected to be sleeping during nocturnal treatments, extra safety precautions have been developed for this modality. In order to prevent air embolism in the case of accidental central venous catheters disconnection, the InterLink system has been utilized, allowing dialysis to be performed through the pre-slit diaphragm of the catheter cap.[10] A plastic nondisposable clamshell-locking box around the catheter-tubing connection can prevent an accidental separation. Blood or dialysate leaks are sensed by moisture sensors placed strategically on the floor and an "enuresis alarm" is taped on both arterial and venous needles.

Patient Selection/Training

A wide variety of people have been selected for quotidian dialysis. In many cases (especially in home programs), patients have selected themselves, in hope of realizing clinical or lifestyle benefits. In other cases, patients were selected to address problems related to hemodynamic instability, uncontrolled hypertension, congestive heart failure, refractory electrolyte or calcium-phosphate metabolism issues, malnutrition, or poor quality of life.[21] The

main selection criteria for home hemodialysis training are the ability and willingness to learn the technique. Patients living in small housing will require extra support from their program, usually through more frequent supply deliveries. Contraindication to heparin precludes the use of nocturnal hemodialysis but not short daily hemodialysis. Serious comorbid conditions and hemodynamic instability such as heart failure, ascites, and symptomatic coronary artery disease have not been contra-indications for daily hemodialysis. Indeed, patients with these conditions may be especially well suited for quotidian hemodialysis. Incident ESRD patients are excellent candidates for daily hemodialysis and can be trained for home modalities. It is speculated that about 20% of the current dialysis population could be trained for home hemodialysis using the current dialysis machines. Training for home dialysis lasts an average of 6 weeks for previously untrained patients,[22,23] with shorter periods for patients already trained to perform self-care hemodialysis. Longer training in a self-care environment allows patients with marginal ability to master the technique over a longer period of time. It is hoped that new or modified dialysis machines will be simpler to operate, thereby allowing more patients to be trained.[2,3]

Kinetics/Dialysis Dose: Solute Removal

The similarity of the patient mortality rates between peritoneal dialysis and conventional thrice-weekly hemodialysis, despite the differences in dialysis dose as quantified by urea Kt/V,[25] has led some to conclude that continuous or frequent dialysis offers better clinical outcomes at an equivalent Kt/V.[25] Assuming that outcomes are mainly related to the dialysis dose, several attempts have been made to create a universal renal toxin clearance metric applicable to all dialysis modalities and residual renal function. These include the EKR (equivalent kidney urea clearance) proposed by Casino and Lopez,[26] the normalized Kt/V proposed by Depner,[27] and the standard Kt/V (stdKt/V) proposed by Gotch.[28] The traditional measurement of dialysis dose by calculating Kt/V assumes that uremic toxicity correlates to time-averaged urea concentration. EKR makes similar assumptions. StdKt/V is based on the mid-week pre-dialysis urea levels, whereas the normalized Kt/V is based on the time-averaged concentration of a theoretical molecule with larger molecular weight than urea. The last two measures therefore favor daily hemodialysis, which is characterized by lower pre-dialysis urea levels. The stdKt/V is commonly used to measure urea dialysis dose and has been expanded to measure the clearance of larger molecules.[29] The calculation of these values is complex and cannot be easily done at the bedside, but they can be used to calculate the appropriate single pool Kt/V for the daily dialysis regimens.

The recently published HEMO study did not demonstrate a decrease in mortality when dialysis dose was increased above the level suggested in the Dialysis Outcome Quality Initiative (DOQI) guidelines.[30] The DOQI guidelines suggest a conventional dialysis dose of 1.2 spKt/V per session or 2.0 stdKt/V per week. This is equivalent to a daily session 0.38 equilibrated Kt/V (eKt/V), which can be delivered by shorter total dialysis duration per week than when using conventional hemodialysis. By choosing to maintain the same weekly hemodialysis duration but perform treatments daily, the weekly stdKt/V increases to about 3.[31] Quotidian nocturnal hemodialysis can provide a higher dose of dialysis than any other outpatient

dialysis modality (spKt/V about 2.0 per daily session or weekly stdKt/V of more than 5).[10,29,31–33]

The removal of larger molecules is dependent on the permeability of the dialysis membranes, length of dialysis, and last, on the presence of convective transport as part of ultrafiltration or hemofiltration. Increase in the frequency of dialysis plays a significant role in the removal of molecules diffusing slowly across the intercompartmental barriers.[34] Large molecule clearance by short daily hemodialysis is increased only modestly if the calculation is based on the time-averaged concentration[35] but substantially when stdKt/V is used.[29] The clearance of large molecules increases significantly by nocturnal hemodialysis irrespective of the method of calculation, since it combines both long duration and high frequency.[29,35] This is exemplified by the enhanced β_2 microglobulin removal by this method which is fourfold that of conventional hemodialysis, leading to lower serum β_2 microglobulin levels.[36] Large molecule removal by short daily hemo(dia)filtration approaches the levels of daily nocturnal hemodialysis despite the shorter dialysis time.[3,29] Quotidian nocturnal hemofiltration would presumably provide the highest dose of large molecule removal.

Floridi and associates[37] have found that advanced glycated end-product (AGE) levels are significantly lower on short daily hemodialysis compared with conventional HD. Friedman and associates[38] have also found that patients on nocturnal hemodialysis have significantly lower total homocysteine levels compared with those on conventional HD. Lower levels of both parameters may lead to decreased cardiovascular morbidity and mortality on daily hemodialysis. It is unclear whether the decrease in circulating levels of these solutes is related to increased removal, decreased production, or increased extrarenal catabolism.

Finally, it is likely that some of the putative benefits of daily hemodialysis are mediated by improvements in hemodynamic parameters or by decreased fluctuations of other biologic parameters. A measure of such fluctuation is the time average deviation (TAD), which Lopot[39] has proposed as an index of physiologic treatment and reflects the variation of the urea values around its time-averaged concentration. The use of this parameter as a predictor of clinical outcomes has not yet been validated.

QUALITY OF LIFE

ESRD reduces both length and quality of life. The quality of life on conventional hemodialysis is equivalent to that seen in patients with hepatocellular carcinoma, or a second recurrence of breast cancer.[40,41]

A variety of studies have quantified the impact of quotidian dialysis on quality of life, using disease independent instruments, such as the Medical Outcomes Study Short-Form Health Survey-36 (MOS SF-36), the Sickness Impact Profile (SIP), the Nottingham Health Profile, the Beck Depression Index, or instruments specific for renal disease such as the Kidney Disease Quality of Life (KDQOL).[42–44] Techniques used to generate utility scores such as the standard gamble and the time trade-off technique have also been used.[45] Unique measures such as the time to recovery after a dialysis session have also been examined.[46] Comparisons have been made prospectively and retrospectively, within patient groups before

and after quotidian dialysis, and between patient groups on different forms of hemodialysis. Despite the variety of measurements and study designs, quotidian dialysis has always been favored.

Quality of life was estimated in a cross-sectional study of 43 demographically similar patients on either conventional in-center or quotidian home nocturnal hemodialysis using utility scores, which measure a patient's preference for health states and are usually expressed on a scale ranging from 0 (a health state equivalent to death) to 1 (equivalent to the best imaginable health).[47] When the standard gamble technique is used to elicit preferences, the utility score can be calculated after determining the highest percentage chance of immediate death that a patient would agree to gamble against for perfect health (SG utility = 1, highest change of immediate death willing to gamble against for perfect health). In this study, utility scores were significantly higher in the intensively dialyzed group (0.77 vs. 0.53). The utility scores for patients on conventional dialysis were similar to those previously published, but the quotidian nocturnal group scores were similar to those seen in kidney transplant recipients, which mirrors anecdotal reports of patients removing themselves from transplant waiting lists in favor of home quotidian hemodialysis.[48] Although utility scores provide a global measure of quality of life through examination of patient preferences for health states, they do not provide insights into why quality of life has changed. For this information we must look at studies that used metrics that quantify quality of life in a variety of different domains.

In a study of 18 patients before and after conversion to quotidian home nocturnal hemodialysis, the mean SIP total score improved significantly from 14 to 10, primarily driven by improvements in Eating and Household Management scores. SF-36 scores also improved, with significant changes in Social Functioning (mean score 54 to 80) and Physical Functioning (mean 61 to 69), and there was a significant reduction in Beck Depression Index scores as well.[42,44] Similarly, in a study of patients switched from conventional to short daily dialysis (at that same weekly urea Kt/V), improvements were seen in SF-36 and Nottingham health index scores, which were primarily driven by improvements in mental health, vitality, and energy.[49] In a study of 11 hemeral, 12 nocturnal, and 22 conventional hemodialysis patients, quotidian dialysis was better tolerated and was associated with preserved quality of life over 18 months of follow-up, while patients on conventional hemodialysis suffered a significant decline in quality of life over the study period.[46] Thus, quotidian hemodialysis is associated with an improved quality of life in selected patients. These results are even more striking when one considers the additional time required for quotidian treatments, the medicalization of the home setting, and additional demands on patients performing home modalities. It appears that global improvements in quality of life reflect a broad impact of quotidian hemodialysis on physical, mental, and social parameters.

CARDIOVASCULAR PARAMETERS

Clinical Improvements

Blood pressure (BP) control is improved with short daily hemodialysis and nocturnal hemodialysis.[10,20,50] Most patients

do not require the use of anti-hypertensive medications. Indeed, in a prospective crossover study involving short daily nocturnal home hemodialysis (SDHD),[51] BP control improved, the need for anti-hypertensive medication fell, and left ventricular mass index decreased during the 6 months of SDHD. Although the exact mechanism leading to the fall in BP with SDHD is unknown, a decrease in extracellular fluid (ECF) volume may be an important contributing factor.[51] Similar blood pressure control can be achieved with nocturnal hemodialysis. The Toronto experience has consistently reported the normalization of BP with this modality.[14] Chan and associates[33] reported on the restoration of normal blood pressure in 28 patients on NHD who were followed for 3 years after conversion from CHD to home NHD. Left ventricular mass index also declined significantly from 147 to 122 g/m^2. A control cohort of home conventional hemodialysis patients did not show any change in BP or left ventricular geometry over this time period. Additionally, there was no difference in post dialysis ECF volume, as measured by bioelectrical impedance. We hypothesize that less fluctuation of ECF volume due to the quotidian frequency of dialysis or the lower average ECF volume may be relevant to the enhanced BP control. Most recently, Nesrallah and associates[50] presented evidence that ECF volume control is less important in the BP improvement while on nocturnal hemodialysis as compared to short daily hemodialysis. Removal or decreased production of neurohormonal or humoral parameters is also conceivable and will be addressed later.

The effect of converting ESRD patients with impaired left ventricular systolic function has also been studied. Six patients with depressed left ventricular ejection fraction ($< 40\%$) were converted to NHD and were followed for 3.2 years. Again, this cohort of patients had a significant improvement in BP control with a marked increase in left ventricular ejection fraction from a mean of 28% to 41% without any change in the post dialysis ECF volume.[52]

Mechanistic Analyses

The dramatic influence of intensive hemodialysis on BP control offers an opportunity for more rigorous mechanistic analyses of the hemodynamic changes conferred by daily dialysis.

Our group performed hemodynamic, neurohormonal, and vascular responsiveness testing in 18 ESRD patients before, and at 1 and 2 months after conversion from conventional hemodialysis to nocturnal hemodialysis.[53] In this prospective cohort study, nocturnal hemodialysis resulted in lower BP while maintaining similar stroke volume and cardiac output. Total peripheral resistance (TPR) fell significantly from 1967 to 1499 $dyne/sec/cm^{-5}$ implicating that the hypotensive effect of NHD is mediated through a reduction in an elevated TPR rather than a fall in intravascular volume. Brachial artery responsiveness to reactive hyperemia (endothelial function) and to sublingual nitroglycerine (vascular smooth muscle cell function) was also assessed. Patients demonstrated a significant increase in endothelium dependent vasodilation with an increase in brachial artery response to hyperemia from −3% on CHD to 5% after 1 month of NHD and +8% after 2 months. The endothelium independent response was augmented similarly over the same time period. These observations are the first to suggest a sustained time dependent improvement in vascular responsiveness with nocturnal hemodialysis.

Zilch and associates[54] found decrease in sympathetic activity on short daily hemodialysis. Decrease in Brain Natriuretic Peptide (BNP) on short daily hemodialysis was reported by Odar-Cederlof and associates.[55]

ERYTHROPOIETIN (EPO) DOSE AND ANEMIA CONTROL

Anemia is associated with poor uremia control and is an established cardiovascular risk factor in patients with end-stage renal disease. A decrease in erythropoietin (EPO) dose of about 30% to 40% and an increase in hemoglobin on daily hemodialysis has been reported by most groups,[20,21,56,57] but negative or equivocal results have also been reported.[10,49,58] We conducted a controlled cohort study to test the hypotheses that augmenting the dose and frequency of dialysis by daily nocturnal hemodialysis would improve the hemoglobin (Hb) concentration and decrease EPO requirement. Sixty-three patients on NHD and 32 self-care patients on conventional hemodialysis were studied.[59] There were no differences in baseline iron indices between the two groups. After transfer from CHD to NHD, there were significant improvements in Hb concentration, despite a fall in EPO requirement. In contrast, the CHD cohort had no change in EPO requirement. There was a higher percentage of patients who did not require EPO in the NHD cohort (24% vs. 3%). Enhancing uremia clearance by NHD resulted in an improvement in Hb and a fall in EPO requirement. Anemia is associated with poor uremia control and is an established cardiovascular risk factor in patients with end-stage renal disease. Further prospective studies are required to elucidate the mechanisms and clinical impact of improving anemia management in patients undergoing nocturnal or daily hemodialysis.

CALCIUM, PHOSPHORUS METABOLISM, AND BONE DISEASE

There is a recent interest in phosphate kinetics[60] with accumulating evidence that improving phosphate control prevents increases in vascular calcifications with implications on cardiovascular mortality.[61] Phosphate removal by conventional hemodialysis is inadequate, sustaining hyperphosphatemia and an elevated calcium phosphate product, which have been linked to increased mortality.[62] Phosphate is difficult to remove due to the slow mobilization of phosphate from the deep tissues during dialysis, resulting in an early decline in the serum phosphate levels during hemodialysis treatments and a loss of the serum to dialysate concentration gradient. Serum phosphate levels rebound during the last hour of dialysis and after the end of dialysis.[63] Therefore, the length of dialysis is the major determinant of phosphate removal.

Short Daily Hemodialysis

There has been only minimal effect of short daily hemodialysis on serum phosphate or the dose of the phosphate binders needed.[49] Dialysate phosphate reflecting phosphate removal increases after conversion to short daily hemodialysis, suggest-

ing that increased phosphate intake as a result of improving appetite prevents a substantial decrease in the serum phosphate levels or the dose of phosphate binders.[64,65]

Quotidian Nocturnal Hemodialysis

The weekly phosphate removal by nocturnal hemodialysis is twice as high as by conventional hemodialysis (4.8 ± 1.7 g vs. 2.2 ± 0.6 g).[66] In some reports, all patients discontinue phosphate binders within 1 week of initiating daily nocturnal hemodialysis and are on an unrestricted phosphate diet. More than 50% of patients require the addition of sodium phosphate into the dialysate at average 1.6 ± 0.9 mg/dL (0.5 ± 0.3 mmol/L). This results in serum phosphate levels within normal limits both pre- and post-dialysis. Use of daily nocturnal hemodialysis has led to the dissolution of tumoral extraosseous calcifications in one patient.[67] Oral calcium intake may be insufficient to balance calcium loss in the dialysate, therefore, periodic bone densitometry may be required in patients receiving nocturnal hemodialysis. Average dialysate calcium of 3.3 ± 0.2 mEq/L (1.6 ± 0.1 mmol/L) was used in one center. By increasing dialysate calcium the serum parathyroid hormone (PTH) was significantly suppressed, from 580 ± 590 ng/mL (61 ± 62 pmol/L) to 228 ± 295 ng/mL (24 ± 31 pmol/L)after 6 months. Preliminary results from bone biopsies showed that 9 out of 15 patients on daily nocturnal home hemodialysis had low bone turnover.[68] This may indicate that a lower dialysate calcium (i.e., 2.5 mEq/L) than was used thus far may be preferable. More studies are needed to establish the criteria for the adjustment of the dialysate calcium levels. The role of vitamin D analogues is unclear, as is the target PTH level for patients on daily nocturnal home hemodialysis.

NUTRITION

Several studies on quotidian hemodialysis have reported improvement in nutritional aspects, including improved appetite and weight gain. Galland and associates[69] described an increase in albumin, prealbumin, cholesterol, body weight, and lean body mass upon conversion to short daily hemodialysis, although Kooistra[49] did not find an increase in serum albumin over 6 months. Spanner and associates[70] reported a trend towards higher protein equivalent of total nitrogen appearance (nPNA), on both short and nocturnal hemodialysis arms of their study, but found an increase in serum albumin and arm circumference in the short daily hemodialysis group only. Although amino acid losses in the dialysate are expected to be higher on quotidian and particularly on the nocturnal regimen,[71] total body nitrogen, as measured by *in vivo* neutron activation analysis, remained stable over 2 years of nocturnal hemodialysis.[72] In our center, body weight significantly increased in 48 patients on nocturnal hemodialysis 78 ± 18 to 80 ± 18 kg over an average of 2 years. More data are needed on the effect of daily dialysis on nutritional parameters.

SLEEP

The prevalence of sleep abnormalities is high in ESRD, and they are associated with poor quality of life[73] and higher mortality.[74] Sleep studies were done prior to and after 14 patients were enrolled in the first quotidian nocturnal hemodialysis project in Toronto.[75] In seven patients with sleep apnea, conversion to nocturnal hemodialysis normalized the frequency of apnea/hypopnea episodes from 46 ± 19 to 9 ± 9 per hour, and the lowest oxygen saturation during sleep significantly increased from $89 \pm 2\%$ to $94 \pm 2\%$. Nocturnal hemodialysis did not have an effect on daytime sleepiness when measured prior to and after the conversion to daily nocturnal hemodialysis in the first 24 patients enrolled in the same project.[76] The effect of short daily hemodialysis on sleep apnea is unknown.

The mechanistic impact of nocturnal hemodialysis on nocturnal cardiac autonomic outflow has recently been examined. Our group performed heart rate variability analysis in nine ESRD patients while on conventional hemodialysis and 6 to 15 months after conversion to nocturnal hemodialysis during stage II sleep. Nocturnal hemodialysis significantly reduced the duration of nocturnal hypoxemia and restored the normal balance between sympathetic and parasympathetic modulation of heart rate.[77]

SURVIVAL

No hard data have been published on patient survival. Woods and associates[20] reported an 80% survival over 5 years on 70 patients treated with short daily hemodialysis. Nocturnal hemodialysis in the Toronto Program demonstrated, similarly, an 85% survival over 5 years.[78] Hospitalization rates of patients on daily hemodialysis were reported to be lower than conventional hemodialysis in a retrospective study on a limited number of patients[44] as well as in a prospective study comparing two cohorts of patients on conventional and nocturnal hemodialysis.[79] Although survival in these studies is higher than expected, it is not possible to separate the effect of intensive dialysis on survival from case-mix bias.

HEALTH ECONOMICS

Local restraints in finances, staffing, physical facilities, and the availability of home programs usually dictate access to quotidian dialysis. Modality-specific costs of dialysis such as the costs of membranes, dialysate, and tubing increase in proportion to the number of treatments. As staff salary and benefits and overhead expenses account for up to a half of conventional dialysis costs, a quotidian home dialysis program can leverage savings in theses areas to offset increased modality costs. In-center quotidian hemodialysis programs must either rely upon savings in areas such as hospital admissions and medications or accept incremental costs for their additional benefits. Even if quotidian dialysis is more effective, the acceptability of additional dialysis costs is controversial, because the costs of conventional dialysis is already considered to be near the maximum that society is willing to bear.

To date, the best comparative costing data come from studies comparing home quotidian hemodialysis techniques with conventional in-center hemodialysis. Based on modeling of data derived from retrospective costing studies, Mohr and associates[44] calculated savings of US$12,500 (18%) for

in-center short daily hemodialysis and US$15,600 (23%) for home hemodialysis. Dialyzer reuse as well as the use of remote monitoring for nocturnal hemodialysis can affect the overall cost.[80] Financial data were also published by Robers.[81]

A prospective descriptive cost analysis by McFarlane and associates[79] showed that home nocturnal hemodialysis was associated with total health care costs that were about CAN$13,000/patient/year, lower than conventional in-center hemodialysis. Nocturnal hemodialysis significantly reduced staffing and overhead costs, which compensated for significantly higher costs for dialysis materials, laboratory tests, and capital items. In a cost-utility study performed on the same population, home nocturnal hemodialysis was the economically "dominant" method, with both lower costs and higher effectiveness as measured by quality of life.[47] In contrast, a study by Kroeker and associates[45] found no significant differences between the costs of conventional in-center and either home quotidian nocturnal or hemeral hemodialysis. However, in a retrospective cost comparison of each study patient from the prior year, total annual costs fell by $7171 per patient in those converted to short daily hemodialysis and by $12,782 per patient in those converted to home nocturnal hemodialysis, compared with a rise by $2247 in those who remained on in-center hemodialysis.[45]

These studies suggest that home quotidian dialysis modalities reduce total health care costs. The impact on costs of in-center quotidian dialysis programs remains to be established. In addition, the reduction of hospitalization costs and medications such as EPO and vitamin D analogues is realized at the societal level but often not at the level of the dialysis program. Indeed, in the United States, some of these cost savings may adversely affect the local budgets of dialysis programs. This disparity highlights the fact that the method of funding dialysis programs may need to be adjusted in order to support quotidian dialysis programs, especially when those programs have been found to be cost-effective at the societal level.

SHORT DAILY HEMODIALYSIS VERSUS NOCTURNAL HEMODIALYSIS

Short daily hemodialysis provides a higher dose of dialysis than conventional hemodialysis, and quotidian nocturnal hemodialysis provides a higher dose still. The advantages of nocturnal methods include increased clearance of small and large molecules, added hemodynamic stability, improvement of sleep apnea, improved phosphate control and secondary hyperparathyroidism, lower burden of dialysis during the day, higher dialysis access fault tolerance, and free diet. The advantages of short daily methods include lower risk of deficiency syndromes, less exposure to the dialysis membrane and possibly poor dialysate quality, lower risk of accidental dialysis needle disconnection, and less sleep disturbance by the dialysis procedure.

The only study comparing the two methods was conducted in London, Ontario, and was recently published.[82] This was a prospective nonrandomized study comparing a group of 11 patients on short daily hemodialysis, 12 patients on nightly hemodialysis, and matched control subjects on conven-

tional hemodialysis. The differences in the dialysis dose and phosphate control among the methods were confirmed as described earlier.[83] Quality of life parameters were better preserved in both daily modalities compared to conventional HD,[46] as was the control of hypertension.[50] The short daily HD group fared better in relationship to some of the nutritional parameters.[70] Furthermore, the overall cost of the treatment was higher in nocturnal compared with short daily HD. When the cost during the year prior to the conversion was taken into account, the savings were higher in the nocturnal HD group.[45] The limitations of the study include the small sample size, the lack of randomization, and higher preexisting comorbidity in the nocturnal HD group. Case-mix differences may also account for the differences in nutritional parameters and cost between the two modalities and point to the need for further studies. At this point, the choice of the daily modality at home depends on patient preference and facility experience.

DAILY HEMOFILTRATION VERSUS DAILY HEMODIALYSIS

The role of hemofiltration as an alternative modality is evolving. The merits of hemofiltration are discussed in a different chapter of this book. Hemofiltration and hemodiafiltration can be performed thrice weekly or daily and can be used for short or long treatments. Based on published reports to this point, the clinical benefits of daily hemofiltration are similar to daily hemodialysis[2,3] and are related to the schedule rather than to the technique. There is laboratory evidence of increased removal of large molecules leading to a decrease in the pre-dialysis levels of β_2 microglobulin.[3] The added effect on middle molecule removal and the relationship to clinical outcomes need further studies.

OBSTACLES/FUTURE

Despite the interest in daily hemodialysis, the penetration of these modalities is low, because few dialysis programs offer them. Many obstacles have restricted availability of these modalities. The infrastructure for home hemodialysis is poor in many areas, and many patients are initially reluctant to undergo hemodialysis at home.[84] Experienced staff will require retraining in order to be prepared for the different clinical issues that arise in intensively dialyzed patients. Even if funding for in-center quotidian dialysis programs is adequate, other restrictions such as the availability of space and staff may limit the ability of a program to offer quotidian dialysis.

To overcome these obstacles, a series of steps will need to be taken. Improvements should be made to home dialysis infrastructure through the education of health professionals, administrators, and payers. Stakeholders such as clinicians and patient organizations should continue to advocate for improved resources for quotidian programs in the home and in-center settings. Larger programs can assist smaller ones to offer quotidian dialysis by providing technical support, staff education, and patient training. The possibility of an increase in home hemodialysis market share may encourage

the industry to develop hemodialysis machines that are simpler to operate and quicker to set up.

The need for data collection on dialysis was recognized by the National Institutes of Health.[85,86] Funds for a pilot prospective randomized, controlled study were granted in 2003. The study will allow comparison of conventional hemodialysis to either short daily hemodialysis or daily nocturnal hemodialysis over at least 1 year. The study is expected to be completed by 2008. The results may lead to a larger prospective randomized, controlled study or may provide enough justification for adequate funding of daily hemodialysis. The need for a randomized study has been debated as representing either a necessary step towards proper funding or a cause of an unnecessary delay for the implementation of a method that has been universally supported by all the nonrandomized studies published to date.

In conclusion, daily hemodialysis in the form of short daily or long nocturnal hemodialysis seems to provide significant benefits to selected patients with ESRD, and these modalities should be considered in suitable patients. Through advocacy and education, more dialysis programs should be able to offer quotidian hemodialysis to patients who are expected to benefit from more intensive dialysis techniques.

Hemofiltration and Hemodiafiltration for End-Stage Renal Disease

Zhongping Huang, Ph.D. • Dayong Gao, Professor •
Lee W. Henderson, M.D., F.A.C.P. • William R. Clark, M.D.

Hemodialysis (HD) has been the primary treatment mode in the management of patients with end-stage renal disease (ESRD) for the past 40 years. In this therapy, the countercurrent flow of blood and dialysate creates gradients for diffusive solute removal across a semipermeable membrane. The hollow fiber dialyzer membranes used for HD are manufactured specifically with diffusion-enhancing characteristics, such as a thin wall structure and a narrow inner diameter.[1] The removal of low-molecular weight (MW) nitrogenous waste products during HD is very effective. However, the limitations of diffusion become increasingly evident as uremic toxin MW increases.[2] Although the use of membranes with high water permeability or adsorptivity may be beneficial,[3] the clearance of middle and large MW compounds is limited by the fundamental dominance of diffusion in HD.

Many variables comprise the dialysis prescription, but factors influencing urea clearance represent the most important prescriptive consideration for many clinicians. Indeed, for both HD patients and those treated with peritoneal dialysis (PD), urea Kt/V or a derivative parameter assumes a prominent role in the assessment of both therapy prescription and delivery. Although generally not considered a uremic toxin *per se*, urea is assumed to be representative of the broad class of low MW nitrogenous compounds from a kinetic perspective.[4] Studies from the late 1970s and early 1980s, performed with dialyzers having very limited middle molecule clearance capabilities, suggested patient survival was more dependent on changes in small solute clearance than on middle molecule clearance.[5,6] Consequently, interest in urea-based therapy quantification developed and its use increased, beginning in the late 1980s.[7] Subsequently, several retrospective clinical trials published in the mid-1990s demonstrated a direct relationship between delivered urea-based HD dose and survival.[8–11] Moreover, one prospective trial and several retrospective studies suggested a similar relationship between total (i.e., peritoneal plus renal) clearance and survival for PD-treated patients.[12–14] By the end of the last decade, the notion that survival in dialysis patients was directly tied to the extent of small solute removal had become nearly axiomatic, and specific urea-based dosing guidelines were in place for both HD and PD.[15, 16]

However, two prospective, randomized studies published in 2002 challenged this axiom. In the American HEMO Study,[17] outcome-related effects of increasing delivered dose significantly beyond a level considered to be standard of care were assessed in approximately 1800 patients. In addition, the effect of treatment with high-flux dialyzers versus lower permeability high-efficiency dialyzers on patient survival was studied. In the HEMO trial, neither the high-dose nor the high-flux intervention resulted in a significant survival advantage. In PD, the **Ade**quacy of Dialysis in **Mex**ico (ADEMEX) Study[18] also failed to confirm a survival benefit for increasing dose delivery in a clinically relevant dose range for this therapy. These studies call into question the utility of small solute clearance parameters, both for quantifying dialysis dose and predicting survival. Moreover, the results of these two landmark studies provide compelling evidence that the conventional approach of managing chronic dialysis patients with either conventional (thrice-weekly) HD or PD has a limited ability to influence patient outcome favorably. Thus, the evaluation of alternative dialytic approaches is urgently needed for the ESRD population.[19]

Alternative therapies that may improve ESRD patient outcome include continuous-flow PD,[20] daily therapies,[21–23] sorbent-based systems,[24] and convective therapies. The last category, which is comprised of hemofiltration (HF) and hemodiafiltration (HDF), is the focus of this review.

CONVECTIVE SOLUTE REMOVAL

The determinants of convective solute removal differ significantly from those of diffusion. Convective solute removal is determined primarily by the sieving properties of the membrane used and the ultrafiltration rate.[25] The mechanism by which convection occurs is termed *solvent drag*. If the molecular dimensions of a solute are such that transmembrane passage to some extent occurs, the solute is swept ("dragged") across the membrane in association with ultrafiltered plasma water. Thus, the rate of convective solute removal can be modified either by changes in the rate of solvent (plasma water) flow or by changes in the mean effective pore size of the membrane. As discussed later, the blood concentration of a particular solute also influences its convective removal rate.

Both the water and solute permeability of an ultrafiltration membrane are influenced by the phenomena of secondary membrane formation[26] and concentration polarization.[27] The exposure of an artificial surface to plasma results in the nonspecific, instantaneous adsorption of a layer of proteins, the composition of which generally reflects that of the plasma itself. Therefore, plasma proteins such as albumin, fibrinogen, and immunoglobulins form the bulk of this secondary membrane. Moreover, the plasma total protein concentration also influences this phenomenon. This layer of proteins, by serving as an additional resistance to mass transfer, effectively reduces both the water and solute permeability of an extracorporeal

membrane. Evidence of this is found in comparisons of solute sieving coefficients determined before and after exposure of a membrane to plasma or other protein-containing solution.[28–31]

Although concentration polarization primarily pertains to plasma proteins, it is distinct from secondary membrane formation. Concentration polarization specifically relates to ultrafiltration-based processes and applies to the kinetic behavior of an individual solute. Accumulation of a solute that is predominantly or completely rejected by a membrane used for ultrafiltration of plasma occurs at the blood compartment membrane surface. This surface accumulation causes the solute concentration just adjacent to the membrane surface (i.e., the submembranous concentration) to be higher than the bulk (plasma) concentration. In this manner, a submembranous (high) to bulk (low) concentration gradient is established, resulting in "backdiffusion" from the membrane surface out into the plasma. At steady state, the rate of convective transport to the membrane surface is equal to the rate of backdiffusion. The polarized layer of solute is the distance defined by the gradient between the submembranous and bulk concentrations. This distance (or thickness) of the polarized layer, which can be estimated by mass balance techniques, reflects the extent of the concentration polarization process.

By definition, concentration polarization is applicable in clinical situations in which relatively high ultrafiltration rates are used. Conditions that promote the process are high ultrafiltration rate (high rate of convective transport), low blood flow rate (low shear rate or membrane "sweeping" effect), and the use of post-dilution (rather than pre-dilution) replacement fluids (increased local solute concentrations).[32]

The extent of the concentration polarization determines its effect on actual solute removal. In general, the degree to which the removal of a rejected solute is influenced is directly related to that solute's extent of rejection by a membrane. In fact, concentration polarization may actually enhance the removal of uremic toxins falling in the low MW protein category that otherwise would have minimal convective removal.[33] This is explained by the fact that the pertinent blood compartment concentration subjected to the ultrafiltrate flux is the high submembranous concentration primarily rather than the much lower bulk concentration.

On the other hand, the use of very high ultrafiltration rates in conjunction with other conditions favorable to solute polarization may significantly impair overall membrane performance. The relationship between ultrafiltration rate and transmembrane pressure (TMP) is linear for relatively low ultrafiltration rates, and the positive slope of this line defines the ultrafiltration coefficient of the membrane. However, as ultrafiltration rate further increases, this curve eventually reaches a plateau.[34] At this point, fouling of the membrane with denatured proteins may occur and an irreversible decline in solute and water permeability of the membrane ensues. Therefore, the ultrafiltration rate (and associated TMP) used for a convective therapy with a specific membrane needs to fall on the initial (linear) portion of the UFR versus TMP relationship with avoidance of the plateau region.

Convective solute removal can be quantified in the following manner[35]:

$$N = (1 - \sigma)J_V C_M.$$

In this equation, N is the convective flux (mass removal rate per unit membrane area), J_V is the ultrafiltrate flux (ultrafiltration rate normalized to membrane area), C_M is the mean intramembrane solute concentration, and σ is the reflection coefficient, a measure of solute rejection. As Werynski and Waniewski have explained,[35] the parameter $(1-\sigma)$ can be viewed as the membrane resistance to convective solute flow. If σ equals 1, no convective transport occurs while a value of 0 implies no resistance to convective flow. Of note, C_M is the average of the filtrate-side and blood-side solute concentrations, with the latter represented by the submembranous concentration rather than the bulk phase concentration. Therefore, this parameter is significantly influenced by the effect of concentration polarization.

CONVECTIVE RENAL REPLACEMENT THERAPIES

Hemofiltration Versus Ultrafiltration

The convective therapies used in the management of ESRD patients are HF and HDF. Although ultrafiltration is a fundamental aspect of convective therapies, it is useful to differentiate between this process and HF. Ultrafiltration (UF) is the extracorporeal removal of plasma water by application of a transmembrane pressure gradient. Although useful for volume removal in the management of "isolated" fluid overload,[36] UF is not effective as a blood cleansing modality based on the following:

1. The concentrations of small solutes not rejected appreciably by an HF membrane are effectively the same in the ultrafiltrate and the plasma water.
2. Although net mass removal from the body is achieved in the ultrafiltrate, the fraction of the total body solute mass removed is the same as the fractional removal of plasma water.
3. Since fractional mass removal of solute and plasma volume reduction occur proportionately, small solute concentrations in the plasma do not change significantly in isolated UF.

On the other hand, the ultrafiltrate concentrations of larger solutes having restricted transmembrane passage are less than their simultaneous plasma water concentrations due to partial or complete rejection by the membrane. Thus, fractional mass removal in the ultrafiltrate is proportionately less than plasma volume reduction, resulting in a net increase in the blood concentrations of larger sized molecules.

On the other hand, HF involves the simultaneous removal of plasma water by UF and replacement with a buffered electrolyte solution (replacement or substitution fluid).[37] Since the ultrafiltration rate used in HF may be as high as 400 mL/min, one obvious function of the replacement fluid in HF is volume preservation in the patient. The difference between this (absolute) ultrafiltration rate and the replacement fluid rate is the net ultrafiltration (weight loss) rate. However, the use of replacement fluid differentiates HF from isolated UF and accounts for the fact that the former is a blood cleansing modality and the latter is not. In HF, replacement fluid administration results in the dilution of nonfiltered toxins remaining in the bloodstream and an associated reduction in blood concentrations. This dilution phenomenon accounts for HF's effectiveness as a renal replacement therapy.

Post-Dilution HF

The location of replacement fluid delivery in the extracorporeal circuit during HF has a significant impact on solute removal and therapy requirements[32] (Figure 24–1). Replacement fluid can be delivered to the arterial blood line prior to the hemofilter (pre-dilution mode) or to the venous line after the hemofilter (post-dilution mode). In post-dilution HF, the relationship between solute clearance and ultrafiltration rate is relatively straightforward.[38] In this situation, solute clearance is determined primarily by and related directly to the solute's sieving coefficient and the ultrafiltration rate. (Sieving coefficient is defined as the ratio of the solute concentration in the filtrate to the simultaneous plasma concentration.) For a given solute, the extent to which it partitions from the plasma water into the red blood cell mass and the rate at which it is transported across red blood cell membranes also influence clearance. For example, the volume of distribution of both urea and creatinine includes the red blood cell water. However, while urea movement across red blood cell membranes is very fast, the movement of creatinine is significantly less rapid. Furthermore, red blood cell membranes are completely impermeable to many uremic toxins. A prominent example of this is the low MW protein toxin class, for which the volume of distribution is the extracellular fluid. These observations lead to the obvious conclusion that hematocrit also influences solute clearance in HF. Finally, through its effect on secondary membrane formation and concentration polarization (see earlier text), plasma total protein concentration is also a determinant of solute clearance in HF.

For a given volume of replacement fluid over the entire MW spectrum of uremic toxins, post-dilution HF provides higher solute clearance than does pre-dilution HF. As discussed below, the relative inefficiency of the latter mode is related to the dilution-related reduction in solute concentrations, which decreases the driving force for convective mass transfer. Despite its superior efficiency with respect to replacement fluid utilization, post-dilution HF is limited inherently by the attainable blood flow rate. More specifically, the ratio of the ultrafiltration rate to the plasma flow rate delivered to the filter, termed the filtration fraction, is the limiting factor. In general, a maximal filtration fraction of 50% usually guides prescription in post-dilution HF. At filtration fractions beyond this value, concentration polarization and secondary membrane effects become prominent and may impair hemofilter performance.

For a hypothetical patient with a hematocrit of 35% and a vascular access capable of delivering a blood flow rate of 350 mL/min, the above filtration fraction limit implies a maximal ultrafiltration rate of 114 mL/min or a total ultrafiltrate volume of approximately 27 L for a 4-hr treatment. For a given filtration fraction, a higher blood flow rate or a lower hematocrit enables attainment of a higher ultrafiltration rate.

In the early clinical application of HF, because replacement fluid was infused generally as a terminally sterilized solution from bags, volumes rarely surpassed 20 L per treatment.[41–43] (As an exception, see the following description of the pre-dilution system described by Henderson and colleagues in the mid-1970s.) This limitation resulted in post-dilution as the predominant mode when HF was performed prior to the last decade. However, the technology of on-line production by sequential ultrafiltration of dialysate[44–46] has allowed significantly larger volumes of replacement fluid to be used in HF. This ready availability of replacement fluid and the resultant capability to employ ultrafiltration rates as high as 400 mL/min permits attainment of clearances in pre-dilution that far surpass maximal achievable clearances in post-dilution HF.[47] Thus, as discussed below, the predominant mode used in contemporary HF is pre-dilution.

Pre-Dilution HF

From a mass transfer perspective, the use of pre-dilution has several potential advantages over post-dilution. First, in contemporary on-line HF, the blood flow and replacement fluid rates typically are similar.[47] As such, both hematocrit and blood total protein concentration are reduced significantly prior to the entry of blood into the hemofilter. This effective reduction in the red cell and protein content of the blood attenuates the secondary membrane and concentration polarization phenomena described earlier, resulting in improved mass transfer.[48] Pre-dilution also favorably impacts mass transfer due to augmented flow in the blood compartment, with the pre-filter mixing of blood and replacement fluid effectively doubling the blood compartment flow rate. This achieves a relatively high membrane shear rate, which also reduces solute-membrane interactions. Finally, pre-dilution may also enhance mass transfer for some compounds by creating concentration gradients that induce solute movement out of red blood cells.[48] The above mass transfer benefits must be weighed against the predictable dilution-induced reduction in plasma solute concentrations, one of the driving forces for convective solute removal. The extent to which this reduction occurs is determined mainly by the ratio of the replacement fluid rate to the blood flow rate, which may be as high as unity in contemporary on-line HF. However, the ultrafiltration rate afforded by such a high replacement fluid rate allows the dilution-related loss of efficiency to be overcome.

Hemodiafiltration

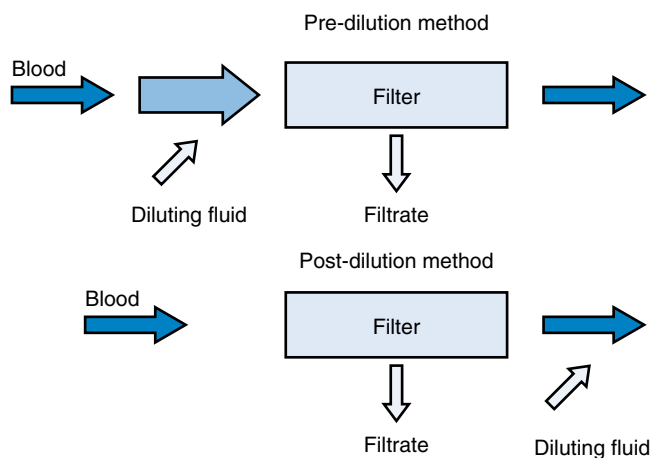
Although considerable enthusiasm for HF existed in the late 1970s and early 1980s, its popularity waned subsequently for


Figure 24–1 Pre-dilution versus post-dilution hemofiltration. (From Henderson LW: Pre vs. post dilution hemofiltration. Clin Nephrol 1979; 11:120–124. Reprinted with permission.)

several reasons. As indicated earlier, logistic and cost considerations limited replacement fluid volumes to approximately 20 L or less per treatment. Urea clearances obtained with such volumes were substantially less than those achieved with HD. The increasing focus on urea-based quantification of dialysis therapy in the 1980s only served to accentuate the relatively low urea clearances in HF.[7]

A solution to this problem was actually published by two different groups in 1978. Leber and colleagues[49] described a system employing simultaneous HF and HD with a polyacrylonitrile (RP6) dialyzer. The operating parameters included a blood flow rate of 200 mL/min, dialysate flow rate range of 200 to 900 mL/min, and ultrafiltration rate range of approximately 40 to 60 mL/min. The replacement fluid was lactate-based and administered post-filter from bags while the dialysate was acetate-based. Relative to pure HF at an ultrafiltration rate of 55 to 60 mL/min, diffusive removal provided by a dialysate flow rate of 900 mL/min increased urea and creatinine clearance by approximately threefold. Kunitomo and colleagues[50] also described a similar post-dilution system employing a high-permeability polymethyl methacrylate dialyzer.

As was the case for HF, the introduction of on-line technology broadened significantly the capabilities of HDF. In the initial characterization of on-line HDF by Canaud and colleagues[46] (Figure 24–2), proportioned dialysate was first ultra-filtered to produce ultrapure dialysate. A portion of this stream was diverted and subjected to a second ultrafiltration step to produce replacement fluid, delivered in the post-dilution mode. The ultrafiltration rate was approximately 70 mL/min, resulting in an exchange volume of 16 L per treatment. As HDF therapy has evolved, ultrafiltration rates and exchange volumes have increased and are now approximately 100 mL/min and 20 to 25 L/session, respectively.[52–54] However, the general approach of using ultrafiltration to generate ultrapure dialysate and replacement fluid sequentially, a process termed "cold sterilization," remains intact.

FACTORS INFLUENCING LOW-MOLECULAR WEIGHT PROTEIN REMOVAL IN HEMOFILTRATION AND HEMODIAFILTRATION

The low MW protein (LMWP) class (Table 24–1) is a relatively large MW class of uremic toxins whose clearance is enhanced by the use of convective blood purification therapies.[33] As noted previously, concentration polarization and secondary membrane effects are relatively important considerations for these solutes. Röckel and colleagues[26] investigated the effect of secondary membrane formation on low MW pro-

tein sieving coefficient (SC) values during clinical hemofiltration with a high-flux polysulfone hemofilter. These investigators measured *in vivo* sieving coefficients for several solutes in this category, ranging in molecular weight from 12 kDa (β2M) to 55 kDa (prealbumin). Sieving coefficient determinations were made in the first 10 min (peak SC: PSC) and at treatment times of 20 and 180 min. For each protein, a significant decrease was observed between the PSC and the 20-min value. This effect was directly proportional to protein molecular weight such that after 20 min of treatment, no measurable filtration of solutes of MW greater than 30 kDa was evident.

For equivalent ultrafiltration rates up to 110 mL/min (with Q_B = 300 mL/min), several investigators have shown that post-dilution HDF is superior to pre-dilution HDF with respect to removal of LMW proteins in the 12 to 33 kDa range.[27,55,56] As discussed previously, the benefit of the post-dilution mode is explained by the thicker polarized boundary layer (relative to the pre-dilution mode), and the associated high concentration submembranous protein upon which the convective forces act. Because the degree of polarization is directly proportional to the degree of rejection, the relative benefit of the post-dilution mode generally increases as LMWP molecular weight increases. Unfortunately, these same considerations also apply to albumin removal. As such, from the perspective of large solute removal, post-dilution HDF requires a balance to be struck between the optimization of LMWP removal while minimizing albumin losses (see later text).

CLINICAL CHARACTERIZATION OF CONTEMPORARY CONVECTIVE MODALITIES

Hemofiltration

Before addressing more recent applications of HF, the first formal application of HF by Henderson and colleagues is discussed. After laboratory experiments demonstrating proof of concept, these investigators reported their clinical experiences, which were groundbreaking in two respects. First, it was the first clinical description of hemofiltration, which they actually termed "hemodiafiltration."[34] In this landmark original work, the pre-dilution system employing blood flow, ultrafiltration, and replacement fluid rates all of about 200 mL/min was characterized, particularly with respect to middle molecule clearances. In a separate report, Henderson and colleagues[41] also first described in detail the on-line production of sterile, non-pyrogenic replacement fluid by ultrafiltration with an Amicon polysulfone filter. The general approach of cold sterilization used in this latter study was the foundation for subsequently developed on-line fluid generation systems, which continue to be used today for both HF and HDF.

Over the past several years, Altieri and colleagues[57–60] from Italy have clearly defined the clinical capabilities of on-line HF. In a multi-center trial involving 23 patients,[57] these investigators first performed a clinical comparison of high-flux HD and on-line pre-dilution HF. The HD arm consisted of ultrapure dialysate and the same high permeability dialyzer (polyamide membrane) used in the HF arm. The HF treatment parameters included a mean blood flow rate of 372 mL/min and a mean substitution fluid rate of 327 mL/min,

resulting in a total substitution fluid volume of 68.5 L per treatment. With respect to intradialytic symptoms, the HF arm was associated with a significantly reduced rate of hypotension, hypertension, arrhythmia, cramps, headache, and nausea, relative to the HD arm. Moreover, the incidence of interdialytic cramps, arthralgia, headache, and fatigue was significantly lower in the HF arm.

A comparison of solute kinetics in the two arms was also performed. Although delivered urea Kt/V was significantly greater in the HD than in the HF arm (mean, 1.4 and 1.1, respectively), no difference in normalized protein catabolic rate (nPCR) was observed. In a subgroup of 18 patients, a regression analysis of nPCR versus Kt/V was performed for both the HD phase and HF arms, the latter occurring after patients had been stabilized on HF for 3 months. The slope of the regression line was significantly higher for the HF arm than the HD arm. Thus, for a given increase in urea Kt/V, the resultant increase in nPCR was greater during the HF phase. One explanation for this finding is the relatively greater removal of middle molecular weight anorectic compounds[61] by HF than HD.

In another Italian study of 24 patients comparing high-flux HD and on-line pre-dilution HF,[60] the same authors used a crossover design (HF-HD-HF) and attempted to achieve equality in the two arms with respect to delivered Kt/V and treatment duration. Similar to the first study, an on-line generation system was used to prepare the ultrapure dialysate for the HD and substitution fluid for HF, and the same highly permeable membrane (polyamide) was used in both phases. However, attainment of an equivalent Kt/V in the two arms required a significantly higher mean blood flow rate of 421 mL/min in HF versus 307 mL/min in HD. Moreover, the surface areas of the dialyzer in the HF and HD arms were 2.0 and 1.4 m², respectively.

The primary aim of the study was achieved in that delivered urea Kt/V was the same in all three phases of the study (mean 1.3). In the HF phases, this was associated with a mean substitution fluid rate and volume (317 mL/min and 69.6 L per treatment, respectively), which closely approximated the values from the first study. Significant differences in the occurrence of intradialytic events, including hypotension, cramps, and need for volume repletion, were observed in both HF arms relative to the HD arm. Likewise, in the interdialytic period, the prevalence of hypotension and fatigue was lower in the HF arms.

Hemodiafiltration

Maduell and colleagues[52] reported the clinical effects of transitioning patients from low-substitution volume ("soft") HDF to on-line HDF, which allowed a much higher substitution fluid volume to be used. Both modalities were performed in the post-dilution mode, which has been nearly the exclusive mode for HDF until very recently (see later text). In the low-volume arm, the mean substitution fluid rate was 22 mL/min, resulting in a mean total substitution volume of 4.1 L per treatment. The mean blood and dialysate flow rates were 402 and 654 mL/min, respectively. In the on-line arm, each patient continued to use the same high-flux dialyzer and, on average, the dialysate flow rate was not significantly changed. However, the mean blood flow rate modestly, but significantly, increased to 434 mL/min versus 402 mL/min in the previous phase. As

far as prescription parameters, the major difference between the two arms was the significantly higher mean substitution fluid rate of 121 mL/min, corresponding to a mean total substitution volume of 22.5 L per treatment.

Several clinical benefits were observed during the 12-month follow-up after the therapy change. During soft-HDF and after 12 months of on-line HDF, mean single-pool urea Kt/V increased significantly from 1.35 to 1.52. Based on a comparison at the same time points, anemia parameters also improved, with a significant increase in hematocrit (32.2% vs. 34.0%) and a significant decrease in weekly mean erythropoietin requirements (3861 vs. 3232 U) (Figure 24–3). Finally, a sustained decrease in mean pretreatment serum β2-microglobulin from 27.4 mg/L during soft-HDF to 24.2 mg/L after 12 months of on-line HDF was also observed.

The above β2-microglobulin kinetic results reported by Maduell and colleagues have been corroborated recently by Lin and colleagues[62] in Taiwan. These investigators treated 58 patients over a mean period of 7.9 months with on-line post-dilution HDF according to the following prescription parameters: blood flow rate, 300 mL/min; dialysate flow rate, 500 mL/min; 1.8 m² polysulfone dialyzer; and total substitution fluid volume per treatment, 20 to 22 L. At baseline prior to HDF therapy, these patients received high-flux HD using similar blood and dialysate flow rates and the same dialyzer. Use of HDF resulted in a significantly higher mean β2-microglobulin reduction rate of 76% compared with 61% during HD. This greater degree of depuration resulted in a significantly lower mean pretreatment serum β2-microglobulin (22.2 mg/L vs. 34.8 mg/L during HD). Moreover, in a subgroup of nine patients receiving at least 12 months of HDF, a significant negative inverse correlation between HDF duration (in months) and pretreatment serum β2-microglobulin concentration was observed.

Although it is tempting to regard the results as seemingly intuitive, it is important to note that the clinical data regarding the effect of on-line HDF on serum pretreatment β2-microglobulin concentration are not entirely consistent. Employing the same high-flux dialyzer, Ward and colleagues[63] compared LMWP clearance and removal during HD and on-line post-dilution HDF (mean 21 L substitution fluid volume per treatment). Although mean dialyzer β2-microglobulin clearance was significantly higher during HDF (61 mL/min vs. 38 mL/min in HD), the effect on pretreatment β2-microglobulin concentration was not significant. Two potential explanations for this somewhat surprising finding were offered by the investigators. First, it is possible that the clearance provided by "internal filtration" (Starling's flow) during high-flux HD is greater than previously considered.[64] Under normal operating conditions of high-flux HD, the large axial pressure drop that occurs in such highly permeable membranes typically results in pressures in a certain portion of the distal (venous) end of the fibers that are less than the corresponding dialysate compartment pressure. This results in the routine occurrence of backfiltration of dialysate during high-flux HD. Although the combination of significant backfiltration and contaminated dialysate may be problematic,[65] this internal filtration circuit is actually beneficial from a large molecule clearance perspective by providing a significant convective component to total clearance. Patient-related mass transfer limitations represent the second potential explanation for this finding. Under standard dialysis conditions, the rate-limiting step for the removal of uremic toxins is not at the level of the dialyzer but rather within the patient's body.[66] Specifically, relatively slow transfer of β2-microglobulin and similar compounds within various compartments in the body, hinders delivery of solute out of the body. With solute delivery to the dialyzer impaired in such a manner, an increase in extracorporeal *clearance* has little effect on extracorporeal *removal*.[67] Despite this failure to find a significant impact on pretreatment β2-microglobulin concentration, Ward and colleagues did observe a significantly greater mean percent reduction in the plasma concentration of a larger middle molecule, complement Factor D (22 kDa), during HDF versus HD (33% vs. –2%, respectively).

Daily Convective Therapies

Due to its greater volume removal capabilities and more favorable solute kinetic profiles relative to thrice-weekly HD, daily HD therapy is considered by many experts to be superior to standard HD. Indeed, multiple small studies demonstrating benefits in such parameters as blood pressure control, anemia

Figure 24–3 Effect of conversion from "soft" hemodiafiltration to on-line hemodiafiltration on erythropoietin requirements. (From Maduell F, del Pozo C, Garcia H, et al: Change from conventional hemodiafiltration to on-line hemodiafiltration. Nephrol Dial Transplant 1999; 14: 1202–1207. Reprinted with permission.)
markers, and nutritional status have appeared in the literature over the past few years.[68–71] Data from these studies have been sufficiently convincing that the National Institutes of Health in the United States is funding a multicenter study to explore further the potential clinical effects of daily HD.

As suggested, significant benefits are derived from performing dialysis therapy on a daily basis. When HD is performed only thrice-weekly, pretreatment solute concentrations increase to relatively high levels due to the long interdialytic intervals. Consequently, diffusive transmembrane concentration gradients are relatively high at the start of therapy. However, efficient depuration results in a relatively rapid dissipation of the concentration gradient, along with the driving force for diffusive removal. Thus, the latter part of a conventional HD treatment is relatively inefficient with respect to solute removal. Therapy delivery on a more frequent basis over shorter duration is advantageous because treatment is truncated before the inefficient phase (i.e., the low solute concentration period) is reached.[72]

A pioneer in the field of on-line convective therapies, Dr. Ledebo,[73] has recently suggested that a daily convection-based therapy approximates native kidney function most closely. However, only a small body of clinical experience with such an approach exists currently. Canaud and colleagues[74] prescribed daily on-line post-dilution HF to a series of ESRD patients more than a decade ago. A mean ultrafiltrate volume of 20.8 L per treatment and blood flow rate of 482 mL/min were prescribed. Despite the brevity of the study (1 week), a significant 35% decrease in the mean pre-treatment $\beta2$-microglobulin concentration from 39 to 25 mg/L was observed. More recently, Maduell and colleagues[75] evaluated the clinical effects of transitioning eight ESRD patients from thrice-weekly on-line HDF to a 6-month period of short daily on-line HDF. The ranges for the prescription parameters, which did not differ between the two arms, were: blood flow rate, 350 to 560 mL/min; substitution fluid rate, 80 to 150 mL/min; and dialysate flow rate, 800 mL/min minus the substitution fluid rate. Although mean treatment duration was shorter in the daily arm (133 min vs. 274 min in thrice-weekly arm), total weekly treatment duration was not significantly different (822 vs. 798 min in daily and thrice weekly arms, respectively). Despite this, urea EKR[76] and standard urea Kt/V,[77] two "continuous-equivalent" clearance measurements that allow for comparisons of therapies of differing frequency, both increased significantly by a mean of 26% and 48%, respectively, in the daily HDF phase (Figure 24–4). This finding is consistent with the argument concerning the kinetic benefits of daily therapy.

Maduell and colleagues[75] also quantified the differences in the clearance and removal of larger molecular weight uremic toxins in the two arms. Although the weekly percent solute removal of urea and creatinine increased significantly by 51% and 55%, respectively, this same parameter increased to an even greater extent for the larger molecules evaluated. Indeed, for osteocalcin (MW, 5.8 kDa), $\beta2$-microglobulin (11.8 kDa), myoglobin (17.2 kDa), and prolactin (23 kDa), the increase ranged from 67% to 75% (Figure 24–5). Specifically for $\beta2$-microglobulin, the mean pretreatment concentration decreased significantly by approximately 15% from a baseline concentration of 29.5 mg/L. Associated with these improvements in solute removal parameters were favorable changes in a number of cardiac parameters defined by echocardiography. After both 3 and 6 months of daily HDF therapy, significant decreases in inter-

ventricular septal thickness, left ventricular mass, and left ventricular mass index relative to baseline were observed.

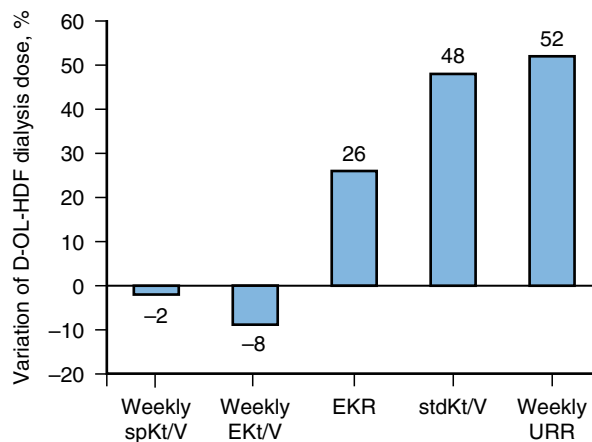
Finally, Zimmerman and colleagues[78] have reported recently their experience with a novel delivery system for daily HF. In 11 patients treated at baseline with thrice-weekly high-flux HD, these investigators assessed the clinical effects of a 4-week treatment period of daily HF. In this approach, substitution fluid was provided as terminally sterilized fluid from bags in volumes generally ranging from 10 to 20 L, depending on the dose requirement and size of an individual patient. The mean treatment duration and substitution volumes were 132


Figure 24–4   Effect of conversion from thrice-weekly on-line hemodiafiltration to daily on-line hemodiafiltration on urea clearance markers. (From Maduell F, Navarro V, Torregrosa E, et al: Change from three times a week on-line hemodiafiltration to short daily on-line hemodiafiltration [D-OL-HDF]. Kidney Int 2003; 64:305–313. min and 11.6 L, respectively, in the daily HF phase of the study. Despite the relatively short duration of the daily HF phase, blood pressure control improved significantly, with mean arterial pressure decreasing from 96 to 86 mm Hg. In addition, mean pre-treatment β2-microglobulin decreased from 22.9 to 19.2 mg/L.

RECENT DEVELOPMENTS

In the next few years, several areas of interest in the convective therapies are likely to be explored. One of the emerging developments is the use of "mixed" dilution HDF rather than the traditional mode of post-dilution only. One approach to achieve mixed dilution was described originally for hemofiltration by Shaldon and colleagues[79] and later adapted by Collins and colleagues[80] in the form of a customized device. Effectively, the use of combined, simultaneous pre-dilution and post-dilution HDF also achieves the same end.[81,82] As described by Pedrini and colleagues,[82] use of the mixed mode avoids high transmembrane pressures, which are typically associated with high filtration fraction and membrane fouling. In addition, relative to post-dilution alone, mixed mode HDF may also result in less albumin loss, as suggested by a recent comparison of pre-dilution and post-dilution HF.[83] Another recently described approach to disrupt membrane fouling and concentration polarization and, thus, attenuate albumin losses is "push-pull" HDF.[84] In this therapy, repetitive application of positive and negative transmembrane pressure effectively achieves this disruption.

SUMMARY AND CONCLUSIONS

Recently performed outcome studies caution clinicians not to be over reliant on urea-based dosing parameters in the management of ESRD patients on maintenance dialysis. More importantly, these studies suggest that new dialytic approaches are needed to improve survival in ESRD patients. One approach that may influence survival favorably is broader application of convective therapies. The widespread availability of on-line systems for the preparation of ultrapure dialysate and sterile, non-pyrogenic replacement fluid allows the convective therapies to have solute clearance capabilities that surpass those of HD and PD. At present, outcome data demonstrating a clear benefit for convective therapies over conventional therapies do not exist. However, it is expected that results from comparative studies assessing this possibility will be forthcoming. For the convective therapies to flourish on a broad global scale, issues related to cost, regulatory concerns, and patient selection will need to be addressed. Nevertheless, in the opinion of the authors, these modalities represent a great opportunity for ESRD therapy to advance and meet the needs of an increasingly complex and challenging patient population.

Peritoneal Dialysis

Chapter 25

Peritoneal Physiology

Olof Heimbürger, M.D., Ph.D.

In patients with chronic renal failure, waste products, which normally are excreted in the urine, accumulate in the blood resulting in uremic intoxication, and the obvious goal of dialysis treatment is to remove "uremic toxins" (including water) from the patient. Peritoneal dialysis (PD) utilizes dialysis fluid infused into the peritoneal cavity and a system of biologic membranes—the peritoneal barrier—for this purpose. Whereas the artificial hemodialysis membrane has well characterized, reproducible, solute and fluid transport characteristics, the peritoneum is not really a membrane but rather a complex structure of living tissues with different transport characteristics, which, furthermore, will differ between patients, a fact that will affect the fluid and solute transport kinetics of PD as well as dialysis efficiency in PD patients. In addition, the transport characteristics of the peritoneal membrane may not be constant in an individual patient but may be altered with time due to effects of the dialysis procedure or the dialysis fluids, in response to various physiologic reactions or due to pharmacologic effects of different drugs.

THE PERITONEAL ANATOMY

The peritoneal cavity is the largest serosal cavity in the body with a surface area of approximately 1 to 2 m^2. Although the peritoneal area is commonly suggested to be similar to the body surface area, recent studies suggest that the anatomic surface area of the peritoneum may be only about 50% of the body surface area in adults.[1–3] Peritoneum etymologically means "wrapped tightly around," which is a good description of the arrangement of this serous membrane that consists of two parts: the parietal peritoneum that covers the abdominal wall and the diaphragm and the visceral peritoneum that covers the intra-abdominal viscera.[4] The parietal peritoneum represents a smaller portion (approximately 10% to 20%) of the total peritoneal surface area[1,2] and receives its blood supply from the vasculature of the abdominal wall. The visceral peritoneum represents the larger part (approximately 80% to 90%) of the total peritoneal surface area[2] and receives its blood supply via the mesenteric vessels. However, it should be pointed out that it is the functional peritoneal surface area that is important not the anatomic surface area.[5] The func-

tional area will be related to the surface area of the capillaries in the peritoneal interstitium, the capillary density, and the spatial arrangement of these capillaries.[3,5] In addition, the peritoneal cavity is only a potential space under normal conditions and the functional contact area between the peritoneum and the dialysis fluid in the peritoneal cavity during PD will be lower than the anatomic area.[6] In particular, functional area of the visceral peritoneum is reduced due to the incomplete contact and poor mixing in small fluid compartments within pockets of the visceral peritoneum. In mice, less than half of the peritoneal surface is in contact with a large volume of solution in the peritoneal cavity, but the contact area could be improved by shaking of the animal, and, particularly, by adding dioctyl sodium sulfosuccinate (a surface-tension lowering agent).[6]

HISTOLOGY

The Mesothelium

The surface of the peritoneal cavity is lined by a single layer of mesothelial cells (fixed to a continuous basement membrane) that under normal physiologic conditions are covered with a thin (5 µm) film of peritoneal fluid that is kept in place by numerous microvilli.[4] The microvilli and the peritoneal fluid have a lubricating function to prevent formation of adhesions and to allow the free movement of the visceral organs during respiration, peristalsis, and body movement.[4] The peritoneal fluid contains protein, electrolytes, cells (mainly macrophages, lymphocytes, and desquamated mesothelial cells), and has a high content of phospholipids that are secreted in from the mesothelium by the formation of lamellar bodies, similar to the production of surfactant from type II pneumocytes.[7]

The mesothelial cells may modulate the peritoneal micro-circulation by secretion of vasodilators like PGE_2 and nitric oxide as well as vasoconstrictors, such as endothelin,[8] and, furthermore, the mesothelial cells have an important role in the initiation of the local immune response regulating leukocyte infiltration via the secretion of chemokines and expression of adhesion molecules.[9,10] Mesothelial cells have a capacity to produce tissue plasminogen activator

(tPA), and the mesothelium normally expresses high fibrinolytic activity.[8,11] However, the mesothelium also have antifibrinolytic capacity by synthesis of fibrinolytic inhibitors like plasminogen activator inhibitor 1 (PAI-1) and PAI-2, and the balance between the synthesis of fibrinolytic and agents in mesothelial cells will determine their capacity to promote fibrin degradation. Under normal conditions the fibrinolytic activity strongly dominates, but the balance may change completely during inflammation when the antifibrinolytic activity of the mesothelium will dominate, and furthermore, the mesothelium may also exhibit procoagulant activity with expression of tissue factor (which is markedly upregulated in mesothelial cells during inflammation).[8] Thus, the mesothelium plays an important role in regulation of the balance between fibrinolytic and procoagulant activity in the peritoneal cavity.

The underlying basement membrane is a very thin laminar network containing collagen type IV, proteoglycans, and glycoproteins such as laminin, and allows macrophages and lymphocytes to pass through it, whereas fibroblasts cannot pass this basement membrane.[8] The thin mesothelial cell layer and their basement membrane seem to offer very little resistance to the transport of small and large solutes, in vitro or in vivo.[3,12] Thus, the mesothelium does not seem to have any major impact on the transport across the peritoneal barrier.

The Interstitium

Beneath the mesothelium lies the interstitial tissue, comprising of an amorphous ground substance or gel-like extracellular matrix interlaced with collagenous, reticular, and elastic fibers, adipocytes, fibroblasts, and granular material, and containing blood capillaries, nerves, and lymphatic vessels.[13–15] The collagen fibers constitute the largest component of the space between the cells in the peritoneum and form a fibrous skeleton in the interstitium.[15] The collagen fibers bind via β1-integrins to fibroblasts and other cells in the tissue.[16] The interstitial ground substance may be subdivided into a colloid-rich and a water-rich phase, the two phases being in equilibrium with each other.[3,12,14] The colloid-rich phase contains several different glycosaminoglycans (GAG), including hyaluronan (HA, which is the major component). All GAGs except HA are covalently bound to a protein backbone forming proteoglycans (the combination of a GAG and a protein), for example, chondroitin sulphate, dermatan sulphate, keratan sulphate, and heparan sulphate. The GAGs are polyanionic, have low isoelectric points, and, consequently, the interstitial ground substance has a high density of negative colloidal charge at physiologic pH.[14] Water and small solutes can easily enter the colloid-rich phase, whereas macromolecules are excluded from large parts of this phase. In a complex manner, the interstitium may act as a mucopolysaccharide hydrogel, penetrated with more or less continuous channels of free fluid.[3] Whereas small solutes may pass through interstitial matrix hydrogels without much hindrance, the diffusion of macromolecules may be markedly retarded.[5,15] However, it is important to remember that the capillary wall determines the amount of solutes that are transported from blood to interstitium, and both the interstitium and the capillary wall need to be taken into account for the description of the peritoneal transport process.

In general, changes in aggregation and hydration of the ground substance in interstitial tissues affect the physicochemical properties and the functional characteristics of the interstitium,[14] but it is at present not established exactly how peritoneal dialysis may affect the functional characteristics of the peritoneal interstitial tissues.[12]

The Capillary Wall

The microvascular exchange vessels in the peritoneal membrane consist of both true capillaries (diameter 5–6 µm) and postcapillary venules (diameter 7–20 µm),[5] and the capillary wall is considered to be the major transport barrier for transperitoneal exchange of fluid and solutes during peritoneal dialysis. The peritoneal capillaries belong to the continuous type (in which endothelial cells form a continuous layer enwrapped in a negatively charged glycocalix),[5,17,18] which functionally restrict solute exchange to less than 0.1% of the total capillary surface area (= the small pores, see later).[3,19] The peritoneal capillaries behave functionally as having a heteroporous structure, with a small number of large pores (radius 200–400 Å) through which macromolecules are filtered due to convective flow and a large number of "small pores" (radius 40–65 Å), which are impermeable for macromolecules larger than albumin (molecular weight 69,000 Dalton) but do not restrict the passage of small solutes.[17,18,20] In addition, "ultra-small" pores (radius 4–6 Å) were postulated to be involved in the water flow induced by the osmotic effect of low molecular weight osmotic agents, for example, glucose[17,20,21] (Figure 25–1). The anatomic correlate of the water channels was later demonstrated to be aquaporin-1, a protein 28 KDa intramembrane protein shown to be one of the water channels in human proximal tubular cells in the kidney as well as in various nonfenestrated epithelia.[22,23] Aquaporin-1 has been demonstrated in peritoneal endothelial cells, at mRNA protein, and functional levels.[24–26] The anatomic correlates to the small pores are possibly the interendothelial clefts.[5,17,20] The three-dimensional structure of the interendothelial clefts has been described in detail.[27] However, the morphologic counterpart to the large pores is not established, although it most likely corresponds to larger interendothelial gaps.[5,17,20] Though there has been considerable controversy about the mechanism of macromolecular transport through the endothelium and the potential role of vesicular transport (transcytosis), it is now established that the quantitative role of transcytosis is negligible.[28,29]

The three-pore concept of transcapillary exchange[18] has been successfully applied by Rippe and associates[17,30–33] to model the peritoneal transport of small solutes and macromolecules as well as the peritoneal fluid transport, supporting the view that the capillary wall is the main resistance for transperitoneal fluid and solute transport.

PERITONEAL BLOOD FLOW

The mesenteric blood flow is generally supposed to be about 10% of cardiac output.[34] The effective peritoneal blood flow, that is, the blood flow to the capillaries that are directly involved in peritoneal transport, cannot be directly measured.[35] Indirect estimations suggest that the effective peritoneal blood flow may vary from 20 to 40 mL/min (using
Figure 25–1 The three-pore model of peritoneal capillary permselectivity, including the transcellular pore (aquaporin-1), the small pore (the interendothelial clefts), and the large pores (possibly large interendothelial clefts). Small circles represent small solutes and large circles represent proteins. The forces are: Π, osmotic pressure and P, hydrostatic pressure. Crystalloid osmotic pressure induced by glucose is very efficient through the transcellular pores, and about 50% of the ultrafiltered fluid will pass through the aquaporins when glucose is used as an osmotic agent in PD. (From Flessner MF: Peritoneal transport physiology: Insights from basic research. J Am Soc Nephrol 1991; 2:122-135, with permission.)

estimations of the maximal possible ultrafiltration rate) to more than 100 mL/min (based on the measurements of the clearance of gases).[36,37] The effective peritoneal blood flow is generally not believed to limit the clearance of small solutes during peritoneal dialysis[37,38] because the diffusive mass transport coefficient for urea is approximately 20 mL/min. Also, tracer disappearance from small plastic chambers glued to the serosa was not reduced with a 30% decrease in blood flow and only to a minor degree with no blood flow (in dead rats).[39,40] However, this issue is still controversial, and there are some observations indicating that peritoneal urea clearance may be blood flow limited.[12,35,41] Recently, Rosengren and Rippe[42] reported that a reduction of blood flow by 40% (caused by bleeding of rats) resulted in a decreased transport of glucose and ^{51}Cr-EDTA by 13% and 24%, respectively. They concluded that there is to some extent a blood flow limitation of peritoneal transport, but that the level of blood flow limitation is much smaller than in other organs. Note that the diffusion rate of small solutes theoretically will not be proportional to the blood flow, but to the square root of perfusion rate, which to a large extent may explain the small change in transport with marked alterations in blood flow.[43]

Vasodilators have been shown to increase peritoneal clearances due possibly to increase in the capillary surface area due to vasodilatation and recruitment of capillaries.[35,44] Furthermore, changes in the distribution of the blood flow may possibly also affect the peritoneal transport rate.

PERITONEAL LYMPHATICS

The Anatomy of Peritoneal Lymphatics

About 4% of the mesothelial surface area is reported to be covered by lymphatic vessels,[45] but the major part of the lymphatic drainage is considered to occur via the lymphatic stomata in the diaphragmatic part of the peritoneum.[46,47] The diaphragmatic lymphatic stomata, that were first described by von Recklinghausen[48] in 1862, are small openings (diameter 4–12 μm) that are formed by intercellular junctions between both mesothelial cells and lymphatic endothelial cells, and opens directly into underlying lymphatic lacunae.[45–47] It is through these specific openings that large particles like erythrocytes and bacteria can directly leave the peritoneal cavity. The underlying lymphatic plexuses (which in humans are situated mainly on the muscular portion of the diaphragm) intercommunicate directly with the plexuses on the pleural surface via intercommunicating vessels.[46] After leaving the diaphragm, the lymph is drained via the large collecting ducts associated with the internal thoracic vessels to reach the venous circulation via the right lymphatic duct.[46] The lymphatic drainage of the peritoneal cavity is to a large extent dependent on the periodic compression and release of the lymphatic vessels caused by the movements of the diaphragm during respiration.[46,49]

In addition to the lymphatic vessels the diaphragmatic part of the peritoneum, subserosal lymphatic vessels can also be found in other parts of the peritoneal cavity, including the omentum,[46] and, furthermore, local lymphatic vessels are also present in the tissues surrounding the peritoneal cavity, although their role in peritoneal transport seem to be minor under normal conditions.[46]

The Importance of Lymphatic Flow for Peritoneal Fluid Absorption

The disappearance of a macromolecular marker from the peritoneal cavity has often wrongly been used to estimate lymph flow from the peritoneal cavity during peritoneal dialysis. It is now well established that the peritoneal absorptive flow of fluid and solutes is comprised of two different pathways[12,50,51]: (1) direct lymphatic absorption (mainly via the lymphatic stomata in the diaphragm, and, to a lesser extent, through visceral lymphatic pathways,[51] and (2) fluid absorption into tissues.[17,52] Studies using tracer appearance in plasma have demonstrated that the direct lymphatic flow represents about 20% of the fluid absorptive flow from the peritoneal cavity in clinically stable CAPD patients.[53–55] See "fluid absorption" below for a more detailed discussion.

PERITONEAL LOCAL REACTION TO INFECTION

The peritoneal host defense reaction to infection is a complex network of interactions between mesothelial cells, peritoneal macrophages (PMø), infiltrating neutrophils, monocytes and other inflammatory cells, and orchestrated by the secretion of vasoactive substances, cytokines, chemokines, growth factors as well as components of extracellular matrix.[8,9] The initiation, resolution, and repair process of inflammation in the

peritoneal cavity are very complex processes, which presently are under intense study, and the regulation of these processes is starting to be understood.[8–10,56,57]

The initial inflammatory activation by bacteria entering the peritoneal cavity is likely to occur on the mesothelial surface, where mesothelial cells together with PMø have an important role in the initiation of the local immune response.[9] The mesothelial cells are able to contribute to the massive neutrophil influx by generation of chemokines like CXCL8 (previously called interleukin-8), a process that is amplified by the PMø-derived cytokines tumor necrosis factor α (TNFα) and interleukin (IL)-1β[9,58,59]; and the mesothelial cells are also capable of expression of adhesion molecules like ICAM-1, VCAM-1, and PECAM-1 as well as integrins, which may promote leukocyte attachment to the mesothelial cells.[8] The PMø produced TNFα and IL-1a are thought to be key mediators in the activation of mesothelial cells.[9] The mesothelial cells are the principal source of IL-6 in the peritoneal cavity and synthesize large amounts of IL-6 upon inflammatory challenge.[60] However, mesothelial cells do not express the cognate IL-6 receptor and therefore they initially are unresponsive to IL-6. There is a rapid accumulation of neutrophils within the peritoneal cavity during the first 12 to 24 hours, however, after a few days the neutrophils are replaced by a more sustained population of monocytes and lymphocytes.[10] In fact, this temporal switch in the recruitment of leucocytes (which is under a complex regulation) determines whether or not the infection is cleared.[61,62] Liberation of the soluble IL-6 receptor (SIL-6R) from the initial neutrophils allows for the formation of the IL-6 and SIL-6R complex, that allows IL-6 responsiveness in cell types (including mesothelial cells) lacking the cognate IL-6 receptor.[61] The IL-6 and SIL-6R complex will downregulate the expression of CXCL8 and other neutrophil-activating chemokines, and the SIL-6R may also directly promote MCP-1 expression resulting in the more sustained mononuclear leukocyte infiltration.[10] In addition, the release of oncostatin M from the infiltrating neutrophils will have a synergistic effect with the SIL-6R for the temporal switch from neutrophil influx to mononuclear cell recruitment as oncostatin M suppresses IL-1β-mediated expression of CXCL8.[56] Interferon-γ (IFN-γ) also has an important role in this process by control of both the initial neutrophil recruitment independently of IL-6 (through regulation of chemokine expression) as well as the neutrophils clearance phase by regulating local IL-6 levels.[57,63] The neutrophils will, to a large extent, undergo apoptosis and then be phagocytized by mononuclear cells.[63] This transition from the recruitment of neutrophils (typically associated with innate immunity) to the leukocytes typically associated with acquired immunity is considered to facilitate the successful resolution on the inflammatory reaction.[10]

PERITONEAL TRANSPORT PHYSIOLOGY

Barriers to Transperitoneal Exchange

The peritoneum is a complex structure of at least five different resistance barriers coupled in a series: (1) the unstirred fluid layer in the capillaries, (2) the capillary wall (endothelium and basement membrane), (3) the interstitial space,

(4) the mesothelium and its basement membrane, and (5) the unstirred fluid layers in the peritoneal cavity.[64] Each of these barriers has its specific transport properties. The capillary wall is considered to represent the major transport barrier for transperitoneal exchange,[17,20] but the interstitium is also important, whereas the mesothelium is highly permeable.[17,20] The mucopolysaccharide hydrogel of the interstitium will exclude solutes from part of the interstitial water volume and force solutes to follow a tortuous path,[12] and, furthermore, the negative charge of the interstitial ground substance may markedly retard the transport of charged molecules through the interstitium.[14] Unstirred fluid layers in the peritoneal cavity may represent transport resistances for the diffusion of small solutes[12,65] but are likely of much less importance than the interstitium as the diffusibility is much less in the interstitium compared to the stagnant fluid layers.[3,66]

Modeling of Peritoneal Transport

To completely model the peritoneal transport process, all transport barriers, and their specific transport characteristics, should be taken into account as well as the distribution of the capillaries within the peritoneal interstitium. This will result in very complex models that are difficult to apply in the clinical situation, and, at present, even complex models fail to predict ultrafiltration with better accuracy than simpler models.

Single-membrane models have been used to estimate transport parameters in clinical peritoneal dialysis.[67–73] In the single-membrane models, the peritoneal barrier is regarded as a single membrane separating the well-mixed blood and dialysate compartments. The single-membrane models will work very well to describe the transport of small solutes (up to the size of small proteins like β2-microglobulin) from plasma to dialysate, but they will not work as well for the description of dialysate to plasma transport, and in particular, they cannot correctly describe the osmotic fluid transport when a high molecular solute (e.g., icodextrin) is used as osmotic agent.[5] The distributed model by Dedrick and Flessner[74–76] takes into account the distribution of capillaries in the interstitium and should be preferred from a theoretical point of view. However, the simpler three-pore model by Rippe and associates,[30–32] which takes into account the three pore systems in the capillary wall (see earlier text), is still as accurate in predicting both fluid and solute transport during clinical peritoneal dialysis, using both small molecular weight as well as macromolecular osmotic agents[30,32,77] (Figure 25–2). Also, a model describing the peritoneum as two heteroporous membranes in series (presumably the capillary wall and the interstitium) has been developed.[78] The detailed description of the different models lies outside the scope of the present chapter.

Fluid Transport

Ultrafiltration

The intraperitoneal dialysate volume over time curves during a peritoneal dialysis exchange are characterized by three phases: (1) initial *net ultrafiltration* (rate and duration is depending on the osmotic pressure of the solution); (2) *dialysate isovolemia* (during which ultrafiltration is counterbalanced by fluid absorption); and (3) *net fluid absorption* (independent on the osmolality of the solution)[79] (Figure 25–3).

Ultrafiltration in peritoneal dialysis is achieved by the application of a high concentration of an osmotic agent (usually glucose) in the dialysate, resulting in a high osmotic pressure gradient across the peritoneal barrier.[12,13,80] However, the osmotic pressure gradient over the peritoneal barrier decreases rapidly due to the absorption of the osmotic agent, when small solutes like glucose, amino acids, or glycerol, are used as osmotic agents. When a large molecular solute, for example, icodextrin, is used as osmotic agent the absorption of the osmotic agent is much slower, resulting in a much longer lasting osmotic gradient and positive net ultrafiltration.

Applying the thermodynamic theory of volume transport through selective membranes to the peritoneal membrane, the ultrafiltration rate (QU) is directly proportional to the ultrafiltration coefficient (L_pA), which, in turn, represents the product of the hydraulic conductance (L_p) and the effective surface area (A).[13,31,80,81] The ultrafiltration rate is therefore described as:

$$QU = L_pA \left(\Delta P - \sigma_{prot} \Delta\pi_{prot} - \sum_{i=1}^{n} \sigma_i \Delta\pi_i \right) \quad (1)$$

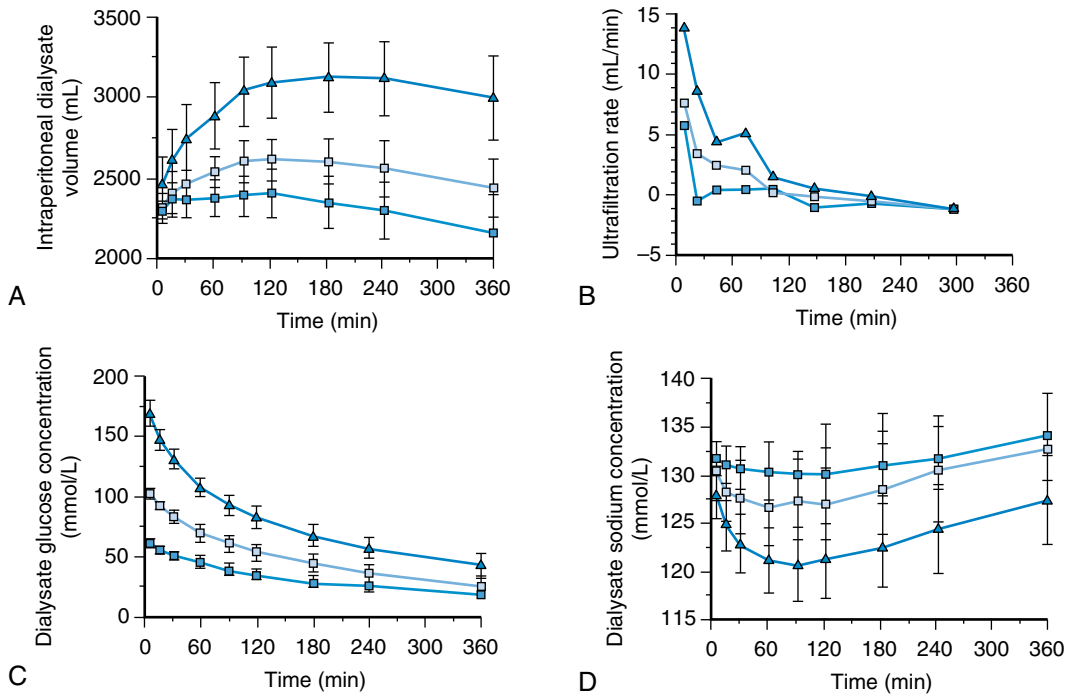
where ΔP is the hydrostatic pressure gradient, σ_{prot} is the reflection coefficient for total protein, $\Delta\pi_{prot}$ is the colloid osmotic pressure difference caused by the plasma proteins, and the third term within the parentheses represents the sum of all effective crystalloid osmotic pressure gradients across the peritoneal barrier.[31,82,83] Note that this equation is a simplification that applies to the capillary wall and, for the full description of the total process, also local effects in peritoneal tissue (e.g., the distribution capillaries in the interstitium, interstitial tissue pressure gradients) will have an impact on the ultrafiltration rate. Thus, the ultrafiltration induced when glucose is used as osmotic agent in PD, is dependent on the osmotic pressure difference for glucose, the hydraulic conductance (L_p), the surface area (A), and the reflection coefficient for glucose (σ_g).[31,82,83] A wide range of values for the ultrafiltration coefficient (L_pA) has been reported in the literature due to that markedly different values of σ_g have been estimated.[13,68,69,84,85] The reason for these discrepancies is that σ_g in several studies have been calculated as $\sigma_g = 1 - S_g$ (where S_g is the "lumped" glucose sieving coefficient for the whole peritoneal membrane), which is true for homogeneous membranes. However, as the peritoneal membrane is a heteroporous membrane, the relationship between σ_g and S_g may vary.[31] In fact, one of the most convincing arguments for the heteroporous character of the peritoneal membrane is that the direct determinations of L_pA for the peritoneal membrane


Figure 25–3 Intraperitoneal dialysate volume **(A)**, net ultrafiltration rate **(B)**, dialysate glucose concentration **(C)**, and dialysate sodium concentration **(D)** versus time, during a 6-hour dwell study with an exchange of 2 L of 1.36% (■), 2.27% (□), and 3.86% (▲) glucose solution (mean ± SD). The intraperitoneal dialysate volumes were assessed from the dilution of the tracer (radioiodinated human serum albumin) with a correction applied for the elimination of the tracer. Note that when hypertonic 3.86% glucose dialysis solution is used, there is a marked dip in dialysate sodium concentration due to dilution of the dialysate by the ultrafiltrate. The sodium concentration in the ultrafiltrate is much less than the sodium concentration in plasma due to sodium sieving as about half of the ultrafiltered fluid will pass through the aquaporins. (From Heimbürger O, Waniewski J, Werynski A, et al: A quantitative description of solute and fluid transport during peritoneal dialysis. Kidney Int 1992; 41:1320-1332, with permission.)

(assuming $\sigma_{albumin} = 0.9$) in cats and rats (scaled to humans using the scaling factor $BW^{0.7}$) yielded an L_pA value of approximately 0.1 mL/min.mmHg, which, in turn, yielded a σ_g of approximately 0.02.[82,83] These values are well in agreement with the reported initial ultrafiltration rate of 10 to 20 mL/min with 3.86% glucose solution.[68,69,79,86]

For the peritoneal barrier, the total σ of a solute is equal to the sum of the product of σ and the fractional hydraulic conductivity α for each set of pores. Thus, when applying the three-pore model for the peritoneal membrane the total σ for a solute will be given by the equation:

$$\sigma = \alpha_A \times \sigma_A + \alpha_S \times \sigma_S + \alpha_L \times \sigma_L \qquad (2)$$

where subscripts A, S, and L denote aquaporins, small pores, and large pores, respectively. As the aquaporins are impermeable for glucose, $\sigma_A = 1$ for glucose across the aquaporins, whereas the relative osmotic efficiency of glucose is much less across the small pores ($\sigma_S = 0.03$) and negligible across the large pores (σ_L approximately 0).[32] During normal conditions, the aquaporins account only for a small fraction (approximately 2%) of the LpA, and they will play a minor role in fluid transport, whereas the small pores account for about 90% of LpA. However, when applying a high crystalloid osmotic pressure over the membrane by using a small molecular osmotic agent, the importance of the aquaporins for fluid transport markedly increases. As $\alpha \times \sigma$ will be quite similar for the aquaporins ($0.02 \times 1 = 0.02$), and the small pores ($0.90 \times 0.03 = 0.027$) about half of the ultrafiltration will pass through the aquaporins resulting in marked sieving of solutes.[32] (For the large pores $\alpha \times \sigma$ will approximately be zero as σ_L is approximately 0.)

Fluid Absorption

During peritoneal dialysis, ultrafiltration is partly counterbalanced by the peritoneal fluid absorption (Q_A).[31,87–89] Thus, the net change in dialysate volume (V_D) is equal to:

$$\frac{dV_D}{dt} = Q_U - Q_A \qquad (3)$$

Because Q_A is considered to be a bulk flow, it can be estimated by the disappearance rate (K_E) of a macromolecular marker applied in the dialysate (see reference 89 for a detailed discussion).

Pathways for Peritoneal Absorptive Flow

The peritoneal absorptive flow consists of two different pathways[12,17,50-52]: (1) direct lymphatic absorption (via lymphatic stomata mainly in the diaphragm, and, to a lesser extent,

through visceral lymphatic pathways[51]) and (2) fluid absorption into tissues (where the fluid is absorbed into the capillaries due to the Starling forces, whereas the macromolecules are absorbed slowly via local lymphatics[17,52]). Sieving of macromolecules is assumed to be negligible with the direct lymphatic absorption, and with the second pathway (fluid absorption into tissues), sieving of macromolecules at the site of the mesothelium is considered to be negligible from a practical point of view. Thus, the macromolecular disappearance rate from the peritoneal cavity may be used as an estimate of the peritoneal bulk absorptive flow[89] because it is mainly dependent on the two components of peritoneal absorption, which both are considered to be bulk flows.[52,89] When the fluid, which has entered the peritoneal interstitial tissue compartment, is absorbed across the capillary wall (due to the Starling forces), sieving of macromolecules should occur at the site of the capillary wall. It is generally agreed that almost no protein may enter the plasma compartment directly through the capillary wall (although direct capillary uptake of radioiodinated human serum albumin, RISA, has been demonstrated under certain conditions[18,90]). The macromolecules that have entered the interstitial tissue compartment may thus accumulate in the interstitial tissue compartment before they are slowly absorbed by local lymphatics.[52]

The peritoneal absorptive flow is independent of the intraperitoneal osmotic pressure[91] and thus not influenced by ultrafiltration induced by the osmotic agent in the dialysate (i.e., osmotic pressure-driven convective flow). On the other hand, the peritoneal fluid and protein absorption rate in animal experiments have been shown to be directly proportional to the intraperitoneal hydrostatic pressure.[92] Studies by Flessner and associates[52,93,94] of tissue concentration profiles of RISA and labelled IgG (absorbed from the peritoneal cavity in rats) strongly support the notion that hydrostatic pressure-driven convection is the most likely mechanism driving the fluid and protein transport into adjacent tissues. It may seem puzzling that osmotic pressure-driven convection during dialysis and hydrostatic pressure-driven convection are considered to go simultaneously in different directions through the peritoneal barrier without any major interaction. However, this apparent paradox may be explained by the nonhomogenous nature of the peritoneal barrier, where different parts have different vascularization, hydrostatic pressure gradients, and so forth.[5,50,52] Furthermore, osmotic pressure-driven convection will only take place close to the capillaries, whereas the major part of the peritoneal surface area will allow hydrostatic pressure-driven convection in the opposite direction.[52]

The Relative Importance of Lymphatic Absorption and Absorption into Adjacent Tissues

The relative contribution of the two different components of peritoneal absorptive flow (lymphatic absorption and absorption into tissues) has been controversial.* In fact, the disappearance rate of a macromolecular marker has previously been assumed to provide an estimate of the lymphatic absorption rate in peritoneal dialysis patients.[95] However, several studies have shown that the plasma appearance rate of a

---

*References 12,17,47,50,52,95.

macromolecular marker is on average only about 10% to 20% of its disappearance rate from the peritoneal dialysate (in clinically stable CAPD patients[53–55, 96] as well as in animals[94,97,98]). Furthermore, studies in animals have demonstrated that a major part of the lost marker accumulates inside the tissues adjacent to the peritoneal cavity, mainly in the liver, diaphragm, and anterior abdominal wall.[66,93,94,97,99] Thus, the interstitial adjacent tissues may serve as a reservoir for RISA from which it is slowly absorbed into local lymphatic vessels.[12,52,94,99]

Theoretically, it is also possible that RISA transport is delayed in lymph nodes compared to the fluid accompanying RISA in the lymphatic vessels.[47] However, trapping in lymph nodes have not been found to be of major importance,[100] and, furthermore, this would not explain the high tissue concentrations of macromolecular tracers reported by Flessner and associates[93,94] from studies in the rat.

Solute Transport

During peritoneal dialysis solutes are transported bidirectionally through the peritoneal barrier mainly by diffusion (due to the concentration gradient between blood and dialysate) and, to a lesser extent, by convection into the peritoneal cavity (due to hydrostatic pressure differences and the osmotic disequilibrium caused by the osmotic agent).[13,79] Also, the solute transport accompanying the convective fluid absorption from the peritoneal cavity (into the surrounding tissues and to blood via the lymphatics; see earlier mention) needs to be taken into account.[13,54,74,97]

Diffusion Transport

Diffusive transport through a membrane is driven by the concentration gradient over the membrane. If diffusion is unrestricted, the solute transfer rate (J_S) is proportional to the concentration gradient between dialysate and plasma (ΔC), the solute's diffusion constant (D, which is inversely proportional to the solutes radius), the surface area available for diffusion (A), and inversely proportional to the diffusion distance (Δ_x)[3]:

$$J_S = \frac{D}{\Delta_x} A\Delta C \qquad (4)$$

The ratio of the solute's diffusion constant to the diffusion distance (D/Δ_x) is called permeability (P) and the product of P and surface area is usually denoted permeability surface area product (PS), which in PD has also been denoted diffusive mass transport coefficient (K_{BD}), mass transfer coefficient (MTC), or mass transfer area coefficient (MTAC). Thus, $PS = K_{BD} = MTC = MTAC$. Inserting PS into equation 4 yields the following description of diffusive solute transfer rate for a solute can across the peritoneal barrier:

$$J_S = PS\Delta C \qquad (5)$$

However, as the peritoneal barrier behaves as a porous structure, the diffusion of a solute may be restricted by the pore passage; the solute has to hit the pore entrance area and the solute may also be restricted by interaction due to friction with the pore wall.[3] The diffusion through the peritoneal barrier will therefore be restricted, and a restriction factor (A/A_0) need to be introduced (where A denotes equal to the apparent

pore surface area and A_0 the total cross-sectional pore surface area), and inserting this into equation 4 yields:

$$J_S = \frac{DA}{\Delta x} \Delta C = \frac{DA_0}{\Delta x} \frac{A}{A_0} \Delta C \qquad (6)$$

From this it follows that the diffusion rate over the peritoneal membrane for a solute will be governed by the solute's diffusion constant (D), the restriction factor (A/A_0), the concentration gradient (ΔC), and the term A_0/Δ_x, that represents the unrestricted pore area over unit the diffusion distance.[3] Because A_0 and Δ_x cannot usually be determined, A_0/Δ_x will be central term describing the membranes diffusive properties. Knowing A_0/Δ_x, the PS can be calculated for different solutes using their diffusion constants (based on the solute radius).[3] Also, when PS is known for one solute, A_0/Δ_x can be estimated and used to estimate PS for other solutes.

PS Under Standard Conditions

Several authors have estimated PS for various small solutes and proteins under standard conditions. The PS values for different solutes decrease with increasing molecular weight, and there seems to be a good agreement between the results from different studies, with reported PS for: urea about 18 mL/min, creatinine 10 mL/min, glucose 11 mL/min, inulin 4 mL/min, β_2-microglobulin 1.2 mL/min, albumin 0.12 mL/min, IgG 0.06 mL/min, and α2-macroglobulin 0.02 mL/min.[3,101,102] The variation in PS from different studies seems to be largest for urea, which is not surprising because dialysate urea concentration is close to equilibration with plasma concentration after 4 hours; the estimated value of PS for urea will be highly dependent on the estimation procedure, in particular, the model applied for PS estimation,[70] and whether or not urea concentrations in plasma are corrected for plasma protein content.[103]

Convective Transport

The magnitude of convective transport is determined by the ultrafiltration rate (J_V) through the peritoneal membrane, the average solute concentration within the membrane (CM, which for low flow rates is equal to the average of dialysate and plasma concentration), and the sieving coefficient (S, describing the fraction of the solute, which passes through the membrane with the water flow; $0 \le S \le 1$). The rate of solute flow through the membrane, J_S, due to diffusion and osmotic-pressure induced convection, can be described as:

$$J_S = PS\Delta C + SJ_V C_M \qquad (7)$$

Note that solutes are also transported from the peritoneal cavity due to the peritoneal fluid absorption (J_A, vide supra), which is considered to be a bulk flow.[52,89,104] Thus, the intraperitoneal solute mass will decrease with a term proportional to J_A and C_D. The net solute flow to the peritoneal cavity (Q_S) is equal to[105]:

$$Q_S = PS\Delta C + SJ_V C_M - J_A C_D \qquad (8)$$

For the peritoneal barrier, the sieving coefficient for small solutes will be dependent of the fraction of ultrafiltration that passes through small and large pores in relation to the total ultrafiltration flow (through aquaporins, small pores and large pores), because no solutes will pass through the aqua-

porins and the convective passage of small solutes through the other pores will not be subject to any sieving.

Importance of Different Parts of the Peritoneum for Peritoneal Transport

Different parts of the peritoneal barrier may have different transport characteristics. These differences will influence the relative importance of different parts of the peritoneum on the total solute and fluid transport through the peritoneal barrier. In particular, the permeability, distribution, and surface area of the capillaries within different parts of the peritoneal membrane may have an impact on the relative importance of different parts of the peritoneal membrane for the overall fluid and solute transport.[41] Furthermore, the mixing of dialysate may be different in different parts of the peritoneal cavity, with particularly poor mixing in pockets of the visceral peritoneum, which may decrease solute transport in regions of the peritoneal cavity where mixing is poor.[6] This is likely one reason why studies of peritoneal transport after evisceration suggests that the hollow viscera may play only a minor role in the overall peritoneal transport as evisceration was found to reduce absorption of urea, creatinine, glucose, and inulin only by about 10% to 20% despite removal of approximately 60% of the peritoneal surface area during experimental peritoneal dialysis in rats.[106] After evisceration the contact between dialysate and the membrane is likely to be improved in some areas due to redistribution of fluid to areas not accessible to the dialysate prior to evisceration.[41]

The parietal peritoneum seems to have only a minor role in peritoneal solute transport, because shielding of the parietal wall with plastic patches did not affect the overall peritoneal transport of urea, creatinine, glucose, or inulin.[106]

The role of different parts of the peritoneal membrane for lymphatic absorption has been studied by Rippe and associates[107] by measuring the peritoneal to plasma clearance of ^{125}I-RISA in rats after evisceration, or after sealing the diaphragm or the anterior abdominal wall with histoacrylate glue, compared to control rats. They concluded that lymphatic absorption mainly occurs (60%) via diaphragmatic pathways, whereas about 30% occurs via visceral lymphatic pathways and just a small fraction passes through parietal tissue pathways. On the other hand, the total bulk fluid absorption from the peritoneal cavity (as assessed by the disappearance of RISA) decreased markedly after sealing of the anterior abdominal wall, indicating that the anterior abdominal wall plays an important role in peritoneal fluid absorption.[107] This is in agreement with the studies by Flessner and associates[93,94,97] demonstrating that a significant portion (28%) of the tracer leaving the peritoneal cavity is absorbed into the anterior abdominal wall resulting in local tracer accumulation within the tissues of the anterior abdominal wall.

Tests to Assess Peritoneal Transport

There are several tests available for the assessment of peritoneal transport characteristics. There are commercial computer programs available to assess basic peritoneal transport parameters and to predict effects of various treatment schedules on peritoneal small solute clearances and ultrafiltration.[33,108–111] In general, the results will be closely dependent on the quality of data used for calculations or put into the

computer. In particular, if only long dwells are used and the solutes are close to equilibration, it will be impossible to calculate transport characteristics (see later text). The lab methods may also be very important for the results, and, in particular, creatinine levels in dialysate measured with the Jaffé method must be corrected for the interference with high concentrations of glucose in dialysate.[112] Sodium levels should preferably be measured with flame photometry because ion-selective electrode measurements may give different results.[113]

Diffusive Mass Transport Coefficients

For small solutes, the diffusive mass transport coefficient PS ($=K_{BD}$=MTC=MTAC, see previous text) can be assessed with high accuracy using equation 8, if the sieving coefficients and the volume flow is known. If there are no large volume changes, PS can easily be determined using the solute concentrations in dialysate at the beginning (C_{D1}) and in the end of a dwell (C_{D2}), the solute concentration in plasma (C_p)[3,114,115]:

$$PS = \frac{\overline{V}}{t_2 - t_1} \ln \frac{C_P - C_{D1}}{C_P - C_{D2}} \qquad (9)$$

Where t_1 and t_2 are start and end of the exchange, respectively, and $\overline{V}$ is the average volume during the exchange. This equation has been widely used for the estimation of PS but should only be used when there is a low ultrafiltration rate. Also, it is important to note that the result is closely dependent on the difference between solute concentration in dialysate and plasma at the end of the dwell. Therefore, when using this method, solute concentration in plasma (C_p) should be preferably recalculated to achieve the concentration in plasma water (C_{PW}) by correcting for plasma protein and lipid content to avoid overestimation of PS.[115] This can be done using the equation[103]:

$$C_{PW} = C_P \frac{1}{1 - V_{Lip} - 0.000718 \cdot C_{Prot}} \qquad (10)$$

where V_{lip} is the fractional volume for lipids (often approximated to 0.016) and C_{prot} is the concentration of total protein (often approximated to 65g/L) in plasma. However, for solutes that are almost equilibrated at the end of an exchange, this method should still not be used, because small random errors in solute concentration will result in large variations in PS. Instead, a shorter dwell time (when the solute concentrations are not equilibrated between dialysate and plasma) should be used for estimation of PS.

There are also much more sophisticated methods to estimate PS for small solutes, but results agree quite well bearing the limitations of different methods in mind. Presently, computer software is available for the calculation of PS.[33,108–111]

The Peritoneal Equilibration Test

The most widely used approach to evaluate peritoneal transport characteristics in individual patients is to measure the dialysate to plasma solute concentration ratio (D/P) for particular solutes during an exchange with conventional peritoneal dialysis fluid (Figure 25–4).[79] This procedure (which was first proposed by Verger[116]) has been standardized in the peritoneal equilibration test (PET) by Twardowski and associates[112] and has won wide acceptance as a routine method to assess clinically important alterations in peritoneal transport characteristics. The PET procedure is standardized as regards sampling procedures, duration of dwell, evaluation of the results, and so forth.[112,117,118] Briefly, the overnight dialysate is drained and 2 L of 2.27% glucose dialysis fluid are infused. The original PET description included several dialysate samples,[112] but usually, the procedure is simplified and dialysate samples are taken after infusion, and then after 2 and 4 hours, at which time the dialysate is drained and the volume recorded. A blood sample is drawn at 2 hours dwell time. Usually, the dialysate drainage volume (used as a measure of ultrafiltration capacity), D/P for creatinine, and D/D_0 (dialysate concentration/initial dialysate concentration) for glucose are compared to standard values. The D/P for creatinine and D/D_0 for glucose from the PET will be closely related to the diffusive mass transport coefficient for these solutes.[119] The patients are usually classified according to D/P creatinine at 4 hours using Twardowski's initial classification into high transporters (above mean + 1 SD), high average transporters (between mean and mean + 1 SD), low average transporters (between mean and mean − 1 SD), and low transporters (below mean −1 SD) (Table 25–1). High and high average transporters have more rapid equilibration of creatinine and poorer net ultrafiltration due to more rapid glucose absorption, whereas low average and low transporters will have lower solute transport, resulting in slow glucose absorption and high net ultrafiltration but low peritoneal clearances for creatinine and larger and larger solutes. Usually, Twardowski's initial limits[112,117] are used to define transport groups, although most studies show an average creatinine D/P equilibration rate that is more rapid than in the study of Twardowski.[120–122]
Figure 25–4 Dialysate to plasma equilibration curves (mean ± SD) for creatinine and urea during a 6-hour dwell study with an exchange of 2 liters of 1.36% (■), 2.27% (□), and 3.86% (▲) glucose solution. (From Heimbürger O, Waniewski J, Werynski A, et al: Dialysate to plasma solute concentrations (D/P) versus peritoneal transport parameters in CAPD. Nephrol Dial Transplant 1994; 9:47-59, with permission.)

Table 25–1 Characteristics of the Four Different Peritoneal Solute Transport Groups as Classified by D/P Creatinine After 4 Hours of a Peritoneal Equilibration Test[112]

Transport Category	D/P Creatinine[112,117]	A_0/Δ_x[108] (cm/1.73 BSA)	Ultrafiltration[118,119]	Standard CAPD 2 L x 4/24 hr[101,120]		APD Compared to CAPD[122a]	
				Kt/V	Creatinine Clearance	Kt/V^a	Creatinine Clearance*
High	>0.81	>30,000	↓↓	=	↑↑	↑↑	↑↑
High average	0.65–0.81	23,600–30,000	↓	=	↑	↑↑	↑↑
Low average	0.50–0.65	17,200–23,600	↑	=	↓	↑↑	=–↑
Low	<0.50	<17,200	↑↑	=	↓↓	↑	=–↓

*The resulting clearances from APD will, of course, be strongly dependent on the APD prescription. The table is based on an APD prescription with a total dialysis fluid volume of about 15–20 L for APD and a wet day with an additional daytime exchange.

Recently, it has been suggested to use 3.86% glucose solution instead of 2.27% glucose solution for the PET because it will give a better estimate of ultrafiltration capacity because the ultrafiltration rate is higher and the discrimination between patients better. Thus, the net ultrafiltration will be less dependent on variations in residual volume between the start and end of the dwell, and the use of more hypertonic solution also makes it possible to use decrease in dialysate sodium as an additional parameter to identify patients with poor ultrafiltration.[123-128] When hypertonic 3.86% glucose dialysis solution is used, there is a marked dip in dialysate sodium concentration due to sieving of sodium as about half of the ultrafiltered fluid will pass through the aquaporins (see earlier text) (Figure 25–3). In patients with normal transport characteristics, the decrease in dialysate sodium is marked during the first 60 minutes, then it decreases slightly to reach its lowest value after approximately 90 minutes and thereafter the dialysate sodium concentration increased due to sodium diffusion from plasma.[79]

PET is a simple procedure and easy to perform, the standard values are well established, and it does not require any complicated calculations. On the other hand, the D/P and D/D0 results are rather sensitive to laboratory errors (only three samples are used), and the net ultrafiltration (measured as drained minus infused volume) is sensitive to variation in the intraperitoneal residual dialysate volume (due to incomplete drainage). Furthermore, PET does not provide any details of the peritoneal transport process. However, a commercial computer software program (PD-Adequest™) has been developed using results from the PET and the preceding overnight exchange to allow for calculation of basic transport parameters and to simulate the effects of changes in treatment schedules in individual patients.[33,111] The PET has also been modified by using more frequent sampling and adding a tracer to the dialysate to allow for more detailed analysis of changes in intraperitoneal volume.[129]

The D/P values generated by the PET procedure show an excellent correlation with the diffusive mass transport coefficient PS for small solutes, and PS as well as D/P for creatinine and PS as well as D/D0 for glucose can be used to identify patients with loss of ultrafiltration capacity due to increased diffusive transport.[124] When using 2 L of 4.25%/3.86 % glucose solution for the PET, it was suggested to define *loss of ultrafiltration capacity* as a net ultrafiltration below 400 mL after 4 hours.[125]

Personal Dialysis Capacity Test (PDC)

The personal dialysis capacity test involves urine, blood, and dialysate sampling. The patient collects urine and dialysate during a standardized CAPD-day using a special exchange schedule, with two short (2 to 3 hours) and two medium long exchanges (4 to 6 hours), each with two different glucose solutions, and one long overnight exchange. A sample is taken from each bag and the volume of each bag is measured, to give the variation in net ultrafiltration and solute equilibration with time, with the two glucose-based dialysis fluids.[108,110,130,131] The data are put into a special software program, Personal Dialysis Capacity (PDC™), based on the three-pore model of peritoneal transport and calculates the following transport parameters (in addition to adequacy parameters and residual renal function): (1) area parameter ($Ao/\Delta x$), determining the diffusion capacity of small solutes, and indirectly, the hydraulic conductance of the membrane (LpA); (2) reabsorption rate of fluid from the peritoneal cavity to the blood after peak time, when the glucose gradient has dissipated; and (3) large pore fluid flow, which determines the loss of proteins to the PD-fluid. The $Ao/\Delta x$ is a more general parameter than PS for a specific solute and can be also used to classify the patients into similar transport groups as the PET (Table 25–1). Because the PDC is based on five different determinations of dialysate concentration, it should have better and more reliable classification of individual patient's transport rate, if a correct sampling procedure has been carried out.[110,130,131]

Effluent Soluble Markers of the Peritoneal Membrane

In addition to solutes originating from the circulation, the drained peritoneal dialysate also contains substances that are locally produced or released from the surrounding tissues or from cells released into the dialysate. These substances include lubricants and surface tension-lowering substances, such as phospholipids, various cytokines, growth factors, chemokines, and prostanoids as well as constituents of the extracellular matrix (e.g., glycosaminoglycans and procollagen peptides), and also coagulation, fibrinolytic, and antithrombogenic substances.[132] Some of these substances have been measured in effluent dialysate to better understand to the local intraperitoneal immune system and the local reaction to complications like peritonitis, and the concentrations of some of these substances have also been used as markers of the peritoneal membrane status in apparently stable PD patients. However, it should be noted that the interindividual variation is very large even in clinically stable patients without overt complications, and surprisingly little data are available on the long-term evolution of these markers in patients treated with PD. It should also be stressed that appearance rate (i.e., the amount of solute in the drained bag multiplied with the drained volume and divided by time) should be used when comparing patients, and not the concentration, if there is a marked interpatient variation in drained volume or dwell time. Otherwise, the marker concentration may vary due to differences in dilution due to, for example, differences in infused volume or in net ultrafiltration.

The most widely used marker of membrane status in clinical studies has been the dialysate effluent concentration of cancer antigen 125 (CA125).[133] CA125 is a 220 kD glycoprotein produced by mesothelial cells, and the CA125 level in dialysate increases linearly with dwell time and correlates with the number of mesothelial cells in the effluent. Patients on long-term PD have low levels of dialysate CA125[134] as well as patients with peritoneal sclerosis. Based on these observations, CA125 has been suggested to be a marker of the mesothelial cell mass or turnover in stable CAPD patients.[133] Increased levels of dialysate CA125 have widely been used as a marker of improved biocompatibility of new PD solutions and effluent levels of CA125 consistently increase with the use of more biocompatible dialysis solutions in clinical studies.[135,136] However, the interpatient variation in dialysate CA125 is large, and it is not completely clear exactly what it represents. Therefore, the CA125 levels in dialysate effluent need to be interpreted with some caution.

Another interesting effluent candidate marker of peritoneal membrane health status during long-term PD is hyaluronan (HA), which is an important constituent of the interstitial tissue and is produced by mesothelial cells and fibroblasts. HA is involved in several physiologic processes, such as tissue repair and wound healing. The fraction of HA that is produced by mesothelial cells forms a coat on the mesothelial cells together with other glycosaminoglycans and phospholipids. HA concentration increases with intraperitoneal inflammation and decreases with use of more biocompatible PD solutions.[136,137] The procollagen peptides, procollagen-1-C-terminal peptide and procollagen-3-N-terminal peptide, are produced locally by fibroblasts and mesothelial cells during the synthesis of collage 1 and 3, respectively, and have also been measured in dialysate as potential markers of local collagen synthesis,[135,136] but it is not completely clear what the levels represent.

Other potentially important markers are the central pro-inflammatory cytokine interleukin-6 (IL-6) and its soluble receptor (sIL-6R) due to their central role in the regulation of intraperitoneal inflammation.[10] Vascular endothelium growth factor (VEGF) is also a potentially interesting marker, because it enhances vascular permeability and angiogenesis, and it is upregulated in peritoneal capillary endothelium in long-term PD patients.[138] Interestingly, both IL-6 and VEGF decrease with the use of more biocompatible solutions.[137]

Factors Affecting Peritoneal Transport

A number of factors have been shown to influence peritoneal transport, possibly by altering the underlying physiologic conditions that govern the exchange rate between blood plasma and dialysate. In particular, vasodilatory factors have been shown to increase peritoneal clearances due possibly to an increase in capillary surface area available for transperitoneal exchange.[139]

Temperature

Klapp[140] reported in the beginning of the last century that heating the anterior abdominal wall resulted in increased fluid absorption from the peritoneal cavity, whereas the opposite effect was noted with cooling of the abdominal wall. The effect of increased temperature was possibly mediated via local vasodilation because local hyperemia could be observed at the serosal as well as parietal peritoneum.[140] An increase in dialysate temperature will also result in an increased solute transport, in addition to the increased fluid absorption.[141]

Intraperitoneal Hydrostatic Pressure

The intraperitoneal hydrostatic pressure is the driving force for convective movement of fluid and solutes into the adjacent tissues.[52] The hydrostatic pressure increases with increasing intraperitoneal dialysate volume[142-144] and varies with body position; the pressure is higher in sitting and standing than in supine position.[142] The intraperitoneal hydrostatic pressure seems to increase in almost linear fashion with increased and infused dialysis volume in PD patients,[142,143] but a study in rats using a larger variation in infused dialysate volume shows that this relationship, in fact, seems to be exponential.[144]

The increased intraperitoneal pressure results in increased fluid absorption,[145] mainly due to increased fluid absorption into adjacent tissues and not to increased lymphatic absorption because the peritoneum to plasma clearance of a radioactive tracer was unchanged when the intraperitoneal pressure was increased in a study in rats.[146] In agreement with these findings, Durand and associates[147,148] reported on a negative correlation between net ultrafiltration and intraperitoneal pressure at the end of a 2-hour dwell in stable CAPD patients.

Dialysate Volume

In a systematic study of infused dialysate volumes between 0.5 and 3 liters in 10 stable PD patients, Keshaviah and associates[149] found that PS for urea, creatinine, and glucose increased in an almost linear fashion between 0.5 and 2 L infused volume, its values almost doubling over this range. Between 2 and 3 L infused dialysate volume there was only a small increase in PS values.[149] However, infused volumes yielding maximum urea PS were found to increase with increasing body surface area.[149] The authors attributed the increase in PS to a more effective contact between dialysate and the peritoneal surface area.[149] Krediet and associates[150] studied the effect of a 3-L exchange compared to a 2-L exchange with 1.36% glucose solution and reported on significantly higher PS for creatinine, kanamycin, and inulin with the larger volume, but no difference in PS for urea, lactate, glucose, β2-microglobulin, albumin, or IgG was found. However, the net ultrafiltration relative to the volume at 5 minutes was lower at almost all occasions due to a markedly increased fluid absorption rate with the 3-L exchange volume, possibly related to an increased intraperitoneal hydrostatic pressure.[150]

The Effect of Body Posture on Peritoneal Transport

The effect of upright body position have been addressed in a few studies showing a slightly slower D/P equilibration as well as a decreased net ultrafiltration rate in sitting or standing compared to recumbent position.[151,152] The slightly slower transport rates are due likely to a decreased contact between dialysate and the peritoneal membrane in sitting position as ultrasound investigation revealed that the bulk of the dialysate was found in the subumbilical region of the peritoneal cavity,[151] and the reduced net ultrafiltration is due to an increased peritoneal fluid absorption due to an increased hydrostatic pressure in upright position compared to supine position.[152] Upright position will also increase the hydrostatic pressure gradient over the anterior abdominal wall, where a large part of the convectively induced peritoneal absorption takes place.[52]

Effect of Dialysate Composition on Peritoneal Transport

Several factors related to the peritoneal dialysis solutions per se may also affect peritoneal transport, for example, hyperosmolality, type and concentration of osmotic agent applied, pH, type of buffer, buffer concentration, glucose degradation products, and other contaminants.

Glucose Concentration and Osmolality

As hyperosmolality is a known vasodilatory factor,[153] it is reasonable to expect that hyperosmolality may induce changes in peritoneal transport rates. The use of a 7% glucose solution for peritoneal dialysis in uremic patients was associated with an increased solute clearance (compared to 1.5% glucose solution), which exceeded the possible contribution of convective transport,[154,155] and similar effects have been found in animal studies. In contrast, the clinical use of the presently available hypertonic 3.86% (anhydrous glucose, corresponding to 4.25% of hydrous glucose) dialysis solutions does not seem to affect the peritoneal diffusive transport characteristics in peritoneal dialysis patients.[79]

In addition, during heat sterilization and storage of glucose containing peritoneal dialysis solutions, several toxic glucose degradation products (GDPs) are formed, for example, formaldehyde, 3-deoxyglucosone, 3,4-Dideoxyglucosone-3-ene, and several other low molecular weight aldehydes.[156-159] Although GDPs do not seem to have any major acute effect on peritoneal transport in the concentration found in currently used peritoneal dialysis solutions, these pollutants are likely involved in the evolution of the changes in peritoneal structure and function observed in the long-term PD patients.[160]

Alternative Osmotic Agents

In general, osmotic agents with a lower molecular weight compared to glucose, for example, amino acids and glycerol, will be absorbed more rapidly than glucose, resulting in a shorter period of positive net ultrafiltration than with glucose solutions of the same osmolality.[161-163] Although the use of the presently available 1.1% amino acids solution does not seem to affect peritoneal transport using the PET,[164] they seem to slightly increase peritoneal solute transport and blood flow in a detailed study,[165] and hypertonic 2.7% amino acid solution has also been reported to be associated with slightly increased peritoneal transport rates.[163,166]

Several large molecular weight osmotic agents, such as starch, glucose polymers, dextran, gelatine, albumin, and polypeptides, have been used in experimental studies.[167] Since the capillary wall is easily permeable to water and small solutes but restricts the passage of large molecular weight solutes, the osmotic effect of colloid during peritoneal dialysis is much more prolonged than the osmotic effect of small solutes. Therefore, even with a relatively low osmolality, the colloid osmotic pressure may ensure the sustained osmotic transport of water.[168] Note that the main osmotic effect of the polymers will occur over the small pores, and sodium sieving will thus not be observed.[77] Thus, the presently used 7.5% icodextrin solution is in fact hypo-osmolar compared to plasma, but will result in a sustained net ultrafiltration for more than 14 hours due to the sustained colloid osmotic gradient.[77] The icodextrin-based solution does not affect peritoneal solute transport characteristics,[169] but the large osmotic fluid flow through the small pores will result in increased clearance of sodium, as well as of low molecular proteins like β2-microglobulin and leptin.[77,169,170]

Effect of pH and Different Buffers on Peritoneal Transport

Conventional glucose-based dialysis solutions were reported to be vasoactive (when applied directly to capillaries) with an initial transient vasoconstriction (for less than 2 minutes) followed by a maximal vasodilatation sustained during the whole study period.[171,172] The high osmolality or high concentration of buffers, acetate, or lactate, were indicated as possible factors.[171,172] The unphysiologically low pH in traditional dialysis fluids is also considered to be vasoactive and may thus theoretically influence the vascular responses in the peritoneum during dialysis. A few studies have been conducted to assess the effect of pH per se on peritoneal transport. However, the low pH in dialysis fluids was not found to induce distinguishable vasoactive responses in the peritoneum[172] or to affect the peritoneal solute transport characteristics in rats[173,174] or humans.[175,176]

Acetate, lactate, and bicarbonate have been used as buffers in peritoneal dialysis solutions. As pH, and other factors, may also differ between solutions with different buffers, it is difficult to assess the possibly independent effects of pH and buffer on peritoneal transport. Furthermore, the long-term effects of the dialysis solution on peritoneal transport seem to differ between similar solutions produced by different manufacturers,[177,178] and it is possible that differences in their production processes may have resulted in differences between the solutions, for example, in different content of GDPs.

Acetate was previously used as a buffer in dialysis fluids. However, although acetate buffered solutions seem to have no effect on peritoneal UFC in short-term studies,[179] long-term use of acetate is associated with high frequency of ultrafiltration capacity failure[177,180,181] and has, furthermore, been suggested to be implicated in the aetiology of encapsulating peritoneal sclerosis.[182]

Because of the side effects of acetate solutions, lactate was for many years the almost exclusively used buffer in commercially available peritoneal dialysis solutions. Recently, bicarbonate solutions have been introduced, and the transport does not seem to differ to a major extent in clinical studies between lactate, bicarbonate/lactate, or pure bicarbonate solutions.[175,183]

Pharmacologic Effects on Peritoneal Transport

Several drugs and hormones have been reported to alter peritoneal transport rates.[35,44,139,184] The results of many of these studies must, however, be interpreted with caution because the experimental conditions are not always standardized, and several other factors may also have been altered by the experimental conditions. Also, accurate determinations of dialysate volume are often lacking.[185]

Vasoactive Drugs

Intravenous administration of norepinephrine significantly decreases peritoneal clearances, whereas dopamine increases the peritoneal solute transport rate, possibly due to vasodilation caused by stimulation of mesenteric dopamine receptors.[184] In general, vasodilatory drugs have been reported to increase peritoneal transport,[35,44,139,186,187] for example, theophylline, furosemide, hydralazine, and sodium nitroprusside (a nitric oxide donor) have all been reported to augment peritoneal clearances—an effect that is possibly related to an increased peritoneal capillary surface area. On the other hand,

splanchnic vasoconstrictors, like norepinephrine,[188] generally tend to decrease peritoneal clearances.[139]

Changes in Peritoneal Transport During Peritonitis

Peritonitis is associated with several changes in peritoneal transport. A fall in ultrafiltration capacity (UFC) is often noted during peritonitis,[189–191] but this alteration is transient and UFC usually returns to normal within less than 1 month.[189,192]

The decreased UFC is most commonly associated with increased small solute transport and rapid glucose absorption and, consequently, loss of the osmotic driving force.[189,191] In addition, the peritoneal fluid absorption is markedly increased.[108,193] Detailed studies of peritoneal fluid absorption have not been performed, but it is likely that the increase in fluid absorption is due to both increased lymphatic flow and increased convective fluid transport into adjacent tissues.[101]

The increased small solute transport seems to be related to an increased peritoneal capillary surface area, probably due to inflammatory recruitment of microvessels.[32,108] This effect is likely, to a large extent, mediated nitric oxide (NO) and both endothelial nitric oxide synthase (eNOS) and inducible nitric oxide synthase (iNOS), which have been demonstrated to be markedly upregulated in a rat model of acute peritonitis with poor ultrafiltration and increased small solute transport.[194] Also, the structural changes, the increased solute transport, and the poor ultrafiltration were much less pronounced in eNOS knockout mice.[195]

Furthermore, peritonitis is associated with markedly increased protein losses in dialysate,[108,189–191] indicating an increase in the number or size of the large pores.[108] The intraperitoneal production of prostaglandins (e.g., PGE2 and PGI2) is increased during peritonitis.[190] As the increased peritoneal protein loss during peritonitis correlates with the increased dialysate concentration of prostanoids, and, furthermore, as the increased protein loss partly may be inhibited by indometacin,[190] it may be suggested that the increased peritoneal protein loss during peritonitis is mediated, at least partly, by the vasoactive prostaglandins.[190]

Changes in Water and Solute Transport with Time on PD

Changes in peritoneal solute transport are common after initiation of peritoneal dialysis. Several studies using the PET have reported on a significant increase in 4-hour D/P creatinine from the PET after 6 months of CAPD compared to initial results obtained during the first 2 weeks of CAPD, whereas ultrafiltration was rather stable.[196–199] It has also been reported that in patients with initially high solute transport, transport rate may, in fact, decrease.[199,200]

Changes in Peritoneal Transport with Long-Term Peritoneal Dialysis

In the majority of patients treated with CAPD for up to 3 years, the peritoneal UFC as well as small solute transport characteristics seem to be relatively stable,[199,201,202] although several studies demonstrate a tendency toward increasing diffusive mass transport coefficients for small solutes as well as a tendency

toward decreasing net UF.[196,198,199,202-204] However, individual patients may behave markedly different; some patients demonstrate increased diffusive solute transport and decreased ultrafiltration, whereas other patients show opposite patterns.

In patients treated with PD for 4 years or more, the tendency toward decreasing ultrafiltration and increasing small solute transport is evident in almost all prospective studies.[196,205] In contrast, macromolecule transport (as assessed by protein clearances) has been reported to be stable or to decrease with time on CAPD[204,206–208] indicating a stable or decreased peritoneal permeability for macromolecules.

However, the interpretation of most studies (and, in particular, the cross-sectional studies) of peritoneal transport with time may suffer from methodologic fallacy in that patients with "inadequate" peritoneal transport will drop out, so that both high transporters (insufficient fluid removal) and low transporters (insufficient small solute clearances) may drop out, resulting in selection bias.

Loss of Ultrafiltration Capacity (UFC)

With time on PD there is an increasing risk of developing loss of UFC, with a markedly higher incidence among patients treated with acetate-containing dialysis solutions.[180,196,205] Using the standard lactate-based solutions, the risk of developing permanent loss of UFC (using a clinical definition) increases markedly with time on CAPD being 9% after 48 months and 35% after 72 months of PD.[196]

There are several pathophysiologic mechanisms behind ineffective fluid removal due to permanent loss of UFC (Table 25–2). Increased transport of small solutes with rapid glucose absorption is the most common mechanism observed in CAPD patients with impaired UFC.* The rapid glucose absorption results in rapid loss of the osmotic driving force (glucose gradient) and, consequently, a rapid decline in ultrafiltration rate. However, detailed kinetic analyses of patients with UFC due to rapid diffusive transport also show that the remaining osmotic gradient cannot induce water flow as effectively as in patients with normal UFC, indicating a decreased osmotic conductance of the peritoneal membrane.[72,211]

A selective decrease in ultrafiltration in patients with normal diffusive glucose transport has also been reported in some

Table 25–2 Suggested Causes of Ineffective Fluid Removal in CAPD

> **A) Obstructed outflow and increased residual dialysate volume**
> **B) Loss of residual renal function**
> **C) Subcutaneous leakage**
> **D) Loss of ultrafiltration capacity due to:**
>   1. Increased solute transport (most common mechanism)
>   2. Reduced efficiency of the osmotic gradient (Impaired transcellular water transport or reduced UF coefficient) (not uncommon)
>   3. "Hypopermeable peritoneum" with decreased water transport or decreased surface area (rare)
>   4. Increased peritoneal fluid absorption (probably rare)

*References 126,127,196,207,209,210.

CAPD patients (with loss of UFC), who also had a minor decline of dialysis sodium concentration when using hypertonic glucose solution.[127,128,212] This may imply a decreased hydraulic conductivity of the peritoneal membrane, and it was suggested that these alterations may be due to decreased transcellular water transport (deficient aquaporin-mediated ultrafiltration) and that this may be an additional cause of UFC failure. However, this finding needs to be interpreted with caution because when the ultrafiltration rate is low, a reduction of dialysate sodium due to dilution of dialysate by ultrafiltrate will not occur to the same degree. Sodium sieving will always be markedly reduced when ultrafiltration is poor, even when the aquaporin function is normal.[213] An alternative explanation to the normal glucose transport without decline of dialysate sodium could be a combination of selective changes in the peritoneal ultrafiltration coefficient due to a reduced surface area in combination with increased membrane permeability. This would result in unchanged diffusive solute transport in combination with reduced ultrafiltration coefficient across both transcellular water pores (aquaporins) and small pores.[123]

Loss of peritoneal surface area with slow solute transport due to fibrosis and the formation of adhesions have been reported during the late stage of encapsulating peritoneal sclerosis (EPS, previously called sclerosing encapsulating peritonitis) in a few cases.[209] However, detailed studies in four patients developing EPS, showed increasing PS in three of the patients,[214] suggesting that loss of UFC associated with increased solute transport in these patients was an early sign that preceded the development of more overt signs of EPS. Thus, initially, EPS seems to be associated with increased peritoneal solute transport, which later is followed by formation of adhesions and finally encapsulation of the intestinal loops, resulting in slow peritoneal solute transfer due to loss of the surface area.[209] However, slow solute transport seems to be an extremely rare cause of UFC loss, and only a few cases have been reported.

Increased peritoneal fluid absorption has also been reported as the cause of UFC loss.[127,207] The increase in peritoneal fluid absorption in these patients is not due to increased lymphatic absorption but to increased fluid absorption into the peritoneal interstitial tissue, indicating changes in the interstitial tissue fluid hydraulic conductivity.[55] The mechanisms behind these changes are not clear.

Relation Between Peritoneal Transport Characteristics and Clinical Outcome

Peritoneal transport characteristics have a major impact on the clinical management and outcome in peritoneal dialysis patients. The patients' peritoneal small solute transport characteristics will have a major impact on the optimal dialysis prescription as regards ultrafiltration and small solute clearances. Furthermore, a high peritoneal transport rate has been identified as an important risk factor for both PD technique failure and mortality.[120,215–218]

Although the reasons for this are not established, several different mechanisms may contribute. At first, there is an association between a high peritoneal transport rate and comorbidity, including diabetes, cardiovascular disease, and chronic inflammation (with elevated plasma levels of CRP and IL-6).[215,219-223] Second, high transporters have a more

rapid glucose absorption and, thus, an impaired fluid and sodium removal and have a high risk to chronic fluid overload,[218,224-226] which in itself is associated with LVH and LV dysfunction in PD patients[227] and may potentially cause immune activation because of bacterial or endotoxin translocation in patients with severe gut edema as a result of severe volume overload.[228,229] In contrast, although a low fluid removal may result in low urea clearance, peritoneal small solute clearances are usually not lower in high transporters. During standard CAPD, the Kt/V urea is not different between transport groups, and creatinine clearance is usually higher in high transporters.[101,230]

Because there is a close relationship between the peritoneal transport characteristics of solutes of different molecular weight up to the size of albumin[30,101] (Figure 25–2), it is not surprising that high transporters also exhibit increased protein losses and that these patients have more severe hypoalbuminemia than patients with lower D/P ratios.[216,231,232] It is interesting to note that the low serum albumin levels are already present in high transporters before the initiation of PD,[233] indicating that another mechanism, such as inflammation, may also contribute. Furthermore, a large influx of glucose absorbed from the dialysate may suppress appetite,[216,234] although Davies and associates[235] reported that calories derived from the dialysate in CAPD patients did seem to reduce appetite in PD patients. The low albumin levels and increased glucose absorption in high transporters lead to the hypothesis that a high transport state will lead to malnutrition, which, in turn, may affect clinical outcome. However, except from low serum albumin levels, high transporters do not seem to be more malnourished as regards other nutritional parameters.[120,232] Furthermore, there were no signs of change in any nutritional parameter in high transporters in a longitudinal study of nutritional parameters.[236]

It is striking that the relation between peritoneal transport rate and serum albumin[120] and some other nutritional markers was seen already at start of CAPD.[236] Therefore, it is likely that the relation between peritoneal transport and some nutritional parameters seen in some studies, in fact, are due to a relation between peritoneal transport and the malnutrition, inflammation, and atherosclerosis (MIA)-syndrome.[237] High peritoneal transport characteristics may thus be another feature of the MIA syndrome.[237]

Moreover, it is important to note that the etiology and clinical features of high transporters may be different. It has recently been suggested that there may be two distinct types of high transporters.[238,239] The Early *Inherent Type* is found in patients who show signs of high PSTR from the beginning of PD. These patients are typically inflamed (systemically and intraperitoneally) and have a high prevalence of comorbidities, low RRF, and high mortality. The Late *Acquired Type* occurs in patients who develop high transport rate over time on PD, perhaps due mainly to local structural changes in the peritoneal membrane as a consequence of the continuous exposure to bioincompatible PD solutions, resulting in an increased vascular surface.[239] These patients do not necessarily have higher prevalence of inflammation or comorbidities, such as diabetes mellitus and cardiovascular disease. In addition, other patients may perhaps exhibit an increase in transport rate over time on PD because of the development of clinical complications, resulting in increasing inflammation. The relative importance of the two main types of high

transporters and their contribution to the poor clinical outcome of high transport patients is not known.

CHANGES IN PERITONEAL MORPHOLOGY WITH TIME ON PD

During the last 15 years, several small studies have demonstrated marked changes in peritoneal morphology in patients treated with PD, including mesothelial denudation, submesothelial thickening and fibrosis, and vascular changes with vascular basement membrane reduplications.[240-243] More recently, vascular changes with subendothelial hyalinization and neoangiogenesis,[244-246] as well as accumulation of advanced glycation end products (AGEs) in the peritoneum[244,247] have been reported, factors which also were related to functional changes with increasing peritoneal solute transport.

Recently, the first results were reported from The Peritoneal Biopsy Registry reporting the analysis of biopsies from the parietal peritoneum in 130 PD patients and compared them to peritoneal biopsies from normal individuals and uremic subjects not treated with PD.[248] The most dramatic changes were the marked increase in the submesothelial compact zone (which approximately equals the interstitium), which was 50 μm in normal subjects, 150 μm in hemodialysis patients, and 270 μm in PD patients. The thickness increased markedly with time on PD from 180 μm in patients treated with PD for less than 2 years to a median value of 700 μm in patients treated for more than 97 months[248] (Figure 25-5). Vascular changes with progressive subendothelial hyalinization and luminal narrowing or obliteration were seen in 56% of the PD patients and increased with time on PD. Patients with membrane failure had higher submesothelial thickness and also a higher density of blood vessels, which correlated with the degree of fibrosis.[248]

In a few patients that had been treated with PD for several years, progressive peritoneal fibrosis with development of encapsulating peritoneal sclerosis (previously called sclerosing encapsulating peritonitis) have also been reported. This is a frightening complication with fibrotic thickening of the peritoneal membrane, formation of adhesions, and in the last phase encapsulation of the intestinal loops and formation of an intestinal cocoon.[182]

Pathophysiologic Considerations

Potentially Causative Factors

The pathogenetic mechanisms behind the structural and functional alterations in the peritoneal membrane are not clear, but both bioincompatibility of the peritoneal dialysis solutions and the effect of peritonitis have been discussed. Davies and associates[198] reported that recurrences or clusters of peritonitis as well as the cumulative dialysate leukocyte count were related to increased D/P creatinine and reduced UFC, whereas D/P creatinine and UFC were stable in patients with no or single isolated peritonitis episodes. Furthermore, the relationship between peritonitis and high solute peritoneal transport rate is not evident in studies of patients with loss of UFC, where most studies have failed to demonstrate any relation between the number of peritonitis episodes and loss of UFC.[207,210] Although numerous studies have demonstrated the bioincompatibility of the presently used peritoneal dialysis solutions in vitro, and bioincompatibility has been extensively discussed as a cause of changes in peritoneal solute transport,[160,249] there are little clinical data demonstrating such a relationship, except from the relation between loss of UFC and the use of acetate as buffer. However, it should be noted that until recently, almost all standard peritoneal dialysis solutions have had similar composition and biocompatibility. Recently, much attention has focused on the relatively high content of reactive carbonyls in the conventional PD solutions.[159,160,250] These reactive carbonyls are particularly of interest because they are more potent promoters of formation of advanced glycation end products (AGEs)

Note the marked expansion of the submesothelial compact zone in *B*. (From Williams JD, Craig KD, Topley N, et al: Morphological changes in the peritoneal membrane of patients with renal disease. J Am Soc Nephrol 2002; 13:470-479.)

than glucose itself.[250] The potential pathogenetic role of carbonyls and AGEs in the changes of peritoneal function are supported by the facts that increased AGE content has been found in the peritoneum of long-term PD patients and was furthermore associated with increased peritoneal small solute transport.[244,247] Furthermore, it was recently reported that patients with increasing small solute transport (as assessed from the PET) with time on PD, had a higher glucose exposure compared to patients with stable peritoneal membrane transport.[251]

Physiologic Mechanisms

The mechanism(s) by which small solute transport increases in patients with poor ultrafiltration and increased small solute transport is not yet understood. It has been suggested that the cause of the increased small solute transport rate is an increase in peritoneal vascular surface area due to neoangiogenesis, which has been demonstrated in the peritoneal membrane.[138,244–246,248] However, if this was the only explanation, the protein losses should also be increased among these patients due to the larger vascular surface area. However, it is possible that the markedly expanded interstitium (submesothelial compact zone) retard macromolecular transport more than small solute transport, resulting in an increased small solute transport and normal macromolecular transport (M. Flessner, personal message).

In reduced osmotic conductance (reduced osmotic efficiency of glucose) observed in many patients, it has been suggested that this is due to decreased transcellular water transport (deficient aquaporin-mediated ultrafiltration).[127,128,212] However, this is still not established, and the aquaporin expression was, in fact, reported to be normal in a long-term PD patients with poor ultrafiltration attributed to impaired transcellular water transport.[252] Furthermore, computer simulations have demonstrated that sodium sieving will always be markedly reduced when ultrafiltration is poor, even when the aquaporin function is normal.[213] Therefore, further research is needed to establish the pathophysiologic mechanisms behind the reduced osmotic conductance in many PD patients with poor ultrafiltration.

Devuyst[253] has suggested a model where the increased reactive carbonyls (due to uremia and the carbonyls in the PD fluid) will amplify the AGE formation in the peritoneal membrane. The carbonyls and AGEs will have several effects, including stimulation of peritoneal cells to produce vascular endothelial growth factor (VEGF), which will stimulate neoangiogenesis and interact with endothelial cells to produce endothelial nitric oxide synthase (eNOS), which is markedly increased in long-term PD patients[138] and will cause vasodilation as well as further stimulate neoangiogenesis. Nitric oxide (NO) is a crucial regulator of vascular tone and permeability, and the finding that eNOS knockout mice, to a large extent, were protected against the structural and functional changes induced by acute peritonitis[195] underscores the importance of NO in the pathophysiology of peritoneal membrane dysfunction. The correlation seen between submesothelial fibrosis and neoangiogenesis suggests that these two processes are related.[245,248] It is in this context of interest that uremia per se and the binding of VEGF to the extracellular matrix will induce the release of basic fibroblast growth factor (bFGF),

which has fibrotic as well as angiogenetic effects.[253] Furthermore, inflammatory cytokines like IL-6 may also stimulate neoangiogenesis and fibrosis.

However, even if much progress has been made during the last few years, very little is still known about which factors will be most important in causing the long-term changes in the peritoneal membrane structure and function, or which basic mechanisms are involved in the evolution of these alterations. Much further research is clearly needed in this area.

Peritoneal Dialysis Access

Elias D. Thodis, M.D. • Vassilis Vargemezis, M.D. • Dimitrios G. Oreopoulos, M.D., Ph.D., F.R.C.P.C., F.A.C.P.

PERITONEAL DIALYSIS ACCESS

After peritoneal dialysis (PD) was recognized as an effective renal replacement, we have had great increases in our knowledge of the clinical and basic science of continuous peritoneal dialysis therapies. However, peritoneal access is still a challenge in our day-to-day practice. The provision of safe and reliable access to the peritoneal cavity is vital to the CAPD patient. The catheter is the patient's lifeline to the peritoneal dialysis membrane.[1]

A good peritoneal catheter should provide adequate rates of solution inflow and outflow, and its design should minimize infection at the skin exit site and should allow successful resolution of peritonitis if it occurs. Finally, it should be safely implantable without major surgery.

Most centers have reduced technique failure, mainly through improved connection technology and cumulative experience acquired by the involved team. The literature does not provide a definite answer concerning the most preferable access, method of implantation, and exit-site care protocol. The individual center's performance effect will always be a confounding variable. On the other hand, the search for evidence-based recommendations faces a major difficulty, namely the small number of randomized, controlled studies and the lack of statistical power of small population studies. However promising, advances in PD technology deserve the close attention of all nephrologists.[2]

This chapter describes the catheters and implantation techniques, which have been used for chronic peritoneal dialysis (CPD) and some of the complications that have arisen from them. Also, it discusses the complication related to the catheters and the implantation and certain difficulties that may arise during their treatment.

Anatomy of the Abdominal Wall and Peritoneum

A working knowledge of the anatomy of the anterior abdominal wall and peritoneal cavity is necessary for an understanding of the various techniques of catheter placement and is vital for those undertaking this procedure.[3,4]

The skin of the anterior abdominal wall is of moderate thickness and is relatively mobile on the underlying fascia and muscle. Most incisions for catheter insertion are relatively short and exposure is equally good whichever their direction.

The skin, fascia, muscles, and parietal peritoneum of the anterior abdominal wall are innervated segmentally largely from the anterior primary rami of spinal nerves T6 to L1.

A well-infiltrated field block around the terminal branches of these nerves as they pass medially towards the incision will provide good local anesthesia down to the peritoneum, which in the thin patient is an obvious layer, but in the obese is lost in a thick, fatty panniculus.

The main muscles of the anterior abdominal wall are four. Three of them: the external oblique, the internal oblique, and the transversus abdominis, pass from their various origins as separate, fleshy muscle bellies in a predominantly medial direction. The major vessels and nerves pass downward and medially in the neurovascular plane, between the transversus abdominus and the internal oblique muscles.

The rectus sheath appears as an elliptical tube with a strong anterior wall. The weaker posterior wall only extends to just below the level of the umbilicus. Supplying the rectus muscle and firmly adherent to its posterior surface are the epigastric vessels. These are easily damaged, particularly during a lateral approach for catheter insertion.

In obese patients there may be a variable amount of preperitoneal fat. The peritoneum is usually a bluish, almost avascular membrane, underneath which bowel or omentum can be seen to move with respiration. In a patient who has had previous peritoneal dialysis or who has had previous surgery, the peritoneum may be thicker and sometimes slightly vascular. Adhesions between the intra-abdominal contents and the parietal peritoneum may be encountered when operating through the scar tissue of previous incisions.[5]

The peritoneal cavity is a large potential space. Conventionally, it is divided into the greater and lesser sacs with the root of the transverse mesocolon dividing the greater sac into the supracolic and infracolic compartments. The intraperitoneal portion of the dialysis catheter should lie wholly in this lower compartment, potentially in contact with the small bowel, greater omentum, transverse and sigmoid colon, and the reproductive organs in the female. If the peritoneal cavity is filled with fluid, the omentum tends to float because of its fat content, as do those parts of the bowel that have a mesenteric attachment. Theoretically, if the tip of a dialysis catheter is well positioned in the most dependent part of the pelvis and the peritoneal cavity is full of fluid, it should be relatively unobstructed by these other intraperitoneal structures.

The peritoneum itself is a single layer of mesothelial cells supported by a basement membrane, which rests upon a bed of connective tissue varying in thickness according to the site. The peritoneum is divided into the visceral layer that covers those parts of the bowel and parenchymal organs that hang by a mesentery within the peritoneal cavity and the parietal layer that covers the walls of the cavity itself.[3,6,7]

Development of Peritoneal Catheters

The ideal catheter should be simple, safe and long-lasting, with a minimal rate of access-related complications and rapid dialysate flows.

Ganter[8] and Putnam[9] made the first attempts to gain access to the peritoneal cavity for dialysis. Although it was recognized that potentially the peritoneum was an effective dialyzing membrane, attempts to use it for this purpose were frustrated by the lack of a useful access device.

Palmer and Quinton[10] were the first to use silicone rubber catheters to provide prolonged access to the peritoneal cavity. Palmer's catheter used a long subcutaneous tunnel, which diminished the risk of sepsis. Several patients dialyzed successfully for long intervals between infections.

In 1964 Gutch[11] made a major step forward in creating a permanent peritoneal access when he noted less irritation of the peritoneum and lower protein losses with silicon rubber catheters, compared to those made with polyvinyl.

In 1968 Tenckhoff and Schechter[12] published the results of their studies on a new catheter, which was an improved version of the Palmer catheter. The intra-abdominal flange was replaced by a Dacron cuff, the subcutaneous tunnel was shortened, and it had a second, external cuff to decrease the length of the catheter sinus tract. The intraperitoneal segment was kept open-ended and the size of the side holes was 0.5 mm to prevent tissue suction. To avoid excessive bleeding and to assist easy penetration, the catheter was inserted through the midline.

The Tenckhoff catheter became the gold standard of peritoneal access. Few complications were reported in patients treated by periodic peritoneal dialysis. Even today, more than 30 years later, the Tenckhoff catheter in its original form is the most widely used catheter type. Some of the original recommendations for catheter insertion, such as an arcuate subcutaneous tunnel with downward directions of both intraperitoneal and external exits, are still considered to be important elements of catheter implantation.[13-15]

A number of subcutaneous and intraperitoneal variations have been proposed as better devices. The catheter may be single- or double-cuffed with a straight or curled intraperitoneal portion and will be described later on in this chapter.

Catheter Design and Insertion: General Principles

Before describing individual catheters, it is worth reviewing some of the general principles of catheter design and use. The catheter can be considered in three parts, each with a separate function. These are the extra-abdominal, subcutaneous, and intraperitoneal sections. It is in the last section that catheters vary so widely (Figure 26–1).

The extra-abdominal section, which protrudes from the skin exit site, needs to be at least 10 cm long for easy handling and have enough length in reserve to permit trimming if a split occurs at the connector site. The subcutaneous section permits a degree of freedom in the siting of the catheter exit at a convenient place on the anterior abdominal wall. In catheters with a single preperitoneal cuff, the subcutaneous tunnel varies in length and is open at the exit site. In two-cuff catheters, this open part of the tunnel is relatively short between the exit site and the subcutaneous cuff. The deep part of the tunnel is then blind at both ends between the subcutaneous and preperitoneal cuffs. In the absence of sepsis the subcutaneous tunnel becomes lined by a downgrowth of epidermal cells. Ideally, the subcutaneous part of the catheter should be designed and implanted in such a way as to avoid skin exit-site infections, superficial cuff erosion, and tunnel infections.[1,13,14]

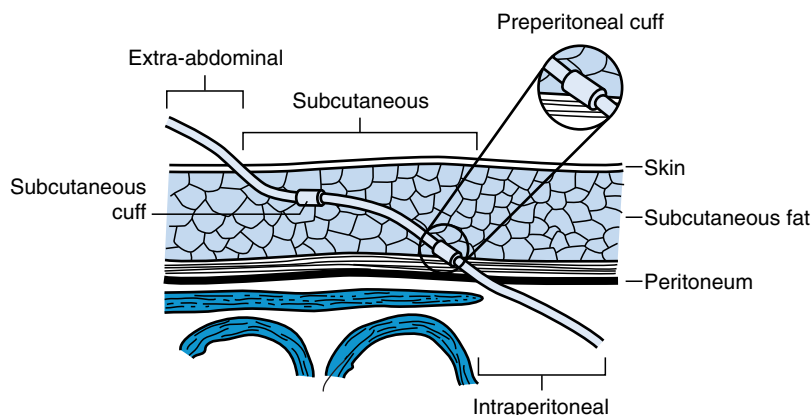
The short transmural section of catheter that passes through the abdominal wall muscles or the linea alba, and which then perforates the peritoneum, has three functions: to provide a mechanical anchorage, a water-tight peritoneal seal, and a further antibacterial seal. All three can be served by a single cuff just superficial to the peritoneum and deep to the overlying structures. The fibrous tissue ingrowth bonds the catheter to muscle and fascia strongly enough to prevent its displacement by traction. When the cuff is routed obliquely through the tissues, this bond will stabilize the intraperitoneal section of the catheter in a direction pointing towards the pelvis. At this level, the cuff also produces fibrosis immediately adjacent to the peritoneum, forming an effective fluid seal. The transmural section should be implanted to prevent catheter extrusion, early and late dialysate leaks and incisional hernias.


Figure 26–1 Functional parts of a peritoneal catheter and the abdominal wall with adjacent tissues.

Types of Catheters

Peritoneal Catheters Categorized as Acute or Chronic

Acute catheters

The catheter design for acute PD and chronic PD differs significantly. Acute PD catheters are straight and relatively rigid with a conduit about 3 mm in diameter and 25 to 30 mm in length without any protective Dacron cuff. It can be placed at the bedside under local anesthesia with a tiny skin incision with the tip of the scalpel. It is used immediately after implantation. It is not recommended to be left in situ for longer than 3 days. With prolonged use, it is associated with significant risk of peritonitis, malfunction, and bowel perforation. Acute PD is still used in the management of acute and chronic renal failure in many developing countries.[12,13]

All acute catheters have the same basic design: a straight or slightly curved, relatively rigid tubing with numerous side holes at the distal end. A metal stylet or flexible wire over which the catheter slides is used to guide insertion.

Acute peritoneal dialysis can also be carried out through a semi-rigid catheter implanted at bedside using a Tenckhoff trocar Seldinger technique or by laparoscopic insertion. The incidence of complications related to peritoneal access (such as hemorrhage, bowel injury) vary from center to center.[16-19]

Because acute catheters do not have cuffs to protect against bacterial migration, the incidence of peritonitis increases prohibitively beyond 3 days of use. Also, the risk of bowel perforation increases with duration of use. If extended dialysis is necessary, the acute catheter must be removed periodically and replaced by a new catheter in a different location.

Implantation of Acute Peritoneal Dialysis Catheters

Planning the access implantation, which is part of an integrated approach to renal replacement therapy and pre-dialysis care, begins with careful patient preimplantation evaluation. Such evaluation includes search for any herniation, or weakness of the abdominal wall, which can be corrected before or preferably at the time of the implantation, determination of the exit site by an experienced member of the PD team, bladder emptying, and the administration of prophylactic antibiotics just as in any abdominal surgery.

The acute peritoneal catheter is placed blindly into an abdomen that has been pre-filled with fluid. Insertion is guided by a sharpened stylet or by flexible guidewire. Examples of acute catheters with stylets are the Stylocath (Abbott Laboratories North Chicago, ID) and the Trocath (Baxter Healthcare, Deerfield, IL). An acute catheter designed to be inserted over a flexible guidewire is available from Cook Co. (Bloomington, IN).[17,19]

The incidence of complications is increased in patients with ileus or adhesions from previous abdominal surgery. Placement is also difficult in comatose or uncooperative patients who cannot tense their abdominal wall during insertion of the catheter or the prefilling needle. Surgical or peritoneoscopic placement of a chronic peritoneal catheter should be considered for such patients.

Procedure

Either a midline or a lateral abdominal entry site can be chosen. The midline site is about 3 cm below the umbilicus. The lateral site is just lateral to the border of the rectus muscle, on a line between the umbilicus and the anterior superior iliac spine. On the right, the lateral site is approximately at McBurney's point. The left lateral site is considered preferable because it avoids the cecum. When choosing an insertion site, avoid areas of previous catheter insertion or scars by at least 2 to 3 cm. The bladder must be empty, because a full bladder can be penetrated inadvertently by the stylet during insertion. The abdomen should be carefully examined to exclude the presence of massive enlargement of the liver, spleen, bladder, or other organs and *to* exclude other remarkable pathology (e.g., abdominal carcinomatosis).[3,18]

Complications of Acute Catheter Insertion (Table 26–1)

Pain

An experienced and skilled operator, either a physician or a surgeon, in a dedicated room, under sterile conditions, must implant the catheter. Pain which is due mainly to dialysis-related complications, is seen in 56% to 75% of patients with the first use of a catheter.[12-14] It occurs because of low dialysis pH, overdistension, low and high temperature of dialysate, free abdominal air, and peritonitis. Pain may occur during flow, dwelling, and outflow of dialysis solution. Outflow pain is caused by the entrapment of omentum in the catheter during the siphoning action of fluid drainage. Constant pain indicates pressure effects on intra-abdominal organs and often produces continuous rectal or low back pain. This may need adjustment in catheter position. In a small percentage of patients, catheter tip irritation of abdominal viscera causes pain. It is relieved with plain water enema. Pain during catheter insertion can be alleviated by adequate local anesthesia and sedation.[16]

Bleeding

After catheter insertion, bloody outflow appears in 30% of cases.[20,21] The reasons for bleeding after rigid catheter insertion are (1) pre-peritoneal placement of the catheter; (2) injury to minor capillaries in parietal peritoneum, subcutaneous space, or mesentery; and (3) puncture of major intra-abdominal vessels.

The treatments usually required for minor bleeding are (1) pressure application over catheter entry side, (2) suitable pursestring suture, (3) rapid exchange of dialysate without dwell to clear the effluent and prevents catheter block, (4) heparin 1000 IU/L of dialysate that minimizes the risk of

Table 26–1 Complications of Acute Peritoneal Dialysis (PD) Catheters

- Pericatheter dialysis solution leak
- Viscus perforation
- Catheter malfunction/poor drainage
- Infections/Peritonitis

Other Complications
- Loss of rigid catheter in the peritoneum
- Extraperitoneal space penetration

catheter block (intraperitoneal heparin is not absorbed in sufficient amount to influence systemic coagulation), (5) the use of room temperature dialysate that may slow or stop capillary bleeding, and (6) fresh blood transfusion; removal of rigid catheter may be required in some patients. Persistent significant bleeding (hemoglobin in effluent >5 g/dL) not only causes blood loss, but it also causes blockage of catheter due to blood clot and is a source of infection.[22]

Pericatheter Dialysis Solution Leak

Pericatheter leak occurs in 14% to 36% of patients after acute PD catheter insertion.[13,20,21] The predisposing factors are (1) frequent manipulation of catheter to improve drainage, (2) catheter not properly secured to skin, and (3) presence of high intra-abdominal pressure due to ascites or polycystic kidney disease. Rarely, fluid may leak into the pleural cavity through a congenital or traumatic defect in the diaphragm. The management of early leak includes temporary discontinuation of PD and supine low volume PD. Catheter replacement may be required if it persists.[23]

Viscus Perforation

Bowel injury

Bowel injury occurs in 0.1% to 1.3% of all procedures.[24,25] It is a rare but serious complication. The predisposing factors are: previous abdominal surgery with peritoneal adhesions, distention of bowel with gas, and paralytic ileus. Minor injury is harmless, but significant injury can cause turbid outflow because of fecal contamination of the peritoneum. The injury also results in poor outflow and can cause watery diarrhea. Filling the peritoneal cavity adequately with dialysis fluid and withdrawing the stylet as soon as the peritoneum is punctured prevents any injury to bowel.

Broad-spectrum antibiotics with anaerobic cover should be started empirically and later modified according to culture and sensitivity. Laparotomy may be required for the repair of gut injury along with removal of the catheter.

Bladder injury

Bladder injury occurs when the bladder is full during catheter insertion and if the stylet is not withdrawn after piercing the peritoneum and the bladder comes beneath the stylet. This complication manifests as suprapubic swelling, and the patient may pass hemorrhagic PD fluid per urethra. The outflow by PD catheter may be poor and hemorrhagic.[24]

Catheter Malfunction/Poor Drainage

Catheter malfunction usually results in poor dialysate inflow and outflow. The reasons for poor dialysate flow are kinked catheter, fibrin or blood clot, omental wrapping, catheter tip migration, loculation of fluid in the peritoneal cavity because of previous peritoneal adhesion, and neurogenic distended urinary bladder. The incidence of acute peritoneal catheter malfunction has been reported to be 12% to 28% in various studies.[26]

Infections/Peritonitis

Exit-site infection is a rare complication of acute peritoneal dialysis. The incidence of peritonitis is about 2.5% of all dial-

yses when stylet catheter is used. The incidence is almost doubled when the duration of dialysis is longer than 60 hours. The incidence of positive culture in the absence of clinical infection is as high as 10% to 30%.[22,27]

Other Complications

Loss of a part or all of the rigid catheter has been reported following its manipulation with the trocar in place.[3,28,29] Its distal end may be amputated after intra-abdominal kinking of the catheter, followed by manipulation. However, the presence of broken catheters within the abdominal cavity does not cause symptoms or ill-effects. During laparoscopy, broken catheters have been found lying freely in the peritoneal cavity without causing a peritoneal reaction, or have been found walled off by mesentery without an inflammatory reaction. On routine postmortem examination, Stein[30] discovered such a catheter in a patient who had had previous peritoneal dialysis. Exploration to retrieve the catheter is unnecessary because laparotomy is more hazardous than leaving the catheter in a severely ill patient. The incidence of catheter loss into the peritoneal cavity has been greatly reduced since the introduction of a design that incorporates a metal disc with a central hole; this not only allows the catheter to pass through the wall but also holds the catheter snugly to the skin of the abdominal wall.[26] The incidence of the accidental penetration of the extraperitoneal space is low varying between 0.5% and 1.3%. In this situation the fluid may become trapped, resulting in poor dialysate drainage.[32,33]

Chronic Peritoneal Dialysis Catheters: General Principles

Chronic peritoneal catheters are constructed from silicone rubber or polyurethane and have one or two Dacron cuffs. Like acute catheters, most chronic catheters have numerous side holes at the distal end of the intraperitoneal part. The silicone rubber or polyurethane surface promotes development of squamous epithelium in the subcutaneous "tunnel" next to the catheter, at the exit site, and within the abdominal wall. The presence of this epithelium increases resistance to bacterial penetration of the tissue near the skin exit and peritoneal entry sites. The Dacron cuffs provoke a local inflammatory response that progresses to form fibrous and granulation tissue within one month. This fibrous tissue serves to fix the catheter cuff in position and to prevent bacterial migration from the skin surface or from the peritoneal cavity (in cases of peritonitis) past the cuff into the subcutaneous tunnel (Table 26–2).

The intraperitoneal segment has multiple 0.5 mm perforations in the 3 to 9 cm terminal part. The variety of catheter lengths permits one to choose an appropriate catheter for every patient size.[1,17,19]

Several modifications have been made to the intraperitoneal sections of various catheters with the aim of obtaining an unrestricted flow of dialysate to and from the peritoneal cavity. This flow is most efficient if the catheter tip lies deep within the pelvis. When the peritoneal cavity is full of dialysate, the mobile parts of the bowel and omentum, although restrained to some extent by their mesenteric attachments, tend to float upon a fluid sump. During run-out, this sump drains under the influence of a positive intra-

Table 26–2 Specifications, Materials, Design of Catheter Types

Catheter	Material	No. of Cuffs	Segment between Cuffs	Intra-Abdominal Segment	Features
Standard Tenckhoff	Silicone	1–2	Usually straight	Straight-coiled	?
Swan-neck arcuate	Silicone	1–2	Arcuate	Straight-coiled	Beads on sites of deep cuff

abdominal pressure coupled with a syphon effect produced by the difference in height between the catheter tip and the empty dialysis bag. Typically, an outflow rate will begin at 100 to 150 mL/min and then decrease gradually towards the end of the run-out period as the catheter side-holes are occluded by the intra-abdominal contents. A small residual volume is always left behind. The outflow may become obstructed at any time if bowel or omentum surrounds the catheter before drainage is complete. This is more likely if the catheter tip becomes displaced from the pelvis into the upper abdomen. Several modifications have been made to the end of the Tenckhoff catheter, all with the object of stabilizing the tip in the lower quadrant. Thus, catheter design and insertion of the intraperitoneal section is aimed at the prevention of one- or two-way obstruction, dislodgement from the pelvis and wrapping by omentum.

Catheters are soft, flexible, and atraumatic to bowel. Catheters are available with barium impregnated either throughout or as a radiopaque stripe to assist in the radiologic localization of the intra-abdominal section.

In order to eliminate the "shape memory" that tends to extrude the external cuff if a straight catheter is forced in an arcuate tunnel, the "swan-neck catheter" was introduced.[34] This catheter has a permanent bend between the cuffs and is placed with both the internal and external part directed downwards. The intra-abdominal part may be straight or curled. Curled or coil catheters reduce discomfort by minimizing the "jet effect" caused by the high flow of dialysate, and potentially are less prone to migration.[35] Several other catheters, designed to prevent obstruction and migration, for example, the Column disk catheter and the Ash catheter[36] are not in use anymore. The Cruz catheter has a larger inner diameter allowing high flow rates and faster bag exchanges.[37] This catheter, in contrast to most others, is made of polyurethane, a material with greater strength, allowing thinner walls. Unlike silicone, polyurethane is degraded by alcohol and iodine. Repeated exposure of the catheter to these agents may result in crack development.[28,38] The Gore-tex catheter, developed to prevent exit-site infection, did not fulfill this expectation.[39] Likewise, the results of silver-impregnated catheters have been disappointing.[40,41]

Chronic peritoneal catheters and fixed in position, are not restricted to a 3-day period of use as are the uncuffed acute catheters. Usually peritonitis can be treated successfully without catheter removal.[19]

There are no long-term controlled studies that suggest the superiority of any one catheter over all the others. Any new catheter must compete with the long-term experience of the Tenckhoff catheter.

Whatever type of catheter is chosen, at best one can expect a 3-year catheter survival rate of 80%. The minimum acceptable catheter survival rate is regarded as 50% at 12 months.[38] A good survival rate seems to depend more on a good insertion technique and meticulous care than on the catheter device chosen. The implantation should be performed by a competent experienced operator under strict sterile conditions. Exit-site care and attention to detail is of paramount importance.

Usually a chronic catheter is implanted by surgical dissection in the operating room. Effective and safe techniques exist for bedside placement, using guidewire and dilators or peritoneoscopy. When it is anticipated that the patients will need peritoneal dialysis for longer than a few days, a chronic catheter should be placed initially, avoiding the necessity for periodic replacement of acute catheters.

Chronic Peritoneal Dialysis Catheter Types (Figure 26–2)

Straight and Coiled Tenckhoff Catheter

The Tenckhoff catheter was the first catheter to enter widespread clinical use, and it is available from several manufacturers in a range of lengths and cuff positions. It remains the most commonly used and has become a standard for comparison with other catheters. The "chronic catheter" consists of a silicone rubber tube of 2.6 mm internal diameter and 5 mm external diameter bonded to two 1 cm cuffs. The intraperitoneal portion varies in length from 6.5 to 19.5 cm, with numerous 0.5 mm perforations in the terminal 2.5 to 9.5 cm. This wide range of lengths permits one to select an appropriate catheter for patients of every stature. The standard length distal to the superficial cuff is 20 cm, which leaves an external segment of approximately 10 cm; an acute catheter, available with a single cuff in a range of lengths, has now been adopted widely for chronic use and is considered by some clinicians to reduce the incidence of exit-site infections.[42,43]
Figure 26–2 Currently available chronic peritoneal catheters showing combinations of intraperitoneal and extraperitoneal designs. Intraperitoneal *(IP)* designs appear on the left, and extraperitoneal *(EP)* designs appear on the right. The letters in circles indicate material of construction: *P* = polyurethane; *P, S* = polyurethane or silicone. (From Gokal R, Khanna R, Krediet R, Nolph K: Textbook of Peritoneal Dialysis, 2nd ed. , Kluwer, 2000.)

The coiled Tenckhoff catheter differs from the straight in having a coiled, 18.5 cm long perforated distal end. As mentioned earlier, the coiled catheter reduces inflow infusion "jet effect" and pressure discomfort. All Tenckhoff catheters have a barium-impregnated radiopaque strip to assist in its radiologic visualization.

The standard Tenckhoff catheter almost always allows easy inflow of fluid. However, effective drainage of the abdomen may be variable and difficult. To minimize outflow obstruction, a number of alternative catheters have been devised (Figures 26–2, 26–3, and 26–4). The curled Tenckhoff catheter provides an increased bulk of tubing to separate the parietal and visceral layers of the peritoneum. Flow into and out of the catheter tip is more protected, and there are more side holes for outflow.[44]

Toronto Western Hospital (TWH) or Oreopoulos-Zellerman Catheter

In an attempt to stabilize the Tenckhoff catheter in the pelvis and to prevent viscera from interfering with fluid drainage, Oreopoulos and colleagues[45] attached two flat silicone rubber discs to the catheter tip. Further developments of this design have become known as the Oreopoulos-Zellerman or Toronto Western Hospital (TWH) catheters. These are available in two forms, TWH1 and TWH2 (Figures 26–2 and 26–3). The former has the dimensions of an adult Tenckhoff catheter with two thin flat Silastic discs 5 cm apart attached to the end of the intra-abdominal section. The latter has an additional modification consisting of a Dacron disc plus a silicone rubber bead

in series with the preperitoneal cuff. The incorporation of a disc just superficial to the peritoneal closure is an attempt to prevent late dialysate leaks by producing a greater area of peritoneal sealing. The bead adjacent to the disc provides a groove to assist in a tight peritoneal closure. This method of fixing the deep cuff is different from that of the Tenckhoff catheters, in which the deep cuff rests entirely in the rectus muscle.

Swan-Neck Catheters

The swan-neck catheter is now the second most frequently used catheter. Swan-neck catheters feature a permanent

bend between cuffs (Figure 26–2)[46] The catheter was dubbed "swan-neck" because of its shape. As a result of this design, catheters can be placed in an arcuate tunnel in an unstressed condition with both external and internal segments of the tunnel directed downward. A downward-directed exit, two cuffs, and an optimal sinus length reduce exit/tunnel infection rates.

A major improvement was in the intercuff shape; the distance between cuffs was shortened from 8.5 cm to 5 cm in swan-neck 2 and to 3 cm in swan-neck 3 catheters, and the bend was increased from 80° to 170° to 180° arc angle. The catheters are supplied with short or long intraperitoneal segments, selected according to patient size and insertion site, to secure the catheter-tip position in the true pelvis.[46,47] Because in several patients infusion pain occurred due to a "jet effect" and/or tip pressure on the peritoneum, the intraperitoneal segment of the catheters, was modified replacing a straight segment with a coiled one (swan-neck coiled). These catheters were introduced in January 1990 and within a month swan-neck straight catheters were phased out.[48]

Swan-Neck Missouri Straight

The swan-neck Missouri catheter has a flange and bead circumferentially surrounding the catheter just below the internal cuff; the flange and bead are slanted approximately 45° relative to the axis of the catheter. The catheters for left and right tunnels are mirror-images of each other. A swan-neck Missouri 2 catheter with a 5 cm intercuff distance is used in average to obese people. The intraperitoneal segment is 21.5 cm long in the swan-neck Missouri 2 long catheters. A swan-neck Missouri 3 catheter with a 3 cm intercuff distance is used in lean to average persons[46,48] (Figure 26–2).

Swan-Neck Missouri Coiled

The intraperitoneal segment in all swan-neck coiled catheters is 34 cm from the bead to the tip of the coil. Swan-neck Missouri 2 coiled catheters with the 5 cm intercuff distance are used in average to obese people. Swan-neck Missouri 3 coiled catheters with 3 cm intercuff distance are used in lean to average persons. The catheters for left and right tunnels are mirror-images of each other.[46] The overall survival times for straight and coiled swan-neck Missouri catheters are not significantly different, but none of the patients experienced infusion or pressure pain with coiled catheters, whereas this complication was seen in several patients, who had catheters with straight intraperitoneal segments.[48] Swan-neck catheters are also available in smaller sizes for children and infants.[49]

Pail-Handle (Cruz) Catheter

This catheter has two right-angle bends: one to direct the IP portion parallel to the parietal peritoneum and one to direct the subcutaneous portion downward toward the skin exit site. It is available only in polyurethane. Its clinical benefits have not been well defined. Its larger internal diameter and position of the coil near the parietal peritoneum allows more rapid outflow than standard silicone catheters, and its shape facilitates placement in obese patients (see Figure 26–2).

Presternal Swan-Neck Peritoneal Catheter

The presternal peritoneal dialysis catheter is composed of two flexible (silicon rubber) tubes, which are connected end-to-end at the time of implantation. The implanted abdominal tube constitutes the intraperitoneal catheter segment and a part of the intramural segment (Figure 26–2). The distal end of the abdominal tube located in the peritoneal cavity is coiled and the central bore with multiple small side perforations that provides for fluid delivery into and drainage from the peritoneal cavity. The proximal end of the abdominal tube carries a polyester cuff to be located in the rectus muscle also the tubing is provided with a flange circumferentially surrounding the tubing just below the cuff and a bead adjacent to the flange. As in the swan-neck Missouri catheter, the flange and bead are slanted at an angle of about 45°. During implantation, the proximal part of the abdominal tube is trimmed to the desired length. After implantation, the proximal end of the abdominal tube extends a few centimeters from the cuff and is provided with a connector made of titanium. The connector is coupled to the distal part of the thoracic tube at the time of implantation. The thoracic tube constitutes the remaining part of the intramural segment and the external catheter segment. The distal-end bore of the thoracic tube communicates with the proximal-end bore of the abdominal tube through the titanium connector. The tube carries two porous cuffs: a superficial cuff and a middle or central cuff. The tube between the cuffs has a permanently bent section (swan-neck feature) defining an arc angle of 180°. Both tubes have a radiopaque barium stripe that helps achieve proper alignment of the tubes during implantation. The stripe is also useful during insertion and postimplantation care, facilitating recognition of catheter twisting. The distal part of the thoracic tube is trimmed to the desired length during implantation.[50,51]

The swan-neck presternal catheter is available for children and infants. Tubing diameter is smaller for pediatric patients.[52]

Moncrief-Popovich Catheter and Implantation Technique

Moncrief and Popovich designed their new catheter, made of silicone rubber, with several important structural changes that differ from Tenckhoff catheter.[50] The changes and the reasons for the changes are as follows: (1) a coiled internal segment, (2) an arcuate bend in the subcutaneous segment similar to the swan-neck Missouri catheter designed by Twardowski and colleagues,[45] and (3) two Dacron cuffs. The external Dacron cuff, however, is elongated to 2.5 cm, and the ends of the cuff are tapered longer than the internal one.

This catheter is similar to the standard swan-neck Tenckhoff, except that the external cuff is much longer. When the catheter is first implanted with 1.000 Units of heparin instilled, the external segment is buried subcutaneously (Initially there is no exit site) for a period of 4 to 8 weeks or longer to allow tissue ingrowth into the external cuff in a sterile environment. Subsequently, a small incision is made in the skin through which the external segment of the catheter is brought out.[52]

Ash (Advantage) Catheter

The Advantage catheter contains a straight portion that is held adjacent to the parietal peritoneum assuring a stable position, without extrusion of the deep cuff or exit site erosion.[53] The intraperitoneal portion contains a short, perpendicular cylinder connected to two limbs with external grooves (flutes) to carry fluid into the catheter from the upper and lower abdomen. The catheter may be placed by a dissective or a peritoneoscopic technique. Due to the apposition of the grooved portion of this catheter against the parietal peritoneum and the T-shape of the catheter, the deep cuff of this catheter is "fixed" in position, and outward migration of the catheter is impossible. Following placement of this catheter in 18 patients, with up to 4 years of follow-up, no catheter developed exit site erosion, exit infection pericatheter hernia, or pericatheter leaks[54] (Figures 26–2 and 26–4).

Catheters Designed for Continuous Flow Peritoneal Dialysis (CFPD)

In 1965 James Shinaberger[55] reported a series of patients treated with CFPD. He used two peritoneal catheters inserted acutely at opposite ends of the peritoneal cavity, 3 L of sterile intraperitoneal dialysate regenerated by an external twin-coil dialyzer in 100 L of dialysate. Dialysate flow rates ranged from 120 to 300 mL/min. Clearances of urea varied from 46 to as high as 125 mL/min! Over the next 2 decades, other groups attempted to reproduce this technique and met with mixed success.[56-62] Ash[63] has designed a catheter with a T-shape configuration in order to maximally separate the tips of the two lumens.[64] This catheter offers promise in CFPD but has not yet been tested clinically (Figure 26–4).[65]

Ronco and colleagues[66] designed a novel catheter for CFPD equipped with a thin-walled silicone diffuser used to gently infuse the inflow dialysate into the peritoneum (Figure 26–4). The holes on the round-tapered diffuser are positioned to allow dialysate to perpendicularly exit 360° from the diffuser, thereby reducing trauma to the peritoneal walls and allowing the dialysate to mix into the peritoneum. The fluid is then drained through the second lumen, whose tip is positioned in the lower pelvis.

CRITICAL COMPARISON OF CATHETER DESIGN

Facing so many different options, which catheter should one choose? Early studies favored the double-cuff over the single-cuff Tenckhoff catheters, because they gave better catheter survival, longer time to the first peritonitis episode, and fewer exit-site infections. Previous ISPD consensus opinion also supported the choice of double-cuffed Tenckhoff catheters. Searching for evidence-based, level A studies, Lewis and colleagues[67] carried out a prospective controlled, randomized study that confirmed such benefits. However, Eklund and colleagues[68] found no difference in the number of peritonitis episodes, exit-site infections, or in catheter survival between single- and double-cuff Tenckhoff catheters[67-72, 96-100] (Table 26–3).

A controversy over coiled or straight catheters also justified some controlled, randomized studies. Theoretically, the coiled catheter would offer less infusion/pressure pain, better flow, less catheter migration, and omental wrapping. A pair of studies gave no conclusive answers, with inconsistent results.[69,70]

Other variations of the intraperitoneal portion of the catheter, such as silicone discs perpendicular to the catheter

Table 26–3 Randomized, Controlled Studies on Catheter Type and Implantation Methodology

Catheter Type	Group (first author)	Patients (n)	Outcome
Double vs. single-cuff	Lewis, 1997[67]	40 (pediatric)	More peritonitis-related catheter loss in single-cuff catheters
	Eklund, 1997[68]	60	Similar peritonitis/exit-site rate and survival
Coil vs. straight	Nielsen, 1995[69]	72	Better survival and fewer mechanical complications
	Akyol, 1990[70]	39	Similar outcomes
Swan-neck vs. Tenckhoff	Lye, 1996[71]	40	Fewer exit-site infections, less catheter-tip migration; similar survival
	Eklund, 1995[72]	40	Similar outcomes
Surgical vs. peritoneoscopic implantation	Cadallah, 1999[96]	148	Less peritonitis, less leakage, better survival
	Tsimoyiannis, 2000[97]	50	No leak or tip migration with peritoneoscopy
	Wright, 1999[98]	50	Similar outcomes
Moncrief technique vs. conventional	Park, 1998[99]	60	Less catheter-related peritonitis, similar survival
	Dasgupta, 1998[100]	39	Fewer exit-site infections, better catheter survival

(Toronto-Western-Hospital catheter) designed to avoid catheter-tip migration, and T-fluted catheters that promised better flow and also less migration, have not shown any consistent advantage over the standard Tenckhoff. Concerning the subcutaneous pathway, some have reported fewer exit-site/tunnel infections with the permanently bent catheters such as the swan-neck and presternal swan-neck catheter. Although this benefit seems promising, several studies[71,72] found no difference in catheter survival between the swan-neck and the straight Tenckhoff catheters. Therefore, the choice of catheter should be based on the experience of the centers.

Catheters with deep cuffs or larger IP portions, such as the Toronto Western and Missouri models, require surgical dissection for placement, whereas standard Tenckhoff-type catheters and the T-fluted catheter can be placed blindly or peritoneoscopically. The Toronto Western catheter, by design, has increased attachment to the abdominal wall, and thus is more difficult to remove. Preliminary data on the new Moncrief-Popovich catheter and technique suggest a reduced incidence of peritonitis but no decrease in exit-site infection.

It was hoped that polyurethane, because it is a stronger and smoother material than silicone, would reduce the formation of biofilm. However, it has not been shown that polyurethane catheters have a lower incidence of recurrent peritonitis, outflow obstruction, or mechanical failure; indeed, they may be more susceptible to damage by chemicals, such as alcohol and polyethylene glycol, and to disruption of the bond between the catheter and its cuffs.

Catheter selection is difficult for patients in high risk for early catheter failure, including those who are known to have intra-abdominal adhesions, who may have had previous difficulties with catheters, or who may be obese with a lax abdominal musculature.

CHRONIC CATHETER-PLACEMENT PROCEDURES

The few absolute surgical contraindications to CAPD, particularly when considering the anatomy of the abdominal wall or previous abdominal procedures within it, are listed in Table 26–4. Relative contraindications include previous extensive pelvic or low abdominal surgery, where it is anticipated that much of the infracolic compartment will be involved by adhesions. In such patients, who are otherwise good candidates for treatment by CAPD, it may be advantageous to perform a small laparotomy to assess the peritoneal cavity or to undertake peritoneoscopy, which is also useful in assessing complications during CAPD.[73] Wu and colleagues[74] suggested that extensive colonic diverticulosis may be a relative contraindication because, in the elderly, it is related to a high mortality from diverticular perforations.

Patient Assessment

Complications may arise from the presence of a hernia that should be identified at the initial patient assessment. This may be repaired in one procedure with catheter insertion. Where hernia defects are large, any use of the catheter should be delayed until a sound surgical repair has been carried out.

Table 26–4 Surgical Contraindications to CAPD

Absolute Contraindications
1. Absence of anterior abdominal wall? prune belly syndrome
2. Severe peritoneal adhesions
3. Sclerosing peritonitis
4. Inflammatory bowel disease
5. Sepsis of anterior abdominal wall
6. Large unrepairable herniae of abdominal wall

Relative Contraindications to CAPD

Pleuroperitoneal leak	Blindness
Low-back problems	Crippling arthritis
Polycystic kidneys	Amputations
Ileostomy	Poor motivation
Colostomy	Overt psychosis
Nephrostomy	Severe pulmonary impairment
Obesity	Hyperlipidemia

Elderly patients have an increased incidence of cholelithiasis and diverticulosis of the colon; The latter is more common in patents with polycystic disease.[75] While both of these conditions may remain asymptomatic during CAPD, an episode of acute cholecystitis or diverticulitis may well mimic an episode of primary peritonitis. When considering the differential diagnosis of peritonitis, one should assess patients over the age of 60 years for these conditions. This can be performed conveniently by ultrasound and flexible sigmoidoscopy. In patients with proven diverticular disease, constipation should be prevented by the adoption of a high residue diet.

Polycystic kidneys may appear to occupy considerable space in the peritoneal cavity, however, in practice this usually does not limit the volume of fluid exchanges. Brown and colleagues[76] and Khanna and colleagues[77] have drawn attention to the symptomatic exacerbation of peripheral vascular disease in patients starting CAPD. Thus, one should consider doing corrective vascular surgery or angioplasty on patients with symptoms of arterial disease before starting CAPD.

Preparation for Catheter Insertion

Before proceeding with catheter insertion, one should demonstrate the technique to the patient, who should be familiar with the catheter as well as with the various connections and lines that will be used. It is important to determine with the patient's own preference concerning the catheter exit site, which should be above or below the belt line, easily accessible and in a direct line of sight. Obviously, skin creases should be avoided, and it is wise to mark the preferred site for easy reference in the operating theater. Thin individuals may wish to avoid a midline insertion, where the cuff can cause discomfort, particularly during sexual activity.[78]

The abdominal wall hair should be clipped from the xiphisternum to the symphysis pubis. The bowel should be empty before catheter insertion and this may be assisted by the administration of an enema. Also, the patient should be asked to empty the bladder as completely as possible. The choice of anesthesia may be dictated by the patient's age, medical condition, or the likely extent of the surgical dissection. In adults who have not had previous abdominal surgery, either local or general anesthesia is acceptable and the patient's preference can be noted. Some discomfort is inevitable during insertion under local anesthesia, but this can be minimized by the administration of a hypnotic or analgesic agent before operation. However, the patient must be informed of what to expect, particularly as one needs some co-operation during certain parts of the procedure. An open insertion is the procedure of choice in patients who previously have undergone a low abdominal procedure.[1,18,19]

Catheters should be inserted by trained personnel-using a strict aseptic technique. Although closed medical insertion can be accomplished at the bedside, access and lighting are often less than ideal. It is strongly recommended that all catheters are inserted under operating theater conditions, where diathermy, suction, and good lighting are available.

Chronic Catheters-Placement Procedures

There are four options for placement or chronic peritoneal catheters: (1) surgical placement by dissection, (2) blind placement using the Tenckhoff trocar, (3) blind placement using a guidewire, and (4) minitrocar placement using peritoneoscopy. The larger catheters, such as the Toronto Western and Missouri models, must be placed surgically. Straight and curled Tenckhoff catheters, with or without a swan-neck section, may be placed by any technique.[17]

Immediately before implantation, the catheter is removed from the sterile peel pack and immersed in sterile saline. Dacron cuffs and the Dacron[79] flange are gently squeezed to remove air.[46] Thoroughly wetted cuffs provide markedly better tissue ingrowth compared to unwetted, air-containing cuffs.[31,80]

Surgical Implantation

This, the most popular method for placement of chronic peritoneal catheters, begins with either extensive local anesthesia or light general anesthesia. There are two general approaches: the lateral and the paramedian. Either can be used with any of the catheters, although usually Toronto Western and Missouri catheters are placed using the paramedian technique.

General anesthesia is avoided, if possible, because it predisposes patients to vomiting and constipation and requires voluntary coughing during the postoperative period as a part of pulmonary atelectasis prevention; coughing, vomiting, and straining markedly increase infra-abdominal pressures and predispose patients to abdominal leaks.[81]

A 3- to 4-cm transverse incision is made through the skin and the subcutaneous tissue. The peritoneum is identified, lifted, and opened using a 1- to 2-cm incision. The space between the anterior abdominal wall and the mass of bowel and omentum is identified.

The catheter is threaded on a long, blunt stiffening stylet. About 1 cm of catheter is left beyond the tip of the stylet to protect the bowel. The edges of the opening are lifted. The catheter is inserted through the opening and introduced into the opposite deep pelvis if there is no resistance. The patient may feel some pressure on the bladder or rectum. When the catheter with stylet is about half to three-quarters inserted, the stylet is removed and the catheter continues to be pushed into the pelvis.[31]

After proper positioning of the catheter tip, the peritoneum is closed tightly around the catheter below the level of the deep cuff using a running lock stitch. The incidence of subsequent leakage will depend largely on the care and skill used to fashion this suture line.

The skin exit site must be selected. The location can be estimated by laying the outer part of the catheter over the skin, accommodating for a V bend to direct the exit toward the patient's feet.

The skin exit site should be exactly 2 cm from the superficial cuff to allow proper epithelialization of the tract down toward this cuff.

A tunneling tool is then passed subcutaneously from below the primary incision to the skin exit site. The skin is nicked over the tool to create the exit site, and the catheter is pulled through the tunnel by attachment to the tunneling tool.

Seldinger (Guidewire) and Peel-Away Sheath

This technique may be used to insert a straight and coiled Tenckhoff catheters as well as a swan-neck Tenckhoff straight and coiled catheters. The pre-insertion patient preparation is similar to that described for rigid catheter insertion. The pro-

cedure may be done with[82] or without[83-86] prefilling the abdomen with dialysis solution. Prefilling of the abdomen is accomplished through a temporary peritoneal catheter.[31]

In the "dry" method a 2-cm incision is made and the "dry" abdomen is entered with an l8-gauge needle, for example, the Verres needle as used for laparoscopy. A guidewire is passed through the needle and the needle is withdrawn. The introducer (dilator) with sheath is passed over the guidewire. The Tenckhoff or swan-neck Tenckhoff catheter, stiffened by a partially inserted blunt stiffening stylet, is then directed down into the sheath.[85,86] As the cuff advances, the sheath is split by pulling tabs on its opposing sides. By further splitting and retraction, the sheath is removed from its position around the catheter. The subcutaneous tunnel is then created as in surgical placement. With this technique, the incidence of early leaks is very low. However, it has the risk of viscus perforation and improper placement of catheter.

Peritoneoscopic Technique

Ash[53,87] developed the use of peritoneoscopy for peritoneal catheter placement. Tenckhoff and Swan-neck Tenckhoff (straight and coiled) catheters may be implanted with this technique. Like blind insertion, it is performed through a single abdominal puncture. No fluid is instilled before insertion of the cannula and the trocar into the abdomen through the medial or lateral border of the rectus. The trocar is removed, and the scope is inserted through the cannula. After assuring the intraperitoneal location by observing motion of glistening surfaces, the scope is removed and 600 cm^3 of air placed in the peritoneal cavity with the patient in the Trendelenburg position. The scope is reinserted, and, during continuous observation, scope, quill, and cannula are advanced into the clearest space and most open direction between the parietal and visceral peritoneum. Following this, the scope and cannula are removed and the Quill catheter guide is left in place. The next step involves the dilation of the Quill and musculature to approximately 0.5 cm. The catheter follows the path previously viewed by the peritoneoscope as directed by the Quill guide. As long as the Quill guide stays in position, the catheter will advance into the desired place. The catheter is advanced on a stylet and is "dilating" its way until the cuff arrives and stops at the muscular layer. Placing the cuff in the musculature can be accomplished using a pair of hemostats advancing the cuff within the Quill guide. Thereafter, the Quill guide is removed, hydraulic function of the catheter checked, the tunnel made subcutaneously using a trocar, and the catheter brought out through the exit site, similar to the surgical insertion technique.[35,88,89]

Its originator reported excellent results with this technique. More recently Copley and colleagues[90] reported 1183 patient-months experience with 135 double-cuff, swan-neck, coiled catheters inserted peritoneoscopically over a 40-month period. Actuarial life-table analysis showed that, at the end of the 40-month follow-up, 62% of the catheters were expected to survive. Twenty-eight patients (20.6%) experienced catheter-related infections and there were five leaks (3.7%). Mechanical complications were recorded in 10 patients (7.4%) due to catheter migration (9 patients) and to preperitoneal placement (1 patient).

Blind Placement Using the Tenckhoff Trocar (Figure 26–5)

This method is still used to place straight and curved Tenckhoff catheters, although less frequently, than are other methods.[19]

- A 2- to 3-cm skin incision is made and blunt dissection carried out down to the fascia. A plastic tube or needle is inserted in the peritoneal cavity, which is then filled with dialysis solution as for acute catheter placement. The plastic tube is removed.
- The patient is asked to tense the abdomen, and the abdominal wall is penetrated in a perpendicular direction using the Tenckhoff trocar. This 6-mm–diameter trocar is surrounded by two half-cylinders which, in turn, are surrounded by an

Figure 26–5 The Tenckhoff catheter introducer, fully assembled *(above)* and with parts separated *(below)*. (From Khanna R, Nolph K, Oreopoulos DG (eds): Essentials of Peritoneal Dialysis, Dordrecht, the Netherlands, Kluwer, 1993, p 57.)
external housing. After insertion of the entire device, the trocar is removed, leaving the half-cylinders in place within the housing. Peritoneal fluid should now well up into the housing.

- An obturator is inserted into the cuffed peritoneal catheter to reinforce it, stopping 2 to 3 cm short of the tip, leaving the catheter with a soft, pliable, leading end. The housing is aimed caudad at the left lower quadrant, and the stiffened catheter is inserted through the housing into the abdomen until the cuff comes to rest against the narrowed "shoulder" of the half-cylinders. The cuff is now near the outer surface of the abdominal wall.
- The housing and half-cylinders are removed carefully from around the cuff and catheter, leaving the cuff next to the abdominal wall on the outer rectus sheath.
- Creation of the subcutaneous tunnel and exit site then proceeds as for surgical implantation.[17,31]

Procedure for Placement of the T-Fluted Catheter

The initial placement steps are the same as for Tenckhoff catheters, up to the step where the dilators are removed and the dilated plastic catheter guide is left in place. Then the T-fluted catheter, with the two limbs folded forward, is inserted into a special spiral-shaped guide that also incorporates a steel tube with wings to aid in cuff implantation.

This catheter may be placed surgically, laparoscopically, or peritoneoscopically. Both limbs fold forward to fit the catheter within a large Quill guide, which can then be advanced through a smaller Quill guide placed peritoneoscopically or by blind puncture.[3,17]

External Cuff Extrusion

The main cause of cuff extrusion is placement of the external segment of the catheter in any shape other than its natural design with the subcutaneous cuff too close to the exit. If the cuff is not infected it should be left alone; however, the cuff usually becomes infected during extrusion and requires systemic antibiotics or even surgical intervention. If there is no peritonitis or deep cuff infection, the catheter may be saved, at least for some time, by shaving off the infected cuff.[91] Ultrasound examination of the tunnel is valuable in detecting collections around the catheter in the tunnel. Cuff infection responds to therapy slowly, if at all, and a complete cure is unlikely. Local care has to be aggressive. Deroofing the sinus tract and cuff shaving have been practiced with some success.[92] Others find these measures ineffective.[93] Catheter replacement and removal can be done in one step if there is no active peritonitis.

Comparison of Various Implantation Techniques

Although each catheter and placement technique has had its advocates, comparative clinical trials have been few and limited in scope and seldom have employed randomized controls (Table 26–3).

Maher and colleagues[94] compared, retrospectively, two types of Tenckhoff catheter insertion, the guidewire method and the surgical method. Poor drainage requiring catheter removal was more common with catheters inserted by the

guidewire (6/23 vs. 1/32). Dialysate leakage requiring temporary cessation of dialysis was seen less often with catheters inserted with the guidewire (7/21 vs. 16/32) surgical method. Dialysate leakage in the guidewire group was usually subcutaneous into the scrotum or abdominal wall (5/7 patients), while leakage was through the incision in the group. No episodes of catheter-related infection were seen in either group.

Ash[53] did a literature review of the frequency of complications according to the technique of catheter placement. Catheters placed peritoneoscopically had the lowest incidence of all complications—6%, 2%, and 1%—for infection, outflow obstruction, and leak, respectively. Blind placement of double-cuff Tenckhoff catheters resulted in a higher average complication rate—16%, 22%, and 10%—as did surgical placement, 25%, 17% and 13%, although some studies of both of these techniques reported much better success.[95] For the curled, double-cuff Tenckhoff catheter, peritoneoscopic placement again seemed to have a lower complication rate than blind or surgical placement. However, only about 10% of all centers placed catheters peritoneoscopically, and those centers had extensive experience.

Cuffs

In a retrospective analysis, Twardowski and colleagues[34] observed that the rates of exit-site infection were similar for single- and double-cuff catheters (55% vs. 46%, respectively), but that the infections with single-cuff catheters were more resistant to treatment as estimated by the duration of treatment for each cuff type (5.7% vs. 1.6%).

Smith[101] compared the incidence of peritonitis, exit-site infection, and catheter tunnel infection in relation to the number of PD catheter cuffs. Tunnel infections were considerably less frequent with double-cuff catheters than with single-cuff catheters (one episode per 60.45 vs. 24.2 patient-months). Peritonitis and exit-site infections were similar for the two types of catheters.

The U.S. National CAPD Registry[102] reported a significant difference in length of catheter survival with respect to cuff types, for example, catheters using a single cuff located in the deep fascia had a shorter survival than double-cuff catheters where the cuff is located in the subcutaneous tissue (relative risk = 1.4). They found no difference with respect to survival between catheters with a double cuff versus those with a subcutaneously placed single cuff. Exit-site infections were more frequent in patients using a single, subcutaneously placed cuff (13%) than in patients using a double cuff (7%).

In a prospective study, Piraino and colleagues[103] investigated the location of the exit site in relationship to the belt line as a risk factor for catheter function and loss. The percentage of catheters that became infected and required removal was the same for catheters exiting above, below, or on the belt line, suggesting that exit-site location is not an important determinant of infection rate or catheter outcome.

Postoperative Use of Peritoneal Dialysis Catheters

The aim of the postoperative dialysis regimen should be to minimize the risk of fluid leak. However, patients may come to catheter insertion in a variety of clinical states, some having an

urgent need for dialysis. In some, the procedure may be wholly elective, when it is performed well before dialysis is necessary and when there is no immediate reason to use the catheter. Then sufficient time can be taken for adequate wound healing and cuff fibrosis before the institution of peritoneal dialysis. These patients rarely have trouble with immediate catheter use.

Conversely, a number of patients will present in acute or chronic renal failure, who are strong candidates for peritoneal dialysis but who need dialysis immediately after catheter insertion. Several groups[104,105] have considered the use of 2 L fluid cycles immediately after operation in these patients that is associated with an unacceptable incidence of postoperative fluid leakage, particularly in elderly patients who have poor tissues. Also, it occurs more frequently after open insertion. All patients require some form of break in regimen, and opinion varies widely as to how this is best achieved. Most units have developed their own particular schedules.

Afterward the insertion on the patient is attached to a cycler to perform additional exchanges. Each liter of dialysis solution contains 1000 units of heparin. One-half or 1 L volumes of dialysis solutions are used for the first supine peritoneal dialysis. Usual cycler settings are: 10 min fill time, 0 min dwell, and 12 min outflow. In spite of clear dialysate in the first post-implantation washout, the dialysate usually is blood-tinged during the first cycler exchange. No-dwell exchanges are continued until the dialysate is clear. If immediate peritoneal dialysis is needed, the patient continues on a cycler in the strict supine position with dwell time prolonged to 30 to 40 min. **Instead of using the cycler, exchanges can be done manually if trained nurses are available.** In addition, the patient may be maintained on hemodialysis using the temporary access before peritoneal dialysis training can be started, or may require hemodialysis because of catheter malfunction.

Prophylactic Antimicrobial Drugs

It has been recorded that early colonization at the exit-site has a detrimental effect on the quality of healing and catheter-related infections complications.[106,107]

The use of prophylactic antibiotics at the time of PD-catheter insertion is controversial. The recent 1998 ISPD guidelines state that it is prudent to use antibiotics and suggest the use of antistaphylococcal antibiotics.[108] Epidemiologic data show that gram positive bacilli and especially *Staphylococcus aureus* is the most common cause of exit-site infection, difficult to treat, and if results in peritonitis is likely to lead to significant morbidity and catheter loss. Regarding antibiotic prophylaxis after PD catheter placement, there have been three randomized, prospective trials. Two showed a benefit using cefuroxime (1.5 gr IV, 250 mg IP) or gentamycin (1.5 mg/Kgr/IV).[109,110]

In both cases the incidence of peritonitis was lower ($p <.001$) in the 1st month after insertion. In contrast, Lye and colleagues[100] found no benefit using gentamicin (80 mg IV) and cephazolin (500 mf IP). Although staphylococcal infections predominate in those untreated, gram-negative infections have also been reported.[109-112] Thus, although the ISPD recommendation is for an antistaphylococcal antibiotic, it seems more prudent to use an antibiotic that also has gram-negative coverage (e.g., cephazolin). During the last 10 years there have been several studies on the use of local antibiotics

mupirocin applied to the exit-site to prevent *Staph. aureus* infections. Bernardini and colleagues[112] (1995), Thodis and colleagues[113] (1998), Casey and colleagues[114] (2000), Utley and colleagues[115] (2001), and Boer and colleagues[116] (2002) found that applying mupirocin at the exit-site as local care, recorded a significant decrease in *Staph. aureus* catheter-related infections (exit-site, tunnel infections, and peritonitis).

Catheter Break–In and Catheter Care

The break-in period for a peritoneal catheter is the time between catheter insertion and routine catheter use. During this period, every effort is made to avoid leakage of fluid around the new catheter.[1,3,117]

Because of the risks of leakage, wound dehiscence, and hernia formation, a break-in period of at least 2 weeks is recommended after catheter insertion. In practice, the time allocated for break-in varies because the urgency for peritoneal dialysis differs from patient to patient. Short break-in periods are associated with increased risks of leakage. Straining during defecation or coughing should be minimized if possible, because both increase intra-abdominal pressure and therefore the chance of herniation and leakage. If one encounters difficulty with inflow, first try simple interventions, including bowel stimulation, clot dislodgement, and brisk ambulation. Often catheter obstruction soon after implantation is due to a clot or fibrin plugs and may respond to flushing. If unsuccessful, heparin or a thrombolytic agent (tissue plasminogen activator or streptokinase) can be used. In countries where Urokinase is not available (United States), the imminent availability of recombinant urokinase is anticipated.

Acute Catheters

In situations requiring acute dialysis, often the patient already is confined to bed and dialysis can begin immediately. Initially, exchange volumes of 500 mL, with 1- to 2-hr dwells, should be used, increasing to exchanges to 1000 mL after the first four exchanges. Unless leakage or discomfort occurs, the volume may be further increased after day 1 or 2. Patients may experience restriction of diaphragmatic excursions and respiratory distress if the volume of exchanges is increased too rapidly, and therefore respiratory function should be assessed periodically, especially in the intensive-care setting.[17,18]

Chronic Catheters

For patients requiring chronic dialysis, the planning can be done over a period of a few weeks. If necessary, intermittent peritoneal dialysis may be started after the initial few days with low volumes (500 to 1000 mL). Exchange volumes may be increased in two to three dialysis sessions to 2000 mL. The patient should remain supine for most of the dialysis period, and activity during dialysis must be restricted. In practice on intermittent peritoneal dialysis schedule of 20 h per session, two or three times a week, during a 2-week period, is sufficient to allow wound healing. Alternatively, symptoms can be managed with regular hemodialysis. In the ideal situation, the catheter should be inserted 4 to 6 weeks before use. Flushes with 1000 mL of 1.5% dextrose solution and 250 units of heparin should be done at time of insertion, then on return to the nursing unit, and again at 24 hours. **Flushing should be**

continued at weekly intervals to maintain catheter patency until dialysis is commenced. Data from the Moncrief-Popovich technique, in which the catheter remains buried without flushing for some weeks, suggest that flushing at weekly intervals may not always be necessary, but to date no trials have been done to answer this question.[31,44]

COMPLICATIONS OF CATHETER INSERTION

Hemorrhage

Intraperitoneal hemorrhage may arise from trauma to omental or mesenteric vessels while manipulating the catheter tip into the pelvis. During a closed insertion, this is usually recognized as heavy bloodstaining of the draining fluid. If a significant hemorrhage is obvious, it is safer to create adequate access to obtain hemostasis and to ensure bowel viability. This situation is easier to deal with during an open insertion, when the patient may already be under general anesthesia or at least it is available. Usually the site of trauma is known and bleeding can be controlled once with a small extension to the wound with adequate retraction. Once the peritoneal cavity is cleared of clot by lavage and suction, catheter insertion can continue. Occasionally intraperitoneal bleeding may occur from a vessel severed during the division of adhesions or omentectomy.

A significant extraperitoneal bleed may occur from the inferior epigastric vessels. If it is difficult to control the bleeding, these vessels should be underrun with a ligature above and below the site of trauma.[3,31,118]

Hemorrhage may occur or be recognized only postoperatively after catheter insertion. If the bleeding is intraperitoneal, it will arise from one of the sources earlier mentioned and present with bloodstaining of the dialysate effluent. If it is slight and the patient can be supported with a zero or minimal blood transfusion, conservative management is indicated. This policy should not be pursued in the presence of heavy bloodstaining clots or a significant transfusion requirement, in which case the patient should be returned to operating theater.

Extraperitoneal bleeding may be obvious with a leak of blood from the wound edge or an enlarging hematoma there. A skin edge bleed can be controlled with additional sutures under local anesthesia. A large wound hematoma should be explored and the source of bleeding arrested. The hematoma needs to be evacuated to prevent postoperative discomfort plus the risk of wound sepsis.

Perforated Viscus

Intra-abdominal perforation is a well recognized hazard of the closed insertion of intermittent PD catheters.[119] A similar incidence (1% or 2%) might be expected using the closed insertion technique for Tenckhoff catheters. The most common injuries appear to be bowel perforation[120] and bladder laceration/perforation,[121] the latter a particular risk in the presence of chronic urinary outflow obstruction. If in doubt about the bladder, it is wise to insert a catheter before the insertion. Perforation of viscera by erosion of the peritoneal catheter is well recognized but rare.[122] This complication is

facilitated by peritonitis, an empty peritoneal cavity, the use of steroids, or the presence of vasculitis.[123]

Urine in the peritoneal cavity, because it is irritating, may give rise to the signs of peritonitis. A small laceration will close spontaneously if the bladder is drained with a urethral catheter. A large laceration should be repaired formally and the bladder drained. If this complication is recognized during the insertion procedure, it is probably best to delay peritoneal catheter insertion because of the risk of contamination of the catheter by organisms from the bladder.

The risk of bowel perforation is higher in patients with intra-abdominal adhesions from previous surgery or peritonitis. The most common mechanism of injury is advancement of the catheter against resistance into a bowel loop that has been fixed in the peritoneal cavity by adhesions. However, damage may occur at any of several stages during catheter insertion, and it may be recognized during or after the procedure.[119, 122]

It is also possible to pass the peritoneal catheter into or through the lumen of the bowel. This may be recognized after insertion when dilute bowel content is returned with the dialysis run-out. After catheter insertion, perforation can present in a variety of ways. The patient, without developing abdominal signs, may pass large volumes of dialysate per rectum. Alternatively, the run-out may be cloudy and contain mixed bacterial organisms with the signs of a mixed-organism peritonitis. Several courses of action are possible. In the absence of clinical signs and in the hope of avoiding a laparotomy, the catheter may be left on free drainage for 7 to 10 days to allow an intraperitoneal track to form. Then it may be withdrawn and the peritoneum allowed to settle for a further 3 weeks before attempting reinsertion of the catheter. In established peritonitis, laparotomy should be done immediately to remove the catheter and repair the bowel. This course of action may also become necessary if conservative management fails. As a general guide, conservative management is more likely to succeed if the laceration is small or if the small bowel is involved rather than the large bowel. Clinical assessment is the most useful guide to the management of bowel perforation.

Catheter-Related Complications

Fluid Leak

Pericatheter leakage, which is most frequent immediately after insertion, is seen in 7% to 24% of patients.[122] Most postoperative catheter leakage can be prevented by observing a break-in period of about 2 weeks, during which the wound can heal and ingrowth of fibrous tissue can anchor the Dacron cuffs. When peritoneal dialysis is started without a break-in period, we recommend a reduction of the dialysate volume (500–1000 mL in adults) for the initial period. Usually leakage can be managed by cessation of peritoneal dialysis for about 2 weeks.[1,26,124,125]

Early fluid leak is defined as the appearance of dialysate through the catheter insertion wound or from the catheter exit site after insertion during the break-in period. In contrast, later leaks present after a period of successful CAPD. In addition to the signs described, they may present as an edematous swelling of the lower abdominal wall without fluid appearing at the skin surface. In both cases the leak arises from the peritoneal closure around the catheter.[3,19]

Some series have divided leaks into early and late. Ponce and colleagues[126] reported an overall incidence of 27% with 9 out of 10 being early leaks, and Francis and colleagues[127] reported an overall incidence of 25% with 14 out of 31 being early leaks.

The type of catheter and mode of insertion appear to have a profound influence on the incidence of this complication. Other factors that may be important (Table 26–5) include the strength of tissues around the closure site and the speed with which healing progresses. Olcott and colleagues[128] reported that 75% of their patients who developed a dialysate leak were taking steroids. Ponce and colleagues[126] suggested that this complication was more common among patients older than 60 years of age, females, and in second or subsequent catheter insertions. The type of break-in regimen also helps determine the early leak rate. Khanna and colleagues[104] suggested that, to avoid early leaks, one should delay the commencement of CAPD for 2 weeks after catheter insertion. No early leaks were reported in this large series, although 7% of patients developed late leaks.

The risk of early fluid leak can be minimized by careful suture technique and avoidance of PD for 7 days, except for an initial 24-hour period of low volume short-dwell cycles. If patients do develop an early leak, PD should be stopped and the peritoneum left empty for 1 to 2 weeks before restarting dialysis. In an established leak unresponsive to conservative management, the catheter should be removed, the wound closed, and a new catheter inserted through an alternative site. Usually late leaks require catheter replacement, although a few may respond to conservative manoeuvres, such as temporary discontinuation of CAPD or conversion to CCPD.

Catheter Obstruction

Obstruction is one of the most common hazards with peritoneal catheters. Usually it occurs early after insertion and presents as a one-way obstruction (outflow obstruction) or occasionally as a two-way obstruction (inflow/outflow obstruction). The overall incidence of both hazards varies widely depending on the type of catheter and the insertion technique used.

One-way obstruction

One-way obstruction presents when PD fluid runs into the peritoneal cavity but only drains slowly or does not drain at all. The defect may occur suddenly in a catheter that has been working normally, or the obstruction may be gradual and thus may be mistaken for the loss of ultrafiltration.

The most common cause of obstruction is catheter migration from the pelvis into the upper quadrants (Table 26–6). Here the catheter tip and side perforations are surrounded by

Table 26–5 Patients at Risk from Early Leak

- Age over 60 years
- Poor abdominal musculature
- Previous treatment with steroids
- Extended incision
- Other recent abdominal incisions
- Previous early leak
- Second or subsequent catheter insertion through the same incision

Table 26–6 Causes and Management of "One-Way" Obstruction Cause

Cause	Action
Constipation	Relief of constipation
Fibrin	1 Flushing with syringe "Milking" transfer set Manual pressure to dialysis bag 2 1000–2000 UI heparin to PD fluid 3 Streptokinase
Displaced catheter tip	Reposition tip by Fogarty catheter Sterile trocar Peritoneoscopy Catheter replacement

the viscera and omentum and cannot drain the fluid, which accumulates within the lower abdomen. Interestingly, not all catheters that migrate suffer from outflow disturbances. In a small series of Tenckhoff catheters, Oreopoulos and colleagues[45] determined radiologically that tip migration had occurred in 15% of catheters 1 month after implantation. Rottembourg and colleagues[129] performed routine radiology every 3 months on 48 straight Tenckhoff catheters implanted with a closed technique. Catheter displacement occurred in 7, 5, and 2 catheters at 0 to 3, 3 to 6, and 6 to 12 months, respectively.

Usually one-way obstruction due to malposition is an early complication that occurs in 1% to 28% of CAPD patients.[122]

The management of one-way obstruction depends upon the cause. A plain abdominal film will show the position of the catheter tip. Cannulography may be of value when one requires information about the potential space around the catheter. If simple measures fail and if the catheter tip lies in the pelvis, it may be useful to instill heparin or streptokinase (5000 U in 2–4 mL into PD catheter with clamping) to clear catheters blocked by fibrin.[104,130]

Among the procedures that have been used to reposition displaced catheters, a Fogarty catheter can be passed intraluminally to move the tip of a Tenckhoff catheter,[131] or a sterile bent trocar is used to manipulate the catheter.[132] However, this was successful only when initial function had been good for over 3 weeks. Jaques and colleagues[133] achieved a higher success rate with this procedure under radiologic control. Peritoneoscopy has also been used in a limited number of patients[134] to relocate malfunctioning catheters without surgical intervention. Unfortunately, the application of these techniques in any center is limited by local expertise. Also, the manipulation of catheters using intraluminal instruments risks visceral damage as well as bacterial contamination of the peritoneal cavity.[135]

Usually, catheter obstruction can be relieved with patience, observation, mobilization of the patient and the administration of enemas to stimulate peristaltic forces. In a few cases, persisting obstruction of outflow was relieved by manipulation of the catheter with a semiflexible probe under fluoroscopic guidance.[108,122]

Total obstruction

Total catheter obstruction occurs when fibrin or blood clots fill the lumen. The cause of the obstruction may be

determined by cannulography[69,122] with or without air contrast. Most patients with two-way obstruction require operative management. When the catheter has become incarcerated in adhesions, one should attempt to estimate the volume of the peritoneal cavity that remains. Occasionally, this revealed only by sharp dissection and digital palpation. Rarely, one may find that the whole of the peritoneal cavity is occluded and that CAPD must be discontinued.

Forcing 20 to 50 mL of dialysate into the catheter lumen with a syringe may relieve the obstruction. Sometimes intraluminal heparin is useful, and finally, fibrinolytic agents such as urokinase may dissolve the clot.[122]

Catheter Migration

The reasons for catheter migration are complex. Colombi and Giancela[132] suggest that the curve imparted to the catheter in the subcutaneous tunnel places the silicone rubber under strain. This produces pressure and damage to surrounding tissue while the catheter attempts to achieve a position of less strain, ultimately leading to a lateral deviation of the intraperitoneal section. Other causes of catheter displacement are an unduly long intraperitoneal catheter section or omental wrapping of the catheter. Occlusion of the catheter perforations by a full rectum or bladder, and a "ball-valve" obstruction of the lumen by fibrin and clot can also reduce the outflow.

Other Complications of Peritoneal Catheters

Genital Oedema

Edema of the labia majora or scrotum and penis is a distressing complication of PD.[136] Early reports suggested that up to 10% of CAPD patients would experience genital edema,[137–139] although more recently authors have reported a lower incidence of this complication.[140,141] It appears that women have a much lower incidence of genital edema than men. This disparity may be due to the fact that more often the processus vaginalis is patent in males; alternatively, labial swelling may not be as noticeable as swelling over the penis and scrotum. On the other hand, rarely dialysate may dissect through the pouch of Douglas, the vaginal vault, or even travel through the fallopian tubes and present as leakage through the vagina.[142–144]

The passage of dialysate through an open processus vaginalis produces a hydrocele, and, if the peritoneal lining of the processus is breached by fluid, this may lead to massive scrotal and penile edema. In the female, labial edema may develop through a similar mechanism.

King[145] was the first to describe intermittent scrotal swelling in an elderly man who developed 1 month after the initiation of CAPD. Eventually, he had surgical correction of a bilateral hydrocele, which increased and decreased in size with dialysate flow. Alexander and Tank[146] drew attention to the importance of identifying a patent processus during catheter insertion in children using peritoneography. These patients may need ligation of the processus at the time of catheter insertion.

On clinical examination the patient should stand. Asymmetry of the abdomen may indicate dialysis leak into the abdominal wall. Moreover, when the dialysate has dissected superficially, the abdominal wall may look pale and boggy.

Treatment of genital oedema

The risk of any of the above complications in a CAPD patient relates to the incidence of a patent processus vaginalis at the time of commencement of CAPD or the ease with which a closed processus recanalises during treatment. In adults the risk of this complication is low and requires no particular measures, apart from a careful search for overt or incipient inguinal hernia before catheter insertion. Once the complication has occurred, conservative measures are unlikely to be successful.

Treatment of actual genital edema includes bed rest, scrotal elevation if symptomatic, and the use of frequent low-volume exchanges by cycler, if possible.[137] In the case of abdominal wall leaks, cessation of PD for 1 or 2 weeks or conversion of nocturnal PD (with dry days) for 2 weeks may permit the leak to close.[130] Many or most patients can resume CAPD.[138]

Some workers have infiltrated the catheter cuff *in situ* with fibrin glue to stop pericatheter leakage.[96]

Peritoneo-Vaginal Leak

In certain circumstances the fallopian tubes can act as conduits for the antegrade passage of dialysate or the retrograde passage of uterine contents. Khanna and colleagues[104] described three woman who had a bloody PD effluent in association with menstrual bleeding and one woman who had a leakage of dialysate per vagina and went on to develop *Candida peritonitis*. In this latter case the leak was stopped by bilateral tubal ligation during an operation for catheter replacement. Occasionally, retrograde bleeding can also give rise to eosinophilic peritonitis.[148] Repetitive episodes of peritonitis have been reported in association with menstruation, which culminated in an episode of Candida peritonitis. Diaz-Buxo and colleagues[149] reported a rare instance of vaginal leakage of dialysate caused by the late erosion of a Tenckhoff catheter leading to a persistent peritoneo-vaginal fistula.

In instances of fungal peritonitis in women, one should consider the possibility of a vaginal leak. In an established leak, if one were to pursue CAPD safely, a surgical correction by tubal ligation would be required. However, if subsequent transplantation is likely, a women may elect conversion to hemodialysis in the hope of a later pregnancy.

Peritoneal Dialysis Solutions

Simon J. Davies, M.D., F.R.C.P.

The last 15 years have seen an encouraging trend in the development of peritoneal dialysis (PD) solutions. As our understanding of how the peritoneal membrane works and how this changes with time on therapy is combined with a clearer view of the issues that face patients requiring renal replacement therapy, new solutions have been devised to address these problems. This, in turn, has both driven and been driven by competition within industry with the result that an increasing number of randomized trials are now performed (Figure 27–1), which, in addition to testing product benefit, they teach us clinicians much about how this therapy works and how to improve it. Hopefully, this is just the beginning.

What are the characteristics of the ideal peritoneal dialysis solution? At the very least, it must do the job of dialysis treatment. This includes the removal of water-soluble toxins, maintenance of electrolyte and acid base status, and the removal of salt and water. This in itself might not be so simple. For example, the physiology of the peritoneal membrane turns out to be more complex than originally thought, with different pathways and mechanisms for solute and water removal, respectively. As a result, the ability to create both osmotic gradients with small osmolytes and oncotic gradients with larger, potentially charged molecules is desirable. Given the chance, however, the clinician would like to do more. Solution development opens up the opportunity for therapy, for example, not just maintenance of electrolyte balance but its very manipulation such that, especially in combination with other drug treatments, specific problems associated with renal failure might be treated. Indeed, the peritoneal cavity offers an alternative method of drug delivery that is already being exploited in nonrenal failure patients.[1–3]

It is also important that solutions used in peritoneal dialysis do no harm to the patient. The literature now indicates that this has not been the case to date, with evidence of both local (e.g., membrane damage) and systemic problems (e.g., obesity) that can be attributed to PD solutions. This issue, termed *biocompatibility*—although "bio*in*compatibility" is perhaps more accurate—has assumed increasing importance in the last few years. The difficulty facing development of solutions in this area is that it may take many years for problems of biocompatibility to develop and, by the same token, studies of many years' duration to demonstrate the benefits of new fluids. This is a problem in a therapy that is used by only 130,000 patients worldwide, which, for many, is relatively short-term.

This chapter will discuss PD solutions under a number of headings, ranging from electrolyte and acid-base homeostasis, through alternative osmotic agents to newer biocompatible fluids. In each case the clinical need for the solution type will be discussed, followed by description and rationale of their formulation, evidence of clinical benefit, and, finally, a discussion of any problems and limitations associated with their use. The chapter will conclude with a discussion of potential future developments, some of which are undergoing clinical trials, others under investigation in animal models.

SOLUTIONS FOR CALCIUM AND MAGNESIUM HOMEOSTASIS

Clinical Need

Patients treated with peritoneal dialysis can be in negative, positive, or equal calcium balance. This has led to the development of PD solutions with a variety of calcium concentrations (Table 27–1), which enable the clinician to control the excretion of these ions, so that, in turn, it is possible to utilize additional therapeutic measures (e.g., phosphate binders and vitamin D analogues), to maintain Ca^{++} and Mg^{++} homeostasis.[4] In general, patients with hypocalcemia in whom hyperphosphatemia is well controlled a dialysate fluid containing a relatively high concentration of calcium will be required. Low calcium dialysate will be needed for the patient in whom there is a need to use larger oral doses of calcium containing phosphate binder, and these were originally designed to enable clinicians to use this as opposed to the more efficient but toxic aluminum containing binders. However, growing concerns over vascular calcification in the dialysis population and its association with increased mortality[5–8] have led to greater concern and, thus, emphasis in controlling the plasma calcium phosphate product and the avoidance of episodes of hypercalcemia. With the development of newer alternative phosphate binders, for example, resins, such as sevelamer (Renagel), hypercalcemia can be minimized further.[9] The impact of calcimimetics in this field is not yet known, although it seems likely that this development will only increase the need for flexibility in controlling calcium losses. The purpose of using a lower magnesium concentration is in the prevention of hypermagnesemia,[4,10] which may itself worsen metabolic bone disease. Reducing magnesium levels, at least in principle, also enable the clinician to prescribe magnesium containing phosphate binders.

Solution Description

It can be seen from Table 27–1 that solutions can be divided broadly into high (above normal ionized calcium concentration, typically greater than 1.5 mmol/L and low calcium concentration, ranging from 1.0 mmol/L down to zero. Usually the difference in the cation concentration is compensated for by a change in the chloride content, although some solutions have also been designed to reduce magnesium content as patients with renal failure can develop hypermagnesemia.

High calcium solutions are designed to keep the patient close to equal balance for calcium by minimizing dialysate losses. By setting the concentration above the normal ionized Ca^{++} concentration in the blood (e.g., dialysate: 1.75 mmol/L vs. plasma: 1.2 mmol/L), this is achieved, although the loss of calcium in the dialysate due to convection will modify this. Typically, when using 1.36% exchanges calcium balance will be achieved at a calcium concentration of 1.38 mmol/L, whereas at 2.27% and 3.86% glucose exchanges this will be at 1.7 and 2.2 mmol/L Ca^{++}, respectively.[11]
Figure 27–1 Increase in the number of randomized clinical trials involving peritoneal dialysis solutions over the last 20 years.

Evidence of Clinical Benefit

Patients commencing dialysis treatment are often in negative calcium balance due to accrued metabolic bone disease and poor nutritional status, and the ability of the clinician to prescribe a dialysis regime that prevents further calcium loss is important. Testimony to the efficacy of this approach is the relatively high proportion of patients who, when treated with calcium 1.75 mmol solution in combination with calcium containing phosphate binders, develop hypercalcemia.[12,13] The concentration of Mg^{++} in these solutions is set at the lower end of the normal range for plasma. This is because there is a tendency for this ion to accumulate in dialysis patients. There is evidence that patients using these solutions can develop mild hypermagnesemia, which appears to be of no apparent clinical significance.[10] Magnesium intoxication has not been reported.

The ability of low calcium solutions to achieve negative calcium balance has also been confirmed by cross-sectional studies,[4,14–16] and their clinical efficacy in reducing the incidence of hypercalcemia in patients using calcium containing phosphate binders only is well established in longitudinal studies.[4,12,13,17–21] With the increasing evidence of the detrimental effect of vascular calcification on survival in PD patients and the poor outcome of individuals with adynamic bone, itself associated with hypoparathyroidism due, at least in part, to hypercalcemia, it would seem sensible to favor the use of lower rather than higher dialysate calcium concentrations. Dialysate with lower magnesium concentration has been shown in clinical studies to resolve hypermagnesemia[22] and is associated with normal magnesium levels in plasma.[10]

Table 27-1 Summary of the Composition of the Principle Dialysis Solutions Commercially Available

Solution Type and Name	Electrolytes (mmol/L)					Buffer (mmol/L)	
	Sodium	Calcium	Magnesium	Chloride	Lactate	Bicarbonate	pH

Electrolyte, buffer, and pH formulations are shown for the three worldwide manufacturers of PD solutions ([a]Gambro, [b]Fresenius, and [c]Baxter). To convert from mmol to mEq for calcium and magnesium, multiply by 2. Where a range is indicated, this reflects the variability due to different solution combinations derived from a multicompartment bag when reconstituting to obtain varying glucose concentrations.

There are no published clinical trials comparing the efficacy of different dialysate solutions in relation to calcium and magnesium homeostasis in children, although calcium balance studies have been performed.[23] The physiology and clinical problems as outlined above are essentially the same in children as in adults, with the added concern of adequate growth and particular emphasis in avoiding aluminum bone disease.[24] Current guidelines favor the use of low calcium concentration fluids[25] to enable concurrent use of calcium containing phosphate binders. Data from the pediatric national registries would indicate that maintenance of growth on peritoneal dialysis in children is reasonable using this strategy.[26,27]

Problems

As might be anticipated, a small proportion of patients treated with lower calcium concentration solutions will experience a rise in PTH levels,[19,28] and, equally, occasional patients will develop hypomagnesemia when using a lower concentration of this cation.[29] Clinicians need to be aware of this potential but entirely predictable problem, by adjusting the oral dose of calcium containing phosphate, vitamin D analogues, and, in the near future, calcimimetics, in response to their monitoring of parathyroid hormone, calcium phosphate product, and markers of bone turnover. Particular care should be taken in using very low, or even zero, calcium concentration solutions, which should be used as a short-term measure only in the treatment of severe hypercalcemia, for example, preparation for parathyroidectomy, because long-term use runs the risk of developing a significant negative calcium balance. Nevertheless, judicial use of the lower calcium containing fluids should reduce the problems of hypercalcemia thought to be etiologic in vascular calcification.

SOLUTIONS FOR ACID-BASE BALANCE

Clinical Need

In replacing the functions of the kidney, there is a requirement to provide buffering capacity to enable excretion of hydrogen ions, continuously produced as a consequence of human metabolism.[30] Peritoneal dialysis fluid must, therefore, contain a buffer in a greater concentration than it is in plasma to ensure net flow across the peritoneal membrane into the patient. There are essentially two issues related to the choice of PD solution that need to be considered in this regard: first, the concentration of buffer required to maintain optimal acid-base status of the patient, and this will be the principal focus of this section. Second, there are issues of biocompatibility that will be dealt with in more detail under the section on biocompatible fluids. Briefly, the buffers that have been employed in PD solutions have changed and continue to change as the therapy develops. Initially, acetate was employed, but this was abandoned following strong circumstantial evidence that it was an etiologic factor in the development of sclerosing peritonitis. Subsequently, lactate has been widely employed, which once it has entered the patient, is metabolized rapidly to bicarbonate.[31] More recently, primarily for reasons of patient comfort and biocompatibility, pH neutral bicarbonate solutions have been developed (see later text), although there is potential for superior acid-base control

using bicarbonate under special conditions, for example, in children or patients with liver disease.

The efficacy of dialysis treatment in controlling acid-base balance and, in particular, preventing the development of metabolic acidosis is usually assessed from measurement of the plasma bicarbonate (or CO_2) concentration.[32] In contrast to hemodialysis patients, who tend to have a fluctuating acid-base status, such that they are frequently relatively acidotic prior to the treatment sessions, patients treated with peritoneal dialysis are usually in a steady state. Typically, 70% of PD patients have a plasma bicarbonate in the normal range, about 12% have low level indicating acidosis, and the remainder have mild degrees of alkalosis. In CAPD patients but not APD patients, there is a modest effect of peritoneal solute transport status on plasma bicarbonate, such that low transport is associated with a tendency for lower levels and vice versa. In both modalities, lower bicarbonate levels appear, at least in part, to be due to inadequate dialysis dose. It should also be remembered that buffering capacity is increased by the oral ingestion of drugs, such as calcium carbonate, also used as a phosphate binder, and sodium bicarbonate. Although the need to achieve adequate buffering capacity is not in doubt, the optimal target for plasma bicarbonate, as will be seen, is not so clear. The need to achieve stable and adequate control of acid-base status in the pediatric population is more important than the adult population.[33] Poorly controlled acidosis is an important reason for poor growth in children with renal failure. The ability of peritoneal dialysis to provide steady state control of acidosis is one reason why this is becoming a preferred treatment modality in pediatric practice.[27,34,35]

Solution Description

The range of buffer types and concentrations that are commercially available are summarized in Table 27–1. Lactate concentrations vary between 35 and 40 mmol/L. Some years ago manufacturers changed from using the racemic mixture, D(−) and L(+) lactate to the L(+) isomer form only. This is of no clinical consequence because the metabolism of both isomers is equally efficient in the human. Bicarbonate containing fluids might be either solely this buffer, at a buffering capacity similar to conventional lactate solutions (buffering capacity is the same mol for mol), or contain a mixture of bicarbonate (e.g., 25 mmol/L) and lactate (e.g., 15 mmol/L). The rationale for this latter choice is that a bicarbonate solution of 40 mmol/L is supraphysiologic and may cause local changes in the microcirculation of the peritoneal membrane. This concern is based from the observation that pure bicarbonate solution is associated with significantly more abdominal pain than the mixture.[36] This argument will be developed further when discussing the relative merits of these solutions and their biocompatibility.

Evidence of Clinical Benefit

The combination of bicarbonate obtained from dialysate lactate and the oral phosphate binder calcium carbonate has been demonstrated to achieve normal, steady state acid-base status in the vast majority of peritoneal dialysis patients.[32] There is good evidence, however, that not only is prevention of acidosis beneficial in peritoneal dialysis patients, but also maintaining higher plasma bicarbonate, albeit within the

normal range. In one prospective study of acid-base status, comparison was made between the formulation lactate 35 mmol/L with lactate 40 mmol/L.[37] In this study further attempts were made to make the lactate 35 mmol/L group more acidotic by avoiding calcium carbonate and the lactate 40 mmol/L group more alkalotic by coprescribing sodium bicarbonate. Between-group separation was achieved, such that plasma bicarbonate levels were 23 ± 0.3 and 27.2 ± 0.3 mmol/L at 1 year, that is, both within normal limits. Patients randomized to the high lactate treatment had fewer hospital admissions and gained lean body mass as determined from anthropometrics. In another randomized study, patients who had been acidotic on conventional fluids had better clinical outcomes, if their treatment was supplemented with oral sodium bicarbonate.[38] It seems, therefore, that patients on PD are better maintained with a bicarbonate level in the upper part of the normal range.

In adults, a bicarbonate-only solution, containing 33 mmol/L when compared to lactate 40 mmol/L did not result in adequate buffering capacity.[39] For mixed solutions, there is no clear evidence that substituting bicarbonate for lactate at a high equivalent buffering capacity (40 mmol/L) results in superior acid-base balance in CAPD patients—indeed the mix of bicarbonate to lactate does not seem to matter.[40] However, for solutions with a lower buffering capacity, when patients are switched from an all lactate (35 mmol/L) to a 25 mmol bicarbonate to 10 mmol lactate mix, there is a significant improvement in plasma bicarbonate (24.4 to 26.1 mmol/L), such that a higher proportion of patients had a value within the normal range.[41] Both these solution combinations (bicarbonate 25 mmol/L, lactate 10 or 15 mmol/L) are effective in controlling acid-base in APD patients, although when using the 25:10 combination, there was a significant fall (~1.26 mmol/L) in the plasma bicarbonate after switch from standard lactate (40 mmol/L) solutions. Patients switched from lactate 40 mmol/L to the 25:15 mix were significantly more likely to achieve plasma bicarbonate in the normal range.[42]

A recent study comparing lactate (35 mmol/L, pH 5.5) with a pure bicarbonate-buffered PD solution (34 mmol/L, pH 7.4) in children suggests that this is safe in the short term,[43] and current recommendations are in favor of using bicarbonate solutions in this patient group.[25] The additional benefits of bicarbonate containing solutions, which by definition are also pH neutral, are of reduced infusion pain,[36,42] and potential benefits to membrane function and host defenses will be discussed under the section on biocompatibility.

Potential Problems

There is a tendency for some patients (approximately 17%) to run bicarbonate levels above the normal range, usually when combining high buffering capacity solutions with oral calcium carbonate. Although reported, this has not been demonstrated to result in detriment to the patient with any certainty.[29] This problem is likely to become less of an issue as clinicians move toward using alternative phosphate binders. Failure to achieve adequate control of acidosis will be uncommon with commercially available solutions. By increasing the dialysis dose in anuric patients, using bicarbonate 25/lactate 15 mmol/L mix, particularly if on APD, and the careful use of oral sodium bicarbonate should always be avoidable. Bicarbonate solutions are not associated with any increase in

peritonitis and may be associated with a slight improvement in ultrafiltration in the long term.[44,45]

GLUCOSE AND GLUCOSE-POLYMER SOLUTIONS

Clinical Need

Ultrafiltration is an essential component of peritoneal dialysis treatment. Apart from the need to remove water to maintain stable fluid status, it is required for the convective component of solute removal. This is proportionally more important for solutes that have a low concentration gradient between blood and dialysate, such as sodium or calcium,[11,46] and for larger molecules, such as β–2 microglobulin, that diffuse relatively slowly compared to their mass transport by convection.[47]

There is also increasing evidence that the ability to obtain adequate ultrafiltration has relevance to clinical outcomes that is currently more convincing than for the achievable variability in peritoneal solute clearance.[48] At present, this is from observational cohort studies only and, in some aspects, only indirect, although the weight of evidence is impressive. First, a number of observational studies have found that in CAPD patients high solute transport is associated with worse outcomes, in terms of both patient and technique survival.[49–52] One likely explanation of this association is the negative relationship between peritoneal ultrafiltration capacity and increasing solute transport when glucose is used as the osmotic agent, such that in longer exchanges there may even be a net reabsorption of fluid during a dialysis exchange. Other studies have related achieved peritoneal fluid and sodium removal (they are tightly coupled in CAPD patients) to either patient or technique survival.[53,54] More recently, the European Automated Peritoneal Dialysis Outcomes Study has found that inability to achieve more than a predefined 750 mL of daily ultrafiltration in anuric patients was associated with worse survival.[55]

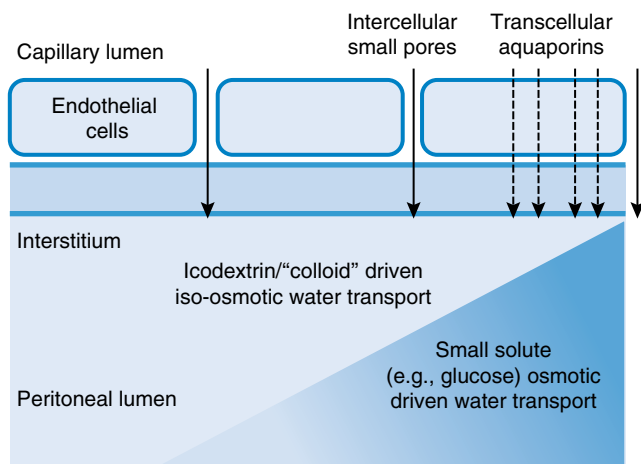
There has also been considerable progress in our understanding of the mechanisms of fluid removal across the peritoneal membrane.[56] There are essentially two pathways of water transport that will work differently with different types of osmotic agent (Figure 27–2). There are water specific pathways, known to correspond to aquaporin channels situated in the endothelium, which are highly efficient but require an osmotic gradient best achieved with small osmolytes, such as glucose.[57,58] There is also a larger set of pores or channels, responsible for allowing the removal of solutes, such as creatinine, that also enable water removal. These are less efficient when using low molecular solutes, such as glucose, than the aquaporins, because they readily permit transport of the osmolyte into the patient, resulting both in a much reduced reflection coefficient but also a drop in the osmotic gradient with time during the dwell. This is why patients with high solute transport have less good ultrafiltration with glucose. When a larger molecule is used, for example albumin or a polyglucose (e.g., icodextrin, Extraneal), a sustained ultrafiltration can be achieved during a long dwell because it will remain in the peritoneal cavity for a much longer period.[59,60] In fact, under these circumstances, the larger the number of these pores potentially the better, because the achieved ultrafiltration will be proportional to their area. Furthermore, it is possible to achieve net ultrafiltration without creating an


Figure 27–2 There are two pathways for ultrafiltration. First, a water-exclusive, high-efficiency transcellular pathway, due to the presence of aquaporins present in the vascular endothelium, which requires an osmotic gradient. Second, an intercellular pathway that is less efficient but still contributes half of the ultrafiltration because it represents the majority of the total pore area. Small osmolytes, such as glucose, amino acids, and glycerol, act across both pathways but require an osmotic gradient. Large molecules, such as icodextrin, are able to exert a "colloidal" gradient across the intercellular pathway.

osmotic pressure because large molecules, by virtue of their size, have colligative properties that will drive convective flow without the need for an osmotic gradient. In the case of albumin, which also has an electric charge, this is a true *oncotic* pressure, a term that is frequently applied to any large molecule, such as a polyglucose, albeit that this is strictly incorrect.

To summarize, therefore, peritoneal physiology dictates the different types of solution that will be required to achieve the best ultrafiltration. There is a need for *both* small osmotic agents to generate short term, efficient, predominantly aquaporin mediated ultrafiltration and larger molecules that can achieve long dwell fluid removal, with properties more similar to albumin, the naturally occurring oncotic agent.

There is another reason why an alternative to glucose may be required: the avoidance of the metabolic complications of excessive peritoneal absorption of glucose. Obesity is a well-recognized complication of PD, as is associated hyperinsulinemia and lipid abnormalities.[61–63] Longitudinal studies have shown that patients on PD tend to gain fat weight and that this weight gain is associated with a worsening lipid profile.[61,64] With an increasing proportion of dialysis patients being diabetics, who do not always appear to enjoy the same benefit from PD as is seen in nondiabetics,[65] the importance of glycemic control is in need of receiving increased attention.

Solution Description

Glucose

Glucose containing dialysate solutions have been manufactured in three strengths for many years. The concentrations are 1.36%/1.5%, 2.27%/2.5%, and 3.86%/4.25% (the alterna-

tive values represent the anhydrous/hydrated form), and these result in fluids with an osmolality of 344–347, 395–398 and 483–486 mOsmol/L, respectively. They enable the clinician and patient to vary the dialysis prescription so as to titrate peritoneal fluid removal and thus maintain the desired dry weight.

Glucose Polymer

Icodextrin is the only polyglucose and thus the only large molecular weight solution commercially available. It is currently formulated to be iso-osmotic with plasma (284 mOsmol/L) at a concentration of 7.5%, with a sodium concentration of 133 mmol/L and a lactate concentration of 40 mmol/L. As its name implies, it consists of several glucose molecules tagged together since they are found in starch, from which it is manufactured (Figure 27–3). Although the prefix to the name ("ico") implies 20 glucose building blocks per molecule, it is, in fact, a poly-dispersed mixture of the glucose polymers (range $2 \rightarrow 1000$ units) found in starch that has been refined to remove the smaller fractions, which would otherwise cross the peritoneal membrane more readily and accumulate or be metabolized by the patient. As it is, a significant proportion of the starches do enter the circulation, where they are metabolized eventually to maltose by circulating amylase.[66,67] In patients using icodextrin for one exchange per day, steady state of these metabolites is reached within 2 weeks. They do, however, contribute to the osmolality of the plasma, resulting in a variable degree of isosmotic hyponatremia, usually about 2 to 5 mmol/L lower than the patient's pretreatment plasma sodium.[68] The maltose cannot be metabolized in the circulation of humans, which lacks maltase, although this enzyme is present in the kidney and intracellularly throughout the body. There is no evidence to date that maltose accumulates within patients treated with icodextrin.

Evidence of Clinical Benefit

Glucose Solutions

Glucose is a highly effective osmotic agent that was well established in the use of intermittent peritoneal dialysis before the inception of CAPD and APD. Its undisputed efficacy
Figure 27–3 Icodextrin has a polyglucose structure found in starch; the number of subunits range from 2 to 1000. Ninety percent of the linkages between subunits are of the a 1-4 type. The majority fraction, accounting for approximately 50%, comprises 30–120 subunits, with a molecular weight range of 5–20,000 Daltons.

combined with its low cost means that it is always likely to have a role in this treatment modality. Carefully conducted single dwell studies have confirmed that the initial ultrafiltration rate across the peritoneum is directly proportional to the initial glucose osmotic gradient.[69] Glucose solutions have also become the standard for assessing peritoneal membrane function. Generally, using a standardized 4-hour dwell period, patients achieving more than 200 mL of ultrafiltration using a glucose 2.27%/2.5% (standard peritoneal equilibration test)[70,71] or more than 400 mL with a glucose 3.86%/4.25% exchange (simplified standardized permeability analysis)[72] will be able to obtain sufficient overall daily ultrafiltration.[73] Values below this indicate relative ultrafiltration failure, although this might not manifest clinically until the residual urine volume of the patient has become critically low.

Glucose dialysate also has the potential of being an important calorie source for patients who are malnourished. Adequate calorie intake appears to be important in maintaining nitrogen balance, especially in long-term PD patients,[74] and it should be remembered that when the dialysis dose is increased, there is inevitably an increase in delivered calories from this route, which may be of help in maintaining nutrition in the malnourished.[75]

Glucose Polymer

There is now considerable clinical experience with icodextrin, a PD solution that has been subjected to more randomized clinical trials than any other (see summary Table 27–2). Used as salvage therapy, in patients with clinically inadequate ultrafiltration, it can extend the life of PD treatment.[76] When used on a daily basis for the long exchange (overnight in CAPD and during the daytime in APD patients), it results in net ultrafiltration that is equivalent to that achieved using 2.27% to 3.86% glucose, depending on length of dwell and peritoneal membrane function.[77] Generally, the longer the dwell the more ultrafiltration will be obtained, although there is rarely any value in extending beyond 14 hours. On average, it is slightly more effective in patients with high solute transport, in keeping with its proposed mechanism of action across the small pores, although there is considerable individual variability. As a rule of thumb, icodextrin will achieve significantly better ultrafiltration than glucose 2.27% in patients with high or high average solute transport characteristics (D/P creatinine ration at 4 hours >0.64),[78] and this is why this has been the main comparator solution used in the randomized studies. As a result of better convection, icodextrin will also remove more sodium when compared to glucose 2.27%.[79] The diffusive removal of sodium, however, is not so well optimized. The length of the dwell ensures that there is time for equilibration, but the sodium gradient is compromised, partly because the concentration of sodium in the dialysate is 133 mmol/L (compared to 132 mmol/L in conventional glucose solutions) but also because patients on icodextrin develop a relative hyponatremia, which influences sodium removal throughout the rest of the day. Nevertheless, provided better ultrafiltration is obtained, icodextrin will achieve better overall sodium losses.

There is now evidence that this improved fluid removal translates into changes in weight, fluid status, and body composition. In a large randomized trial comparing icodextrin with glucose 2.27% over 12 months, a divergence in weight was observed, such that weight gain was prevented in the patients treated with icodextrin.[78] This could have, of course, been due to either fat of fluid gain in the glucose treated patients or the opposite, including loss of lean body mass in the icodextrin treated group. More detailed studies in smaller patient groups, using more sophisticated techniques, such as bioelectric impedance, isotope dilution methods, and DEXA scan, have shown that weight loss in patients randomized to icodextrin lose fluid from the extracellular compartment.[80,81] In one such study, conducted over 6 months, there was also a weight gain in the patients randomized to glucose, supporting the findings of the 12-month study cited earlier. This weight gain was not fully explained by increases in fluid status, implying that there was also an additional increase in body fat.[81]

This latter observation emphasizes the metabolic advantages in utilizing icodextrin when compared to the more hypertonic glucose solutions. In nondiabetic subjects, the hyperinsulinemia associated with the continuous use of glucose containing solutions is significantly improved by the use of icodextrin, and this is associated with an improvement in insulin sensitivity.[82] In diabetic subjects, a recent randomized study has shown that diabetic control is improved in treatment regimes that include icodextrin and amino acids.[83] Gastric emptying, which is delayed in PD patients and may be responsible for lack of appetite, is less marked when using icodextrin than glucose.[84] The effect of icodextrin on lipid profiles has been variable, although there is evidence that they can improve when using icodextrin.[85] The reason for these discrepancies may well reflect the fact that many PD patients are already receiving lipid-lowering treatment when they commence icodextrin.[81] This may also be the explanation for the lack of effect on blood pressure observed in these studies, which might be expected to have fallen following reduction in the extracellular fluid volume. With the exception of one single center, open study,[86] randomized studies have not shown a significant effect on blood pressure.[80,81] Blood pressure control in these studies has been good in both randomized groups, which were designed to give maximum freedom to the clinician in terms of antihypertensive drug prescription.

Apart from extending life of therapy, avoiding some of the detrimental metabolic effects of glucose and improving both achieved ultrafiltration and fluid status, there is evidence that use of icodextrin improves the quality of life of PD patients. In the short term (13 weeks), patients randomized to icodextrin reported better physical and mental health status than those using standard glucose.[87]

Potential Problems
Glucose Solutions

The problems associated with using glucose solutions are threefold. First, there is issue of local tissue damage to the peritoneum, which will be discussed later under bioincompatibility. Second, there are the unwanted systemic metabolic effects, which have largely been dealt with. Third, there is a more general problem associated with the use of any osmotic agent that relies substantially upon its effects across the aquaporins to achieve ultrafiltration. Precisely because this mechanism of ultrafiltration is water exclusive, solutes, such as sodium, that are dependent on convective for their loss may not in fact be removed so efficiently due to their sieving by

Table 27–2 Summary of Randomized Controlled Trials Establishing the Safety and Efficacy of Icodextrin

Author, Year, Reference	n	Length	Comparator fluid (Design)	Comment
Mistry, 1994[77]	I: 106 G: 103	6 months	1.36% or 3.86%	MIDAS study: Ultrafiltration compared to 1.36% was 3.5 times greater for 8-hour and 5.5 times greater for 12-hour dwell length and equivalent to that achieved with 3.86% exchanges.
Gokal, 1995[171]				Using icodextrin for the long dwell in CAPD does not increase the rate of peritonitis or alter the outcome of peritonitis. Peritonitis does not affect uptake of icodextrin from the peritoneum.
Posthuma, 1997[172]	I: 11 G: 12	12 months	2.27%	Icodextrin enhances ultrafiltration during the daytime dwell in CCPD patients, increasing convective clearance of creatinine.
Postuma, 1997 & 1998[68,173]	I: 19 G: 19	12 months	2.27%	Icodextrin preserved the daytime dwell ultrafiltration in CCPD patients during peritonitis. Serum icodextrin metabolites increased during icodextrin use, accounted for the osmolar gap and associated hyponatremia, but remained stable during peritonitis.
Plum, 2002[79]	I: 20 G: 19	12 weeks	2.27%	Icodextrin produced increased, sustained ultrafiltration during the long dwell period, increasing (convective) clearance and sodium removal in APD patients. No effect on residual function.
Wolfson, 2002[78]	I: 90 G:85	4 weeks	2.27%	Efficacy study showing icodextrin increases UF in long dwell preventing fluid reabsorption. Greatest comparative benefit to glucose observed with higher solute transport.
Wolfson, 2002[78]	I: 175 G:112	52 weeks	2.27%	Safety study showing a significant difference in body weight between groups (lower with icodextrin, gain with glucose) when compared to baseline.
Guo, 2002[87]	I: 58 G:35	13 weeks	2.27%	Peritoneal dialysis patients treated with icodextrin experienced substantial quality of life improvement at 13 weeks after the start of treatment, in particular, improvement of patients' mental health, general health, and symptoms, such as muscle spasms or twitching, cramps during an exchange or treatment, cramps after an exchange or treatment, itchy skin, and faintness or dizziness.
Konings, 2003[80]	I: 22 G:18	4 months	1.36%) (Open-label RCT)	Patients randomized to icodextrin experienced a large increase in UF, reduction in extracellular fluid volume, left ventricular mass and weight, and a small but significant reduction in urine volume. No changes in glucose group. No changes in BP or CRP.
Davies, 2003[81]	I: 28 G:22	6 months	2.27% (Double-blind RCT)	Icodextrin patients achieved greater ultrafiltration, sodium removal, weight loss, and a reduction in extracellular fluid volume. Weight in glucose patients increased without increase in body water suggesting fat gain. Residual renal function better preserved in the icodextrin group. No change in BP, CRP, or lipid profiles.
Ota, 2003[174]	18	3 months	1.36% (Open, crossover)	Confirms better UF in Japanese PD patients with icodextrin. Peritoneal absorption of fluid ranges between 36% and 42%.

G, glucose; *I*, icodextrin. See Table 27–3 for randomized trials combining icodextrin and amino acids.

these pores. When APD is used with multiple short exchanges using hypertonic glucose, there might be quite efficient ultra-filtration but insufficient time for the diffusive component of sodium loss to occur. This leads to relatively poor sodium losses in APD patients, despite apparently good ultrafiltration, an issue the prescribing clinician should be aware of.[88] There is some evidence to suggest that APD patients have less good blood pressure control, perhaps for this reason,[89] and certainly anuric APD patients with poor ultrafiltration (< 750 mL/day) seem, by whatever mechanism, to have worse clinical outcomes.[55] Optimizing daytime ultrafiltration, for example, with icodextrin, can ameliorate the problem.[88]

Glucose Polymers

As discussed, there is absorption of glucose polymer fractions across the peritoneum, which results in a number of potential problems that the clinician needs to be aware of. First, these polymers and their metabolites reach a steady state in plasma between 1 and 2 weeks of treatment. The slight hyperosmolality that they cause, combined with its associated hyponatremia, do not appear to have any clinical adverse effects. It does result in some reduction in the efficacy of icodextrin as an ultrafiltration agent, however, and patients who initially report very high ultra-filtration volumes may see a modest reduction with time. The presence of icodextrin and its metabolites in plasma can also interfere with some analytical methods. For example, certain blood sugar measuring devices that employ glucose oxidase will overestimate the blood sugar,[90,91] whereas the usual method for determining plasma amylase in the diagnosis of pancreatitis is unreliable due to its underestimation.[92,93]

The other potential problem with the use of icodextrin is the development of allergies and sterile peritonitis. Skin rashes are well described and appear to be due to an allergic reaction to starch.[94] Usually these are mild, localized, and typically occur on the palm of the hand. In most cases they are transient, and the patients can put up with them until they resolve over a few weeks. Occasionally (1%–3% of patients), the patient develops an exfoliating dermatitis that is often generalized and can be quite severe causing erythroderma.[95] In these situations the icodextrin should be withdrawn and not reintroduced since the problem will recur. Sterile peritonitis has also been described in patients using icodextrin, and mini-epidemics of this problem have been described.[96] At least one of these outbreaks was found to be due to contamination of the icodextrin solution by proteoglycans, the product of bacterial cell walls that were contaminating the refining of raw product. Typically, patients with this problem have a sterile peritonitis that does not respond to antibiotics, which on differential white cell count is associated either with raised eosinophils or mononuclear cells but not neutrophils.[97] The patient is not usually unwell and the problem responds very rapidly to withdrawal of the product. Although this problem has been identified and largely put right by tightening the quality controls of fluid production, isolated cases of icodextrin-associated sterile peritonitis are occasionally reported. Importantly, however, none of the controlled trials (summarized in Table 27–2) have reported a higher incidence of peritonitis using icodextrin.

Concern has been expressed that too rapid ultrafiltration induced by icodextrin might precipitate a significant fall in residual renal function. There is certainly increasing evidence

that episodes of volume depletion, intentional or otherwise, are associated with a fall in urine volume.[98] The majority of randomized trials using icodextrin have not shown any significant differences in the effect of icodextrin compared to glucose. In the detailed study in which icodextrin was compared to glucose 1.36% solution, a very large increase in average ultrafiltration (from 744 to 1670 mL/day) was associated with a fall in urine volume (1131 to 913 mL/day).[80] In contrast, the change and between-group difference in ultra-filtration, typically 400 mL/day, was more modest in patients selected for greater risk of fluid-related problems (urine volume <750 mL, high or high average solute transport), using glucose 2.27% as the comparator fluid. In this study residual function was better preserved in patients randomized to icodextrin, despite a similar average reduction in extracellular fluid volume.[81] The conclusion that should be drawn is that sudden large increases in ultrafiltration should be avoided in PD patients (by whatever fluid regime), and that provided icodextrin is introduced carefully, it is possible to achieve the desired effect safely.

AMINO-ACID SOLUTIONS

Clinical Need

It is well recognized that many patients on dialysis treatment are, or become, malnourished.[99] It is also known, especially for peritoneal dialysis patients, that malnutrition is an independent predictor of poor survival.[55,100] The causes of malnutrition are, however, complicated. Reduction in renal function is associated with a spontaneous fall in appetite,[101] which does to some extent improve following the commencement of dialysis treatment,[102] although this is certainly reduced once residual renal function is lost.[103] There is also evidence that positive nitrogen balance is better maintained in the short term when protein intake is high, although in longer-term PD patients, it may be that adequate calories derived from carbohydrate are important.[104] It is increasingly clear, however, that protein-calorie malnutrition is also influenced by comorbid disease, in particular, cardiovascular atheromatous disease when associated with an inflammatory state.[105] PD patients with increasing comorbidity, now known to be the dominant determinate of survival on dialysis report reduced dietary protein and calorie intake for a given small solute clearance[106] and generally fail to improve their intake following an increase in delivered dialysis dose.[75] In patients who cannot or will not eat, it is tempting to try an alternative approach to delivering nutrition, hence the development of amino-acid containing solutions.

There is, however, perhaps another equally important clinical need for an amino-acid solution, an alternative low molecular weight osmolyte to glucose, for reasons both discussed previously and in further detail below, when considering biocompatibility.

Solution Description

The only commercially available dialysate fluid containing amino acid is a 1.1% solution (see Table 27–1 for description) that exerts sufficient osmotic force to give an average ultrafiltration equivalent, or a little more, to that achieved with

glucose 1.36%. It contains 87 mmol/L of amino acids the majority of which (61%) are essential amino acids.

This is not the only amino acid solution that has been formulated over the last few years and several different formulations have been evaluated. The aims of solution design have been to give the patient sufficient nitrogen in the form of amino acids to at least replace the nitrogen losses associated with both peritoneal amino acid (3–4 g/day) and protein losses (4–15 g/day), and, if possible, to normalize the plasma amino-acid profile that is associated with uremia and acidosis. In the early stages of solution development, a number of different amino acid concentrations were investigated, ranging from 1.0% to 2.7% in concentration, to establish their osmotic effectiveness, effects on membrane function, absorption profiles, and their potential for inducing acidosis.[107–109] Typically 72% to 82% of amino acids are absorbed, with a peak in amino acid concentrations in the plasma occurring by 1 hour. The higher concentration solutions (e.g., 2.7%) resulted in increased estimates of solute mass transfer indicating a vasodilatatory effect on the peritoneal membrane,[110] possibly mediated by locally generated prostanoids or nitric oxide.[111] They also resulted in nonphysiologically high concentrations of amino acids and were thus abandoned. Even the 1.1% solution has a small but detectable effect on peritoneal blood flow resulting in a small but significant increase in small solute transport.[110] Earlier amino-acid formulations resulted in excessive acidosis due to the catabolism of lycine, arginine, and methionine, which when replaced by anionic amino acids was largely prevented.[112]

Evidence of Clinical Benefit

Initial balance studies were able to establish that the nitrogen absorbed in the form of amino acids from a single daily dwell of 1.1% solution is sufficient to counterbalance the losses associated with amino acid and protein in the daily dialysis effluent. The typical amount of amino acids adsorbed per day is 18 g, which, if compared to oral protein, would represent about one quarter, typically 0.3 g/kg, of the daily recommended intake.[107,113] One advantage of this method of delivery is that it avoids the phosphate load associated with the equivalent dietary protein and thus the need for phosphate binders. Furthermore, improvement but not normalization of the plasma amino acid profile has been reported.[114] Thus, the primary aims of solution design are largely successful. However, to provide convincing evidence of clinical benefit, three things are further required. First, demonstration that nitrogen from amino acid absorbed from the peritoneal cavity can be incorporated into somatic protein. Second, that patients with impaired nutrition can show an improvement, and third, if possible, that this translates into improved clinical outcomes (see Table 27–3 for summary of studies).

Detailed studies employing ^{15}N-glycine, ^{2}H$_3$ leucine, and ^{13}C leucine have shown that of the total amino acid dose, 55% is absorbed by 1 hour and 80% by 5 hours; about half (48%) is utilized for protein synthesis, whereas a significant proportion (16%) is oxidized as an energy source during the dwell period.[115,116] By giving the patient an oral calorie meal at the same time as the amino acid solution is used, the proteolysis that occurs during this period can be reduced by 25%.[116] Amino acids delivered via the peritoneal cavity can, therefore, be incorporated into protein, and where possible patients should be encouraged to consume a calorie rich meal or snack, typically 600 kcal, during the course of the exchange.

Several randomized controlled trials have been performed to evaluate the safety and efficacy of amino-acid solutions in PD patients with varying degrees of nutritional status. Summarized in Table 27–3, along with open studies describing clinical experience, these have given mixed, although generally encouraging, results. Smaller earlier studies evaluating precursors to the current commercially available solution failed to demonstrate clear benefit and noted variable beneficial or no effects on plasma lipid profiles. A later multicenter study of malnourished patients studied for just 3 months demonstrated an increase in circulating IGF in patients randomized to amino-acid solution, suggesting an increase in protein synthesis.[117] In a subgroup of patients with a plasma albumin below 35 g/L at the start of the study, those randomized to amino acids had increases in the plasma prealbumin and transferrin levels but no increase in mid-arm muscle circumference (MAMC). In contrast, those with albumin levels above 35 g/L at baseline showed fewer changes in plasma proteins (these deteriorated in the glucose group) but did experience an increase in MAMC if using amino acids. The only long-term (3 years) randomized study of amino acid solutions was performed in malnourished Chinese PD patients and did examine clinical outcomes, although was probably not sufficiently powered to detect a difference in patient survival.[118] Of the 60 patients randomized, both groups had similar mortality, hospitalization duration, serial C-reactive protein levels, and drop-out rates during the study. Patients using amino acids had an improvement in triglyceride levels and more stable biochemical markers of nutrition (e.g., albumin, total cholesterol), combined with an increase in the appearance of nitrogen and a reported increase in dietary protein intake. Anthropometrics improved, especially in women in the amino acid treated group, but composite nutritional scores were no different.

In summary, the true benefits of amino-acid solutions used in malnourished patients remain equivocal. Certainly they are absorbed and utilized in healthy PD patients, but it is likely that their relatively disappointing effect in malnourished patients reflects the underlying difficulty of reversing this problem in dialysis patients in whom comorbidity, combined with associated inflammation, is blunting the therapeutic effect. The potential benefit to lipid profiles is also variably reported. It is perhaps more logical to use amino-acid solution as part of a dialysis regime that prevents the use and complications associated with heavy use of glucose solutions, for example, in improving glycemic control in diabetics,[83] improving gastric emptying,[84] preventing fat gain and associated hypertriglyceridemia, and even membrane preservation (see later), with a hope that protein-calorie malnutrition may be prevented to some extent.

Potential Problems

The most common side effect seen in patients using amino-acid solutions is increased nausea and anorexia. The former may be reported in association with the very slight odor that some patients detect or reflect the modest increase on plasma urea levels that might be observed. In these circumstances there may be symptomatic benefit from increasing the dialysis dose. Some patients will develop mild evidence of

Table 27–3 Summary of Clinical Trials Examining Safety and Efficacy of Amino-Acid Solutions

Author, Year, Reference	n	Length	Trial Design	Comments
Bruno, 1989[109]	6	6 months	Open-label, cross-over	1% AA solution. Nitrogen balance became positive and patients gained weight. Lipid profiles improved significantly, and AA profiles became more normal.
Young, 1989[175,176] Dibble, 1990 [177]	8	12 weeks	Open, non-randomized	Malnourished patients (albumin <35 g/L). 1% solution. Lipids improved (LDL cholesterol fell). Modest benefit in nutrition only. No changes were seen in body weight, body fat, arm muscle circumference, fasting plasma glucose, insulin, growth hormone, triglyceride, nonesterified fatty acids, or HDL cholesterol.
Faller, 1995[178]	15	3 months	Open, non-randomized	Evaluation of a 1.1% solution. Albumin and transferring improved significantly. Plasma urea but not bicarbonate increased.
Kopple, 1995[115]	19	20 days	Open, non-randomized	Detailed inpatient nitrogen balance studies in malnourished patients. 1.1% solution made nitrogen balance significantly more positive.
Jones, 1997[112]	12	14 days	Randomized, cross-over	Study to evaluate a modified 1.1% AA formula containing reduced lysine, arginine, and methionine to reduce acidosis. Despite a good total protein/nitrogen intake, bicarbonate was higher with modified solution.
Mirsa, 1997[179]	18	6 months	Randomized, cross-over	The use of 1.1% AA, although clinically safe and without side effects, had no effect on the dyslipidemia in these CAPD patients.
Jones, 1998[113]	20	2–3 days	Open-label, cross-over	Using a 1.1% solution daily loss of AAs and proteins into dialysate more than offset by gains absorbed from one exchange; such net gains exceeded losses in all patients studied.
Jones, 1998[117]	AA:54 G: 51	3 months	Randomized, open-label	1–2 exchanges daily of 1.1% AA solution is safe and provides nutritional benefit for malnourished PD patients (anthropometrics and insulin-like growth factor) while improving plasma phosphate levels.
Grzegorzewska, 1999[119]	8	6 months	Open, non-randomized	Overnight administration of 1.1% solution using concomitant antacids to avoid acidosis. Relatively well-nourished CAPD patients resulted in increased serum concentration of AAs without changes in other nutritional parameters.
Plum, 1999[180]	10	6 hour dwell	Randomized, cross-over	1.0 % bicarbonate buffered solution compared to both bicarbonate and lactate buffered glucose (1.5%). Reduced serum glucose concentrations were found with AA solution, but bicarbonate buffering (34 mmol/L) did not change blood acid-base status combined with either glucose or AAs.
Qamar, 1999[120]	7	3 months	Randomized, cross-over	Only randomized study in children. Caloric intake increased and protein intake improved. Appetite and total body nitrogen increased in at least half the children during AA dialysis. Total plasma protein and albumin concentrations did not change significantly.
Van, 2002[84]	61	Single dwell	Randomized, cross-over	PD patients have impaired gastric emptying even when empty of dialysate fluid. This is worse with glucose instilled than either AA or icodextrin.
Marshall, 2003[83]	8	72 hours	Randomized, cross-over	Glycemic control (both concentration and variability determined from continuous measurements) was improved in insulin-dependent diabetics with a dialysis regime that included AA and icodextrin.
Li, 2003[118]	60	3 years	Randomized, open-label	Long-term administration of amino acid dialysate is well tolerated, tends to improve nutritional status in high-risk patients, especially women, but does not alter patient survival.

AA, amino acid solution.

metabolic acidosis, manifested by a fall in the plasma bicarbonate.[109,115,119,120] This can almost always be corrected by adjusting the dialysate buffer in the remaining exchanges, adding sodium bicarbonate or calcium carbonate to the medications, or again increasing dialysis dose, as a negative relationship between plasma bicarbonate levels and urea clearance has been reported.[32] It is strongly advised that the product be used in combination with expert dietetic support to ensure that the solution supplements rather than replaces adequate total calorie intake.

BIOCOMPATIBLE SOLUTIONS

Clinical Need

The degree of "biocompatibility" of a treatment might be considered as its lack of interference with normal physiologic function, although at the same time achieving the desired therapeutic effect. It has been formally defined as the ability of a material, device, or system to perform without a clinically significant host response in a specific application.[121] As already discussed, the instillation of high glucose concentrations within the peritoneal cavity undoubtedly affects systemic physiology in a fashion that can be considered bio*in*compatible. The purpose of this section, however, is to discuss biocompatibility of PD solutions locally within the peritoneal cavity and specifically their interaction with the peritoneal membrane, specifically its biology and function. The need to develop biocompatible solutions derives from several strands of evidence which, although largely circumstantial, taken together make a very powerful case. These lines of evidence include the intrinsically bioincompatible nature of standard fluids, including their established in vitro and ex vivo toxicity, and the demonstration of both functional and morphologic changes to the peritoneal membrane that culminate in ultrafiltration failure and, in the worst cases, sclerosing encapsulating peritonitis.

Bioincompatibility of Standard Fluids

This can be conveniently divided into short-term toxicity, associated with low pH, high osmolality and the use of lactate as buffer, and long-term toxicity due to the damaging effects of glucose, either because of direct cellular toxicity, the formation of glucose degradation products as a consequence of the sterilization procedure, or the formation of advanced glycosylation end products within the membrane or systemic circulation.

The short-term effects of bioincompatibility result in infusion pain, experienced by many patients but considerably variable in severity, combined with cellular toxicity shown in both in vitro and ex vivo studies.[36] Because of the insistence by regulatory authorities throughout the world to heat sterilize PD solutions, this has to be performed at low pH to prevent gross caramelization of glucose. As a result, for the first 45 minutes or so of a dialysis exchange the intra-abdominal fluid is at an unphysiologically low pH, which causes a fall in the intracellular pH of local cell populations (macrophages, mesothelial cells), that is potentiated in its toxicity by the presence of lactate.[122] This results in repeated damage to the local host-defense mechanism and the mesothelial cell lining of the

luminal surface of the membrane that is thought to have a protective and modulatory role in membrane damage and prevention of inflammation.[123,124] This damage is always exacerbated when solutions of higher osmolality are used.

Standard dialysis fluids also contain glucose degradation products (GDPs), which along with glucose are thought to contribute more to the long-term bioincompatibility of these solutions.[125] Generally, these molecules, which are highly reactive and toxic to cells, are formed from the nonenzymic autocatabolism of glucose within the dialysate during sterilization that is accelerated by heat and slowed down at low pH. The exception might be acetaldehyde, which also results from catabolism of lactate. Extended shelf life will also increase their concentration in dialysate, especially if the storage has been at room temperature or even higher. (Anders Wieslander, personal communication, data awaiting publication.) The list of culprits is growing steadily (Table 27–4), and some, in particular, are thought to be especially toxic (e.g., 5-hydroxy-methyl-2-furaldehyde). However, long-term toxicity might also result from glucose exposure by at least two other mechanisms: the intracellular toxicity of high glucose concentrations resulting in hypoxia due to excess metabolism via the sorbitol pathway, and the formation of advanced glycosylation end products (AGEs), resulting in damage to extracellular and intracellular proteins.[126] This latter mechanism is, again, nonenzymic and is thought to occur in situ within the peritoneal membrane where glucose concentration may be very high, simulating an extreme diabetic milieu.

Functional and Morphologic Changes to the Membrane

There is now convincing evidence from longitudinal studies that peritoneal membrane function changes with time on treatment. There is considerable variability between patients, but the overall pattern is one of increasing rates of small solute transport and reductions in the ultrafiltration capacity of the peritoneal membrane.[103,127,128] The latter is mostly explained

by the increases in solute transport, which accelerates the rate of glucose absorption across the peritoneal membrane, thus causing earlier loss of the osmotic gradient during any dwell. This rise in the solute transport rate is thought to reflect an increase in the effective peritoneal surface area, such as would occur with increasing vascularity of the membrane. There is now, however, increasing evidence that a second process is contributing to loss in ultrafiltration capacity with time on treatment. This process results in a reduction in the osmotic conductance of water convection—literally less ultrafiltration for a given osmotic gradient—that might result either from altered hydraulic conductance of the membrane or impaired aquaporin function, or both.[129,130]

These functional alterations in the membrane are associated with important morphologic changes with time on treatment. Although it is difficult to perform longitudinal studies of membrane morphology, data from the Peritoneal Biopsy Registry have built a convincing picture of what appears to happen.[131–133] The two overwhelming abnormalities observed with increasing severity when associated with time on treatment have been thickening of the submesothelial compact zone and the development of a diabetiform occlusive vasculopathy of the small arterioles and venules (Figure 27–4). There was a modest increase in vessel numbers, although it should be remembered that it is the capillary circulation that is responsible for the bulk of solute diffusion, and further examination of this aspect of morphology is still awaited. Other studies have reported increased capillary vessels, and this has also been reported consistently in animal models of PD solution exposure.[134]

How can these morphologic changes be linked to functional changes of the membrane? There are only two studies, so far, linking morphology and function, but both show that worse membrane damage is associated with worse function, in one case a link between high solute transport and sclerosis,[135] the other with increased area of microvessels.[134] This supports the concept that increasing small solute transport results from a greater vascular surface area. Although intuitively it seems logical to assume that increasing thickness of the submesothelial compact zone might reduce solute transport, it is possible to conceive of a situation in which the interstitium enables faster transport of small solutes, including water, because its structure is disrupted and yet offers resistance to convective movement of water, which is a quite different process at a molecular level.

Solution Description

The ideal biocompatible solution would have a physiologic pH, use bicarbonate as its buffer, contain no GDPs, be isosmotic, and only contain osmotic agents in concentrations that are not toxic to human tissue. No such single solution can
Figure 27–4 Images from the Peritoneal Biopsy Registry showing the two most striking abnormalities found in long-term peritoneal dialysis, thickening of the submesothelial compact zone (left lower panel compared to upper) and an obliterative diabetiform vasculopathy (right lower compared with upper panel). (Photographs shown courtesy of Professor John Williams, Cardiff, UK.)

exist, however, because without the presence of an osmotic gradient, short-term ultrafiltration, which will always be needed, cannot be achieved. Nevertheless, solutions are now available that go some considerable way toward meeting these objectives. As already discussed, glucose can be avoided by using either amino-acid solutions or polyglucose (icodextrin), and the latter is also isosmotic with plasma and contains less GDP than conventional glucose 1.36% solutions.[136]

The development of pH neutral solutions has necessitated a different approach, however, with the use of dual or triple compartment dialysate bag technology. In each case the principle underlying this approach is the same, although different manufacturers have come up with differing designs. By using more than one compartment during the manufacturing process, it is possible to do two things. First, it is possible to confine the glucose to a compartment that has a very low pH (optimally ~3.5), such that during the sterilization process the formation of GDPs is minimized. Second, when the two components of the dialysis fluid are brought together, just prior to instillation by the patient? performed by manually breaking a small septum? the final solution can be made to have a normal pH. This general model can be developed to enable the predominant buffer to be bicarbonate by separating this from magnesium during storage, so as to prevent its precipitation. Alternatively, by utilizing a third compartment, the potential number of recombinations can be increased, enabling all three glucose concentrations to be obtained from the same bag, for example, Gambrosol Trio.

Evidence of Clinical Benefit

A considerable number of studies have demonstrated that normal pH, low GDP solutions result in reduced cellular toxicity in vitro as well as improved function of cell populations derived from dialysate effluent when examined ex vivo.[137–141] Mesothelial cell layers when grown in culture as a monolayer, similar to that seen on the surface of the peritoneal membrane, may be physically damaged by scratching with a needle. Their subsequent ability to regrow to confluence is inhibited by standard high GDP solution but unaffected by low GDP fluids.[142] There is, however, a problem when it comes to demonstrating the benefit of these solutions in the prevention of long-term functional and morphologic changes to the peritoneum. Studies that involve serial biopsies of the membrane are difficult to justify on ethical and practical grounds, and both functional and morphologic changes take many years to develop which, when combined with high drop-out rates, mean that they are not financially viable. Furthermore, the equipoise of many clinicians is such that the justification for the use of biocompatible fluids can be made on *a priori* grounds and if cost implications were not an issue, that it would be unacceptable to randomize patients to bioincompatible solutions.

Nevertheless, this difficulty has led to another approach, namely the use of biomarkers within peritoneal dialysis effluent that act as surrogate measures of peritoneal damage or integrity. The example most studied is the cancer antigen, CA 125, which is a product of mesothelial cells usually used to track the bulk of tumors derived from this cell type. It has been demonstrated that CA 125 is present in dialysate effluent in concentrations that imply its local production, and it is argued that its relative concentration reflects a

changes in viability and thus integrity of the mesothelial cell layer.[143] Randomized trials of all the normal pH, lower GDP biocompatible solutions have shown that they are associated with a relative increase in the dialysate concentrations of CA 125, implying their greater biocompatibility in vivo as well as underlining the role GDPs appear to have in adversely affecting mesothelial cell function.[144–146] The benefit appears to be independent of the buffer type used. Other markers that have been investigated include hyaluronan and procollagen peptides, thought to represent interstitial damage or turnover, respectively, the inflammatory cytokines interleukin-6 (IL-6) and tumour necrosis factor (TNFα), and vascular endothelial growth factor (VEGF). In each case the biocompatible solutions have been associated with evidence of better preservation of the interstitium, reduced inflammation (Il-6 but not TNFα), and reduced production of VEGF.[140,145]

Although there is no clear evidence as yet that biocompatible solutions preserve membrane function for longer than conventional fluids, there are apparent clinical benefits. Bicarbonate-lactate neutral pH solution has been demonstrated to reduce infusion pain compared to either lactate or bicarbonate-only solutions.[36,45] Because bicarbonate-only solution was associated with more pain than the mixed buffer solution (although still less than lactate only low pH solutions) is of interest. One possible explanation is that supraphysiologic concentrations, which are required in a bicarbonate only solution, result in hyperemia of the peritoneal vasculature. Bicarbonate-lactate solution in a 12-month randomized study was also associated with a significant increase in the achieved daily ultrafiltration by 150 mL.[147] The explanation for this is not certain, because peritoneal solute transport characteristics did not change, although it is possible there was an improvement on the osmotic conductance of the membrane.

There are also data supporting better biocompatibility of icodextrin and amino-acid solutions when compared to conventional glucose containing fluids. Ex vivo studies of macrophages derived from the effluent following an icodextrin exchange show better phagocytosis compared to those derived from glucose effluent, and mesothelial cells in culture also have better function and viability when exposed to icodextrin rather than glucose,[148–150] although concern has been expressed over the effect of icodextrin on mesothelial cells, albeit less severe than hypertonic glucose.[151] Similarly, amino acid based solutions also show better biocompatibility than glucose solutions, with demonstration in both in vitro and ex vivo studies improved phagocytosis of macrophage and a reduction in the secretion of inflammatory cytokines, presumably due to the lack of glucose or GDP toxicity.[152] Compared to conventional glucose solutions, GDP concentrations in icodextrin and amino acid solutions are significantly reduced, especially in the latter case, such that in both cases single dwell studies show a net loss of AGEs demonstrated by the time-dependent appearance of these compounds into the dialysate effluent, presumably due to their removal from the circulation or peritoneal membrane.[153] One study evaluating a neutral, bicarbonate compared to lactate buffered amino acid solution suggests that this is more biocompatible.[154] Data awaiting publication would suggest that adverse changes in membrane occurring in anuric APD patients are, to some extent, ameliorated by use of icodextrin (Davies, et al. European Automated

Peritoneal Dialysis Outcome Study, American Society of Nephrology, Philadelphia, 2003).

Potential Problems

As would be hoped, there are few, if any, problems associated with the use of more biocompatible solutions (with the exception of specialized solution specific issues discussed previously). Peritonitis rates, if anything, are reported as being lower than with conventional fluids, supporting the in vitro and ex vivo observations of improved cellular function of the innate immune system.[155] Due to their dual or triple compartment bag design, they are perhaps a little more complex for patients to use than conventional fluids, and some patients are said to not be able to manage this. In each case, however, they have been designed with safety in mind so that patients cannot infuse a solution that might be harmful. Their benefit in APD is not fully established, although it would be anticipated that with the short night-time exchanges during which pH does not fully normalize, their advantages would be greater. There is recently published evidence confirming the safety and efficacy of bicarbonate-lactate solution in two short-term prospective open-label studies evaluating 25/10 mmol and 25/15 mmol mixes, respectively. In each case, when compared to the 35 and 40 mmol lactate solution, respectively, patient reported less infusion pain, although no specific data on biocompatibility (e.g., membrane markers) have yet been published.[42]

FUTURE DEVELOPMENTS

It can be seen from the previous that, although significant advances in solution design have been made, there remains room for further improvements. In addition, there is still a lack of evidence that those improvements already made will actually translate into perceived clinical benefit, such as improved technique and patient survival rates or better health status/quality of life. A number of potential areas are considered.

Optimization of Ultrafiltration of Sodium Removal

Although the presence of sodium sieving is a good sign in a PD patient, because it is evidence of efficient ultrafiltration induced by small osmolytes via the aquaporin pathway, it results in a potential deficit between sodium and water removal (see Figure 27–2). As discussed previously, this is maximal when a regime employs short exchanges, such as APD, and may result in worse blood pressure control, poor fluid status, and contribute to the poor survival seen in APD patients achieving low fluid losses.[88,89] Optimizing sodium removal is also an attractive way of improving blood pressure control, especially when residual renal function has dropped off. As discussed previously, sodium removal is dependent mainly on convective losses, although diffusion plays a significant part.[46] There are, therefore, essentially two strategies available for increasing sodium loss: increasing ultrafiltration or enhancing diffusion with the use of low sodium dialysate fluids. Combining these processes by using the long exchange, to allow time for the diffusion to occur, also makes sense.

For example, combining a low molecular weight osmolyte (e.g., glucose, glycerol, or amino acid) with icodextrin will increase ultrafiltration that enables sodium to follow due to the long dwell time. This approach has already been shown, by combining icodextrin with glucose, to significantly enhance ultrafiltration.[193] Studies using low sodium dialysates have been performed and have also shown to increase sodium removal, although their beneficial effects have been variable.[156–159] Some have reported improvements in blood pressure and echocardiographic parameters, whereas others have observed worrying side effects. There is clearly room for further research on both safety and efficacy.

Optimizing Biocompatibility

As indicated earlier, the evidence that improved biocompatibility of dialysate solutions results in preservation in either preservation of membrane function or the prevention of membrane morphology is keenly awaited. So far, the main target of improving long-term biocompatibility has been the creation of low GDP solutions. Further understanding of the mechanisms of how they act and which are important can only enhance this approach. However, at least two other mechanisms of glucose toxicity, intracellular hypoxia via the sorbitol pathway and non-GDP dependent AGE formation, and probably more, exist. This invites alternative strategies, and several have been proposed that are either undergoing animal testing or clinical evaluation. These include the use of pyruvate as an alternative buffer,[160,161] glycerol as an alternative low molecular weight osmolyte,[162,163] or different combinations of existing dialysate fluids during the 24-hour period to achieve a period of glucose free treatment, often referred to as *portfolio* approach.[164]

A Drug Delivery System?

The concept that PD solutions may also act as the vehicle for drug delivery is not a new one. As already mentioned, the delivery of cytotoxic therapy directly to the peritoneal cavity is already being evaluated and used clinically.[1–3,165] In dialysis patients both desferrioxamine, used as an aluminum chelating agent,[166] and erythropoietin[167,168] have been administered via the intraperitoneal route. Antibiotics for the treatment of peritonitis and insulin for the treatment of diabetic patients have been standard therapy for many years. However, more potentially exciting possibilities might be considered in an attempt to preserve or enhance peritoneal membrane function. For example, the intraperitoneal injection of hyaluronan, in an attempt to replace the dialysate losses and thus the integrity of the interstitium, has been performed in experimental animals.[169, 170]

Peritoneal Dialysis Prescription and Adequacy

Peter G. Blake, M.B., F.R.C.P.C., F.R.C.P.I. • Rita Suri, M.D., F.R.C.P.C.

Since the late 1980s, efforts have been made to apply to peritoneal dialysis (PD) the principles of quantification and prescription of dialytic dose originally established for hemodialysis (HD) by the National Cooperative Dialysis Study and other subsequent publications.[1-3] Over this period, numerous attempts were made to validate this approach by investigating whether measures of small solute clearance are associated with, or are predictive of, patient well-being and survival on PD.[4-6] Initial controversy seemed to have been, at least partly, resolved by large cohort studies from North America and Italy, published in the mid-1990s. These showed a clear association between small solute clearances received and subsequent clinical outcomes, including survival.[7,8] These findings gave rise in a number of countries to influential guidelines proposing relatively high solute clearance targets.[9,10] This, in turn, altered the practice of PD significantly in many jurisdictions.[11,12] However, the recent publication of the results of the first large randomized, controlled trials looking at the effects of raising clearance have brought into question the validity of this approach in PD and have certainly undermined existing guidelines.[13,14] Analogous results in the large randomized, controlled HEMO trial have lead to a similar questioning of the validity of the model in HD as well.[15] The result is that the whole "adequacy of dialysis" field is now in a state of flux.[16]

In this chapter, the standard adequacy indices used in PD will be defined, and the methods by which they are measured will be addressed. The strategies used in clinical practice to raise PD dose will be reviewed. The literature assessing the effectiveness of raising clearance in PD will then be critically evaluated. Special attention will be given to the value of residual renal function (RRF). Evidence-based recommendations will be proposed.

Alternative aspects of PD adequacy will then be reviewed with particular attention to nutritional factors and volume status in PD patients.

PERITONEAL DIALYSIS ADEQUACY INDICES

Small solute clearance in PD is measured using either urea clearance, normalized to total body water (Kt/V), or creatinine clearance, normalized to body surface area (CrCl). In each case, clearance includes a dialytic and a residual renal component. The latter is particularly important in PD because it accounts for a greater proportion of the overall clearance achieved than is typically the case in HD, and because it appears to persist longer in PD patients.[17,18] It should be remembered, however, that generally it is only the dialytic component that can be modified by the prescribing physician.

The dialytic component is calculated by measuring the urea and creatinine content of a 24-hour collection of dialysate effluent. These values are then divided by the serum urea and creatinine levels, respectively, to give the urea and creatinine clearance (Boxes 28–1 and 28–2). Dialysate creatinine levels need to be corrected for the high dialysate glucose content, which interferes with the assay used in many laboratories. The timing of the serum urea and creatinine samples is not important in continuous ambulatory peritoneal dialysis (CAPD) because levels do not vary significantly during the day. In automated peritoneal dialysis (APD), however, there may be a 10% or greater variation in serum urea and creatinine from a trough value after the patient finishes cycling in the morning to a peak value before the patient resumes cycling in the evening. It is thus recommended that serum samples be taken approximately half way through the noncycling period, which, in practice for most patients, means the mid afternoon. The renal component of urea and creatinine clearance is calculated in the same manner with a 24-hour urine collection, except that, in the case of creatinine clearance, an average of residual renal urea and creatinine clearance is typically used. This is because unmodified creatinine clearance substantially overestimates the true glomerular filtration rate.

The dialysate and residual renal component of clearance are added to give a total clearance, which is normalized to body water (V) to give Kt/V, or to 1.73 m² body surface area to give CrCl (see Tables 28–1 and 28–2). The value for V is estimated using anthropometric formulas, such as those of Watson or Hume, based on age, sex, height, and weight.[19,20] Estimates of V from the Watson formulas, when compared to a gold standard, such as deuterium oxide dilution, are, on average, slightly low but the discrepancy varies substantially from patient to patient, especially in the obese.[21] Nevertheless, because most of the clinical literature is based on a V calculated from the Watson equations, and because they have the advantage of simplicity, they remain the current method of choice. In children, the Mellits-Cheek formulas are used.[22] The value for body surface area is similarly estimated using the du Bois formulas.[23] In general, the edema free body weight should be used in the formulas to calculate V and body surface area.[9,10] In the case of patients who have lost a substantial amount of body weight due to malnutrition, it is suggested that the desirable rather than the actual body weight be used in these formulas. This desirable or "normal" body weight can be obtained from the National Health and Nutrition Evaluation Survey tables. These tables give the median body weight of North Americans of the same age, sex, height, and frame as the patient and are regularly updated. It can be

Table 28–1 Formulas Required to Calculate Urea Clearance Normalized to Body Water (Kt/V) and Normalized Protein Equivalent of Nitrogen Appearance (nPNA)

Kt/V

Kt/V per week = 7 (daily peritoneal Kt/V plus daily renal Kt/V)

$$\text{Daily Peritoneal Kt} = \frac{\text{24-hr dialysate urea content}}{\text{serum urea}}$$

$$\text{Daily renal Kt} = \frac{\text{24-hr urine urea content}}{\text{serum urea}}$$

According to Watson and colleagues[19]:

V (in males) = 2.447 − 0.09516(A) + 0.1704(H) + 0.3362(W)

V (in females) = −2.097 − 0.1069(H) + 0.02466(W)

where A = age (yr)
       H = height (cm)
       W = weight (kg)

nPNA

According to Bergstrom and colleagues[95]:

PNA (g/day) = 13 + 7.31 (daily dialysate plus urine urea content *) + daily dialysate plus urine protein content *

or

PNA (g/day) = 19 + 7.62 (daily dialysate plus urine urea content *)

The first formula is preferred because it requires urine and dialysate protein losses to be specifically measured rather than estimated.

$$\text{nPNA} = \frac{\text{PNA}}{\text{standardized or desired body weight (kg)}}$$

---

*Measured in g/day.
PNA, protein equivalent of nitrogen appearance.

argued, however, that they are applicable only to a North American population. The use of the desirable body weight to normalize clearance values avoids the situation where malnourished emaciated patients have a misleadingly high, normalized clearance value and, conversely, one where obese patients have a misleadingly low value. Both Kt/V and CrCl values are conventionally expressed as weekly, rather than daily, clearances to facilitate comparisons with HD.

It has been observed that there is substantial intraindividual variation when repeated clearance measurements are done in the same patient on the same prescription.[24] The variation is particularly marked for the renal component of clearance. Some of this variation may be accounted for by inevitable inaccuracies in collections of dialysate and urine, but some undoubtedly represent genuine day-to-day variation in urinary volume, peritoneal ultrafiltration, and degree of equilibration, consequent upon alterations in hydration, fluid intake, timing of exchanges, and tonicity of peritoneal fluids used.

Dialysate collections may be cumbersome because of the relatively high volumes involved. In CAPD, it is feasible for the patient to bring the entire effluent collection to the clinic. This volume is then measured either in the clinic or in the laboratory, and a representative aliquot is taken for urea and creatinine measurement after appropriate mixing. In the case of APD, the dialysate volumes involved are typically greater. Many centers train patients to record or measure cycler effluent volumes in the home, using the machine reading, and then to take a representative aliquot of the effluent into the clinic for measurement of urea and creatinine levels.

Typically, the residual renal component of clearance declines gradually toward zero over the first 2 to 3 years on PD, but there is great variation. Total clearance will therefore tend to decrease if the dialysis prescription is not modified (Figure 28–1). This was commonplace until relatively recently but, as a result of influential publications and

Table 28–2 Formulas Required to Calculate Creatinine Clearance Normalized to Body Surface Area (CrCl) and Lean Body Mass

---

$$\text{CrCl} = \text{creatinine clearance} \times \frac{1.73}{\text{body surface area (m}^2)}$$

Creatinine clearance = 7 (daily peritoneal plus daily renal creatinine clearance)

$$\text{Daily peritoneal creatinine clearance} = \frac{\text{24-hr dialystate creatinine content*}}{\text{serum creatinine}}$$

$$\text{Daily renal creatinine clearance} = \frac{\text{24-hr urine creatinine content}}{\text{serum creatinine} \times 2} + \frac{\text{24-hr urine area content}}{\text{serum urea} \times 2}$$

Body surface area (according to *du Bois and colleagues[23]*):
Log A = 0.415 Log W + 0.725 Log H + 1.8564
where A = body surface area (cm²)
       H = height (cm)
       W = weight (kg)

Lean body mass (kg) (according to *Keshaviah and colleagues[25]*) = 7.38 + 0.029 (creatinine production [mg/day])

Creatinine production (mg) = Creatinine excretion + creatinine degradation

Creatinine excretion (mg/day) = 24-hr dialysate creatinine* content (mg)
                                Plus 24-hr urine creatinine content (mg)

Creatinine degradation (mg/day) = 0.38 (serum creatinine [mg/dL]) (body weight [kg])

---

*Corrected for dialysate glucose content by a formula specific to each laboratory.
Figure 28–1 Changes in clearance with time in standard CAPD. (Modified from Blake PG, Balaskas EV, Izatt S, Oreopoulos DG: Is total creatinine clearance a good predictor of clinical outcomes in continuous ambulatory dialysis? Perit Dial Int 1992; 12:353-358.)

guideline recommendations, alterations in the dialytic prescription have become common.

Notwithstanding this, total weekly Kt/V values achieved in PD are typically half to two-thirds of those on HD. This might suggest substantial under-dialysis, but it must be remembered that the efficiency, in terms of small solute removal of clearance delivered continuously, is much greater than that of a similar quantity of clearance delivered intermittently.[25,26] Also, continuous modalities avoid the substantial disequilibria of intermittent ones. Furthermore, continuous modalities may be at a relative advantage because peak levels of uremic toxins are theoretically lower for a given clearance than is the case with intermittent modalities. This concept underlies the "Peak Concentration Hypothesis" of Keshaviah and colleagues,[25]

which proposes that peak rather than mean levels of small solutes are the determinant of uremic toxicity (Figure 28–2). Recently, driven by the interest in models of daily HD, as well as in PD, a number of investigators have attempted to define indices or methodologies that allow more realistic comparison of intermittently and continuously delivered clearance.[27] None of these has been clearly validated, but there is some evidence that urea clearances, corrected to take into account the frequency of dialytic delivery, are associated with similar patient survival rates. As will be subsequently shown, such indices generally give equal weight to peritoneal and renal clearance, but recent trials suggest that this is not a valid approach.[13,14]

PERITONEAL EQUILIBRATION TEST (PET)

Before discussing peritoneal clearances any further, it is important to have an understanding of the PET and what it measures.[28] The PET is a simple clinical method for assessing the differences in the rapidity with which urea, creatinine, and other solutes diffuse across the peritoneal membrane in different patients. Classically, this involves measurement of dialysate and plasma urea and creatinine levels during a 4-hour duration, 2 L, 2.5% dextrose dwell done under standard conditions. Equilibration curves are constructed based on dialysate to plasma ratios for urea and creatinine, and patients are classified as low, low average, high average, or high transporters with cutoff values being defined by the frequency distribution for the population in the original study by Twardowski[28] (Figure 28–3). Those with values greater than one standard deviation above the mean are classified as high transporters, and those between the mean and one standard deviation above the mean are classified as high average. Those below the mean are classified as low and low average in the same manner. Patients who are high transporters equilibrate quickly and so dialyze well, but they tend to ultrafiltrate poorly because their osmotic gradient for glucose dissipates relatively rapidly. These patients might be expected to do better with short dwell times as in APD. However, any long duration day dwells may be largely resorbed and so, if one is
Figure 28–2 Peak concentration hypothesis. (Redrawn from Keshaviah PR, Nolph KD, Van Stone JC: The peak concentration hypothesis: A urea kinetic approach to comparing the adequacy of CAPD and hemodialysis. Perit Dial Int 1989; 9: 257-260.)

Figure 28–3 Peritoneal equilibration curves. (From Twardowski ZJ, Nolph KD, Khanna R, et al: Peritoneal equilibration test. Perit Dial Bull 1987; 7:138-147.)

required, it should be of short duration or, alternatively, be replaced by the polyglucose solution, icodextrin.[29] In contrast, low transporters ultrafiltrate well but equilibrate slowly and, consequently, large dwell volumes and long dwell times may be more effective. In general, in CAPD patients, urea clearance is much less affected by PET status than is creatinine clearance. This is because a greater than 90% urea equilibration will usually occur, regardless of transport status, with the long dwell times that are typical of CAPD. This is not the case for creatinine equilibration, which may show a twofold to threefold difference between low and high transporters, even after a 4- to 6-hour dwell (see Figure 28–3). In APD, where dwells are typically 1 to 2 hours or less in duration, both urea and creatinine equilibration will vary substantially with PET status and hence, this is a critical determinant of the clearances achieved. As will be seen, this is an important consideration in prescribing APD. Notwithstanding all of this, it should be said that the constraints imposed on achieving clearances in patients with different peritoneal transport characteristics are often not apparent until residual renal function is lost.

CLEARANCES AND OUTCOMES IN PD

Initial studies carried out in the late 1980s and early 1990s to look at the influence of small solute clearance on outcome in PD were small and, in retrospect, methodologically naive.[4,5] Results varied with some showing good correlation between clearance and outcomes and others finding little or no relationship.[4,5,30,31] It soon became apparent in the early studies that, in the context of a relatively uniform CAPD prescription, variations in clearance were due primarily to changes in residual renal function.[4] In subsequent analyses, the need to separate out peritoneal and renal clearance became more evident. In addition, analyses had to take into account the tendency of residual clearance to decline with time, and so frequent remeasurement of clearance indices was required, as were statistical methodologies that attributed outcomes to recent, rather than remote, measurements.

Canada–USA (CANUSA) was a large prospective cohort study of 680 incident CAPD patients done in multiple centers in Canada and in the United States.[7] Follow-up was for 2 years, and the investigators found an impressive association between clearance received and a number of outcomes, including survival. In particular, for every extra 0.1 Kt/V a patient received, the relative risk of dying fell by 6%, and for every extra 5 L a week CrCl, the risk fell by 7%. Maiorca and colleagues[8] found an association between weekly Kt/V values greater than 1.96 and subsequent survival in a cohort of 86 prevalent Italian CAPD patients followed over 3 years. These two studies had a major influence on the U.S. National Kidney Foundation Dialysis Outcomes Quality Initiative (K/DOQI) guidelines published in 1997 and revised in 2000.[9] These K/DOQI guidelines recommended a weekly Kt/V of 2.0 for those on CAPD with modestly higher targets of 2.2 and 2.1 for those on "day dry" APD and on APD with day dwells, respectively. The rationale behind the higher targets for the APD modalities is that they are slightly more intermittent than CAPD and, as already mentioned, intermittency decreases the efficiency of any given amount of delivered clearance.[25,26] The corresponding CrCl targets were 60, 63, and 66 liters a week for CAPD, "day dry" APD and APD with day dwells, respectively.[9]

Criticism of the CANUSA and Maiorca studies and of the consequent DOQI targets focused on the concern that residual function was severely confounding interpretation of the evidence.[32] The bulk of the variation in delivered clearance in CANUSA was due to declining residual function and not to variations in peritoneal clearance, which was left relatively constant. Neither the CANUSA nor the Maiorca studies were able to show any independent effect of peritoneal clearance on outcome.[33] In a sense, all that was shown was that more residual renal function was associated with superior survival, a not unexpected finding given the associated benefits of native kidney function, such as better volume control, superior preservation of nutritional status, greater middle molecule clearance, and renal endocrine and metabolic function. Clearly, there was a need to show an independent effect of

peritoneal clearance on outcome, if the expense and inconvenience of increasing dialytic dose was to be justified. The proponents of the new targets would have argued that peritoneal clearance and residual renal clearance are, at least partly, interchangeable and that existing studies, coming from an era of uniform prescription, did not have a sufficient range of peritoneal clearance to detect the supposed beneficial effect on outcomes. Subsequent data from the late 1990s, when there was greater variation in peritoneal prescribing, continued, however, to show no independent effect of peritoneal clearance and outcomes.[12,34] It was clear that randomized, controlled trials were required.

The first two randomized trials addressing this issue appeared in 1997 and 2000 and came from the United Kingdom and Hong Kong, respectively.[35,36] Harty and colleagues[35] used 2:1 randomization of 68 CAPD patients with 42 CAPD patients receiving a 0.5 liter increase in their 1.5% dextrose dwell volumes only. Follow-up was for 1 year, but tolerance of the greater volumes was poor with 12 of the 42 not accepting the increase and only 17 completing the year. No difference in survival was identified but the study was severely underpowered. Mak and colleagues[36] randomized 82 prevalent CAPD patients to 3×2 L dwells as compared to 4×2 L dwells with 1 year follow-up. Again, there was no difference in survival, but this study was also significantly underpowered.

The ADEMEX study, published in 2002, is the largest randomized trial ever done in PD.[13] Almost 1000 incident and prevalent Mexican PD patients were randomized to receive either the standard 4×2 L CAPD prescription or an augmented prescription designed to achieve 60 L per week peritoneal CrCl. This study was well designed and carried out. Baseline characteristics of the two groups were almost identical, both in terms of demographics, comorbidity, baseline peritoneal clearance, and residual function. This study was large enough to have the power to detect a 20% increase in mortality, equivalent to a 4% absolute difference in 1-year survival. As one would expect, not all of the intervention group reached the demanding peritoneal clearance target of 60 L a week, but separation between the two groups was substantial (Table 28–3). Survival was identical between the two groups and, furthermore, there was no difference between subgroups, designated

by age, sex, diabetes, body size, and presence or absence of residual function (Figure 28–4). This impressively negative study had no major flaws and deals with exactly the range of doses that can be delivered in clinical practice.[11] One objection to the study was the claim that it was carried out in Mexican patients only and might not be applicable to populations elsewhere. In 2003, however, Lo and colleagues[14] reported another large randomized trial comprising 320 incident CAPD patients from six centers in Hong Kong who were randomized to high, normal, and low Kt/V prescriptions of greater than 2.0, 1.7 to 2.0, and 1.5 to 1.7 per week, respectively. In this study, the Kt/V target took into account residual function as well as peritoneal clearance, and so the high target was less demanding. The baseline characteristics of the three groups did, unfortunately, vary somewhat in that, for example, the sex distribution, the age, and the body size differed substantially across these groups. Follow-up was 2 years and, again, there was no survival benefit for the high clearance group, as compared to the other two. The low clearance group did a little worse in terms of erythropoietin requirements and study withdrawals, but the fact that this was an open-label study makes the latter finding hard to interpret.[14] Overall, the Lo study appeared to support the ADEMEX finding that high clearance PD prescriptions do not improve outcomes.

Another criticism of ADEMEX, and implicitly of the Lo study, was that both comprised populations with relatively lower rates of cardiovascular disease as compared to those seen in North America and Western Europe.[37] In the case of

Table 28–3 Weekly Kt/V and CrCl Values in ADEMEX

	Standard Group	High Clearance Group
Peritoneal Kt/V	1.62	2.13
Total Kt/V	1.80	2.27
Peritoneal CrCl	46 L	57 L
Total CrCl	53 L	63 L

Kt/V, urea clearance, normalized to body water; *CrCl*, creatinine clearance, normalized to body surface area.

Figure 28–4 Survival in ADEMEX study. (From Paniagua R, Amato D, Vonesh E, et al: Effects of increased peritoneal clearances on mortality rates in peritoneal dialysis: ADEMEX, a prospective, randomized, controlled trial. J Am Soc Nephrol 2002; 13:1307-1320.)

ADEMEX, patients with overt cardiac disease were excluded, and in Hong Kong the prevalence of this complication in PD patients is relatively low to begin with. However, 60% of deaths in the ADEMEX study were cardiovascular in etiology, and this did not differ between the two groups. Another concern relates to the possibility of noncompliance in the intervention groups in these studies. This is always an issue in any study, or real-life situation, that requires the patient to deliver a treatment. Analyses based on blood work from ADEMEX, however, suggest that the extra dialytic dose was generally delivered. An additional issue raised regarding ADEMEX was the finding that, although the absolute number of deaths did not differ across the two groups, those attributed to congestive heart failure and uremia, hyperkalemia, and acidosis were significantly more frequent in the control group. Similarly, there were more dropouts attributed to uremia in the control group. Overinterpretation of these findings should be avoided, however. ADEMEX was, by its nature, an open-label study and there is a strong possibility that physicians classifying the etiology of deaths and withdrawals from the study would be more likely to designate those in the control group as being due to uremia or volume overload.

Residual skepticism about these two large and impressive controlled trials should also be tempered because the findings do not differ from those of the CANUSA[7] and Rocco and colleagues'[12] studies. Each of these studies, a randomized, controlled trial, a prospective cohort study, and a retrospective analysis, respectively, showed a very similar effect of residual renal function on survival, and each showed no effect of peritoneal clearance (Table 28–4). There is a convincing consistency about these findings. Accordingly, apart from some reservations about unreservedly applying the results to patients with overt cardiac disease, it seems unreasonable to not accept the findings of ADEMEX and of Lo and colleagues as valid and highly relevant. There is now a broad consensus that guideline groups need to reconvene and revise existing recommendations.

NEW RECOMMENDATIONS

A reasonable approach might be to use the dialytic dose received by the control group in the ADEMEX study, perhaps with a modest increment for safety, as the new minimum target Kt/V.[13] This would, therefore, be about 1.7 peritoneal per week or 45 to 50 L per week CrCl. There is no longer justification for the old policy of adding peritoneal and residual renal clearance together because the two are clearly not interchangeable in their implications for patient outcomes. Residual clearance should be treated as a precious bonus to be protected but should not be part of a clearance target. A target Kt/V value of 1.7 peritoneal is, with a bit of effort, feasible in almost all patients. In most, it will not require prescriptions that unreasonably disrupt the already impaired quality of life of dialysis patients.

The justification for having both CrCl and Kt/V targets also needs to be questioned. There is no evidence from any of the randomized, controlled trials that one index is any better than the other in predicting outcome. The apparent superiority of CrCl in some previous prospective and retrospective studies is merely a mark of the fact that CrCl gives greater weight to residual renal clearance.[30] A reasonable approach, for simplicity, might be to have a single peritoneal Kt/V target. The evidence for having separate targets for CAPD and APD was never strong and introduces an unnecessary degree of complexity. All of these PD modalities are relatively continuous, compared to three times weekly HD, for example. There is also no convincing need for different targets by transport type either, especially when CrCl is taken out of consideration.

If "incremental" or "early start" PD is practiced with patients being initiated on dialysis while residual function is still substantial, there is justification for a lower peritoneal prescription, such as two to three CAPD exchanges daily or "day dry," low-volume APD.[38] If the residual function exceeds 2 mL/min, a peritoneal Kt/V of 1.2 per week would likely be sufficient in that the total Kt/V in such a case would still easily exceed the old K/DOQI targets.

Trials of higher peritoneal clearances than 1.7 per week might still be indicated if patients have persisting uremic type symptoms, and, particularly, if there is coexisting cardiovascular disease, but expectations for a beneficial effect would have to be guarded and alternative diagnoses and treatments considered.

WHY HIGHER CLEARANCES DO NOT HELP?

Why is high clearance PD not more successful in improving quality and quantity of life? Similar questions are being asked

Table 28–4 Relative Risks for Mortality by Peritoneal and Renal Clearance Indices in Three Major Studies

	CANUSA	Rocco and Colleagues	ADEMEX
Type of Study	**Prospective Cohort**	**Retrospective Analysis**	**Randomized Trial**
Peritoneal CrCl	1.04 (ns)	0.90 (ns)	1.03 (ns)
Renal CrCl	0.83 (p = .001)	0.60 (p <0.001)	0.89 (p = .013)
Peritoneal Kt/V	1.00 (ns)	1.00 (ns)	1.00 (ns)
Renal Kt/V	0.68 (p <.001)	0.88 (p = 0.003)	0.94 (p = .005)

ns, not significant. (Adapted from Canada-USA [CANUSA] Peritoneal Dialysis Study Group: Adequacy of dialysis in nutrition in continuous peritoneal dialysis: Association with clinical outcomes. J Am Soc Nephrol 1996; 7:198-207; Rocco M, Souci JM, Pastan S, McClellan WM: Peritoneal dialysis adequacy and risk of death. J Am Soc Nephrol 2002; 13:1307-1320.)

about high clearance HD in the aftermath of the equally negative HEMO study. A number of possible answers need to be considered.[16]

One is that relative to the clearance provided by normal kidneys, the levels being tested in these trials are very low. Comparisons of 4 to 6 mL as compared to 6 to 8 mL a week, as was done in ADEMEX, seem very modest if 100 mL/min or more is considered to be normal. Proponents of this point of view argue that dialysis will significantly improve survival only if substantially greater clearances are delivered, as might be the case with daily or nocturnal HD.[39] An alternative view is that survival in ESRD is primarily determined by associated comorbidity and not by variations in dialytic dose. Once frank uremia is prevented by a baseline amount of dialysis, incremental survival requires not more clearance but rather a more successful strategy for preventing and treating cardiovascular disease and infection, the two great killers of dialysis patients.[16]

Others still argue that the small solute clearance is the wrong "yardstick" and that middle molecule clearance has been neglected or that indices of volume control may be more important. These theories may be correct, but the HEMO study gives little support to the middle molecule hypothesis and no new dogma should be accepted unreservedly without more convincing proof.[15]

Last, the notion that high clearance PD is doing no harm and that patients should therefore be given "the benefit of the doubt" also needs to be addressed. Not only is high-dose PD more costly, but it is also potentially onerous for patients.[40] Larger dwell volumes in the ADEMEX and other studies were associated with mechanical symptoms leading to dropout, hernias, and so forth.[13] More exchanges may increase the risk of peritonitis, and there is evidence that patient noncompliance also results.[41] Cycler prescriptions with 2, 3, or more day dwells may also impair quality of life. Furthermore, increases in dialytic dose generally lead to more peritoneal glucose exposure and absorption, and there is a growing body of evidence that this is deleterious, not only to the peritoneal membrane but also, more critically, to the patient's cardiovascular risk profile.[42,43]

STRATEGIES TO INCREASE PERITONEAL CLEARANCE

Notwithstanding recent skepticism concerning the benefits of augmented PD prescriptions, it will still be necessary to prescribe more than the conventional 4×2 L CAPD or 10 L per night APD regimens to bring many patients above the proposed 1.7 peritoneal Kt/V target.[44]

In CAPD, an increase in dwell volume from 2 to 2.5 L is the least disruptive approach, is usually well tolerated, and leads to approximately a 20% increase in peritoneal clearance.[44] The need to use 3-L volumes should be noticeably less with future lower Kt/V targets. The alternative strategy of adding a fifth exchange is less attractive because it is more expensive and disruptive of a lifestyle and because it is associated with increased noncompliance.[40,41] If this strategy is chosen, however, the most effective way to add the extra exchange would be to use a night exchange device to break up the long nocturnal dwell.[45]

APD is increasingly the chosen option for PD patients.[11] The addition of a day dwell is the most effective way to increase clearances with this modality. This is particularly so in the patient who is "day dry," where the resulting increase in clearance is often 30% to 35%.[44] If a day dwell is already being used, the addition of a second one will also have a substantial effect, provided that each is in place for at least 4 hours to allow good solute equilibration. Strategies based on using the cycler as a "docking station" reduce the cost and inconvenience of adding a second day dwell, although they do require the patient to return to the cycler to do the exchange.[46] A manual "double bag" exchange is an alternative for the patient who does not wish to return to the cycler. If there is just 1 long day dwell, fluid resorption may be a problem. In this situation, an early drain after 4 to 8 hours may be an option that increases ultrafiltration, preserves clearance, and even enhances lifestyle in that many patients prefer being "empty" for at least some of the day. An alternative approach to maintaining ultrafiltration is to introduce the polyglucose solution, icodextrin, for the long day dwell.[29] This approach is also useful for the long nocturnal dwell in CAPD.

Alternative methods of raising clearance in APD are to increase the number of cycles per treatment session. Typically, this effect starts to plateau out once the number of cycles exceeds about seven per 9-hour cycling session.[44,47] This number may be a little higher for high transporters, but the cost of more than seven cycles per night is also a factor.[40] Lengthening the cycler time is also somewhat effective in increasing clearance, but, again, there are lifestyle constraints. Larger dwell volumes may also help; that is, 4×2.5 L give better clearance than 5×2 L. The effect is modest and some argue that the rise in intraperitoneal pressures with higher volumes may impair ultrafiltration.[48]

Measurement of peritoneal clearance should be carried out once the new PD patient stabilizes on the initial prescription. It would seem appropriate to measure clearance every 6 months, as part of a general check on the prescription that the patient is doing.[9,10] Measurement should also be repeated soon after any prescription change and in the event of any unexpected or unexplained change in clinical status. Residual renal and urinary volume should be measured at the same time as peritoneal clearance. However, if the patient is on an "incremental" PD prescription with an initial low peritoneal clearance, residual renal clearance should be measured at 2-month intervals to avoid missing a decline in residual function and consequent "under-dialysis."[38]

MAINTENANCE OF RESIDUAL RENAL FUNCTION

One lesson that PD practitioners have learned in the past decade is the impressive value of preservation of even very modest amounts of residual renal function. Thus, in the CANUSA study, an extra 5 L a week creatinine clearance, which is equivalent to 0.5 mL/min glomerular filtration rate, was associated with a 7% increase in survival.[7] Similarly, a 250-mL increment in urine volume was associated with a 36% decrease in relative risk of death. When both renal clearance and urine volume were added to the same Cox model, the urinary volume appeared to be the stronger predictor of survival.[33] Other studies have shown that RRF is a crucial factor in maintenance of good volume, cardiac status, control of hyperphosphatemia and that it may also decrease the risk of malnutrition.[49-51]

Of course, all of this may not be cause and effect. It is plausible that preserved renal function may be a marker of general well-being, of less systemic inflammation, or just of an earlier stage in the evolution of ESRD.[52] However, the possibility that better preserved function enhances survival through its effects on volume status, middle molecule clearance, metabolism, or nutrition is also quite conceivable.

Regardless, the preservation of residual function would seem to be a priority. A recent randomized, controlled trial showed that angiotensin converting enzyme inhibition and, in particular, ramipril 5 mg daily, was associated with better retention of residual function and lower probability of anuria.[53] This study, based on 60 CAPD patients in Hong Kong, with no other indication to be on an angiotensin converting inhibitor, showed a small but significant effect with a 1 mL/min greater clearance at 12 months and a 42% lower chance of development of anuria.

In another randomized, controlled trial, Medcalf and colleagues[54] randomized 61 incidence PD patients to either furosemide 250 mg/day or no diuretic. Urine volume was better maintained at 1 year in the furosemide group with a difference of just over 350 mL/day. Urine sodium excretion was also enhanced and volume status appeared better in that percentage of body water by bioimpedance rose in the control group but stayed constant in the treatment group.

Both ACE inhibitors and high dose furosemide appear to be safe interventions in PD patients and this evidence that they are reasonably effective in maintaining urinary clearance and volume, respectively, would appear to justify their routine use. Other strategies to consider in preserving residual renal function are to avoid, as much as possible, volume depletion, the use of aminoglycosides, nonsteroidal anti-inflammatories, and radiologic contrast. When the latter has to be used, renoprotection with intravenous saline and administration of acetylcysteine should be considered, if residual renal function is still significant.[55]

NUTRITION

The influence of nutrition on outcomes and survival in dialysis patients has long been appreciated. A variety of nutritional indices predict survival in PD patients. These include serum albumin, subjective global assessment, lean body mass, and other indices of creatinine production, total body nitrogen, a variety of other composite nutritional indices, and, in some studies, protein intake.[7,8,56-58]

The mechanism of this association of nutrition and survival is not clear. A crucial issue is whether it represents cause and effect or just association. In other words, is the poor nutrition the proximate cause of the inferior outcomes, or are they both common consequences of underlying comorbid conditions that are the true cause of the patients' poor survival? Traditionally, nutrition and clearances have been linked together with the theory being that inadequate clearances lead to poor protein intake, which, in turn, leads to malnutrition and premature death.[13] This theory stems from the general observation that degree of uremia and appetite for protein are closely correlated and also from the suggestion in the 1980s that Kt/V and protein intake were closely associated.[54] However, this paradigm has been shown to be an oversimplification. The original observations relating clearance and protein intake were confounded by the phenomenon of "mathematical coupling."[60,61] More significantly, there is now a greater awareness that much of the malnutrition seen in dialysis patients is independent of dialytic dose.[62]

Contributors to impaired nutritional status in PD patients can be divided into those that are found in ESRD in general and those that are specific to PD (Table 28–5). The former include inflammation, metabolic acidosis, impaired protein anabolism, and uremic anorexia. The latter include the obligatory dialysate protein losses and some of the impairment of gastric emptying.

The greatest area of interest, recently, with regard to the etiology of malnutrition in renal failure has been in the notion that persistent inflammation is a critical underlying factor. Inflammation, as indicated by elevated serum C-reactive protein (CRP) and interleukin-6 levels, is present, usually without any clinically obvious cause, in as many as 30% to 60% of dialysis patients.[63-66] Most importantly, it is associated with decreased survival in ESRD patients. It has been associated in some studies with progressive atherosclerosis, giving rise to the concept of the "malnutrition inflammation atherosclerosis," or MIA, syndrome.[63,67] Inflammation has also been shown to account for much of the hypoalbuminemia seen in both PD and HD patients, an effect mediated through decreased hepatic albumin production, consequent on a chronically "turned on" acute phase response.[68]

Table 28–5 Factors Contributing to Malnutrition in PD Patients

General ESRD-Related Causes	PD Specific Causes
Uremic anorexia	Dialysate protein losses
Inadequate dialysis	Impaired gastric emptying (present in ESRD but worse in PD)
Systemic inflammation	
General comorbidity	
Gastrointestinal comorbidity (e.g., gastritis, ulcers, constipation, diabetic gastropathy)	Anorexic effect of dialysis glucose absorption
	Peritonitis episodes
Metabolic acidosis	
Growth hormone resistance	
IGF-I resistance	
Medication side effects (e.g., oral iron, phosphate binders)	
Socioeconomic deprivation	
Poor dietary habits (e.g., previous low protein diets)	
Decreased activity	
Depression	

Why ESRD patients should have chronically stimulated immune responses is unclear. Initial theories proposed a role for the bioincompatible aspects of dialysis, such as the blood membrane interaction in hemodialysis and the dialysis solution peritoneal membrane interaction in PD.[63-65] However, the finding that inflammation is equally common in patients with advanced renal failure prior to initiation of dialysis argues against this being the major cause.[67] Another possibility is that the inflammation is directly related to renal failure per se and the associated impaired clearance of cytokines.[69] However, there is no clear proportionality between clearances and inflammation, and so this cannot be more than a modest part of the overall explanation. Coexistent comorbid conditions, in particular, cardiovascular disease, may be a critical player in cytokine activation, though which is the cause and which is the consequence are unknown.

Management of the inflammation of ESRD has not been very successful. The cardiology literature varyingly suggests roles for statins, aspirin, and even angiotensin converting enzyme inhibitors in suppressing inflammation, but there is little evidence as to how effective these strategies are in ESRD.[70–74]

Numerous studies in recent years testify to the contributory role of acidosis to the impaired nutritional status of renal failure.[75-77] The mechanism here is increased breakdown of muscle protein due to activation of the ubiquitin-proteasome proteolytic system.[76,77] In PD patients, acidosis tends to be less of an issue because the continuous nature of the dialysis usually ensures good maintenance of serum bicarbonate.[78] Interestingly, two recent randomized trials have shown that supplementation to increase the serum bicarbonate to levels that are in the high normal to alkalotic range improves nutritional parameters modestly in PD patients.[79,80] Oral sodium bicarbonate should therefore be considered in the small minority of PD patients with a serum bicarbonate level less than 25 mmol/L. More aggressive use of bicarbonate is probably not justified by the available data. The introduction of bicarbonate based PD solutions will have only a very mild effect on serum bicarbonate levels.[81]

Another important factor in the malnutrition of ESRD is impaired anabolism. The etiology of this relates to uremia being a state of resistance to a number of hormones involved in nutrition and metabolism, most notably insulin, growth hormone (GH), and insulin-like growth factor one (IGF-I).[82-84] The etiology of this state of resistance is complex and multifactorial. Some theories have implicated high levels of GH and IGF binding proteins or abnormalities of GH and IGF receptors, whereas others focus on post-receptor mechanisms.[82-84] Whatever the etiology, the consequence of this is that nitrogen supplements are frequently not effectively anabolized in renal failure and may just result in increased levels of blood urea. Strategies to deal with this include administration of recombinant GH, recombinant IGF-I, and anabolic steroids.[85-87] All these approaches are, however, constrained by concerns about side effects.

Obligatory protein losses in PD average 8 to 9 g/day, about half of which is accounted for by albumin.[88] This is the primary cause of the hypoalbuminemia seen in PD patients.[56,68,89] Protein losses increase in the presence of peritonitis and generally tend to be greater in those with high transport status.[56,69] Losses are not generally influenced by dialysate flow rates, but they may be less in patients who are left "dry" for part of the day. No convincing method of decreasing dialysate protein losses has been identified.

Suboptimal protein intake is a frequent feature in PD patients.[7,13] The widely quoted protein intake PNA target of 1.2 g/kg body weight/day is based on observations made in younger, healthier patients than those typically seen in contemporary PD programs.[90] Even more modest targets of 0.9 to 1.0 g/kg/day are often not achieved.[91] Some of this reflects the decreased activity, the comorbidity, and the general poor health of many patients. However, an additional factor is the impaired gastric emptying seen in many PD patients.[92,93] This is more marked in diabetics and seems, at least in part, to be related to the dialysate glucose content.[92]

DIAGNOSIS OF MALNUTRITION

High awareness of the frequency and significance of malnutrition is important. Basic history taking and clinical examination with assessment of food intake, appetite, weight, fat stores, and muscle mass should be routine practice in the evaluation of PD patients. Some of this can be formalized in the technique of subjective global assessment.[7] Regular evaluations by a experienced dietitian are also important with particular regard to assessment of nutrient intake. Low serum levels of urea, potassium, and phosphate are all suggestive of poor nutritional intake. Urea kinetics can be used to estimate the normalized protein equivalent of nitrogen appearance (nPNA), a surrogate for protein intake in a stable patient.[94] The rationale here is that urea generation and excretion in the stable patient is proportional, in a predictable manner, to protein intake. A variety of formulas have been used to estimate protein intake from urea and other nitrogen losses. Some are taken from the chronic renal failure or hemodialysis literature, whereas others were derived directly from PD patients (see Table 28–2).[91,95,96] The best validated are those of Bergstrom.[95] Normalization of the calculated protein intake is typically done using desirable rather than actual body weight because the latter can be misleading if there is marked malnutrition or obesity.[9,10,98] Desirable body weight can be taken from standardized tables based on age, sex, height, and body frame. Simple estimates of body composition can be performed using creatinine excretion in dialysate and urine to estimate lean body mass.[99] Formulas for this take into account extrarenal creatinine degradation as well as level of serum creatinine. Estimates based on these measurements have been shown to be predictive of outcomes.[7,57] More sophisticated methods of assessing body composition include bioelectric impedance, DEXA, and total body nitrogen measurements.[58,100–102]

Serum albumin is now recognized to be a poor measure of nutrient intake in the PD patient but a low value, along with a high CRP level, may be a clue to ongoing inflammation.[68] The other major contributor to hypoalbuminemia in this setting is high peritoneal transport status and the associated dialysate protein losses.[56,90]

MANAGEMENT OF MALNUTRITION

Malnutrition is a frustrating complication of ESRD because it is frequently not amenable to correction. A multidisciplinary

approach is preferred involving the dietitian, the nurse, and the social worker as well as the physician.[9,10] Attention to social, economic, and educational factors is important. Medications should be reviewed, looking particularly at those, such as oral iron, phosphate binders, and nonsteroidal anti-inflammatories, which may be irritating to the stomach. Comorbidities, such as poor dentition, gastrointestinal disease, and depression should be looked for and addressed. Counseling concerning the importance of protein intake is essential, but frequently patients cannot achieve the recommended targets of 1.0 to 1.2 g/kg/day, and, in these situations, it is important that more modest increments be encouraged.[9,10] Indeed, there is evidence that patients can go into nitrogen balance at lower levels of protein intake.[91]

Identification and correction of under-dialysis is an important aspect of managing malnutrition but, as already mentioned, this is now understood to be a less significant contributor than was thought to be the case in the past. However, peritoneal Kt/V values less than 1.7 in the presence of malnutrition should be considered an indication for increasing clearance. Oral sodium bicarbonate supplements should also be considered if the serum bicarbonate is low.[78, 79] If symptoms are suggestive of impaired gastric emptying, a trial of a promotility agent, such as domperidone, should be considered.[93] There may also be a role for empiric use of antacid agents, such as protein pump inhibitors or histamine antagonists. Identification and treatment of *Helicobacter pylori* infection may also help.[103] If elevated serum CRP levels indicate the presence of inflammation, a search for a primary cause may be made, but a specific treatable entity is uncommonly identified and, more often, there is nothing definitive or just generalized comorbidity.[65]

Trials of protein and/or nitrogen supplements are commonly carried out even though there is little evidence that this approach is effective in improving clinical outcomes in ESRD patients. If oral supplements are not of benefit, consideration should be given to using intraperitoneal amino acids. Modest benefits have been demonstrated for these in clinical trials.[104-106] They have been shown to improve nitrogen balance and, in some studies, to induce an anabolic response and to ameliorate hypoalbuminemia. However, substantial improvement to clinical outcomes has not been demonstrated. Care has to be taken to ensure that intraperitoneal amino acids do not induce uremia or acidosis. For this reason, use is limited to one 2- or 2.5-L bag of 1.1% amino acids daily, given at the same time as ingestion of an energy source. Feeding by gastrostomy tube has occasionally been attempted in adults with ESRD but is more frequently done in children. This intervention can be successfully carried out in patients on PD but complications are significant, and, again, there is little evidence of long-term benefit.[107]

Approaches based on improving anabolism have also been studied. One randomized trial done in both HD and PD patients showed benefits for the use of anabolic steroids.[87] This trial was small but still showed important functional improvements in the patients receiving the intervention. The anabolic effects of recombinant GH and of IGF-I have also been demonstrated in a number of studies, but their use is not practical in view of concerns about side effects and high costs.[85,86]

If all these approaches are ineffective and the patient is clinically failing, a trial of HD may be worth considering. Some patients improve after such a switch, but there is often no change.

VOLUME STATUS IN PD

The importance of achieving optimal volume status in both PD and HD patients has been emphasized recently for a number of reasons. First, the failure of an approach based on small solute clearance to reduce ESRD mortality substantially has encouraged investigators to look at other approaches to improving outcomes.[13,14,16] Second, the increasing realization that dialysis, as presently practiced, is not normalizing blood pressure in most patients has caused concern, given that cardiovascular disease is the commonest cause of death in these patients.[108,109] The notion that hypertension usually reflects inadequately managed volume status and may be contributing to adverse cardiovascular outcomes has therefore become popular.[109,110]

In PD patients, there is some evidence that volume status is even less well controlled than in HD patients.[111,112] This is most likely to be the case after residual renal function is lost.[51] As a consequence of all this, an International Society of Peritoneal Dialysis Committee published recommendations on management of volume status in 1999.[113]

Much of the literature on fluid overload in PD deals with the differential diagnosis of problems with the peritoneal membrane for which the term *ultrafiltration failure* (UFF) is commonly used. However, it should be emphasized that UFF is not the only cause of fluid overload in PD patients. Indeed in the early years of PD, UFF is relatively uncommon and other causes should be sought.

Nonmembrane causes of fluid overload are shown in Table 28–6. Excess salt and water intake and declining urine output are often major contributing factors. In some patients, noncompliance with the PD exchanges or inappropriate selection of dialysis solution strengths contributes to the problem. Mechanical complications that impair peritoneal fluid drainage may also be an issue. These lead to greater residual volumes and consequent fluid resorption. Examples include poorly functioning catheters, peritoneal leaks, loculations in the peritoneal cavity, and even hernias. Hyperglycemia may also contribute by decreasing the glucose osmotic gradient driving ultrafiltration.[113]

Careful history taking, physical examination, and inspection of dialysis records should help to identify these nonmembrane causes of UFF. In some situations, direct observation of dialysate drainage, assessment of residual volume and contrast peritoneography may be helpful.[113]

ULTRAFILTRATION FAILURE (UFF)

The term *ultrafiltration failure* (UFF) is best used to refer to cases of clinical fluid overload in which membrane dysfunction is identified as the primary cause of the problem. The classic definition is a net ultrafiltration volume of less than 400 mL at the end of the standard 2-L, 4-hour duration 4.25% dextrose dwell.[114]

The commonest cause of this, known as type I UFF, is where equilibration across the membrane is so rapid that the osmotic gradient for glucose dissipates before adequate ultra-

Table 28–6   Causes of Fluid Overload

Membrane Causes	Nonmembrane Causes
Type I—high effective membrane area	Excess salt and water intake
Type II—inadequate effective membrane area	Marked decline in urine output
Type III—excessive peritoneal fluid absorption	Noncompliance with PD prescriptions
Other types:	Inappropriate choice of solution tonicity
Impaired aquaporin function	Peritoneal leak (abdominal wall, retroperitoneum, perineum)
Impaired hydraulic conductance	Poor catheter function with resulting high residual volume
	Hyperglycemia— inadequate osmotic gradient

filtration has had time to occur. Rapid transport status is present from the initiation of PD in a minority of patients, whereas, in others, it appears with time. Thus, the cumulative incidence of UFF in one study was 2.6% after 1 year on PD, rising to 9.5% after 2 years, and to 30.9% after 6 years. This cumulative rise in incidence is partly related to the tendency for peritoneal transport to increase significantly in many patients. It is, however, frequently made more overt by the simultaneous tendency to lose residual renal function over the same time course.

The causes of the increase in peritoneal transport that tends to occur with time, has been a focus of research interest. Pathologically, there is an association of decreased ultrafiltration with submesothelial fibrosis, vasculopathic changes, and neovascularization.[116] The latter is believed to be the most significant finding in that vascular proliferation increases the effective peritoneal surface area and so results in more rapid transport.

The most popular hypothesis is that exposure to hypertonic glucose is the key factor in this process. Analogous pathologic and functional changes occur in diabetic animal models. There is a plausible pathway by which glucose and glucose degradation production (GDPs) in PD solution induce vascular endothelial growth factor (VEGF), which, in turn, promotes neovascularization through the action of nitric oxide.[117,118] De Vriese and colleagues[119] have, for example, shown that anti-VEGF antibodies can prevent much of the deterioration of ultrafiltration in animal models of PD.

Recently, Davies and colleagues[42] have strengthened this glucose related hypothesis by showing that patients who develop increased transport characteristics tend to have been exposed to more hypertonic glucose exchanges in their early years on PD, as compared to other patients who maintain relatively stable membrane transport. Glucose exposure may not be the only factor, however. The Davies' study also found that patients with stable peritoneal transport were more likely to have maintained their residual renal function for longer.[42] This may be association or it may be cause and effect. It is possible that some factor associated with residual renal function is protective for the peritoneal membrane. Chung and colleagues[120] have speculated that systemic inflammation might be such a factor. As previously discussed, systemic activation of cytokines can be detected in approximately half of all PD patients. Chung and colleagues[120] have shown that these patients are more likely to show increases in peritoneal transport in the first year on PD. The same patients are more likely to show faster declines in residual renal function.[52] The evidence for this hypothesis, is, as yet, not as strong as for the dialysate glucose mechanism.

Other bioincompatible features of PD solutions may contribute to peritoneal membrane damage. The glucose degradation products that arise during glucose sterilization may, in addition to stimulating VEGF production, also give rise to advanced glycosylation end products, which may themselves damage membrane function.[117,118] Other potential PD solution-related factors include low pH and lactate. Evidence for these is less convincing. The contribution of cumulative episodes of peritonitis to membrane function is relatively controversial with different studies yielding contrasting results.[121] The consensus at this stage is that mild peritonitis causes little permanent damage to the membrane, but severe peritonitis may be a contributor.

Type II UFF is much less common. In this condition, peritoneal transport of small solute as well as of water, actually decreases. This reflects a loss of peritoneal surface area. Most often, this is seen in the context of peritoneal adhesions acquired during severe peritonitis or after surgical complications. The available surface area for dialysis is too small and neither solute nor water transport is adequate. Some investigators have proposed that type II UFF may be a harbinger of encapsulating peritoneal sclerosis, but many cases of this condition show high rather than low transport characteristics in the early stages.[122]

Type III UFF is where lymphatic reabsorption of fluid from the peritoneal cavity is large enough to impair ultrafiltration. Peritoneal fluid absorption from the cavity occurs by two routes.[123] One is direct lymphatic absorption, occurring predominantly through diaphragmatic stomata. The other is hydrostatic pressure driven absorption of fluid across the peritoneal membrane into, predominantly, the tissues of the anterior abdominal wall. From here, the fluid is gradually resorbed, either by the lymphatics or directly into the systemic capillaries. The total fluid absorption by the two routes is difficult to measure but is thought to approximate 1 to 2 mL/min or 60 to 120 mL/hr. The main variation is thought to be in the direct lymphatic flow component. If this is significantly above the normal range, it is likely to become a clinical problem, especially if salt and water intake is high or urine volume is minimal. The proportion of cases of UFF due to this cause is unclear, but, in one review, Heimburger and colleagues[121] found that two of nine cases had high fluid resorption as the principal abnormality. In other cases, however, it may be a contributory factor.[114] In general, it is a diagnosis of exclusion because most PD units do not routinely measure peritoneal lymphatic flow or fluid absorption. Recent work by Fussholler and colleagues[124] suggests that peritoneal lymphatic flow does increase somewhat with time on PD.

Less common causes of UFF include aquaporin dysfunction and impaired hydraulic conductance of water by membrane.[123,125] The diagnosis of these is discussed in more detail in the "Physiology of PD" chapter. In practice, these conditions

will only be suspected when UFF occurs in the presence of relatively well maintained peritoneal transport and even then, it is not easy to differentiate them from type III UFF. One clue to aquaporin dysfunction is a loss of the normal sodium sieving that occurs when hypertonic PD solutions are used.[114] However, this finding is not truly specific for aquaporin related problems.

Investigation of fluid overload and UFF should follow the broad sequence outlined in the algorithms from the 1999 ISPD recommendations (Figure 28–5).[113] These emphasize history taking, clinical examination, inspection of dialysis records, and observation of catheter drainage. If a diagnosis is not then apparent, a PET using 4.25% dextrose is indicated and will allow a formal diagnosis of UFF to be made. The equilibration characteristics shown in the PET will then allow the UFF to be divided into the three distinct categories. Of course, many cases are multifactorial with, for example, a mixture of a membrane and a mechanical problem or perhaps a combination of excess lymphatic drainage issue and high salt intake.

MANAGEMENT OF FLUID OVERLOAD

Management of fluid overload includes general and specific measures.[113] The general approach applicable to all cases is to review salt and water intake and to ensure the patient is making appropriate choices of dialysate tonicity and is avoiding excessively long duration dwells, such as which may occur with the nocturnal dwell of CAPD or the daytime dwell of APD. An additional aspect of the general approach is to maximize urinary output using loop diuretics and angiotensin converting enzyme inhibitors.[53,54] Recent randomized, controlled trials are helpful in this regard. Medcalf and colleagues[54]

Figure 28–5 Management of fluid overload. (From Mujais S, Nolph K, Gokal R, et al: Evaluation and management of ultrafiltration problems in peritoneal dialysis. International Society for Peritoneal Dialysis Ad Hoc Committee on Ultrafiltration Management in Peritoneal Dialysis. Perit Dial Int 2000; 20[suppl 4]:S43-S55.)

have shown in a small placebo-controlled trial that furosemide 250 mg/day is associated with better preservation of urinary volume. Similarly, Szeto and colleagues[53] have shown in a randomized, controlled open-label study that ramipril 5 mg daily is associated with better preservation of renal clearance and with a lower probability of progression to anuria. These medications can easily be prescribed and are generally safe in the PD population, although the risk of volume depletion and disorders of serum potassium must be kept in mind.

More specific management measures depend on the cause of the fluid overload. Mechanical problems, such as leaks, hernias, and malfunctioning catheters will need surgical interventions. Noncompliance with the prescription, excess salt, and water intake, or inappropriate choice of solution tonicity require educational interventions. Glycemic control may need attention.

In the case of type I UFF, long duration dwells are a particular problem. They can be avoided in CAPD by using a night exchange device to split up the nocturnal dwell or, alternatively, a cycler based APD prescription can be introduced. The long day dwell in APD can be avoided by doing an extra exchange, either manually or from the cycler, midway through the day, or by simply draining the daytime fluid after 3 to 6 hours and leaving the patient "dry" until cycling commences again.[34] The decision as to which of these strategies should be followed will depend on the patient's lifestyle and clearance requirements.

An alternative approach is to continue with the long dwell in CAPD or APD but to instead use the polyglucose solution, icodextrin.[29] Icodextrin does not diffuse across the peritoneal membrane and so remains an effective osmotic agent, inducing ultrafiltration for many hours. Use of icodextrin is limited only by cost and by concerns that more than one dwell per 24-hour period might lead to accumulation of metabolites with unknown consequences. Wilkie and colleagues[126] have shown that icodextrin can prolong technique survival significantly in patients with UFF. Data from this study have been used to show that icodextrin, despite its expense, is a cost-effective intervention.[127]

In type II UFF, general measures may be tried, but PD is rarely viable because clearance and ultrafiltration are both compromised.

General measures are also the focus in management of type III UFF. Specific agents to decrease peritoneal lymphatic flow, such as lecithin, have been proposed but evidence to support their use has not been convincing.[128] Patients with type III UFF can also be maintained on PD because the problem is frequently moderate in severity and not progressive. Simply switching to APD may deal effectively with the fluid retention.

GLUCOSE SPARING STRATEGIES

The concept of glucose sparing strategies has become popular in recent time for two main reasons. First, the evidence that hypertonic glucose exposure is damaging to the peritoneal membrane has become stronger.[42,117,118] Second, and perhaps more significantly, there is a concern that systemic absorption of glucose from the dialysate has an adverse effect on the cardiovascular risk profile in that it may promote hyperglycemia, hyperlipidemia, hyperinsulinemia, and obesity. Glucose sparing strategies include the use of alternative nonglucose

solutions, such as icodextrin and amino acids. However, it may also involve consideration of strategies that reduce the need for more hypertonic glucose. These include salt and water restriction and use of loop diuretics and ACE inhibitors to maintain or increase urine output.

Glucose sparing strategies are very attractive, and, although the evidence to justify them is circumstantial rather than conclusive, it seems prudent to follow them as far as is feasible. However, they should not be considered as a justification to leave volume overload and hypertension inadequately treated. The adverse effects of hypertension and fluid overload are likely more immediate than those of excess glucose exposure. However, a general approach of optimizing volume status while avoiding excess glucose exposure would be ideal.

CONCLUSION

An approach to optimizing PD adequacy involves prescribing the modality with attention to clearances, maintenance of good nutrition, and achievement of normal volume status. Such an integrated strategy is more likely to be successful than was the previous paradigm, which was largely limited to small solute clearance. Such an approach may also be helpful in improving the cardiovascular risk profile of these vulnerable patients.

Peritoneal Dialysis-Related Infections

Cheuk-Chun Szeto, M.D., M.R.C.P. • Philip Kam-Tao Li, M.D., F.R.C.P., F.A.C.P.

Peritoneal dialysis (PD) related infections are serious complications in PD patients.[1–3] The classification of PD-related infections is summarized in Table 29–1. Complications resulting from peritonitis and catheter infections include catheter loss,[4,5] transfer to hemodialysis, either permanent or temporary, hospitalization, and death.[6–12] Peritonitis is probably the most important cause of technique failure in PD patients.[2,3] In Hong Kong, over 16% of the deaths in patients being treated with PD are secondary to peritonitis.[13] Similarly, 18% of the infection-related mortality in PD patients are results of peritonitis in the United States.[14]

During the early phase of the development of PD, peritonitis was common. For example, Rubin and colleagues[15] reported a rate of 1 episode per 1.9 patient-months at risk. The incidence of peritonitis decreased markedly over the following decade, largely as a result of improvements in connection technology.[16–17] More recently reported peritonitis rates are lower than 1 episode per 20 patient-months at risk.[18–20] However, there has been little reduction in the peritonitis rates over the past 10 years, and PD-related infection remains a major problem in dialysis practice.

PD infections result in technique failure, hospitalization, pain, and inconvenience to the patient. Less often, the consequence is death or peritoneal fibrosis. An understanding of the pathogenesis and management of PD is essential for the health care worker caring for these patients. Prevention of infection is critical to the success of a PD program.

PERITONITIS

Pathogenesis

The common causes of PD-related peritonitis are summarized in Table 29–2. Despite the advances in PD system connectology, contamination at the time of the PD exchange remains a major cause of peritonitis.[4,21] The following exchange practices are associated with peritonitis[22, 23]:

- Touching the connection
- Dropping the tubing on the floor or table
- Not wearing a mask during the exchange
- Performing the exchange in an atmosphere filled with dust or animal hair

Holes in the catheter or tubing and accidental disconnections are obvious but uncommon causes of PD-related peritonitis.[24]

Organisms that are commonly grown from specimens in contamination-related peritonitis are coagulase-negative staphylococci (CNS) and diphtheroids (*Corynebacterium*).[20,23,25] Nasal carriers of *Staphylococcus aureus* often have *S. aureus* on their hands and at the exit sites, which can lead to peritonitis through either touch contamination during connections or catheter-related infection. Careful hand washing with a disinfectant followed by thorough drying of the hands is critical in reducing the risk of infection.[23] In addition, organisms found in the oral cavity, such as streptococci, may cause peritonitis, if a mask is not worn during an exchange or may occur via transient bacteremia (for example, after a dental procedure).

Approximately 15% to 20% of peritonitis episodes are caused by catheter infection,[4,8,12] especially those due to *S. aureus* or *Pseudomonas aeruginosa*. Exit site infections can spread to involve the catheter tunnel and then the peritoneum.[8,26,27] Such infections are often refractory or relapsing.[28] In addition, there is substantial seasonal variation in the incidence of dialysis-related peritonitis, with peak incidence in the months that are hot and humid.[29–31] A warm and humid climate favors the accumulation of sweat and dirties around catheter exit site, and therefore the growth and colonization of bacteria.

Peritonitis, particularly in patients with multiple episodes of infection, is not uncommonly caused by the release of planktonic bacteria from biofilm on the walls of catheters.[32] In fact, bacteria can form biofilm on the walls of catheters within 48 hours of their placement. These bacteria within the slime layer are resistant to both host defenses and many antibiotics[33] and may be the cause of recurrent peritonitis.[34–36] This hypothesis is supported by the observation that catheter exchange, after dialysis effluent clears up, is effective in preventing the relapse of peritonitis.[37,38] However, biofilm is present in most patients undergoing PD after the catheter is in place for a time and, in many cases, do not result in peritonitis.[39] Peritoneal immune defenses are important in preventing peritonitis related to biofilm (see later text).[40]

Gram-negative bacteria that cause PD-related peritonitis, especially in the absence of known contamination or a catheter infection, are generally considered to originate from the bowel.[25] Similar to the spontaneous bacterial peritonitis in patients with liver cirrhosis, most of the cases of gram-negative PD-related peritonitis are due to transmural movement of bacteria rather than to perforation.[41,42] Constipation,[43,44] diarrhea,[45,46] and diverticular disease may predispose to such an event. Gastric acid inhibitors may also predispose to gram-negative peritonitis.[47] Intra-abdominal disease, such as appendicitis, cholecystitis, or ischemic colitis, may also result in enteric peritonitis.[48,49]

Traditionally, polymicrobial peritonitis is believed to be caused by the perforation of internal viscus, and surgical exploration is often recommended.[50,51] The latest guideline for the management of dialysis-related peritonitis by the International Society of Peritoneal Dialysis also recommends

Table 29–1 Classification of Peritoneal Dialysis-Related Infections

Catheter Iinfections	Peritonitis
• Exit-site infections	• Catheter-related
• Tunnel infections	• Non—catheter-related

Table 29–2 Causes of Peritonitis

Etiology	
• Contamination	
• Catheter-related	
• Enteric	
• Bacteremia	
• Gynecologic	
Common Organisms	
Bacteria	80%–90%
• *S. epidermidis*	30%–45%
• *S. aureus*	10%–20%
• *Streptococcus* species	5%–10%
• *E. coli*	5%–10%
• Other gram-negative species	5%
• *Pseudomonas* species	5%
• Others	<5%
• Mycobacterium	<1%
Fungus	<1%~10%
Culture Negative	5%~20%

early consideration of surgical exploration for polymicrobial peritonitis.[52] However, this recommendation is based on reports early after the invention of peritoneal dialysis.[50,51,53] Recent reports show that most of the patients with dialysis-related polymicrobial peritonitis responded to antibiotic therapy.[54–57] Surgical exploration is only needed in a small selected group of patients.

Peritonitis may follow colonoscopy with polypectomy,[49,58] hysteroscopy,[59] endoscopy with sclerotherapy,[60] and dental procedures.[61] Peritonitis following dental procedures is most likely related to transient bacteremia. Vaginal leak of dialysate,[62,63] the use of intrauterine devices,[64,65] and endometrial biopsy[66] are other recognized causes of peritonitis. Because of the risk of peritonitis related to such procedures, antibiotic prophylaxis administered prior to any such procedure is necessary.

Host Defense Mechanisms of the Peritoneal Cavity

Uremia per se causes a wide spectrum of defects in the immunologic defense against infection, which is beyond the scope of this chapter. Both humoral and cellular factors participate in the local peritoneal defense processes against peritonitis.[67] Theoretically, bacteria entering the peritoneal cavity are digested by peritoneal macrophages and neutrophils. Individual variation in the phagocyte function may partly account for interindividual differences in the incidence of peritonitis.[68] Here, we will discuss only the relationship between abnormalities in peritoneal defense mechanisms and the frequency of peritonitis, as well as the effect of dialysate on peritoneal defense mechanisms.[68–70]

Humoral Immunity

Opsonization of bacteria takes place when immunoglobulin G (IgG) molecules bind to specific epitopes on bacterial surface antigens via the antigen-binding site of the IgG molecule. In addition, microbial cell surface activates the complement system, either directly via interaction with microbial polysaccharides through the alternate pathway or indirectly via interaction with IgG or IgM bound to bacteria through the classic pathway. C3b formed during C3 cleavage by either pathway is deposited on the bacterial surface and augments phagocytosis. Other activated complement compounds contribute to recruitment of neutrophils by chemotaxis. In vivo, both IgG and C3b are important opsonins. Phagocytic cells, either neutrophil or macrophage, have specific surface receptors for the Fc region of the IgG molecule as well as C3b. The opsonized microbe is ingested via receptor-mediated phagocytosis.[70] Phagocytosis is further amplified by fibronectin, which has binding sites for both macrophages and bacteria. For example, there is evidence that fibronectin augments the phagocytosis of *S. aureus*.[70]

The concentrations of IgG, complement, and fibronectin in normal peritoneal fluid are similar to those in the normal serum. In peritoneal dialysis effluent, however, these values are reduced by 100- to 1000-fold,[71,72] even after several hours of dwell time. This dilutional effect severely compromises the humoral immunity within the peritoneal cavity. In comparison, the low levels of IgG and complement in the ascitic fluid of cirrhotic patients are associated with a high incidence of spontaneous bacterial peritonitis.[73] In patients receiving CAPD, an inverse relationship between either peritoneal opsonic activity or IgG concentration and frequency of CAPD peritonitis has been reported.[40] However, this finding is not universally observed,[70] and peritoneal IgG levels failed to prospectively predict the risk for peritonitis.[74] In addition, IgG levels in spent dialysate vary markedly over time in any given patient,[74] and the opsonic activity in a given sample of spent dialysate against different strains of *Staphylococcus epidermidis* is also inconsistent.[75]

The opsonic activity of spent dialysate against gram-negative bacteria is substantially lower than that against gram-positive bacteria.[40] In fact, both IgG and C3b have different affinities for gram-negative and gram-positive organisms. This may account, at least in part, for the greater severity of the gram-negative peritonitis. Fibronectin has opsonic activity against gram-positive organisms,[70] especially *S. aureus*, but apparently not against gram-negative bacteria. Low concentrations of fibronectin in the spent dialysate has been found to be a risk factor of PD-related peritonitis.[71] Fibrinogen polymerizes to fibrin in the spent dialysate during episodes of peritonitis. In addition to the effect on bacterial biofilm, intraperitoneal administration of urokinase enhances opsonic activity of spent dialysate against *S. aureus*,[76] probably due to splitting of the fibrin strands.

Cellular Immunity

The leukocyte count in peritoneal dialysis effluent is 100- to 1000-fold less than in normal peritoneal fluid.[69] The differential leukocyte counts in uninfected spent dialysate vary greatly among patients but remain stable over time in a given individual.[77] In general, macrophages predominate in spent

dialysate, lymphocyte percentages may vary between 2% and 84%, and neutrophils are usually 5% to 10%.[77] However, baseline peritoneal leukocyte count is not associated with the risk of CAPD peritonitis.[77]

Resident peritoneal macrophages, believed to originate from blood monocytes, constitute the first line of defense against bacterial invasion of the peritoneal cavity. In the early stages of peritonitis, both polymorphonuclear cells and macrophage migrate intraperitoneally from the systemic circulation as well as the interstitial matrix of the peritoneal membrane. Compared to cells from normal individuals, blood neutrophils from CAPD patients exhibit decreased binding of C5a, decreased chemotaxis, and impaired opsonic activity.[69] The oxidative metabolism of blood polymorphonuclear cells is adversely affected by low serum albumin levels.[78]

In CAPD patients, phagocytic capacity of peritoneal macrophages incubated in culture media (i.e., not dialysis effluent) is normal.[67] Bacterial killing capacity of peritoneal macrophages studied in dialysate-free media has been reported as either normal[67] or slightly decreased.[79] However, the oxidative metabolism of macrophages from noninfected spent dialysate is lower than that of macrophages from normal peritoneal fluid[69] but higher than that of peripheral blood monocytes.[79]

The oxidative metabolism of peritoneal macrophages is impaired in CAPD patients with frequent peritonitis.[72] Moreover, peritoneal macrophages, in comparison to blood monocytes, exhibit increased binding capacity of C5a (a chemotactic factor) and expression of Fc receptors, HLA-DR (Ia) antigens and CD14 antigens (which binds bacterial lipopolysaccharide). Taken together, these findings suggest that peritoneal macrophages are activated in CAPD patients.[80] Long-term CAPD may also have adverse effects on Fc-receptor-mediated phagocytosis and adhesion of polymorphonuclear cells and macrophages to endothelial cells.[81] Similar to peritoneal macrophage, T lymphocytes in peritoneal cavity, both helper and suppressor, appear to be activated in CAPD patients.[72] An increased percentage of blood and peritoneal T-suppressor cells has been associated with frequent peritonitis in isolated case reports.[82]

Mesothelial cells lining the serosal surface of the peritoneal membrane represent another important cell line in the defense against peritonitis and containment of infection within the peritoneal cavity.[83] The vital interaction between mesothelial cells and peritoneal macrophages early in the course of peritonitis occurs via cell–cell interaction, secretion of cytokines (both pro- and anti-inflammatory), prostaglandins, growth factors and fibrinolytic factors, and expression of adhesion proteins affecting leukocyte traffic.[83]

Cytokines

A panel of cytokines are synthesized by mesothelial cells, peritoneal macrophages, and lymphocytes, representing an important component of the immunologic defense against peritonitis. Activated macrophages release tumor necrosis factor alpha (TNF-α) early in the course of peritonitis,[83] whereas other cytokines, including interleukin (IL)-1b, IL-8, and IL-6 are released later.[68] Both IL-8 and IL-6 are synthesized by mesothelial cells and are stimulated by IL-1b and TNF-α. IL-8 plays a role in the recruitment of leukocytes, whereas IL-6

may modulate the inflammatory response by inhibiting the transcription of other cytokines.[83,84]

Lymphocytes activated by IL-1b and TNF-α release IL-2 and interferon-gamma (IFN-γ). The latter enhances macrophage bactericidal activity, whereas IL-1b stimulates prostaglandin E2 (PGE2) release from macrophages and mesothelial cells. PGE2 has a negative feedback effect on IL-1b production. In addition, IL-6, IL-8, and PGE2 modulate the synthesis of IL-1a and IL-1b.

Effects of PD Solutions on Peritoneal Defense

The effects of CAPD solutions on peritoneal defense mechanisms are related to the dilution, high osmolality, low pH, lactate, and heat sterilization of the dialysate. In addition to the dilutional effects on humoral defense mechanisms, decreased density of peritoneal macrophages reduces the phagocyte-bacterium encounter and thus bacterial killing.[69] Both sustained high dialysate osmolality and low dialysate pH suppress peritoneal neutrophil and macrophage functions.[85] Although dialysate pH rises rapidly after intraperitoneal infusion and reaches blood pH by 30 minutes, the dialysate infusion period carries a high risk of bacterial entry at the same time that peritoneal defenses are compromised by low dialysate pH.

Lactate in commercial dialysate preparations appears to have independent adverse effects on peritoneal inflammatory cell function, specifically affecting macrophages, polymorphonuclear cells, mesothelial cells, and fibroblasts.[86] The development of peritoneal dialysis solutions containing nonlactate buffers may augment peritoneal defense mechanisms. The cytotoxicity of bicarbonate-based dialysate appears to be less than that of lactate-based dialysate. However, polymorphonuclear cell function studied in vitro after incubation in bicarbonate-based dialysate remains deficient.[87] Pyruvate-based dialysate has fewer adverse effects on macrophage and polymorphonuclear cell function than does lactate-based dialysate.[88] Finally, heat sterilization of the dialysate causes a decrease in the adhesion of leukocytes to endothelial cells.[89]

Presentation

Patients with peritonitis usually present with cloudy dialysis effluent and abdominal pain.[15,90–92] The severity of illness varies widely, depending on the etiologic microorganism.[12,93] For example, *S. epidermidis* or diphtheroids often cause minimal abdominal pain. On the other hand, virulent organisms, such as *S. aureus, P. aeruginosa,* and fungi, often cause severe abdominal pain and, not uncommonly, diarrhea. In general, fever indicates systemic sepsis. Hypotension indicates severe peritonitis.[93,94]

Diagnosis

Although most practicing nephrologists can diagnose PD-related peritonitis on clinical ground, the diagnosis needs to be confirmed by an effluent white blood cell (WBC) count, which should exceed 100 cells/μL (i.e., 0.1×10^9 cells/L), with more than 50% neutrophil. In the absence of peritonitis, the effluent WBC count is less than 25 cells/μL with primarily mononuclear cells.[95–100] If the patient is already taking antibiotics, a WBC count of 50 cells/μL or greater is suggestive of peritonitis. If the specimen is obtained after a short dwell time

or in the absence of a dwell, the percentage of neutrophil (>50%) is a more sensitive marker than total WBC count.[98, 99]

Occasionally, patients with peritonitis present with abdominal pain without cloudy effluent.[95,100] Koopmans and colleagues[100] reported that in 6% of peritonitis episodes, the effluent WBC count is initially less than 100 cells/μL. The effluent becomes cloudy in most cases within a few hours. It is possible that patients who present with pain and the absence of cloudy effluent has delayed intraperitoneal cytokine response to the infection, signifying an underlying immunologic abnormality.[100] In the future, the application of diagnostic strip may enhance early diagnosis of peritonitis prior to the onset of cloudy effluent.[101]

The differential diagnosis for infectious peritonitis includes eosinophilic peritonitis, chemical peritonitis, pancreatitis, chylous ascites, intra-abdominal malignancy, and hemoperitoneum. In eosinophilic peritonitis, a large number of eosinophil is present in the effluent. It usually occurs early in the course of PD, resolves spontaneously, and is usually not associated with infection.[102–106] The mechanism is generally believed to be allergic reaction to the plasticizers on the dialysis tubing, and the eosinophilia generally resolves spontaneously within 2 to 6 weeks.

Intraperitoneal administration of generic vancomycin[107,108] and amphotericin[109] can cause chemical peritonitis, which mimics bacterial infection. Recently, cases of sterile chemical peritonitis have been attributed to icodextrin.[110] The episodes are characterized by mild abdominal discomfort, cloudy effluent only with icodextrin dialysates, dialysate leukocytosis with a predominance of macrophages and sterile cultures, and the absence of systemic symptoms.

A patient receiving PD who has pancreatitis may present with abdominal pain and cloudy peritoneal fluid, but cultures of the fluid are sterile and the effluent amylase concentration should be greater than 100 μ/L.[111–114] Chylous ascites is a rare cause of sterile cloudy effluent, and the effluent WBC count is normal.[115,116] Patients with intra-abdominal malignancy may also have cloudy effluent, and the diagnosis can be established by cytologic evaluation.[117,118]

Treatment of Peritonitis

Initial Evaluation

In patient presenting with possible peritonitis, evaluation should include close questioning about a history of possible touch contamination, compliance in sterile dialysis technique, recent procedures that may have led to peritonitis, and change in bowel habits, either diarrhea or constipation. The physician should review any history of peritonitis to assess for the possibility of recurrent peritonitis with the same organism or previous infection with a methicillin-resistant organism. In addition to the usual physical examination, one must carefully assess the exit site and tunnel for edema, erythema, tenderness, and discharge. The effluent should be examined, and specimens should be collected for cell count, differential count, Gram stain, and culture. The Gram stain result, if positive, is helpful in guiding the choice of antibiotic therapy.[119] Rapid institution of treatment once the appropriate assessment is completed is essential.

Despite a careful history, physical examination, and Gram stain of the effluent, frequent empirical treatment of peritoni-tis has to be initiated in the absence of appropriate diagnostic information. An arbitrary decision regarding antibiotic therapy must be made after considering the likely causative organisms.[52, 120, 121] As discussed earlier, the application of diagnostic strip may enhance early diagnosis of peritonitis prior to the onset of cloudy effluent.[101]

Evolving Trend of Empirical Therapy

There is a growing consensus for a standardized approach, which combines the continuation of peritoneal dialysis with intraperitoneal administration of antibiotics. Such an approach has been further emphasized in the 2000 update of the Advisory Committee on Peritoneal Dialysis (a subcommittee of the ISPD).[122]

In their 1993 recommendations, the Ad Hoc Committee advocated (1) the use of vancomycin to treat gram-positive infections; (2) the use of ceftazidime or aminoglycoside to cover the gram-negative organisms as first-line agents; and (3) empirical therapy, if an organism has not been identified on Gram stain at presentation.[120] Since the publication of that report, however, increasing numbers of vancomycin-resistant microorganisms have emerged, a trend that has been particularly evident in larger hospitals. Vancomycin resistance has been associated with resistance to other penicillins and aminoglycosides, thus presenting a treatment dilemma. Many of the second-line antimicrobial agents that could be used have not been proven to be effective in therapeutic trials.

With increasing numbers of vancomycin-resistant microorganisms, the use of vancomycin is discouraged for prophylaxis, for routine use, and for use in oral form against *Clostridium difficile* enterocolitis.[123–125] The major concern is that the vancomycin resistance will be transmitted to staphylococcal strains, creating a situation of major epidemiologic importance. In fact, a case of vancomycin-resistant, CNS peritonitis in a patient being treated with CAPD has been reported.[126] This situation has prompted the Ad Hoc Committee to move away from the use of vancomycin as a first-line therapy, and in 1996 the ISPD subcommittee on peritonitis has reverted to recommending use of first-generation cephalosporins in large doses for all cases.[127] Recent study shows that there is no significant difference in clinical response or relapse rate between vancomycin and cefazolin as the initial antibiotic for gram-positive peritonitis.[128] Furthermore, empirical treatment with intraperitoneal cefazolin was as effective as vancomycin for *S. epidermidis* peritonitis, despite a high prevalence of methicillin resistance.[129]

On the other hand, many authorities continue to advocate vancomycin as the first-line therapy in spite of the concern on VRE. For example, Sandoe and colleagues[130] found that at least 50% of cases of peritonitis due to CNS would not be adequately treated with a cephalosporin. The reasons given for continuing to use vancomycin were the low prevalence of VRE and a high prevalence for CNS methicillin resistance. In short, each program should assess the local patterns of sensitivity and methicillin resistance before a decision is made whether to use vancomycin or cephalosporin for initial therapy of peritonitis. If, however, the patient has a history of frequent methicillin-resistant staphylococcal infections or seems seriously ill, vancomycin, along with a second drug for gram-negative coverage, is still a good choice. In addition, for the

patient who is allergic to penicillin and cephalosporins, vancomycin remains a good alternative.

In their 1996 recommendations, the Ad Hoc Committee Recommendations involved the use of a combination of a first-generation cephalosporin and an aminoglycoside.[127] However, there is some evidence suggesting a more rapid loss of residual renal function in patients receiving aminoglycosides.[131] Since residual renal function is an independent predictor of patient survival,[132] there has been a growing concern to avoid routine use of aminoglycoside so as to preserve residual renal function. As a result, in their 2000 recommendations, the Ad Hoc Committee recommended ceftazidime, instead of an aminoglycoside, as empirical therapy for coverage of gram-negative organisms in patients with significant residual renal function,[122] which was arbitrarily defined as a daily urine output of 100 mL or more. Although empirical monotherapy of broad-spectrum antibiotic is an attractive alternative, and certain success has been reported from the use of cefepime[133] and imipenem-cilastatin,[134] the evidence is preliminary, and empirical combination antibiotics remain the standard of practice.

Figure 29–1 is an algorithm for the assessment and antibiotic therapy of peritonitis. Table 29–3 lists the agents and dosages. As shown, empirical treatment depends on the patient's residual urine output. This approach prevents unnecessary use of vancomycin and lessens the risk of the development of vancomycin-resistant organisms, and also avoids unnecessary exposure to aminoglycosides, which may adversely affect the residual renal function. The rationale for using the recommended large dose of a first-generation cephalosporin is that the organisms are, in fact, "sensitive" to the drug because of the high local level achieved at the site of the infection (i.e., within the peritoneal cavity).

Once-Daily Antibiotic Therapy

Another major change in the Ad Hoc Committee Recommendations in 2000 is the routine application of once-daily intraperitoneal antibiotics.[52] Once-daily therapy has the advantage of ease of use by patient and staff, both in hospital and at home. More importantly, there are theoretical advantages to administering aminoglycosides as a single dose in a long-dwell exchange.[135] Aminoglycosides given as a single daily dose may result in less ototoxicity and nephrotoxicity[135–139] and improved bacterial killing in association with prolonged post-antibiotic effect. In a pharmacokinetic study by Low and colleagues,[140] intraperitoneal (IP) gentamicin 0.6 mg/kg was given in one exchange with a 6-hour dwell. Intraperitoneal drug levels were high throughout the dwell but negligible thereafter. Serum levels remained low.

Lai and colleagues[135] studied the efficacy of once-daily IP cefazolin and gentamicin for treatment of peritonitis. Of the 14 episodes of gram-negative peritonitis in the series, 6 were due to *Pseudomonas* and required alteration in therapy. In spite of the change in therapy, catheter removal was eventually needed in 3 of the cases. One third of the non–*Pseudomonas* gram-negative infections required alteration of therapy. Bailie

Table 29–3 Empirical Initial Therapy for Peritoneal Dialysis-Related Peritonitis, Stratified for Residual Urine Volume

	Residual Urine Output	
Antibiotic	**<100 mL/day**	**>100 mL/day**
Cefazolin or cephalothin	1 g/bag daily or 15 mg/kg BW/bag daily	20 mg/kg BW/bag daily
Ceftazidime	1 g/bag daily	20 mg/kg BW/bag daily
Gentamicin, tobramycin, netilmicin	0.6 mg/kg BW/bag daily	Not recommended

Figure 29–1 Algorithm of the initial assessment and therapy for peritoneal dialysis infections.

and colleagues[141] used once daily gentamicin (in combination with an initial dose of vancomycin) and reported resolution of two-thirds of the non–*Pseudomonas* gram-negative peritonitis episodes in their patients. The "nonresponder" organisms include *Acinetobacter* and *Alcaligenes* species. These results show that gentamicin given in one exchange per day provides adequate coverage for gram-negative organisms for most of the peritonitis episodes.

Although the Ad Hoc Committee recommends the use of once-daily intraperitoneal cefazolin and ceftazidime, there is, at best, incomplete evidence for this practice. In the study of once-daily IP cefazolin and gentamicin by Lai and colleagues,[135] all 19 episodes of gram-positive peritonitis resolved, with only one infection due to *S. aureus* requiring modification of the initial therapy. The organisms in 3 episodes of *S. epidermidis* in this study were shown by sensitivity testing to be resistant to both gentamicin and cefazolin yet responded to therapy with these agents. In another study reported by Goldberg and colleagues[142] once-daily IP cefazolin for the initial treatment of PD-related peritonitis was at least as effective as the historical control of a vancomycin-based regimen. However, it is important to note that episodes of peritonitis with associated catheter infection were excluded from both of the studies, accounting, in part, for the excellent results.

Therapy for Specific Organisms

Gram-positive Microorganisms

The therapy for gram-positive peritonitis is outlined in Table 29–4. Peritonitis episodes due to CNS, *S. aureus,* and *Streptococcus* are distinctly different in presentation, pathogenesis, and outcome. Therapy must therefore be individualized.

Coagulase-Negative Staphylococci   For CNS, the first-generation cephalosporins are usually sufficient. If, however, the organism is methicillin-resistant *S. epidermidis* (MRSE), vancomycin or clindamycin should be used. Cefazolin tends to be less effective than vancomycin for the treatment of MRSE peritonitis. In a study by Vas and colleagues[143] there was no difference in cure rates for the two agents in treatment of CNS that were methicillin-sensitive (92% for vancomycin vs. 100% for cefazolin). For MRSE, however, the cure rate was 73% for vancomycin and only 45% for cefazolin.

Inadequate treatment of CNS peritonitis, for example, with once-weekly vancomycin in a patient with residual renal function, is not an infrequent cause of relapsing infection.[144] CNS exit site infection does not usually lead to peritonitis, and exit site infection is rarely a concern in the pathogenesis of CNS peritonitis.[8,28] However, CNS may exist within a biofilm of bacterial exopolysaccharides encasing the intra-abdominal portion of the catheter, frequently in conjunction with a healthy appearing exit site or tunnel.[145]

Recurrent peritonitis must be treated aggressively. To prevent further relapse of peritonitis, the catheter may be replaced as a single procedure after the dialysis effluent clears up with antibiotics.[146–148] Alternatively, the use of fibrinolytic agents, such as urokinase (5000 units in 5 mL normal saline injected into the catheter with the abdomen drained and allowed to dwell for 2 hours), is successful in approximately 50% of the patients with recurrent CNS peritonitis.[149–152] In a randomized study, Williams and colleagues[150] found that catheter replacement was superior to urokinase in preventing further relapse. Thrombolytic therapy should be reserved for infections for which no other cause or complication is evident (e.g., tunnel infection) and probably should be limited to CNS or culture-negative infection.

Staphylococcus aureus   *S. aureus* is the major cause of exit site and tunnel infections and is also an important cause of peritonitis.[153] Patients with *S. aureus* peritonitis often have severe abdominal pain, require hospitalization, and may require catheter removal for resolution, especially when a concomitant tunnel infection is present.[28,93] *S. aureus* peritonitis occurs predominantly in patients who have a history of *S. aureus* catheter infections. Patients who have *S. aureus* colonization in the nares,[154–156] on the skin,[157] or at the peritoneal catheter exit site[157–159] are at particular risk of developing *S. aureus*

Table 29–4   Treatment Strategies After Identification of Gram-Positive Organism on Culture

Enterococcus	Staphylococcus aureus	Other Gram-Positive Organism (Coagulase-Negative Staphylococcus)
At 24 to 48 Hours		
• Stop cephalosporins • Start ampicillin 125 mg/L/bag • Consider adding aminoglycoside • If ampicillin-resistant, start vancomycin or clindamycin	• Stop ceftazidime or aminoglycoside, continue cefazolin • Add rifampin 600 mg/day, oral • If MRSA, start vancomycin or clindamycin	• Stop ceftazidime or aminoglycoside, continue cefazolin • If MRSE and clinically not responding, start vancomycin or clindamycin
Duration of Therapy		
• 14 days	• 21 days	• 14 days
At 96 Hours		
• If no improvement, reculture and evaluation for exit-site or tunnel infection, catheter colonization, etc. • Choice of final therapy should always be guided by antibiotic sensitivities.		

VRE, vancomycin-resistant enterococcus; *MRSA,* methicillin-resistant *S. aureus; MRSE,* methicillin-resistant enterococcus. peritonitis. Even one positive nose culture increases the risk of S. aureus peritonitis.[154,160]

After empirical therapy and once the organism is identified as *S. aureus*, its sensitivity to methicillin will dictate further choice of antibiotics. If the organism is sensitive to methicillin, cefazolin should be continued. We prefer adding rifampin (600 mg/day) orally to the IP cephalosporin in all cases of *S. aureus* peritonitis. Vancomycin and cefazolin have similar efficacy in the treatment of methicillin-sensitive *S. aureus* peritonitis. For example, Vas and colleagues[142] reported that 58% of cases of *S. aureus* peritonitis resolved with vancomycin treatment and 67% with cefazolin. The cure rate for *S. aureus* peritonitis is relatively low because concomitant catheter infections are common. As a result, removal of the catheter should be considered early, if a concomitant exit site or tunnel infection is present.

If methicillin-resistant *S. aureus* (MRSA) is isolated from dialysis effluent, rifampin should be added, and the cephalosporins should be replaced by vancomycin. The vancomycin (up to 2 g IP, depending on body weight) may be repeated every 5 to 7 days. To avoid inadequate treatment, therapeutic drug monitoring and more frequent vancomycin dosage may be needed in selected cases with substantial residual renal function. Unfortunately, MRSA peritonitis is always difficult to treat and frequently requires catheter removal.[161,162]

Streptococci   A respiratory, cutaneous, digestive, or urinary tract infection precedes Streptococcal peritonitis episode in 25% of patients.[163] It is our experience that most cases of peritonitis caused by *Streptococci* have satisfactory response to 2-week course of IP cefazolin. Alternatively, 90% of cases respond to ampicillin, which appear to be more effective than vancomycin.[163] In some cases, Streptococcal species cause a severe form of peritonitis,[163–167] and shock followed by death may occur within a short time.[165]

Enterococci   In contrast to *Streptococcus viridans*, the occurrence of enterococcus peritonitis has not been decreased with the use of disconnect systems, probably because enterococcal infection is related more to a bowel source than to contamination or bacteremia.[163] As a rule, enterococcal infection does not respond to cephalosporins. Peritonitis due to enterococcus is severe and has a slower response to antibiotics,[163] partly as a result of the current Ad Hoc Committee Recommendation of cephalosporins as initial therapy. Although still fairly uncommon in patients undergoing PD, VRE peritonitis has been reported by Troidle and colleagues[168] VRE peritonitis is associated with previous hospitalization and antibiotic use (particularly cephalosporins and vancomycin) and has a high mortality rate even with catheter removal.

Gram-Negative Microorganisms

Peritonitis due to gram-negative organisms is often associated with fever, nausea, vomiting, and abdominal pain. The care of gram-negative peritonitis is summarized in Table 29–5. Good results have been reported with either IP aminoglycoside or ceftazidime.[169] Alternatively, quinolones, which have the advantage of convenient oral administration, can be used with acceptable results.[170]

Pseudomonas and Stenotrophomonas   Recent antibiotic therapy is the major risk factor of Pseudomonas peritonitis.[171] Patients with immunosuppression are also at higher risk for Pseudomonas peritonitis.[172,173] If the effluent culture reveals a *Pseudomonas* infection, especially one due to *P. aeruginosa*, the ceftazidime should be continued, and a second antipseudomonal agent should be added to the regimen. In general, IP gentamicin or oral ciprofloxacin are reasonable choices. One needs to look carefully for evidence of catheter infection. Exit site infection and recent antibiotic therapy are associated with poor therapeutic response to antibiotics.[171] When therapeutic response is suboptimal, early catheter removal may help preserve the peritoneum for further peritoneal dialysis. Elective catheter exchange after clear up of PDE may also reduce subsequent relapse.[171]

Stenotrophomonas maltophilia (formerly *Pseudomonas* or *Xanthomonas maltophilia*), a common environmental organism, is the cause of 1.5% of all peritonitis episodes.[174] Recent bacterial peritonitis with broad-spectrum antibiotics therapy was the major risk factor. The outcome was poor with medical treatment alone. Treatment should consist of two antibiotics, such as ceftazidime and cotrimoxazole. However, fungal peritonitis was a common consequence, probably related to the prolonged course of antibiotics.[174] Most, if not

IV, intravenously; *DS*, double strength; *IP*, intraperitoneally. (Modified from Keane WF, Bailie GR, Boeschoten E, et al: Adult peritoneal dialysis-related peritonitis treatment recommendations: 2000 update. Perit Dial Int 2000; 20:396-411.)

all, patients eventually required removal of catheter, either because the effluent failed to clear up or because of secondary peritonitis.

Acinetobacter   *Acinetobacter* is a ubiquitous bacterial species that causes peritonitis when peritoneal host defenses are suppressed from previous peritonitis episodes.[175] As a result, peritonitis due to *Acinetobacter* frequently occurs within a few months of a previous episode of peritonitis due to another organism and is infrequently associated with catheter infection.[175,176] Treatment with ampicillin-sulbactam or imipenem-cilastatin may have a better response rate than the conventional regimen.[175,176] However, relapse peritonitis is common, and change of therapy from PD to hemodialysis is needed in 17% of the cases.[176]

Enteric and Polymicrobial Peritonitis   Polymicrobial peritonitis is a serious complication in peritoneal dialysis patients and is present in 6% to 11% of all peritonitis episodes.[54–57] Traditionally, perforation of internal viscus and underlying gastrointestinal pathology are believed to be the cause, but many cases may be due to touch contamination or catheter infection. Response to antibiotics is excellent when only gram-positive organisms are isolated from dialysis fluid, which accounts for approximately one third of the polymicrobial peritonitis episodes.[57] The presence of fungus, anaerobes, and *Pseudomonas* species in dialysis fluid are independent predictors of poor response to antibiotic therapy. Pooled analysis of four case series[54–57] shows that less than 6% of the polymicrobial peritonitis have a surgical cause. Although it is possible that some of the cases with underlying surgical pathology responded to conservative management and were not identified, the finding suggests that surgical pathology that needs aggressive surgical intervention is uncommon. A careful examination of the organisms isolated may help identify patients who need catheter removal or surgical intervention.

Intra-abdominal abscess is an uncommon complication of PD-related peritonitis, occurring in 0.7% of all peritonitis episodes. Abscess is more common following *P. aeruginosa*, *Candida albicans*, and polymicrobial peritonitis.[177,178] Persistent fever, abdominal tenderness, and peripheral leukocytosis despite antibiotic therapy and catheter removal are all consistent with this diagnosis, which can then be confirmed by CT scan or ultrasonography. The abscesses require drainage.

Fungal Organisms
Fungal peritonitis occurs in patients undergoing PD at the rate of 0.01 to 0.19 episodes per dialysis-year, accounting for 3% to 6% of episodes.[7,179–182] Over 70% of the episodes of fungal peritonitis are caused by *Candida* species.[182, 183] Recent antibiotic therapy, frequent episodes of bacterial peritonitis, and immunosuppression are the major risk factors of fungal peritonitis.[180,184] Patients are often severely ill with marked abdominal tenderness.[183,185,186]

The management approach of fungal peritonitis is outlined in Box 29–1. It is imperative to remove the catheter, if there is no improvement after 4 to 5 days of adequate therapy. The outcome is generally poor, with only 37% patients managed to continue PD.[183] Conversion to long-term hemodialysis is needed in 14% of patients, and mortality is 44%. Many clini-

cians still believe that catheter removal is indicated immediately after identification of a fungal infection by Gram stain or culture.[184,187] In an uncontrolled trial, Goldie and colleagues[180] found that mortality at 1 month was 15% in patients in whom the catheter was removed within a week of diagnosis but 50% in those in whom the catheter was left in place.

Mycobacterium Peritonitis
Tuberculous peritonitis is rarely seen in peritoneal dialysis patients in the Western world, but is more common in Asian countries. Contrary to the common belief, the WBCs in the effluent are predominantly polymorphonuclear cells, and an acid-fast bacilli stain of an effluent specimen is generally negative.[188] Abnormal chest radiograph findings and ascitic fluid lymphocytosis could only identify 33% and 37% of the cases, respectively.[189] Conventional microbiologic diagnostic methods are slow and may not be sensitive enough for establishing a diagnosis in a timely manner. Standard antituberculous chemotherapy is highly effective,[188,189] although ultrafiltration failure may occur, if PD is continued.[190] Advanced age and delayed initiation of therapy are associated with higher mortality rates.[189]

Culture-negative Peritonitis
In approximately 14% to 20% of episodes that meet the criteria for peritonitis on the basis of cell count, culture of the effluent results in no growth of organisms. Most of the culture-negative peritonitis could be explained by recent antibiotic therapy or technical problems during dialysate culture.[191] Placing 5 mL of the effluent into trypticase soy broth-blood culture bottles (aerobic and anaerobic) decreases the rate of negative culture results to 25% compared with a 50-mL centrifugation culture technique, for which the rate is 42%. On the other hand, approximately 75% of patients presenting with peritonitis, when tested for the presence of antibiotics (some taken surreptitiously), have sterile cultures. In cases of no growth, repeated culture of the effluent results in identification of an organism in about one-third of episodes.

The management approach of patients with culture-negative peritonitis is summarized in Table 29–6. Most authorities suggest that if a patient is clinically improving after 4 to 5 days of therapy, and there is no suggestion of gram-negative organisms from Gram stain of the effluent, only cefazolin should be continued. Recent peritonitis and antibiotic therapy are associated

with poor treatment response.[191] Early catheter removal is recommended in this group of patients.

Reassessment After 48 Hours of Therapy

Most patients with PD-related peritonitis show considerable clinical improvement within 2 days of starting antibiotics. Occasionally, symptoms persist beyond 48 to 96 hours. At 96 hours, if a patient has not shown definitive clinical improvement, a reevaluation is essential. Dialysis effluent cell counts, Gram stain, and cultures should be repeated. Antibiotic removal techniques may be used in an attempt to maximize culture yield. Catheter removal should be considered if the response to antibiotic therapy is poor after 96 hours.

One should be aware of the presence of unusual organisms, such as mycobacteria, fungi, or fastidious organisms, which require specific cultures and the potential of surgical disorders. If *S. aureus* and *P. aeruginosa* peritonitis are related to catheter or tunnel infection, catheter removal should be considered.

Special Considerations

Refractory and Relapsing Peritonitis

Refractory peritonitis is generally defined as episodes in which the effluent remains cloudy after 5 days, despite appropriate antibiotic therapy. Recurrent or *relapsing* peritonitis, defined as a second episode of peritonitis with the same organism within 2 to 4 weeks of the end of antibiotic therapy[21] may also be due to catheter biofilm without clinically obvious involvement of the catheter tunnel. Catheter removal should be considered in most cases of refractory peritonitis. Catheter exchange after dialysis effluent clears up is also effective in preventing the relapse of peritonitis.[37,38]

Peritonitis in Patients Undergoing Automated Peritoneal Dialysis (APD)

As in CAPD peritonitis, the majority of APD peritonitis episodes are caused by gram-positive bacteria. In a randomized study comparing continuous cyclic PD (CCPD) with CAPD using a Y-connector, peritonitis rates were lower with the former (0.51 and 0.94 per dialysis year at risk, respectively).[192] Holley and colleagues,[193] using case controls, also found peritonitis rates to be lower in patients undergoing CCPD than in patients undergoing CAPD using Y-connectors (0.3 vs. 0.5 per dialysis year at risk, respectively). Rates may be lower with CCPD because of longer dwell times, which result in improved peritoneal macrophage functioning and opsonic activity, thereby leading to better host defense.[194] Leaving the peritoneal cavity free of fluid during the day time (dry days), as in nocturnal intermittent PD, offers no further improvement in peritoneal macrophage functioning.[195]

The choice of first-line antibiotics in CAPD also applies to APD. In many centers, during peritonitis, APD patients are changed to a CAPD schedule because it is then easier to evaluate the clinical course using standardized procedures for obtaining dialysate for cell count and culture and sensitivity. Furthermore, the recommendations for antibiotic treatment are based mainly on data obtained using CAPD and limited experience in APD.[196] If patients stay on APD, antibiotics can be given continuously or intermittently. Because the bactericidal action of aminoglycosides is dose-dependent, once-daily administration of aminoglycosides is recommended. Vancomycin can be given intermittently because of its unique pharmacokinetic properties. With all other antibiotics, the dose in APD can only be extrapolated from pharmacokinetic studies in CAPD, because no such studies are available in APD patients.

There is a limited report on the clinical outcome of peritonitis in APD patients.[197] Attention should be given to an adequate dwell time of at least 4 hours to allow absorption of antibiotic agents. An interesting option for treatment of peritonitis in APD patients is oral administration of antibiotics. However, pharmacokinetic studies are lacking and this route of administration can therefore be recommended in uncomplicated episodes only due to coagulase-negative *staphylococci*. As with CAPD, adjustments for APD prescription may be needed in patients who experience altered ultrafiltration during episodes of peritonitis.

Peritoneal Lavage

As discussed previously, fresh dialysis solutions have detrimental effect on the local peritoneal defense mechanisms.[198] Rapid-exchange peritoneal lavage is therefore not advisable in the management of peritoneal infection. After two to three in-and-out exchanges that remove inflammatory products and lessen abdominal pain, CAPD should be resumed with usual long-dwell exchanges. Ejlersen and colleagues[199] reported poor outcome in patients treated with 24 hours of initial lavage. Peritoneal lavage, however, is still indicated prior to surgical exploration in cases of fecal peritonitis.

Nevertheless, ultrafiltration problem is common during acute peritonitis because peritoneal permeability is increased during an episode of peritonitis.[200] The dwell time may therefore have to be shortened or the dialysate dextrose level increased. The use of dialysate containing icodextrin in this situation has been shown to improve ultrafiltration.[201]

Catheter Removal

Infections are the cause of catheter removal in approximately 85% of cases.[4] *S. aureus* and *Pseudomonas* species are the common organisms responsible for the greatest catheter loss.[153,171]

It is usually suggested that after an episode of severe peritonitis that requires catheter removal, peritoneal dialysis can be resumed after a minimum of 3 weeks. In a series of 100 CAPD patients with catheter removed for severe peritonitis, catheter was successfully reinserted, and peritoneal dialysis was resumed in 51 cases, and 45 of them required additional dialysis exchanges or hypertonic dialysate to compensate for the loss of solute clearance or ultrafiltration, although there was no significant change in dialysis adequacy or nutritional status.[202] Eleven patients were changed to long-term hemodialysis within 8 months after their return to CAPD. An early assessment of peritoneal function after catheter reinsertion is therefore advisable.[202]

On the other hand, if a catheter is removed for catheter infection or relapsing or recurrent peritonitis with clear effluent, it can be placed simultaneously.[146–148,203] It is critical that the effluent WBC count be less than 200 cells/L before one can proceed with simultaneous removal and replacement of a catheter.[146,204–206] Data suggest that this is feasible procedure that decreases costs and minimizes the use of temporary hemodialysis. If the peritonitis can be transiently cleared, in a patient with relapsing *Pseudomonas* peritonitis, simultaneous removal and replacement of the catheter may be feasible.[171,205] Simultaneous removal and reinsertion of catheters is also a safe and effective method for the treatment of refractory exit site infection.[207] However, this approach is less successful for fungal, which generally requires some time off PD.

Complications

Peritonitis results in a marked increase in effluent protein losses, which may contribute to the protein malnutrition of PD patients.[208–210] More importantly, ultrafiltration problem is common during acute peritonitis because peritoneal permeability is increased during an episode of peritonitis.[200] The pH of the effluent falls, especially in the presence of gram-negative peritonitis, and results in a further impairment of neutrophil activity.[211] These physiologic changes in the peritoneal membrane are usually transient.[209,212] However, after an episode of severe peritonitis, an increase in solute transport and loss of ultrafiltration may occur, resulting in a hyperpermeable membrane and permanent loss of ultrafiltration capability.[202,213] This process is probably proportional to the extent of inflammation and the number of peritonitis episodes.[214]

The final stage of this process is peritoneal fibrosis, sometimes referred to as sclerosing encapsulating peritonitis (SEP).[213,215] SEP is possibly more common in Japan, and the condition is present in 0.9% of patients undergoing PD.[216] The peritonitis rate among patients who experienced SEP was 3.3 times higher than that among the rest of the patients. Peritoneal fibrosis is a severe complication of PD. In addition to ultrafiltration failure, the patient becomes progressively malnourished because of recurrent partial intestinal obstruction from encasement of the bowel. PD cannot be continued, and this complication is frequently lethal, despite conversion to long-term hemodialysis.

CATHETER INFECTIONS

Colonization of the PD catheter exit site with bacteria may lead to infection of the catheter exit site, which may further

Box 29–2   Classification of Exit-Site Appearance in Peritoneal Dialysis

Good
Equivocal
Infected
  • acute
  • chronic

spread along the subcutaneous tunnel of the catheter to the inner cuff and, subsequently, to the peritoneum, resulting in tunnel infection and peritonitis, respectively. Catheter infection generally encompasses both exit site and tunnel infections and occurs at an incidence of around 1 episode per 20 patient-months of treatment. However, reported figures vary considerably because definitions have not been standardized in the literature.[14,217] In general, *S. aureus* and *P. aeruginosa* are the most common, and infection with either of these two organisms is difficult to resolve and commonly results in peritonitis and catheter loss.* However, the prevalence of individual organism varies markedly in different centers. Lye and colleagues[219] reported that 77% of all catheter infections is caused by *S. aureus* and 11% caused by *Pseudomonas* species. In our center in Hong Kong, 46% of all catheter infections is caused by staphylococcal species, 28% caused by *Pseudomonas* species, and 13% caused by other gram-negative bacteria (our unpublished data).

Definitions

An exit site infection is present, if there is purulent discharge at the peritoneal catheter exit site with or without erythema.[220–222] The presence of induration and tenderness indicate poor prognosis.[222] Isolated erythema can represent either skin irritation or an early infection. The classification of catheter exit site appearance is summarized in Box 29–2.[223] The classification of catheter exit site appearance forms the basis of management as presented in a regimen adopted in 1998 by the report of the Committee on Catheter and Exit Site Practices of the International Society of Peritoneal Dialysis (ISPD).[224]

A catheter tunnel infection is defined as the presence of pain, tenderness, erythema, induration, or any combination of these signs and symptoms present over the subcutaneous tunnel of the catheter. Nevertheless, catheter tunnel infections are commonly occult and often only detected by ultrasonography of the subcutaneous catheter tunnel.[26, 227-228] Tunnel infections occasionally occur in the absence of an exit site infection.[26,27,225–227] However, it is present in approximately half of all exit site infections as detected by the use of ultrasonography. The infection can involve the outer-cuff, the inter-cuff, or the inner-cuff of the catheter.[26,27,226–228] As the infection spreads along the tunnel toward the peritoneum, the risk of peritonitis increases.[26,227]

Risk Factors

The major risk factor in *S. aureus* catheter infections is carriage of *S. aureus*.[154,229–231] Approximately 50% of new and prevalent

---

*References 8,27,28,43,204,218.

PD patients are *S. aureus* carriers.[229,230] In approximately one third of them, repeat cultures revealed carriage of the same phage type; in 16%, either only one culture was positive or subsequent culture was positive but showed a change in phage type with time.[230] Patients who were *S. aureus* carriers had significantly higher incidences of *S. aureus* exit site infections, tunnel infections, and peritonitis than patients who were not carriers.[154,229–231]

Intravenous (IV) antibiotics given at the time of catheter insertion reduce infection risk.[4] Tunnel infections are probably more common in diabetic patients.[232] Immunosuppressed patients are at increased risk for catheter infections.[233] A downward-directed catheter exit site is associated with easier-to-treat infections, with fewer episodes of catheter-related peritonitis.[4]

Treatment

The treatment of exit site infections is summarized in Box 29–3 and in Figure 29–2.[218] Intensified local care with chlorhexidine or diluted hydrogen peroxide is often used together with systemic antibiotic therapy.[71,72] Mupirocin or gentamicin ophthalmic solution is sometimes used without concomitant systemic antibiotics for an exit site with an equivocal appearance or when only erythema is present.[224,234,235]

Box 29–3   Treatment Options for Catheter Exit-Site Infection

Intensified local care
Local antibiotics
Systemic antibiotics
Tunnel or cuff revision
Catheter removal

Oral antibiotic therapy for catheter infection should be tailored according to the specific organism identified. *S. aureus* catheter infections are treated with antibiotics, such as penicillinase-resistant penicillin or trimethoprim-sulfamethoxazole.[222,224,236] Exit site care is intensified. Rifampin may have activity within bacterial biofilm and can be used as additional therapy, although it should not be used alone. Oral antibiotics appear to be as efficacious as parenteral agents.[222] In view of the growing concern about vancomycin-resistant enterococci, this agent should not be used to treat exit site or tunnel infections unless the infecting organism is methicillin resistant.[161]

Prolonged antibiotic therapy (over 2 weeks) is often necessary for *S. aureus* catheter infections.[237] Effectiveness of antibiotic therapy for *S. aureus* tunnel infections may be assessed

Figure 29–2 Flow chart for diagnosis and management of exit-site infections. (From Keane WF, Bailie GR, Boeschoten E, et al: Adult peritoneal dialysis-related peritonitis treatment recommendations: 2000 update. Perit Dial Int 2000; 20:396-411.)

and further therapeutic decision guided by repetitive ultrasonography of the tunnel.[233] In a study of deep tunnel infection without peritonitis caused by *S. aureus*,[233] sonographic examination of the tunnel was performed every second week. If the hypoechogenic area around the cuff decreases for 30% or more, conservative treatment with antibiotic therapy had an 85% success rate. In cases without sonographic improvement (less than 30% decrease in the pericatheter fluid collection 2 weeks after therapy), the failure rate for antibiotic therapy was high, and catheter removal is recommended.

Antibiotic therapy is generally prescribed for bacterial colonization or collection around the catheter external cuff. Surgical revision of the exit site and tunnel, with removal of the external cuff and exposure of the infectious portion of the catheter tunnel may be considered.[236,238,239] However, the procedure is associated with a risk of immediate peritonitis and should not be attempted without systemic antibiotics coverage. Revision of the tunnel and exit site is contraindicated, if the deep cuff is involved or if simultaneous peritonitis is present. If the inner cuff is involved with the infection, as demonstrated by ultrasonography of the tunnel, the catheter should be removed because peritonitis is likely to develop within weeks in untreated cases.[26] In addition, if the response to antibiotics is inadequate, it is appropriate to replace the catheter in a single procedure.

PREVENTION

There are several approaches to reduce the risk of peritonitis. First, the risk of touch contamination at the time of the exchange has decreased owing to the improvement in connection technology. Peritonitis rate is improved after the introductions of various disconnect systems.[18–20] The fundamental concept of the disconnect system is "flush-before-fill," which carries with it any contaminating bacteria introduced during connection.[240] Results from the Y-set disconnect systems consistently give lower peritonitis rates than standard spike set.[241,242] Previous study found that Y-set disconnect system was cost-effective and had a lower peritonitis rate as compared to the conventional spike system.[18] Amongst the disconnect systems, double-bag had a better peritonitis rate than Y-set and is better accepted by patients.[19,20] The two systems had similar incidences of exit site infection.

Careful selection of patients and an emphasis on training also diminish the rate of peritonitis secondary to contamination. Prowant[243] outlines the importance of nursing intervention in the prevention of peritonitis. Training by experienced nurses is the key to keep peritonitis rates low. Continued monitoring of peritonitis rates is necessary in a dialysis program so that intervention can be made if peritonitis rates are problematic.[244] Peritonitis rates should be less than 1 episode per 18 patient-months; a higher rate of peritonitis should be followed by a critical appraisal of the pathogenetic organisms and the training program, so that an intervention to reduce rates can be implemented.

Patients with *S. aureus* nasal carriage and all immunosuppressed patients are at high risk for *S. aureus* infections.[159,233,245] The rate of such infections may be reduced with prophylactic antibiotics. Antibiotic prophylaxis with mupirocin applied at the exit site[246] or intranasally[247–249] or with oral rifampin[250] reduces the risk of *S. aureus* catheter infection. The protocol to prevent *S. aureus* infection is outlined in Box 29–4. In general, we prefer mupirocin because rifampin prophylaxis is associated with side effects and may result in resistant organisms.[246–250] Repetitive courses are needed if either intranasal mupirocin or rifampin is used, because recolonization is frequent.[159,248–250] Alternatively, a randomized controlled trial found that a regimen of one single-strength tablet of trimethoprim-sulfamethoxazole on alternate days resulted in fewer staphylococcal peritonitis episodes, especially of those due to *S. aureus*, with the most prominent effect during the first 3 months of therapy.[159] Without prophylaxis, the rates of *S. aureus* exit site infection are about 0.3 to 0.4 episodes per year at risk.[251,252] Prophylaxis reduces the rate to less than 50% of this average.[28,246–250] Long-term use of prophylaxis also reduces *S. aureus* peritonitis secondary to catheter infection.[28,156] However, we have to be aware of the potentials for developing resistance with long-term prophylaxis.

Antibiotics given at the time of catheter insertion have been found to decrease catheter-related peritonitis and catheter infections. In general, single-dose cefazolin immediately before catheter insertion is sufficient. However, Gadallah and colleagues[253] found that single-dose vancomycin is superior to single-dose cefazolin in reducing the risk for postoperative peritonitis, and vancomycin should be considered in high-risk cases. Prophylactic antibiotic therapy with adequate coverage of gram-negative organism is recommended prior to colonoscopy or similar interventions because the procedure can lead to gram-negative peritonitis.

The use of povidone-iodine ointment at the exit site prevents exit site infections during the first 20 weeks of PD. Catheter immobilization, proper location of the exit site, sterile wound care immediately after placement of the catheter, and avoidance of trauma are all preventive measures recommended by most authorities.[254] Downward-pointing exit site locations, suggested as a method of reducing exit site infections, decrease the risk of catheter-related peritonitis.[4,255] Although new catheter designs or modifications have been proposed as a means of reducing peritonitis from catheter insertion, results of clinical trial are largely disappointing. Subcutaneous burying of the distal catheter segment prior to starting PD does not reduce the risk of contracting peritonitis or exit-site infection,[256,257] and delayed use of the catheter may actually be associated with a greater risk of infection.[257] Surface modification of catheters with ion beam implantation of silver produced no clinical effect with respect to reducing dialysis-related infections.[258]

Studies in both children and adults have shown that the risk of *Candida* peritonitis can be reduced with prescription of oral nystatin or fluconazole during antibiotic therapy.[259–262] Patients requiring frequent or prolonged antibiotic therapy benefit from such prophylaxis. Since oral nystatin is safe and

Box 29–4 Protocols to Prevent *Staphylococcus aureus* Infection

Mupirocin	Intranasal application bid for 5 days every month in S. aureus carriers; or Daily at the exit-site as part of routine care
Rifampin	300 mg bid for 5 days every 12 weeks

inexpensive, we advocate routine prescription of oral nystatin during empirical antibiotic treatment for PD-related peritonitis.

The success of peritoneal dialysis depends, in part, to the prevention and treatment of peritoneal dialysis associated infections.[263] The need to prevent and treat the infections also requires resources like cost relating to double-bag system, the prophylactic and the therapeutic antibiotics as well as the cost in removing the catheter, the need to switch to hemodialysis, and the need to reinsert another catheter.[264] With good prevention and treatment of peritoneal dialysis infections, we can help in reducing a lot of patient morbidity and even mortality in relation to the problem.

Metabolic and Noninfectious Complications of Peritoneal Dialysis

Sarah Prichard, M.D., F.R.C.P.C. • Joanne M. Bargman, M.D., F.R.C.P.C.

METABOLIC COMPLICATION OF PERITONEAL DIALYSIS

All renal failure patients face a number of metabolic disturbances that are the result of the uremic condition. These include acid-based abnormalities, disturbances of mineral metabolism, electrolyte imbalances, and nutritional disorders. This chapter focuses on the common systemic metabolic problems that are related specifically to the modality of peritoneal dialysis (PD).

Systemic Metabolic Effects of Glucose Dialysate

Glucose has served as the osmotic agent added to standard peritoneal dialysate since its inception. It has proven to be generally safe, inexpensive, and stable.[1] More recently there have been concerns about its local effect on the peritoneum.[2] Glucose and its degradation products have been implicated in the long-term changes that are seen in the structure and function of the peritoneum in long-standing peritoneal dialysis patients. There has been a search for an alternative to glucose as an osmotic agent since PD was introduced as a chronic therapy. Today amino acids and icodextrin, a glucose polymer, are used in many parts of the world as a glucose alternative in one exchange per day. However, glucose remains the standard osmotic agent in PD fluids in the majority of patients for the majority of their exchanges. Glucose has systemic metabolic effects that need to be understood and treated.[3,4]

Glucose Absorption

Glucose has a molecular weight of 180 and is easily transferred across the peritoneum by diffusion. Given that the normal blood sugar is approximately 5 mmol/L and that the 1.5%, 2.5%, and 4.25% glucose concentrations in PD fluids are approximately 80 mmol/L, 130 mmol/L, and 230 mmol/L, respectively, there is rapid absorption of glucose into the patient.[5] There is variability from patient to patient as to how much of the glucose is absorbed.[6] Based on the standard peritoneal equilibrium test (PET), at 4 hours, the concentration of glucose in the dialysate will have decreased by 20% to 80%.[7] This is usually expressed as a ratio of the concentration of dialysate glucose at the time of drainage (G_4) over its concentration at the time of infusion (G_0) and, together with the dialysate creatinine, serves to characterize a patient as being a rapid or slow transporter. Those who are rapid transporters will be subject to the greatest glucose loading with its positive and negative effects.[8]

The positive aspect of the glucose absorption is its contribution to the nutritional needs of the patients. Each gram of glucose absorbed contributes 4 calories. Thus, if a patient absorbs 50% of the glucose from a 1.5% 2-L bag, he or she will have absorbed 15 g of glucose and 60 calories. Because most patients use a prescription with variable glucose concentrations and, on average, approximately 60% of dialysate glucose is absorbed regardless of the bag used, the caloric intake from the dialysis alone can range from 300 to 800 calories per day. Current recommendations are that PD patients take in 35 calories/kg of body weight per day.[9] Yet many PD patients remain malnourished for a variety of reasons ranging from gastric motility disorders to depression. This dialysate glucose absorption makes an important contribution toward reaching the nutritional goal with respect to caloric intake.

Adverse Effects of Glucose Absorption

Hyperinsulinemia has been implicated as an important risk factor for the development of atherosclerosis.[10] Most all renal failure patients have insulin resistance.[11] Inevitably, insulin levels rise as glucose loading takes place during a PD exchange. Hyperinsulinemia has been suggested as one of the particular risk factors attributable to the renal failure population, who have such a high incidence of cardiovascular morbidity and mortality. Just how important this is as a cardiovascular risk factor remains uncertain. Rosiglitazone appears to improve insulin resistance and to decrease insulin levels in nondiabetic PD patients.[12]

Weight gain is common when patients start peritoneal dialysis.[13,14] Although part of this is attributable to the relief of uremic symptoms and overall improvement in nutritional status, at least part of the weight gain must be attributed to the caloric loading from the dialysate. In PD patients, the weight gain results in significant fat accumulation,[15–17] particularly an accumulation of abdominal fat.[18,19] This fat distribution is implicated as a risk factor for cardiovascular disease and is part of the metabolic syndrome characterized by abdominal obesity, insulin resistance, hyperlipidemia, and endothelial dysfunction. Type II diabetes remains the most common cause of renal failure in most parts of the world, and most of these patients already have the abnormalities associated with the metabolic syndrome. Thus, PD can further exaggerate these metabolic disturbances.[20,21] Recent studies have shown that low carbohydrate diets facilitate weight loss.[22,23] PD patients will always have carbohydrate loading through the dialysate and, therefore, this may impair weight loss as well as contribute to weight gain.

High transporters have been reported to have a worse outcome on PD.[24] These patients will have higher glucose absorption as well as greater protein losses across the peritoneum. Whether the high transporter status simply reflects an underlying higher comorbidity burden, an inflammatory state, or a predisposition to chronic fluid overload, is unknown.[25] A role for the glucose loading in contributing to that worse outcome cannot be excluded.

Studies have repeatedly demonstrated that a high body weight is associated with better, or is neutral with regard to, outcomes for dialysis patients.[13,26–30] This is the opposite to the general population.[31] The explanation for the protective effect of obesity in uremia remains uncertain. It could be that it is simply a marker for good nutrition. Interestingly, there are now studies that show obesity is associated with inflammation and worse outcomes in PD patients.[32,33] Therefore, obesity in PD patients, which, as noted, is abdominal obesity, may predispose them to metabolic changes that increase their risk for cardiovascular events. This remains speculative and is being further investigated.

Some patients who have no history of glucose intolerance will develop hyperglycemia following the initiation of PD. Tight glucose control has been found to reduce diabetic complications and may help to preserve residual renal function. Poor glycemic control at the initiation of dialysis is associated with worse outcomes.[34] Therefore, every effort should be made to keep patients euglycemic. Hyperglycemia needs to be corrected through judicious use of hypertonic PD solutions, diet, and medication. New insulin receptor sensitizing agents have proven to be effective in this regard and significantly reduce the insulin resistance.[12] Some patients require the initiation of hypoglycemic drugs and insulin. Current recommendations are to keep the hemoglobin A1C at less than 7.2% for patients on PD. Insulin therapy, when required, can be administered via a subcutaneous or intraperitoneal route, and some patients use a combination of administration of both routes.[35] Either strategy can result in good glucose control.[36]

PD patients with hyperglycemia are at particular risk for the development of hyperosmolar states. Since the peritoneum allows for sodium sieving, that is, the movement of water in excess of solute into the peritoneal cavity, PD patients will continue to lose water from the extracellular space in spite of hyperosmolality. In this regard, PD patients have the equivalent of an osmotic diuresis even in the absence of renal function. At the same time, their impaired renal function makes them incapable of conserving water. Furthermore, they drink fluids in response to the thirst stimulated by the hyperglycemia, which PD patients then try to remove by using more hypertonic PD solutions, causing more glucose loading, and a vicious cycle follows. It is, therefore, imperative that blood glucose levels be normalized.

All of these negative effects of glucose-based PD solutions have led investigators and clinicians to adopt a glucose sparing strategy in prescribing peritoneal dialysis[37] for patients who are at high risk for the adverse effects of glucose.[38,39] This includes the use of amino acid-based solutions, icodextrin, and minimizing the use of hypertonic glucose exchanges. There is evidence that the lipid profile of patients can be improved when daily amino acid and icodextrin exchanges are used to replace glucose-based exchanges. Insulin levels fall with the use of icodextrin.[40] However, detailed studies on the metabolic advantage of glucose sparing strategies in PD are not yet available.

DYSLIPIDEMIA IN PERITONEAL DIALYSIS

A great deal has been written about the lipid abnormalities found in patients with chronic kidney disease, including those requiring renal replacement therapy.[41,42] This keen interest in the lipid abnormalities arises from the search for treatable risk factors for cardiovascular disease in this population, in whom the rates of cardiovascular death are staggeringly high.

Patients on peritoneal dialysis have a variety of lipid abnormalities.[43–49] Typically, they have high total and low-density lipoprotein (LDL) cholesterol, high triglycerides, low high-density lipoprotein (HDL) cholesterol, high apolipoprotein B (apoB), low apoA-I, and high lipoprotein(a) [Lp(a)] levels. The apolipoprotein E genotype 2/3 is associated with high cholesterol and TG levels in PD patients.[50] Compared with hemodialysis patients, the most striking differences are the high apoB protein and LDL cholesterol levels, which are usually normal in hemodialysis patients.[51] Levels of oxidized LDL and antibodies to oxidized LDL are elevated in end-stage renal disease (ESRD) patients on both PD and hemodialysis.[52]

Intermediate density lipoprotein (IDL) levels are also elevated. These are the lipoprotein particles that are intermediate in size between VLDL and LDL, and an increase in their levels represents the delay in removal of the triglyceride component of the VLDL as it is transformed into the cholesterol ester rich LDL. These abnormalities are summarized in Table 30–1.

This lipid/lipoprotein profile of peritoneal dialysis is markedly atherogenic. The LDL particles are small and dense, indicated by the high apoB protein levels with modest elevations of LDL cholesterol.[47,53] Small, dense LDL particles are particularly atherogenic in that they cross the endothelium with greater ease and are oxidized more readily than larger LDL particles.

The pathogenesis of the overproduction of LDL particles in peritoneal dialysis remains obscure. Hypoalbuminemia secondary to peritoneal protein loss may partly contribute to the abnormality. In this regard, PD patients can be considered similar to patients with nephrotic syndrome. Studies using HepG2 cells, a cell line derived from hepatomas, suggest that low amino acid levels might also contribute to overproduction of the apolipoprotein B hepatic derived VLDL, which

Table 30–1   Lipid Abnormalities in End-Stage Renal Disease

Factor	PD	HD
Total cholesterol		↑	normal
LDL cholesterol		↑	normal
HDL cholesterol	↓	↓
Triglycerides	↑↑	↑
Apo A1 protein	↓	↓
Apo B protein	↑↑		normal
Lp(a)	↑↑	↑↑
LDL oxidation	↑	↑

PD, peritoneal dialysis; *HD,* hemodialysis; *LDL,* low-density lipoprotein; *HDL,* high-density lipoprotein; *Lp(a),* lipoprotein(a).

would account for the high LDL levels because LDL is derived from VLDL.[54,55] However, a randomized, controlled trial using a single daily amino acid exchange did not improve the lipid profile.[56] More recently, the use of an icodextrin to substitute for a glucose-based exchange did result in an improved lipid profile.[39] This implies that glucose loading may contribute to the dyslipidemia. Glucose can exacerbate hypertriglyceridemia in glucose intolerant patients. One study has reported that the use of amino acid dialysate increased homocysteine levels.[57] Therefore, the use of the new nonglucose-based solutions to modify the cardiovascular risk profile of patients cannot yet be strongly advocated.[58]

The high level of IDL is attributed to the overproduction of VLDL and to defective function of lipoprotein lipase. The low HDL levels seen in PD patients is also poorly understood, but the loss of HDL across the peritoneum may be a contributing factor.[59] High Lp(a) levels have been associated with malnutrition and inflammatory states and may simply be part of the overall inflammatory response, similar to the other observed elevations of acute phase reactants.

The hypertriglyceridemia (hyperTg) seen in peritoneal dialysis results from the overproduction of VLDLs and a deficiency in lipoprotein lipase. There may also be a partial deficiency of hepatic lipase. The pathogenesis of these abnormalities is not understood, but the use of glucose-based peritoneal dialysis solutions and a variety of drugs, such as β-blockers, aggravate the problem. The usual level of triglycerides seen in peritoneal dialysis patients is 220 to 400 mg/dL (2.5–4.5 mmol/ L), but levels greater than 530 mg/dL (6 mmol/L) are not unusual.

Compared with hemodialysis patients, PD patients have a more obviously atherogenic lipid profile. The importance of these abnormalities as a cardiovascular risk factor in renal failure patients remains uncertain. There are no clinical studies to demonstrate the efficacy of treating dyslipidemias in dialysis patients with respect to improving cardiovascular outcomes in PD patients. Furthermore, in many studies that have analyzed risk factors for cardiovascular disease in dialysis patients, lipids have often not been shown to confer significant risk in this population. The explanation for this difference in the role of lipids as a risk factor in renal failure patients compared to the general population in whom it is a very powerful risk factor, remains unclear. Perhaps other factors, such as inflammatory states,[60–64] abnormalities of mineral metabolism, and preexisting comorbidities, have such a powerful impact on outcome that the lipid profiles fail to emerge as significant. At least one study has linked coronary artery calcification with abnormal lipid profiles.[65] This implies that there could be an interaction or facilitation for calcification when dyslipidemia exists. Alternatively, since almost all dialysis patients have lipid abnormalities, it may not be a discriminating risk factor in this population.

In spite of this lack of data, guidelines from the International Society for Peritoneal Dialysis[66] and from the National Kidney Foundation Dialysis Outcomes Quality Initiative[67] (K/DOQI) recommend treating lipid abnormalities in all renal failure patients. The recommendations for treatment follow the same targets for therapy that are currently applied to patients in the general population who have known coronary artery disease. Thus, it has been the best judgment of experts that, notwithstanding a lack of clear evidence, and given the extraordinarily high rate of cardiovascular morbidity and mortality in renal failure patients, this patient population be regarded as having equivalent risk to someone with established coronary artery disease.

Treatment for PD patients with lipid abnormalities is usually successful in reaching the set targets for therapy. Although dietary and weight management is a strategy that can be applied to all patients, it has limitations in PD patients. Achieving adequate nutrition can be a challenge for all PD patients, and adding dietary restrictions for purposes of lipid management may compromise the patient's ability to achieve the daily nutritional goals that are recommended. Daily exercise and achieving optimal body weight might be desirable, but the patient's general condition can preclude an active exercise program, and weight loss plans could compromise the patient's nutritional status. Therefore, medications are the mainstay of lipid management in the PD population. Specifically, HMG Co-A reductase inhibitors (statins) are recommended as first-line drugs.[67] They have proven to be both safe and effective in studies of dialysis patients, including PD patients.[68] As in the general population, the most common side effects are muscle pain, elevations of creatine kinase, and, rarely, abnormalities of liver enzymes. Severe rhabdomyolysis is a rare but serious complication. It is recommended that the relevant muscle and liver enzymes be followed after a patient is started on a statin. However, only a small percentage of patients have enzyme abnormalities severe enough to warrant discontinuing the drug.

Fibrates as a class of drugs should be used with caution in renal failure.[67] They are excreted by the kidneys and dose adjustment is required. The combination of a statin and a fibrate is not recommended in dialysis patients.

Ezetimibe is the first of a new class of drug that blocks the absorption of cholesterol in the small intestine.[69] It usually lowers LDL cholesterol levels by approximately 20%. The drug has been reported to be safe in renal failure patients and might be a good option for patients who are intolerant of statins or for those who are unsuccessful in achieving the therapeutic target with statins alone.

Sevelamer, a noncalcium-based phosphate binder, has also been shown to reduce LDL and total cholesterol levels in hemodialysis patients by 20% on average.[70,71] Although no recommendation has been made to use sevelamer for the purpose of managing the lipid abnormalities found in dialysis patients, its lipid-lowering effect is a side effect of the drug that helps patients to achieve the therapeutic goal for their cholesterol.

Finally, with regard to the dialysis itself, the use of nonglucose-based dialysate has been shown to improve the lipid profile. Icodextrin, in particular, may have an advantage in this regard.[39]

PROTEIN LOSS

PD patients have lower serum albumin and total protein levels than hemodialysis patients, with typical values being 3.3 to 3.6 g/dL in PD patients. This is, at least in part, related to significant loss of protein across the peritoneum.[72] The loss is about 0.5 g/L of dialysate protien but can be higher and account for as much as 10 to 20 g/day in patients who are high transporters.[73–75] The major component of the

protein losses is albumin, but immunoglobulin G (IgG) accounts for up to 15%.

Protein losses are greatest in high and high-average transporters. Amino acid losses of approximately 3 to 4 g/day also occur. Acute peritoneal inflammation, as seen in peritonitis, is associated with substantially greater protein losses, and a rapid reduction in serum albumin is common during episodes of peritonitis. Unresolving peritonitis is associated with protracted and exaggerated protein losses causing protein malnutrition. The protein loss itself sometimes becomes an indication to terminate peritoneal dialysis temporarily or, on occasion, permanently. In addition, inasmuch as peritoneal dialysis may help preserve residual renal function,[76] in patients with nephrotic syndrome, this preserved renal function may be at the cost of ongoing protein losses. Therefore, measurements of both peritoneal and urinary protein losses need to be evaluated in peritoneal dialysis patients, and appropriate dietary adjustments should be made.

Low serum albumin levels should not be attributed solely to protein loss in the dialysate and urine. Poor nutrition can occur because of persistent uremic symptoms due to under dialysis, gastroparesis, or other gastrointestinal pathologies,[77] depression, side effects of medications, and even limited financial resources to buy appropriate food.[78] Additionally, inflammatory states of known or unknown etiology are associated with low serum albumin levels.[79,80] Thus, a thorough evaluation of all PD patients is needed to appropriately assess the cause of low total serum protein and albumin levels.

Overall prognosis for PD patients is linked to hypoalbuminemia.[81] But the linkage between inflammatory conditions, as reflected by high C-reactive protein and Il-6 levels and hypoalbuminemia can make it difficult to ascertain how much of the low albumin level is actually due to the peritoneal losses.[82–84] There is also a linkage of markers of malnutrition to elevated homocysteine levels Lp(a) and other risk factors for cardiovascular disease.[85,86]

Amino acid dialysate was developed to serve as a nutritional supplement in response to the known protein losses of PD.[87–90] A 1.1% amino acid dialysate contains 22 g of amino acids and has an osmolality of 345 mmol/L, which is similar to a 1.5% glucose bag. It has proven to be safe and stable. Between 70% and 90% of the amino acids are absorbed in a 6-hour dwell. In a study of 20 patients, an average of 17.6 g of amino acids were absorbed with each 2-L exchange of 1.1% amino acid dialysate.[87] These patients went into positive nitrogen balance, but markers of improved nutritional status, such as serum albumin levels, did not significantly improve. Subsequent studies have failed to give convincing data to support the efficacy of amino acid based dialysate as an effective therapy for malnutrition in PD patients.[91] Amino acid dialysate has been found to reduce leptin levels, but the clinical significance of this is unclear.[92] New interest in amino acid solutions is now focused on its glucose sparing effect.

Patients with advanced liver disease and ascites have particularly large protein losses on PD. In spite of this concern, there are several series of such patients that report very successful use of PD as renal replacement therapy.[93] The dietary counseling of these patients should include consideration for the extra protein losses, but this should not preclude the use of PD, if the patient is otherwise suitable for PD. The caloric loading of glucose from the dialysate may be of special benefit to these challenging patients with advanced liver disease.

HYPONATREMIA/HYPERNATREMIA

Standard peritoneal dialysis solutions contain 132 mmol/L of sodium. Most patients maintain a normal serum sodium on peritoneal dialysis. With a better understanding of peritoneal physiology, we can now better account for observed changes in serum sodium in certain situations.[94–99] During an exchange, the dialysate sodium concentration falls early in the exchange as water moves across the endothelial aquaporin channels.[100] Sodium then moves into the peritoneum across the small pores, by diffusion. This dissociation of water and sodium movement across the peritoneal membrane accounts for the sodium sieving that has been observed since PD was started as a therapy.[101]

Hyponatremia

Patients who are excessive water drinkers can get a dilutional hyponatremia if the water intake exceeds the total water loss. The water losses in PD patients will be the sum of insensible losses, urinary free water clearance, and dialysate water losses. Insensible losses will vary according to the patient's losses through sweating, changes in body temperature, and respiratory losses. In this regard, PD patients are no different from the general population. In contrast, with loss of renal function, the ability to generate significant urinary free water loss is usually lost. The urine of patients with advanced renal failure is usually close to that of plasma. The water loss from dialysate occurs through the water channels and will increase with more hypertonic exchanges because the hypertonicity stimulates aquaporin function. But this water loss is a function of the peritoneal water channels and does not vary with water loading from diet. Therefore, even with the usual ongoing water losses, PD patients can become hyponatremic, if water intake is too large.

The use of icodextrin is associated with a small reduction in serum sodium levels.[102,103] In patients with marked hyperglycemia, hyponatremia can be seen as a result of water shifting into the extracellular fluid. Typically, the serum sodium falls about 1.3 mmol/L for each 100 mg/dL (5.6 mmol/L) rise in blood glucose. Finally, severe hyper Tg can also give hyponatremia, which is classified as factitious because it is caused by a reduction in the amount of water per liter of plasma rather than a true reduction of sodium per unit of plasma water.

Hypernatremia

With rapid ultrafiltration using hypertonic solutions, hypernatremia may occur due to the sieving effect of the peritoneal membrane on sodium. This is most pronounced in slower transporters, in whom the transfer of water across the ultrasmall pores, or aquaporin channels, remains in tact but the diffusion of sodium across the small and larger pores is relatively slow due to a reduction in the effective peritoneal surface area. Therefore, patients on frequent, short,

hypertonic exchanges can become hypernatremic. Some authors have advocated a lower dialysate sodium concentration in hypertonic (4.25%) bags to enhance sodium removal by diffusion.

This same phenomenon accounts for the observation that some patients who change from CAPD to APD have a significant reduction in sodium removal across the peritoneum in spite of adequate fluid removal.[104] These patients maintain a good ultrafiltration volume, but because of the sodium sieving, the ultrafiltrate will be relatively hypotonic.

Correcting this problem requires that the exchanges be lengthened to allow sufficient time for sodium diffusion to take place.

HYPOKALEMIA/HYPERKALEMIA

Standard peritoneal dialysis solution contains no potassium. Potassium is removed during peritoneal dialysis by diffusion and convection; after a 4- to 6-hour exchange, the dialysate potassium level is slightly lower than plasma. As ultrafiltration increases, so will the removal of potassium. Total potassium losses through dialysis closely relate to total sodium losses.[105] For patients draining 10 L of dialysate daily, potassium loss through the dialysis would be 35 to 50 mmol/day, depending on the serum potassium level. Residual renal function may allow the further output of 10 to 30 mmol of potassium per day. These renal and peritoneal outputs of potassium are insufficient to account for the usual 80 mmol of potassium intake in most patients. Yet most patients maintain a normal serum potassium.[106] It is concluded, therefore, that in renal failure, gastrointestinal secretion of potassium is enhanced.[107]

Usually, only patients who are noncompliant in performing their dialysis exchanges or who have excessive potassium intake have ongoing problems with hyperkalemia. Medications, such as β-blockers and ACE inhibitors, may exaggerate the problem. Treatment of hyperkalemia in a PD patient is similar to HD and includes dietary counseling, increased dialysis, medication changes, and, occasionally, the addition of potassium binders. In acute renal failure treated with PD, hyperkalemia has been reported.[108]

Hypokalemia is reported in 10% to 30% of CAPD patients.[109] Occasionally, it is profound when associated with vomiting and diarrhea.[110] However, most cases are associated with poor nutritional intake, and most can be managed by liberalizing the diet. Increased bowel losses and the intracellular shift of potassium may also play a role. The high intracellular muscle content of potassium observed in PD patients supports this latter mechanism.[111]

The abnormal potassium metabolism of end-stage renal disease has been implicated in the high level of cardiac morbidity and mortality, and treatment is recommended.[112] Persistent levels lower than 3 mmol/L should be managed with potassium supplementation. For patients on digoxin, potassium levels are recommended to be kept above 3.5 mmol/L. Potassium chloride can be added to the dialysate, if necessary, but the risk of errors and infection make this option less attractive than oral supplementation for patients at home. Patients in a hospital setting, in whom intensive PD is being prescribed and oral intake is reduced, may benefit from adding the KCl to the dialysate, usually 2 to 4 mmol/L, but

higher levels can be used when appropriate. In a case report, 20 mmol/L of KCl was added and the rate of increase in the serum potassium was 0.44 mmol/L over 2 to 3 hours.[113] The toxicity of high intraperitoneal potassium levels is unknown, and its use should be reserved for the short-term treatment of an urgent situation.

HYPOCALCEMIA/HYPERCALCEMIA

Peritoneal dialysis solutions are available with 2.5 mEq/L (1.25 mmol/L) or 3.5 mEq/L (1.75 mmol/L) calcium.[114–116] The standard solution is now considered to be the 2.5 mmol/L calcium solution.

Calcium balance with regard to the dialysis itself depends on the patient's serum calcium level, the dialysate calcium concentration, and the rate of ultrafiltration.[117–125] At the end of a 6-hour exchange, the dialysate calcium concentration is close to that of plasma. Given that the normal serum ultrafiltrable calcium is 1.12 to 1.33 mmol/L, when a 1.75 mmol/L bag is used, there will be a net gain of calcium by the patient. In the absence of ultrafiltration, the patient gains approximately 30 mg of calcium. With a large ultrafiltration, there can be a negative balance for calcium. However, over the course of a day, most patients will use a mix of hypertonic and less hypertonic exchanges, and the total calcium balance with respect to the dialysis, using the 1.75 mmol/L dialysate, will be positive. When this is added to the calcium absorbed from calcium-based phosphate binders, the net calcium balance can be positive by as much as 400 to 700 mg/day.[126] In contrast, the 1.25 mmol/L calcium solution will give neutral calcium balance in the absence of ultrafiltration. The larger the volume of drainage, the greater the output of calcium through the dialysis.[127,128] The net effect is that, on most exchanges with any degree of ultrafiltration, the 1.25 mmol/L calcium solution will put the patients in slightly negative balance for calcium with respect to the dialysis itself.[90] There are increases in serum PTH levels reported with the use of the low calcium solutions, which may be beneficial to patients with low turnover bone disease.[129,130] However, most patients remain in neutral or positive balance overall for calcium, using the 1.25 mmol/L calcium dialysate because of the high oral intake of calcium from diet and calcium-based phosphate binders. As concerns increase with regard to the risks of hyperphosphatemia,[131] phosphate binders, most commonly calcium-based phosphate binders, are prescribed in almost all dialysis patients. This likely accounts for the observation that hypercalcemia is frequent in PD and that the most common form of bone disease seen in PD patients is low turnover bone disease, with low PTH levels, which is unrelated to aluminum toxicity.[132]

Currently, there are concerns about widespread vascular and valvular calcification in dialysis patients, including PD patients.[133–137] This is often associated with other markers of inflammation and lipid abnormalities, although it is unclear whether the calcification is causal or secondary to the inflammation.[65] Because of these issues, the K/DOQI guidelines for bone metabolism and disease recommend the use of the physiologic 1.25 mmol/L calcium PD dialysate as the appropriate first-line solution for almost all PD patients.[138] Although sevelamer has not been studied in PD patients, its effect to reduce

the progression of vascular calcification in hemodialysis patients has also led to its use in the PD population.[70] When noncalcium-based phosphate binders are not used in a PD patient, and the 1.25 mmol/L dialysate is used, the patients will often be in negative calcium balance, depending on the dietary intake of calcium. PTH rises when sevelamer replaces calcium-based binders in PD patients with low turnover bone disease.[139]

Hypocalcemia

Hypocalcemia is not common in patients initiating dialysis treatment because of the widespread use of calcium-based phosphate binders and vitamin D. When it does occur, it can be managed with calcium and vitamin D supplements and, when necessary, the use of 1.75 mmol/L calcium dialysate. This high-calcium dialysate brings about a net positive transfer of calcium to all patients except those with continuous high ultrafiltration. Patients using the higher calcium dialysate should be monitored for hypercalcemia and decreasing PTH levels. If either occur, they should be switched to the lower 1.25 mmol/L calcium solution.

There are a few case reports of hypocalcemia post parathyroidectomy, which were managed by the addition of calcium to the peritoneal dialysate.[140]

Hypercalcemia

Hypercalcemia is common in peritoneal dialysis patients, which, together with low PTH levels and low turnover bone disease, requires a strategy to correct the problem. It is usually the result of large doses of calcium supplements being used as phosphate binders and/or from inappropriate use of vitamin D and/or dialysis using the higher calcium dialysate. The use of the lower calcium dialysate, noncalcium-based phosphate binders, and the discontinuation of vitamin D supplementation are required in this situation. Recommendations in this regard are reviewed in the K/DOQI guidelines on bone disease, calcium, and phosphate.[138]

Peritoneal dialysis has occasionally been used in the treatment of severe hypercalcemia, using either the commercially available 1.25 mmol/L solution or a locally prepared calcium-free dialysate.[141–144]

ELEVATED SERUM LACTATE

The usual base in peritoneal dialysis solutions is lactate. The lactate is metabolized by the liver to bicarbonate. Under most circumstances, the liver's ability to metabolize lactate easily exceeds the daily delivery of lactate. However, patients on oral hypoglycemic agents (metformin and related compounds), with advanced liver disease, and with thiamine deficiency may not have sufficient reserve to handle the lactate load of peritoneal dialysis, and a lactic acidosis may ensue. In patients with ongoing lactic acidosis, as in patients with acute hepatic failure or other conditions seen in the intensive care setting, the addition of lactate-containing peritoneal dialysis solutions may exacerbate the problem. In such cases, bicarbonate-based solutions should be used. These are commercially available in many countries but may be locally prepared if necessary. See the chapter on PD

solutions for a full discussion on the use of bicarbonate-based solutions.

NONINFECTIOUS COMPLICATIONS OF PERITONEAL DIALYSIS

Peritoneal dialysis is a home-based therapy that lends the patient autonomy to manage most aspects of treatment. It is evident to those who care for these patients that this modality of dialysis is underappreciated and underused in many parts of the world. There are many reasons for this, but part of the problem may be unfamiliarity or even discomfort with the unique complications that can occur in association with peritoneal dialysis.

The purpose of this chapter is to discuss some problems that can be encountered with the use of peritoneal dialysis. Some, like hernias, are common and not usually serious; others, like encapsulating peritoneal sclerosis, are very rare but result in marked morbidity and mortality for the patient. It is crucial that those who look after patients on peritoneal dialysis be familiar with the diagnosis and management of these noninfectious complications.

Hemoperitoneum

Bloody peritoneal dialysate, or hemoperitoneum, is an occasional complication of peritoneal dialysis that can be very distressing to the patient. Many of the causes of intraperitoneal bleeding occur also in individuals not on PD but remain clinically unnoticed. However, since peritoneal dialysis offers a "window" into the peritoneal cavity, the bleeding is detectable because it appears as a bloody effluent. So, for example, the intraperitoneal bleeding associated with menstruation probably occurs very frequently but is routinely seen only in the menstruating woman on peritoneal dialysis.

Causes of hemoperitoneum can be divided into those that likely occur routinely but remain undetected, such as menstruation, and those related to the peritoneal dialysis procedure itself and would not otherwise occur if the patient were not on PD. An example of the latter cause would be the traumatic laceration of an intraperitoneal blood vessel by the peritoneal dialysis catheter. Another way of subdividing the causes of hemoperitoneum is the benign versus more sinister causes of bleeding.

A recent review of recurrent hemoperitoneum reported that 46 of 549 (8.4%) of PD patients had at least one episode of hemoperitoneum during their time on PD, and half of these patients had recurrent episodes.[145] An earlier study found a similar incidence: 26 of 424 (6.1%) patients on peritoneal dialysis had one or more episodes of this complication.[146] Looked at another way, hemoperitoneum was temporally associated with the menses in over half of menstruating women on peritoneal dialysis.[147,148]

The majority of episodes of bloody dialysis effluent are indeed the result of menstruation.[145,146] There are two ways that menses can lead to blood in the peritoneal cavity. In the case of retrograde menstruation, the uterine blood is expelled not only through the cervix, but also with uterine contraction, retrogradely through the Fallopian tubes, which open into the peritoneal cavity. Therefore, intraperitoneal bleeding may occur regularly in this way and becomes obvious in the patient

routinely draining intraperitoneal fluid as part of dialysis. Another possible cause for hemoperitoneum is studding of the intraperitoneal cavity, a known site for endometriosis, with ectopic endometrial tissue. The endometrial tissue sheds at the same time, under the same hormonal influence, as the intrauterine endometrium as part of the menstrual cycle. This could be a situation analogous to the cyclic pulmonary bleeding seen when ectopic endometrium is deposited in the lungs or pleura.[149]

Although the majority of episodes of hemoperitoneum are associated with menstruation, there are many other causes reported in the literature (see Table 30–2). It is clear that in the nonmenstruating individual other causes should be sought, and some of these may be serious.

Although there seems to be little in the way of long-term sequelae to hemoperitoneum, a more immediate worry is that the intraperitoneal blood may coagulate in and around the intraperitoneal portion of the dialysis catheter and lead to its obstruction. Although this appears to be an uncommon complication, it is recommended that heparin be instilled in the peritoneal fluid for as long as blood or fibrin is visible. The administration of anticoagulation in the setting of bleeding may sound counterintuitive, but the heparin does not exacerbate the bleeding of the most common causes, menstruation and ovulation. With other causes, the risk of heparinization worsening the bleeding would have to be weighed against the risk of the blood clotting inside the PD catheter, jeopardizing the whole PD process. In addition, since a negligible amount of heparin administered by this route is absorbed systemically, it is safe to give in patients in whom systemic anticoagulation is contraindicated. However, little is known about the use of intraperitoneal heparin in a patient with heparin-induced thrombocytopenia (HIT). In the absence of any evidence, it is best to avoid heparin in these patients because of the possibility that IP heparin may serve as an antigenic stimulus and a

Table 30–2   Causes of Hemoperitoneum other than Menstruation

Cause or Disease	Reference
Rupture of the liver	150
Rupture of the spleen	151–153
Hepatocellular carcinoma and other liver tumors	154–157
Insertion of the PD catheter	158, 159
Acute systemic cytomegalovirus (CMV) infection	160
Bleeding diathesis/systemic anticoagulation	153
Colonic perforation as presentation of dialysis-associated amyloidosis	161
Retroperitoneal hematoma	162
Post-pericardiocentesis	163
Polycystic kidney or liver disease	164
Renal cell carcinoma	164
Ruptured ovarian cysts	166
Ovulation	147
Encapsulating peritoneal sclerosis (sclerosing peritonitis)	148
Spontaneous hematoma of iliopsoas muscle	167
Collagen vascular disease	160
Tuberous sclerosis	168

source of ongoing production of antibodies directed against that protein.

At the first appearance of bloody effluent, the patient should undertake a flush of the peritoneal cavity, which may be helpful in some instances to clear the blood and blood products. If it is not uncomfortable, the patient could also try infusing unwarmed dialysate, at room temperature. Because the temperature of the dialysis fluid is cooler than core body temperature, the consequent vasospasm may stop the source of the bleeding.[169] This maneuver would be particularly helpful in cases of hemoperitoneum from trauma induced by the PD catheter. This is analogous to patients who have blood in the peritoneal cavity at the end of PD catheter insertion, where flushing may be important to ensure the patency of the catheter.[159]

It is important to warn females of menstrual age that they may see bloody effluent at the time of ovulation or menstruation. The amount of blood loss is usually insignificant, but it can make the liters of fluid in the drain bag appear overtly bloody, falsely magnifying the amount of blood loss.

The diagnostic approach to the patient who presents with hemoperitoneum depends on the clinical setting. In a menstruating female, there is no need to undertake an extensive investigation, if the patient is otherwise well. However, if the bloody effluent is unassociated with menses, then investigation should include at least an abdominal ultrasound, which can screen for pathology of several of the implicated organs, including liver, spleen, and kidneys. The coagulation profile should be checked, along with the hemoglobin concentration, although hemoperitoneum infrequently leads to serious blood loss. As shown in the table, hemoperitoneum may be the first presentation of encapsulating peritoneal sclerosis, and this should be kept in mind, if bleeding occurs with no other explanation in the long-term PD patient.

Follow-up studies in patients who have experienced one or many episodes of hemoperitoneum suggest that the presence of the blood does not act as a growth medium for bacteria, leading to peritonitis.[145] Furthermore, the blood itself does not appear to compromise the integrity of the peritoneum or the ability to continue peritoneal dialysis.[145,170]

ENCAPSULATING PERITONEAL SCLEROSIS

Encapsulating peritoneal sclerosis (EPS) is one of the most dreaded complications of peritoneal dialysis. It was previously referred to as sclerosing encapsulating peritonitis (SEP), but given its chronic, noninflammatory characteristics, it less resembles "peritonitis" than a progressive sclerosing condition.

Literature on this condition is difficult to reconcile, given the inherent rarity of this complication, the differing rates of incidence in different countries, and a lack of uniformity in defining what constitutes the EPS syndrome.

The "classic" syndrome occurs in a long-term peritoneal dialysis patient and may be temporally associated with a severe case of bacterial peritonitis, especially if this has necessitated PD catheter removal and transfer to hemodialysis. In this classic scenario, some time afterward, the patient develops nonspecific complaints of anorexia and abdominal discomfort, which then progresses to malnutrition and recurrent

episodes of small bowel or, less commonly, large bowel obstruction. Radiographic imaging typically shows thickened peritoneal membrane binding down or encapsulating loops of bowel. If laparotomy is undertaken, a thick cocoon of fibrous tissue can often be seen overlying and binding down underlying bowel.

In the case of the syndrome outlined previously, the diagnosis is straightforward, although if the patient has been changed to hemodialysis for awhile, the connection of symptoms to a complication of peritoneal dialysis may not be obvious. The patient may develop hemoperitoneum as in the case of the PD patient, but this would not be detected unless paracentesis is undertaken.[171] It is possible, therefore, that the incidence of EPS is underestimated, if the diagnosis is not considered in former PD patients who have been transplanted or transferred to hemodialysis. On the other hand, this condition can also be overestimated. For example, a thickened or even calcified peritoneal membrane[172,173] does not in itself constitute a diagnosis of EPS. Labeling long-term PD patients with anatomic changes in the peritoneal membrane as suffering from EPS will necessarily overestimate the incidence. These uncertainties must be kept in mind when discussing this condition.

Much of the literature on EPS comes from Japan, where, as a result of the low rate of renal transplantation, patients who undertake peritoneal dialysis tend to stay on this modality for a long time. A recent analysis from Japan[174] has shown that the incidence of EPS in patients on PD for less than 5 years is 0.3%, for 5 to 10 years is 4.5%, and rises to 7.1% in those who have been on this dialysis modality for more than 10 years. Similar values have been reported from Australia.[175] Given that patients in other countries tend to not stay on PD for as long as they do in Japan, these results are consistent with reports of a 0.5% to 1.5% prevalence elsewhere.[176–179]

Identified risk factors for the development of EPS include long duration of PD, an initial rapid transporter state, the use of more hypertonic glucose dialysate (which could be consequent to the rapid transporter status and unrelated to the development of EPS), and severe or recurrent episodes of peritonitis.[171] When this syndrome was first described, putative risk factors also included the use of acetate, instead of lactate, as the buffer in dialysis fluid, and spraying the catheter connection device with antiseptics such as chlorhexidine.[180,181] However, even though both of these practices have been discontinued, EPS continues to complicate peritoneal dialysis. Since the β-blocker practolol was withdrawn from patient use because of the development of retroperitoneal fibrosis,[182] inquiry has been made into a possible association between the use of β-blockers in general and the development of EPS.[183] Once again, however, given the rarity of this complication, it is difficult to pinpoint epidemiologic links. The observation that high transporters may be more prone to develop EPS suggests that subclinical inflammation may predispose to this complication. Interestingly, in one large center, the only two patients who developed EPS both had active systemic lupus erythematosus, which can lead to peritoneal inflammation as part of the polyserositis seen in this condition.[177] Perhaps EPS is the result of a "two hit" model, where the peritoneum is primed by one risk factor (such as long-term PD, serositis, β-blockade), but the disease is set off by another factor, such as an episode of peritonitis.

The clinical presentation of established disease has been outlined earlier. Certainly the onset of recurrent bowel obstruction in a patient on PD, or formerly on PD, should suggest the possibility of EPS. Investigators in Japan have suggested that there may be an earlier, more inflammatory stage, where there is a window of opportunity to better treat and, perhaps, reverse this complication. The earlier inflammatory stage is reported to be characterized by fever, increased C-reactive protein levels, and episodes of abdominal ileus.[184] If the patient is no longer on peritoneal dialysis, abdominal ascites may be noted.[183,171] It had been suggested previously that the acquisition of a "slow transporter" state coincident with poor ultrafiltration (type II ultrafiltration failure) may herald this complication, but this has not been a general observation.

Computer tomographic (CT) images of the abdomen reveal a thickened, dense peritoneal membrane that binds down loops of bowel. There may be air-fluid levels consistent with associated bowel obstruction.[185,186] The presence of intraperitoneal fluid in a patient no longer on PD may also be consistent with this diagnosis but is not the same condition as the poorly-understood "post peritoneal dialysis ascites" syndrome, which is usually not associated with disturbances of bowel motility and gradually resolves without specific treatment. It is important to note that the isolated finding of a thickened or calcified peritoneal membrane, in the absence of symptoms, also does not make a diagnosis of EPS. Many long-term PD patients will have these anatomic changes in the peritoneal membrane without any sequelae. Some reports suggest that on ultrasound there is a distinct trilaminar appearance to the membrane, with a lucent zone sandwiched between two more dense layers.[185]

Pathologic findings are perhaps what would be expected from the description earlier. The peritoneal membrane is densely fibrotic, with little in the way of active inflammation.[187] The fibrosis may encroach into the bowel wall itself [188] or extend transmurally.[189] Foci of calcification, and even ossification may be found.[188]

Treatment is difficult, and there is a high mortality rate. In the early inflammatory state, if it is recognized, pulse corticosteroids have been recommended.[184] This may be a difficult decision to make in the subclinical stage, because high dose corticosteroid therapy is not without risk. Further, it isn't clear which patient is going to proceed to the more established syndrome.

In established disease, therapy is based on three approaches, alone or in combination:

- Nutritional support, including parenteral feeding
- Anti-inflammatory and antifibrotic medication
- Emergent or planned surgical intervention

Much of the high mortality rate is the result of progressive malnutrition. Therefore, careful attention has to be paid to nutritional supplementation through the use of pureed feeds or other easily digested supplements. In those patients in whom enteral nutrition has become impossible, total parenteral nutrition is another option. Frequently, these patients have been converted already to hemodialysis, and therefore have vascular access. Intrahemodialytic parenteral nutrition can be administered, although a regimen of 4 hours thrice weekly may be too intermittent to effect a significant improvement in nutritional status,[190] and the patient may need ongoing total parenteral nutrition.[184,191] There has been a

long-standing interest in the use of anti-inflammatory or immunosuppressive medications, such as corticosteroids and azathioprine, for treatment of this disorder.[192–194] Reports of treatment remain anecdotal, however. It is reasonable to conclude that corticosteroids are likely more effective in any earlier, inflammatory stage of the disease, rather than when the sclerosis and fibrosis are well established. In the latter case, there are reports of the use of antifibrotic medications. Tamoxifen, better known for its role in treating breast cancer, has antifibrotic properties. There are case reports of the use of tamoxifen in EPS[195] with benefit. The antifibrotic and immunosuppressive agent colchicine has also been reported to be helpful in one patient.[196] The antirejection drug sirolimus also has antifibrotic properties and has been advocated as a treatment for EPS[197] but, again, the rarity of this condition, and the variation in definition and outcome parameters make these claims difficult to assess.

Surgical intervention in the emergent setting is usually done for unremitting obstruction or secondary bowel perforation. The mortality rate is extremely high when surgery is done for these reasons. More attention, however, is being paid to planned surgical intervention with careful adhesiolysis and enterolysis. Careful release of intestinal loops, reexposing peritoneal surface area (neoperitonization), and avoiding primary anastomosis in the case of enterectomy, appears to be associated with a good outcome in a subset of patients.[184,198,199] Bowel perforation must be avoided at all costs, as it is associated with an early septic death.[184]

A basic question, which remains unanswered, is whether the patient, when first diagnosed, should be intentionally left on peritoneal dialysis to keep the loops of bowel "afloat," or whether it is best to change the patient to hemodialysis. Clearly, if the peritoneal dialysis is not working, then the patient must necessarily change to hemodialysis, although one could keep the peritoneal catheter in situ to periodically flush out the peritoneal cavity. On the other hand, change to hemodialysis and keeping the peritoneal membrane empty of fluid will allow the (inflamed?) loops of bowel to be in close contact with each other, and perhaps that is how a cocoon of fibrosis is able to encapsulate the loops of bowel. There are reports of good outcome in changing patients with EPS to hemodialysis,[199] but the decision must be weighed against the risk of accelerating the process with a dry abdomen.

COMPLICATIONS OF PD-RELATED INCREASED INTRA-ABDOMINAL PRESSURE

The instillation of dialysis fluid into the peritoneal cavity leads to increased pressure within this cavity. Patients new to PD will often comment on this sensation of tightness and raised intra-abdominal pressure. The pressure effects have been studied by introducing a pressure transducer into the peritoneal dialysis system.[200,201] Factors that increase the intra-abdominal pressure include increasing volume of dialysis fluid, increased body mass index, and the sitting and standing position compared to the supine position. Furthermore, coughing, straining at stool, and lifting weights are all associated with increases in the pressure. Indeed, coughing and straining at stool are associated with very high pressures for the duration of those activities.[200] These observations are important in managing complications in PD related to raised intra-abdominal pressure. These pressures can be reduced by having the patient assume the supine position during dialysis and by the use of smaller dwell volumes.

Hydrothorax in Peritoneal Dialysis

An interesting, but uncommon, complication of peritoneal dialysis is movement of dialysate from the peritoneal to the pleural cavity resulting in a pleural effusion composed of peritoneal dialysis fluid. This complication is referred to as *hydrothorax.* It shares much in common with "hepatic hydrothorax," where ascitic fluid migrates across the hemidiaphragm into the pleural space.

A recent review of 10 major series reporting hydrothorax between 1978 and 2002 found that the incidence of this complication ranged between 1.0% and 5.1%, with an average of 1.9%.[202] It is possible that some patients have a chronic mild hydrothorax that does not come to clinical attention, and so the incidence may be even higher.

The commonest presentation is shortness of breath, commensurate with a large pleural effusion. Rarely, we have seen patients complain of some chest discomfort. In the asymptomatic patients, the pleural effusion may be found incidentally during radiography or CT scanning done for some other reason. Other causes of pleural effusion, such as pulmonary embolism, tuberculosis, or congestive heart failure, need to be considered. However, since hydrothorax usually occurs soon after commencing peritoneal dialysis, the clinical presentation should suggest itself. Since many dialysis patients who are short of breath have fluid overload and congestive heart failure, the inclination may be to use more hypertonic dialysate to increase ultrafiltration. However, in the case of hydrothorax, increased ultrafiltration will increase intraperitoneal volume and pressure. This may encourage even more dialysis fluid to migrate across the hemidiaphragm, worsening, rather than improving, the symptoms. Therefore, the worsening of breathlessness with the use of hypertonic dialysate should suggest the possibility of dialysis-associated hydrothorax.

Sometimes hydrothorax does not occur at the beginning of peritoneal dialysis, but months to years later. It has been observed that hydrothorax can develop at the time of peritonitis, suggesting that defects in the diaphragm may somehow be exacerbated by the intraperitoneal infection.[203,204] A transient increase in intra-abdominal pressure can also predispose to acute hydrothorax. This phenomenon has been reported after a fit of coughing[205] or with the use of abdominal corsets.[206] A patient on peritoneal dialysis who fell and broke two left ribs developed hydrothorax on the left side, wherein it was postulated that the flail ribs tore diaphragmatic muscle fibers, allowing a conduit for the dialysate to enter the pleural space.[207] Patients with polycystic kidney disease may also be more at risk for hydrothorax.[208] One explanation is that the large kidneys occupy more space in the abdominal cavity, thereby leading to increased intra-abdominal pressure. Another possibility is that defects in the hemidiaphragm are more examples of the multiple defects in connective tissue seen in this disorder.

Interestingly, most series report a female predominance with hydrothorax.[208–213] The exception is reported from a large collaborative study in Japan, where the majority (54%) of the 50 patients with hydrothorax were male. However, the

sex distribution of the PD population as a whole was not given, so that the 46% who were female may have still been a relative overrepresentation.[214] The reason for the predominance of females is unexplained, although stretching of the diaphragm as a result of previous pregnancy has been suggested.[203]

The dialysis fluid must traverse the hemidiaphragm to enter the pleural cavity. The pathway is felt to consist of congenital or acquired defects in the structure of the diaphragm. During development, pleuroperitoneal membranes form to separate the thoracic from the abdominal cavity, and myoblasts populate the membranes to form the muscular component of the diaphragm. Defects in this process, perhaps combined with raised abdominal pressure, can lead to gaps and herniations of this structure.[215] Autopsy studies have demonstrated discontinuities in the tendinous portions of the hemidiaphragms, and absence of the normal muscle fibers, which have been replaced by a disordered collagen network.[203,216] In some instances the weaker diaphragmatic tissue balloons into the pleural space, resulting in "blebs" that can be detected on inspection at surgery or thoracoscopy. In other instances these blebs have appeared to broken open completely, leaving a pathway of free communication across the hemidiaphragm between the peritoneal and pleural space.[216] Because of the higher intraperitoneal pressure, fluid will move along the pressure gradient from the intraperitoneal to intrapleural space, but a valve effect may stop the fluid from moving in the opposite direction. Others have suggested that the movement of fluid and particulate matter from the peritoneal to pleural space may occur through diaphragmatic lymphatics rather than discrete interruptions in the hemidiaphragm.[217] If the lymphatics contribute to this complication, however, it is likely in only a minority of cases.

Another interesting feature of the hydrothorax associated with peritoneal dialysis is that it is almost always on the right side. This is also seen in hepatic hydrothorax[215] and in ectopic endometriosis syndromes. Indeed, a review of thoracic endometriosis demonstrated that the pulmonary complications occurred in the right lung in more than 90% of cases.[149] Explanations include the observation that the right hemidiaphragm is more vulnerable to embryologic variation; that the heart and pericardium cover much of the left hemidiaphragm and so protect against the development of free communication between the peritoneal and pleural cavities; and that the solid fixed liver acts as a piston across the right side, whereas the increased mobility of the left subphrenic organs minimize spikes in pressure on that side.[218] Peritoneal dialysate has also been found in the pericardial space under extraordinary circumstances. In one case the patient had an indwelling pigtail catheter in the pericardial space for drainage of a pericardial effusion presumed secondary to uremic pericarditis. Pericardial fluid reaccumulated with the characteristics of PD fluid, and it was felt that the catheter had been the connection between the peritoneal and pericardial spaces.[219] In another patient whose pericardium had been disrupted for aortic valve surgery, massive pericardial effusion, composed of dialysate, developed.[220]

The diagnosis is straightforward when the patient, usually female, presents with sudden onset of shortness of breath at the initiation of peritoneal dialysis and chest X-ray shows a right-sided pleural effusion. As mentioned earlier, other causes of pleural effusion should be considered, especially if it is left-sided or in a clinical setting different from the one described. Hydrothorax from peritoneal dialysate can be usually confirmed by thoracentesis or imaging studies.

Thoracentesis is not only helpful for diagnosis but can be very effective to rapidly improve the dyspnea. The withdrawn fluid should have the characteristics of the dialysis fluid and so should be transudative. The LDH levels and white blood cell count are low. Because the glucose concentration in conventional peritoneal dialysis fluid is very high, in most instances the pleural fluid in the hydrothorax will be similarly elevated. Therefore, the finding of markedly elevated glucose concentration above blood glucose is virtually diagnostic of dialysate hydrothorax and obviates the need for further diagnostic study. However, if the fluid has been left in the pleural cavity for many hours, it is possible that the glucose can diffuse out of the pleural cavity along its concentration gradient, in which case the fluid may have a falsely normal glucose concentration. In other words, a very high glucose rules in the diagnosis of hydrothorax, but a normal glucose concentration does not rule it out. A recent study has suggested that if the pleural fluid glucose concentration is at least 50 mg/dL (2.8 mmol/L) higher than simultaneous blood glucose, then the pleural fluid is composed of peritoneal dialysate.[212] However, there have been subsequent reports where the glucose gradient was less than 50 mg/dL.[213]

Diagnostic and therapeutic thoracentesis is perhaps the most efficient way to confirm dialysis hydrothorax and relieve symptoms with one maneuver. In some instances, however, it may not be feasible to perform thoracentesis. Examples include an anticoagulated patient, a small pleural effusion that may not be amenable to drainage, or multiple comorbid conditions. In the case that thoracentesis is not done, there are other studies, which can document movement of dialysate from peritoneal to pleural cavity.

It has been previously recommended to instill a dye, such as methylene blue, into the peritoneal cavity, and then subsequently sample the pleural fluid to detect a blue coloration.[221] This technique should be used with caution. First, methylene blue can act as a chemical irritant to the peritoneum, causing additional discomfort to what is already a source of distress to the patient.[222,223] Second, there are many false negatives with this procedure, where, despite a leak, no obvious blue color appears in the pleural fluid.[213,224]

Peritoneal scintigraphy involves the instillation of radiolabel along with dialysate into the peritoneum. Examples of radiolabel include Technetium-99m macroaggregated human albumin,[225] and Technetium-99m sulphur colloid.[226–229] The macroaggregated albumin is larger than sulphur colloid and, theoretically, may more easily demonstrate the large defects felt to be responsible for the leakage across the diaphragm. However, one form has not been found to be uniformly superior to the other. Doses of radioisotope have ranged from 0.5 to 10 mCi. Subsequent scanning with a gamma camera can then locate radioactivity extending above the diaphragm, thereby demonstrating the peritoneal-pleural communication. There appears to be variability in the time it takes for the radioligand to cross the diaphragm, likely related to the size and patency of the diaphragmatic defect. It is recommended that the patient ambulate after instillation of the dialysate and label to increase the intra-abdominal pressure and facilitate the efflux of the dialysate from the peritoneal cavity.

Magnetic resonance imaging can be used to detect abnormal movement of dialysate. It has been used without gadolinium to detect dialysate leaks.[230] It has been used in hepatic hydrothorax where the diaphragmatic defect was detected as a hypodense jet flow across the diaphragm.[231]

If there is significant dyspnea and no contraindication to the procedure, thoracentesis should be done for relief of symptoms and for pleural fluid analysis. As mentioned above, a high glucose concentration in the pleural fluid may obviate the need for further investigation. The peritoneal dialysis should be discontinued immediately. If the patient has just started on dialysis and has significant residual renal function, there may be no need for urgent initiation of hemodialysis, and management of the hydrothorax can be undertaken.

There are a number of approaches to management of hydrothorax. Generally, the prevention of recurrence mandates either specific closure of the defects in the hemidiaphragm, which are allowing the movement of the dialysate into the pleural space, obliteration of the pleural space itself (pleurodesis), or dialysis under conditions of low intra-abdominal pressure so that there is not enough of a transdiaphragmatic pressure gradient to promote the flux of dialysate out of the peritoneal cavity.

Sometimes a rechallenge of the peritoneal dialysis, after a temporary hiatus from PD, can be done without recurrence.[232,233] The interruption of PD should be for at least 2 weeks, ideally even longer. The absence of recurrence may be the result of sclerosis of any defects as a result of the effect of the hyperosmolar, acidic dialysate on the pleural lining. A recent review of outcome studies of hydrothorax suggested that more than half of patients with hydrothorax have been able to resume PD successfully after a period of temporary discontinuation and rechallenge.[202] This seems somewhat high, but it does speak to the value of a trial of temporary discontinuation and subsequent rechallenge of PD as a first step in the management algorithm.

Because increased intra-abdominal pressure plays a role in movement of the dialysate from peritoneal to pleural cavity, sometimes dialysis under conditions of lower intra-abdominal pressure can be carried out without recurrence.[234] Lower intra-abdominal pressure can be attained by the use of a smaller dwell volume of dialysate with the patient in the supine position, such as in automated peritoneal dialysis.

The use of more aggressive interventions depends, of course, on how intent the patient is to pursue PD, and/or the availability of hemodialysis as an alternative option for renal replacement therapy. Conventional pleurodesis agents have been used successfully to effect pleurodesis for dialysis-related hydrothorax. These include talc,[213,235,236] autologous blood,[237–240] mechanical rubbing of the pleura,[234] bleomycin, tetracycline,[209,210] and, less frequently, fibrin glue,[241,242] N-CWS (*Nocardia rubra* cell wall skeleton),[214] and the hemolytic streptococcal preparation OK-432.[214] The effectiveness of one agent over the other is not clear. Autologous blood appears to be less painful than, for example, talc or tetracycline, but may require more than one instillation to effect pleurodesis. Some studies use thoracoscopy, either video-assisted (VATS) or conventional, to perform the pleurodesis. It is best to seek consultation from a thoracic surgeon who has experience in pleurodesis, and use the agent with which the surgeon feels most comfortable. In review of the literature, a closed chemical pleurodesis is

not as effective as one with a chest drain and pleural visualization.[202] There have been no reported cases of pleurodesis agents leaking from pleural to peritoneal cavity and leading to, for example, peritoneal sclerosis.

Another option is surgical or VATS intervention to visualize the defects in the hemidiaphragm and close them directly. These can be closed by clipping,[243,244] suturing[242] and reinforcement with Teflon patches,[245,246] surgical stapling, and spraying of the surface with fibrin glue.[247]

It is important, in anticipation of a surgical or VATS intervention, to warn the surgeon or VATS operator that methylene blue is irritating to the peritoneum, and so should be avoided as a method to try to visualize the diaphragmatic blebs or locate the source of leak across the diaphragm. If a dye is to be used, indocyanine green is reported to be less irritating than methylene blue. Also, any dye instilled with dialysate into the peritoneal cavity can become too diluted to be detected, and so produce a "false negative" test for visual detection of a leak.[213]

It is unclear what the success rate is for the interventional procedures, because there is likely a bias to report successful results. Overall, there is roughly a 50% success rate. A review of the outcome studies in the literature concluded that results were even better in males, in those with a diagnosis other than polycystic kidney disease, and in late leaks (>30 days after catheter insertion).[202] The rate of successful return to PD will also be dictated by the necessity to perform peritoneal dialysis and the availability of hemodialysis as an alternative.

Hernias

The increased intra-abdominal pressure, which results from the instillation of dialysis fluid into the peritoneal cavity, can lead to new defects or unmasking of occult defects in the supporting structures of the abdominal wall. One consequence is the development of hernias.

Most studies suggest that between 10% and 20% of PD patients will develop a hernia some time on that modality,[248–250] although a recent study found that 25% of patients developed a hernia, for an incidence rate of 0.08/patient/year.[251] The detection rate may be affected by how vigorously the diagnosis is pursued with the use of radiography and other investigations.

Many different kinds and locations of hernias have been described in PD patients. The most common type of hernia is umbilical. Herniation can occur through the inguinal canal, where both direct and indirect hernias can occur. Other hernias described include ventral hernias, those at the catheter insertion site, or at the incision from some previous surgery (Figure 30–1). Less commonly-encountered hernias include epigastric hernias, cystocele or rectocele,[252] Spigelian,[253] paraesophageal hernia presenting as a mediastinal mass,[254] and herniation through the foramen of Morgagni.[255]

The most common presentation is of a lump or a bulge at the site in question. The PD patient will usually bring this to clinical attention. The relationship to the increased intra-abdominal pressure is highlighted by the observation that many of these patients will notice a lump or a swelling on the abdomen after a bout of physical exertion or coughing. Less frequently, and particularly in an obese patient, the lump or bulge may not be clinically obvious, but the patient may report a vague discomfort in the area.

Figure 30-1 Ventral abdominal hernia.

Because a hernia can be associated with a defect in the integrity of the peritoneum, it may be associated with leak of dialysis fluid into the anterior abdominal wall. Therefore, the patient can present with abdominal wall edema (discussed later) or diminished dialysis effluent return, in association with a clinically occult hernia. Finally, a hernia can be a site of bowel incarceration and strangulation, with the strangulated bowel serving as a source of peritonitis, particularly with multiple enteric organisms. Rarely then, the first presentation of a hernia can be with this kind of peritonitis as a result of an undiagnosed hernia, which has incarcerated and then strangulated the involved bowel.[256]

It was originally observed that patients who are at risk for hernias include those with higher body mass index, because these patients will have higher intra-abdominal pressure for a given dwell volume.[200] Other studies have found the opposite result, namely that it is smaller patients who have the greater risk for hernias, when the height and weight are adjusted for sex.[250,257]

The relationship of dwell volume to the size of the patient may be a factor, and small patients may be more malnourished with less tissue strength, which may predispose to hernia. The insertion of the PD catheter through a midline abdominal incision is associated with risk of hernia development[258] because this is an area lacking in anatomic support. This practice has been avoided for many years and a paramedian approach is recommended.[259] Other risk factors for hernia development include older age, multiparity, and previous laparotomy or hernia repair.[260] Given the reduction in intra-abdominal pressure in the supine position, it is not surprising that patients ambulatory with CAPD are more at risk for this complication than those supine on cycler dialysis.[261]

Polycystic kidney disease (PKD) is also a risk for the development of hernias through multiple mechanisms. First, indirect inguinal hernias as a result of patent processus vaginalis has been encountered frequently in PKD males on PD, and it has been suggested that patent processus vaginalis may be another complication of this condition.[262] If the kidneys are massively enlarged, they may encroach upon the peritoneal space, so that a given volume of dialysate has less room to dwell and increases the pressure therein. A recent review of abdominal wall complications in PD patients found that PKD was the only factor significantly associated with the development of hernias,[251] although this finding has not been universal.[257,263]

One of the ways to increase clearance on PD is through the use of larger dwell volumes. There has been concern that the routine use of larger volumes may be associated with an increased risk of hernia. Although this concern has not been borne out in the literature,[249,257,261] there is a relationship between higher volumes and intra-abdominal pressure. This relationship should be kept in mind when prescribing dwell volumes, and the size of the patient should be taken into consideration. The volume-pressure curve is blunted by assuming the supine posture, so this is less of a problem in the APD patient (at least for the supine dwells at night), then in a patient who is on CAPD. In a patient who is at risk for hernia, or who perhaps has had a recent hernia repair, an optimum regimen might include night cycler with more normal volumes, but the use of smaller dwell volumes during the day, when activities will lead to an increase in pressure in the abdomen. Furthermore, if patients are anticipating an activity that could increase the pressure, such as an exercise class, they should be instructed to use a minimal volume of dialysate, or no dialysate at all, for the duration of the strenuous activity.

The diagnosis of hernia is usually straightforward. For example, a patient who reports being active and then feeling a "pop" in the groin and now has an inguinal mass is very consistent with an inguinal hernia. However, particularly in the obese patient, the diagnosis may not be as obvious. Further, a lump around the catheter exit site or tunnel could be a hernia, a collection of dialysis fluid from a leak, or infection. Therefore, there are ancillary tests to diagnose or confirm the hernia.

CT scanning can be helpful. The diagnostic utility is improved by the use of intraperitoneal dye. Depending on the volume of dialysate used, 100 to 150 mL of dye should be instilled into the peritoneal fluid and this fluid infused into the peritoneal cavity.[264–267] It is important that after this infusion the patient be ambulatory for some time (30 to 60 minutes) before going for CT examination. This ambulatory time will allow for the dye to distribute within the peritoneal fluid and, under the increased intra-abdominal pressure associated with being ambulatory, should allow the dye-labeled dialysate to enter the hernia sac and any potential area of leak. Placing the patient in the prone position for scanning is another way to increase the abdominal pressure.[268] It is also of benefit to speak to the radiologist about this study. In a center with a small PD population, this kind of study is uncommon, and so the radiologist may not be familiar with the dialysate and what exactly is happening with the patient. Most of the instilled dye will be removed from the patient when the dialysis fluid is drained, but a small amount may be absorbed systemically because sometimes a slight nephrogram effect will be reported.

A similar study can be done without dye. Radionuclide imaging using technetium-labelled tin or sulphur colloid, is an alternative method to investigate hernias and leaks. Subsequent scanning by gamma camera can then track the movement of dialysate, such as through the inguinal canal as a result of indirect inguinal hernia.[269–274] As with the CT studies, it is important for the patients to raise the intra-abdominal pressure for the labeled dialysate to move into the hernia sac. In suspected indirect inguinal hernia, the patient may

be instructed to lean forward in the sitting position to increase the pressure in the abdomen.

Patients on peritoneal dialysis who develop a hernia should undergo laparoscopic or operative repair. Most patients find hernias to be unsightly and request that they be repaired. In addition to cosmetic considerations, hernias pose a risk for bowel incarceration and strangulation. As mentioned earlier, this can be the first presentation of a previously-undiagnosed hernia. It is the smaller hernias, with smaller orifices, in which bowel can get caught, that pose the greater risk of incarceration, compared with large ventral hernias. Given their prevalence and size, umbilical hernias are most frequently associated with these bowel complications.[248] A patient with a hernia awaiting repair should be reminded that they should always be able to manually reduce the hernia. If the hernia becomes irreducible, and especially if it becomes tender, the patient should report to the hospital as soon as possible. The third problem with hernias is that they represent a break in the integrity of the peritoneal membrane and, therefore, pose a source for dialysate leak, as discussed later. For these three reasons, most PD patients with hernias should undergo repair.

The repair is undertaken by conventional surgical techniques. The patient should be drained of dialysate before the surgery. The management of dialysis requirements around the surgery depends on the residual renal function. If the patient has about 3 mL/min residual glomerular filtration rate (the mean of a 24-hr urine urea and creatinine clearance) or more and is without significant comorbidity, such as a Grade IV left ventricle, then the patient can carry out the usual dialysis up until the day of surgery. Postoperatively, the patient should not recommence PD for at least 1 or 2 days.[275] The use of a mesh repair may allow for the faster return to PD.[275–277] Again, depending on the residual kidney function, the patient may need additional diuretics or dietary salt and potassium restriction during the time without dialysis, although oral intake during this postoperative time is usually not so much in any case. Dialysis should be gradually restarted under conditions of low intra-abdominal pressure, that is, small volumes and performed in the supine position. This is done so that a sudden increase in abdominal pressure does not threaten the repair. If the patient uses a home cycler, dialysis can be performed with small volume exchanges overnight, leaving the patient dry during the day. If the patient uses CAPD, 1 L exchanges can be used four or five times daily. While this is less than the usually accepted dose of dialysis, it should have little consequence in the face of residual renal function and for a short period of time. It is well to remember that the risk of "under-dialysis" has to be weighed against the risk of insertion of a temporary hemodialysis line and the hemodialysis procedure itself. On the other hand, if the patient is anuric and has multiple comorbid conditions, recommencing suboptimal dialysis could have deleterious consequences. Caution has to be taken about reducing the dialysis, especially the ultrafiltration, for any length of time. In this case, consideration may have to be given to a transient move to hemodialysis until the repair is healed. If the patient has significant comorbidity, another option is to forego the hernia repair altogether. In this instance, the patient should be warned about incarceration, but the hernia itself could just be observed, if it is not a source of leak.

Abdominal Wall and Genital Leaks

Under the influence of increased intra-abdominal pressure, dialysis fluid can leak out of the peritoneal cavity into other sites. Movement of dialysis fluid across the hemidiaphragm, leading to PD hydrothorax, has been discussed elsewhere in this chapter. Dialysate can also move into the abdominal wall, leading to abdominal wall edema, and into the genitalia.

In order to facilitate movement of the dialysate, there needs to be some pathway of low resistance through which the dialysate moves. In the case of the abdominal wall, the defects include the incisional site for the insertion of the PD catheter, at least until that has healed, the catheter tunnel and exit site, and other congenital or acquired defects, including hernias.

Genital edema can occur in two ways. The processus vaginalis is a connection from the peritoneal cavity into the scrotum or labia. It is through the processus vaginalis that the testes migrate into the scrotal sac. Normally, but not inevitably, the canal then obliterates. If the processus vaginalis remains patent, it can serve as a conduit between the peritoneal cavity and the scrotum or labia. If bowel or omentum migrates along the patent processus vaginalis, an indirect inguinal hernia can result. If fluid moves along the same path, the result is a hydrocele. Therefore, in the face of a patent processus vaginalis, dialysis fluid, under increased intra-abdominal pressure, can move into the scrotum or labia[278] leading to genital edema. This may or may not be accompanied by an indirect inguinal hernia.

The other defect that can result in genital edema is in the abdominal wall. If sufficient fluid traverses the defect, the dialysate can then migrate caudally by gravity and collect along the mons pubis or penis.

The patient is usually the first to notice abdominal wall or genital edema and will seek attention for it. Sometimes a patient may notice only that the abdomen has become more protuberant or asymmetric. Even less often, the presenting complaint is that of diminished effluent return and weight gain. In this instance, it is not the result of ultrafiltration problems, but rather that the fluid is moving into another compartment and so is not available for drainage through the PD catheter.

In the case of scrotal or labial edema, the diagnosis should be apparent. Local processes should be considered, such as epididymitis, but the scrotal swelling from leak is usually not as tender as that associated with acute local inflammation. On examination, an associated indirect inguinal hernia should be looked for, although it may be better discerned by CT scanning (see later text). In the case of abdominal wall edema or complaint of a protuberant abdomen, careful examination should be made with the patient standing. In the standing position, it is easier to see any obvious asymmetry, such as a bulging flank or a protuberance on the abdomen. In the supine position, the abdomen should be palpated for any fascial defects that may be allowing the passage of dialysate out of the peritoneal cavity. The abdominal wall often has a distinctive appearance when it is edematous. It truly looks somewhat "puffy," and the usual indentations made by the waistband of underpants or the catheter itself lying across the wall look deeper than normal.

A less common site of leakage is through the vagina. The peritoneal cavity reflects over the vaginal vault, and a defect in that location can leak to movement of dialysate

through the vagina itself. Thankfully this is an uncommon event.[279–281] A pathway for communication should be suspected not only if there is a new complaint of clear vaginal "discharge," but also if there is peritonitis with a vaginal organism, such as *lactobacillus*.

Radionuclide scanning and CT scans are very helpful in the diagnosis. In the case of scrotal or labial edema, 3 to 10 mCi of technetium-labeled ligand or 100 to 150 mL of CT dye can be infused into the peritoneal cavity with the usual volume of dialysate. The patient should be instructed to move around to raise the intra-abdominal pressure. The subsequent scanning, if positive, will demonstrate movement of dialysate through a patent processus vaginalis into the scrotum or labia.[282] On CT scanning sometimes contents of a hernia are also seen in the processus vaginalis.[283] This information can be helpful if surgical intervention is being planned.

The same studies can be used for abdominal wall edema. There is experience with CT scanning[264,267,268,284] and isotopic scanning[269,272–274,285] for this condition. In this case the study can confirm that the edema is indeed the result of leakage of dialysate (now labeled with dye) and sometimes even demonstrate the site of the leak, such as a fascial defect or occult hernia. There is recent experience with magnetic resonance (MR) scanning, with and without[230] the use of gadolinium. Interestingly, one report on the use of MR scanning, using the dialysate as its own "tracer," demonstrated more extensive spread of dialysate through the surrounding tissue than what is usually detected with conventional CT peritoneography.[230] Ultrasound examination of the anterior abdominal wall can sometimes detect a fluid collection and may serve as a reasonable initial test.[286]

Since both abdominal wall and genital leaks are the result of some combination of increased intra-abdominal pressure and a low-resistance pathway for movement of peritoneal dialysate, the approach to management should address both these risk factors. First, if there is sufficient residual renal function, it is not automatic that the patient has to immediately be managed by hemodialysis. Often these leaks occur early on, and there is adequate renal function so that the dialysis dose can be adjusted and manipulated without worry of under-dialysis. The patient should be dialyzed under conditions of lower intra-abdominal pressure. This can be effected by having most, if not all, of the dialysis done while the patient is in the supine position by cycler dialysis. For example, the patient can be converted to nocturnal intermittent peritoneal dialysis (NIPD) with 1.5 or 2.0 L exchanges and be without dialysate during the daytime. This dialysis regimen is satisfactory in the face of kidney function but is not really a good long-term solution, because NIPD is not an ideal form of peritoneal dialysis when the patient eventually loses renal function. Sometimes a small day volume can be used without recurrence of edema, such as 1 L after coming off the cycler, and then a 1 L mid-day exchange. The CAPD patient can have smaller dwell volumes compensated for by more frequent exchanges. A suggested regimen is 1.5 L, five times a day. Again, this is not a satisfactory long-term solution, but it keeps the intra-abdominal pressure low and minimizes the recurrence of edema while other strategies to address the potential anatomic defect are considered.

Sometimes leak is the result of some abdominal tear, which can heal spontaneously. In this scenario NIPD for 2 weeks can be associated with spontaneous resolution of the leak without any other kind of intervention.[264,284,287] This conservative approach works better for early leaks, which may be related to incomplete healing of the surgery for catheter insertion.[287] There are a few reports of infiltration of a leak around the PD catheter with fibrin glue.[288] In the case of established hernias or patent processus vaginalis, it is likely that the leaks will recur unless more definitive surgical correction is undertaken. In the case of leak through the catheter exit site, a trial of NIPD is worthwhile, but if the leak recurs catheter replacement may be necessary.[289] It is important to discuss any leaks with the surgeon or laparoscopist to ensure that the peritoneal entry site is well-sealed with purse-string sutures to minimize leak.

There is a risk of developing peritonitis, if the leak occurs to the external surface. It has been recommended that prophylactic antibiotics be given for the duration of the leak[146] to minimize this risk.

In the case of surgical repair of leak secondary to hernia or patent processus vaginalis, the same postoperative principles apply as to repair of hernias, discussed earlier. If there is residual renal function (GFR >3 mL/min), the patient can usually miss dialysis for 2 to 3 days postoperatively and then recommence PD under conditions of lower intra-abdominal pressure, that is, smaller dwell volumes and the use of the supine position. In the case of the CAPD patient, 1 L exchanges can be done four or five times daily. Although this will transiently cause the patient to be relatively under-dialyzed and lead to increase in the concentration of creatinine and other dialyzable solutes, the long-term sequelae are likely unimportant and must be balanced against the risk of insertion of a temporary hemodialysis catheter. However, if the patient is likely to have a prolonged healing time (elderly patient or prolonged use of corticosteroids, as in the case of past renal transplant) and has borderline or no renal function, temporary hemodialysis may be required.

MALFUNCTION OF THE PERITONEAL DIALYSIS CATHETER

Malfunction of the peritoneal dialysis catheter, which usually occurs soon after the insertion of the catheter, remains one of the most dissatisfying aspects of starting a patient on PD. Oftentimes the patient has only recently learned that he or she has kidney failure, chooses home dialysis, undertakes the insertion of the catheter, only to find out that the catheter is not draining well. This complication will delay the instruction in home dialysis and is the source of much frustration. Further, unless the personnel involved have experience with sorting out the catheter complications, the easier option is to "default" to hemodialysis.

Catheter drainage problems include:

- "Two-way obstruction," that is, poor inflow and poor outflow
- "One-way obstruction," usually satisfactory inflow but poor outflow
- Pain associated with either inflow or outflow

The combination of poor inflow and poor outflow is not as common as poor outflow alone. The "two-way obstruction" is usually the result of some obstruction in the lumen of the catheter or a kink in the catheter that similarly will obstruct flow bidirectionally.[291] Material that has caused intraluminal

obstruction includes blood clots, fibrin strands,[292] and, more rarely, fungus balls, stones, and cryoglobulins.[293] Very rarely, the ovarian fimbriae and related structures have been reported to block the intraperitoneal portion of the catheter.[294–297] If two-way obstruction is found, particularly soon after implantation of the PD catheter, the catheter should be flushed under high pressure with a syringe of heparinized saline.[298] Both vigorous flushing and aspiration should be attempted.[299] A brush to clean the lumen has also been used.[300,301] If that maneuver is unsuccessful, the catheter lumen can be filled with more heparinized saline, urokinase,[302–304] or tissue plasminogen activator (tPA) for a couple of hours, to try to effect thrombolysis of the occluding material.[305,306] If the catheter is still obstructed, consideration should be given to instilling dye through the catheter to determine whether there is indeed an intraluminal occlusion or whether the catheter itself is kinked. At the same radiologic sitting, the occlusion or kink can be treated by the intraluminal insertion of a rigid trochar, to either dislodge the occluding material or to attempt to straighten out the kink.

In the case of satisfactory inflow but poor outflow, the usual cause is obstruction around the holes in the intraperitoneal portion of the dialysis catheter. With inflow, the flow pressure pushes the obstruction away from these holes, so inflow proceeds normally, or perhaps just a little more slowly than normal. However, with the suction effect of the outflow, the obstructing material is sucked closer to the catheter, impeding the outflow of the effluent from the peritoneal cavity into the catheter. Causes of this kind of obstruction include constipation, with stool-filled colon taking up much intraperitoneal space and impinging on the catheter surface; wrapping of omentum and *appendices epiploicae* around the intraluminal portion of the catheter[307]; or catheter migration into the upper quadrants, where the draining holes may be out of contact with the effluent, which may be pooling caudally, particularly if the patient dialyzes in the sitting position.

Since constipation is such a common cause of early one-way dysfunction, it is strongly recommended that careful attention be paid to bowel movements, starting before the catheter insertion. The patient should receive regular treatment with docusate or sennosides to ensure that constipation does not supervene.[308] If the patient is on oral iron or calcium supplements, consideration should be given to temporarily holding these around the catheter insertion, because they can be constipating for many patients. In the postoperative period, the patient may need cathartics or enemas. Importantly, one bowel movement does not mean that the constipation has been relieved. We have seen patients with one-way obstruction after catheter insertion, who had large bowel movements with enemas, but whose flat plate radiographs of the abdomen still demonstrated copious amounts of stool in the colon. Interestingly, one of our patients had poor catheter function until he underwent a bowel preparation for an unrelated colonoscopy, at which point his catheter started to function perfectly.

In the case of catheter migration or omental wrapping, once again a semirigid wire can be inserted, under aseptic conditions, through the catheter. In the case of migration, the catheter can be gently brought down from the upper quadrant into the pelvis.[309–315] This procedure is associated with variable rates of success.[298] It must be done gently, because there is a risk of bowel tearing or perforation.[316] With omental wrap-

ping, the catheter can be gently tugged free from the omentum in the successful instances. There are reports of manipulation with a Fogarty catheter instead of semirigid wire.[302,317]

In recent years laparoscopy has become very valuable, both to place the catheter[318–321] and to treat catheter malfunction.[315,322–325] Laparoscopy can be used to reposition a catheter that has migrated and even secure it in place with a suture.[326–329] The laparoscope can also be used to remove[330,331] or secure the omentum and associated *appendices epiploicae* so that they do not block the catheter holes.[332–334] This procedure can be done prophylactically at the time of catheter insertion or as needed to treat drainage problems.[335] Laparoscopy has even been used to free up the PD catheter from the fimbriae of the Fallopian tubes.[336]

Transplantation

Chapter 31

Transplantation Immunobiology

Nader Najafian, M.D. • Alan M. Krensky, M.D. • Mohamed H. Sayegh, M.D.

When an organ or tissue from one member of a species is transplanted into a nonidentical member of the same species, an immune response ensues. This response is termed the *alloimmune response*. The alloimmune response is primarily orchestrated by initial T cell recognition of alloantigens (allorecognition) followed by a series of cellular and molecular events leading to the effector mechanisms of allograft destruction. The first and major component of this chapter reviews the mechanisms of the alloimmune response and how it leads to allograft rejection. Last but not least, the ultimate goal in clinical transplantation is to induce a state of donor-specific immunologic tolerance, where recipients can accept organs without the need of exogenous immunosuppression. Greater understanding of the interplay of the various costimulatory and inhibitory signals has led to important insights into how lymphocytes differentiation is specified, how effector cells are regulated, how memory is generated, and how tolerance is maintained. The second part of this chapter will review these concepts.

THE ALLOIMMUNE RESPONSE

Transplantation Antigens

Major Histocompatibility Complex

The major histocompatibility complex (MHC) antigens are the strongest transplantation antigens and can stimulate a primary immune response without priming. The alloimmune response arises as a direct result of the normal function of MHC molecules. T lymphocytes recognize foreign (nonself) antigens in the context of self cell-surface molecules encoded in the MHC.[1] In humans, this genetic region is located in a 3.5-million base-pair region on the short arm of chromosome 6. This locus is further subdivided into three clusters based on the structure and function of the proteins encoded by the genes. Human MHC molecules are called *human leukocyte antigens* (HLAs), and the three regions have been designated HLA class I, class II, and class III (Figure 31–1).

HLA class I molecules (classic HLA-A, -B, and -C and other nonclassic molecules) are composed of a 44-kD heavy chain and a 12-kD light chain (Figure 31–2A; see Color Figure).[1,2]

The amino terminus portion of the heavy chain that extends into the extracellular space is composed of three domains: $\alpha 1$, $\alpha 2$, and $\alpha 3$. The $\alpha 1$ and $\alpha 2$ domains interact to form the sides of a cleft (or groove). The cleft is the site where foreign proteins bind to MHC molecules for presentation to T cells. The highly variable amino acid residues located in the groove determine the specificity of peptide binding and T-cell antigen recognition. The light chain, β_2-microglobulin, stabilizes the heavy chain, such that displacement of β_2-microglobulin from the class I molecule causes a loss of heavy chain native structure. The function of intact class I molecules is to present antigenic peptides as protein fragments (peptides) in the context of self to T lymphocytes. HLA class I molecules are highly polymorphic. This polymorphism aids in maximizing the potential for peptide binding by the species. Peptides bind within the HLA class I groove (Figure 31–3A; see Color Figure) based on the sequence of amino acids in the peptide-binding region.[3] HLA class I molecules tend to bind peptides of 9 to 10 amino acids in length. These peptides fit tightly into the groove and do not extend out of the ends of the molecule.

MHC class I molecules generally present endogenous proteins (Figure 31–4). These proteins, such as viruses and normal self proteins, are degraded in the cytoplasm in proteosomes. Short peptide sequences are then moved to the endoplasmic reticulum through specific transporters associated with antigen presentation (TAP transporters). In the endoplasmic reticulum, these peptides associate with class I heavy chain and β_2-microglobulin, and the mature complex is transported to the cell surface, where it can be recognized by T lymphocytes. Peptides sit in the middle of the groove and run the length of the cleft. The rules for peptide binding are restricted to certain "motifs" based on the polymorphisms described earlier but are lax enough to permit the binding of many different peptides to a single HLA type (allele). Antigens associated with class I molecules are recognized by cytotoxic CD8+ T lymphocytes.

The second major region of the MHC is called the *class II locus* (see Figure 31–1).[1] HLA class II molecules, HLA-DP, DQ, and DR, are composed of heavy (α) and light (β) chains of about 35 and 31 kD, respectively. These two chains associate to form a peptide-binding region, but unlike class I molecules, determinants of the peptide-binding region are contributed by both
Figure 31–1   Genomic organization of the human major histocompatibility complex (MHC). See text for explanation. Figure 31–4   Antigen processing and presentation. In the endogenous pathway *(left)*, HLA class I molecules bind to peptides from endogenous antigens. The proteosome breaks up cytoplasmic proteins into peptides that enter the endoplasmic reticulum via specific transporters. In the endoplasmic reticulum, peptides associate with HLA class I molecules and from the mature complex which is exported through the Golgi apparatus to the plasma membrane. In the exogenous pathway *(right)*, HLA class II molecules bind peptides from exogenous antigens. Exogenous proteins enter the cell by endocytosis and are degraded to peptides in endosomes and lysosomes. Class II molecules bind peptides in the "compartment for peptide loading" and are transported to the plasma membrane. (From Krensky AM: Transplantation Immunobiology. *In* Jamison R, Wilkinson R [eds]: Nephrology. London, Chapman and Hall, 1997, p 1051. Reprinted by permission of Hodder Arnold.)

chains (see Figure 31–2*B*).[2] MHC class II molecules bind longer peptides, typically of 12 to 28 amino acids. In contrast to class I, MHC class II molecules have binding grooves that are open at the ends, permitting peptides of greater length to extend beyond the groove (see Figure 31–3*B*).[4] Class II molecules tend to bind antigens derived from the exogenous pathway (see Figure 31–4). MHC class II α and β chains associate in the endoplasmic reticulum with an invariant chain, a portion of which binds in the antigen-binding groove. This invariant chain appears to both protect the groove from peptide binding and permit proper folding of the class II complex. A nonameric form exits the endoplasmic reticulum and moves through the Golgi apparatus and into an endosomal compartment. Within the endosome, the invariant chain is degraded, leaving a shorter class II–associated invariant chain peptide (CLIP) fragment in the groove. Peptides from the extracellular space are taken up into endosomes by endocytosis and targeted to the "compartment for peptide loading." Within this specialized intercellular compartment, exogenous peptides displace CLIP, and the mature heterotrimeric complex (α, β, and peptide) is transported to the cell surface, where it can be recognized by T lymphocytes.

In addition to the classic class II antigens, the MHC class II region encodes proteins that make up the proteasome (low-molecular-weight proteins, LMP-2 and LMP-7) and the TAP transporters (TAP-1 and TAP-2) (see Figure 31–1). Polymorphisms associated with these structures also contribute probably to the specificity and diversity of peptide binding and antigen presentation.

The class III region encodes a variety of proteins of immunologic relevance (see Figure 31–1). These include tumor necrosis factor (TNF) and complement proteins, factor B, and C4.

The alloimmune response is strong and does not require priming.[5] At least part of the basis for the greater magnitude
Figure 31–2 **(A)** Computer model of HLA class I (HLA-B27) and **(B)** class II (HLA-DR1) structures. The peptide-binding region, made up of two a helices supported by a floor of b strands, is at the top of both views. For HLA-B27, a_1 domain is yellow, a_2 domain is red, b_1 domain is blue, and b_2 domain is green. The colors are the same for homologous domains in the two proteins. (From Germain R: MHC-dependent antigen processing and peptide presentation: Providing ligands for T lymphocyte activation. Cell 1994; 76:288.)
Figure 31–3 **(A)** Peptide binding to HLA class I (HLA-A2) and **(B)** class II (HLA-DR1). The view is looking down on the molecule as a T lymphocyte might "see" it. The two a helices forming the rim of the peptide binding site are blue, and electron densities corresponding to bound peptides are shown in red. Nature 1987; 329:506; *B* from Brown JH, Jardetzky TS, Gorga JC, et al: Three-dimensional structure of the human class II histocompatibility antigen HLA-DR1. Nature 1994; 364:35.)

of the allogeneic response is the relatively high frequency of T cell precursors capable of responding to a foreign MHC antigen. For example, the frequency of specific T cells to conventional antigens is approximately 1 in 10^4 to 10^5, whereas the frequency responding during allogeneic stimulation can be as high as 1 in 10^1 to 10^2. The concept of positive and negative selection in the thymus (see Mechanisms of Self Tolerance) also helps to explain the strength of the alloimmune response.[6] During development, T cells with receptors of too high affinity are deleted (negative selection), whereas those with too low affinity are not selected. The end result of this selection is that TCRs of intermediate affinity exit the thymus and enter the periphery. Within an individual, clonal deletion occurs early in development. Potentially, autoreactive clones (with too high affinity for self) are deleted; failure of deletion of some clones may lead to autoimmunity. In the case of transplantation across an allelic difference, however, the recipient's T cells do not contact allo-MHC molecules during development in the thymus and thus escape the deletion (negative selection) imposed by interaction with self-MHC. Thus, the end result is the large number of donor MHC/peptide complexes on the graft to which a potential recipient has not been tolerized during ontogeny. Moreover, the relatively low affinity of any given TCR for its ligand suggests that each T cell could potentially recognize more than one MHC/peptide complex.[7] The high density of alloantigens on the surface of an allograft contributes additionally to the strong T-cell response. In addition, because recipient T cells recognize intact allogeneic MHC molecules directly (see following text), they are stimulated maximally by the high density of MHC on the surfaces of transplanted cells.

Minor Transplantation Antigens

Studies involving MHC identical grafts in mice indicate that minor histocompatibility antigens can also mediate rejection. Recipient T cells can be directly primed to minor histocompatibility antigens. A minor histocompatibility antigen is molecularly defined as a donor-derived peptide presented on a donor cell by an MHC molecule shared by donor and recipient. Note that donor and recipient express the same MHC molecules. Donor DCs directly prime CD8+ T cells to become effector cells without the need for further antigen processing by recipient APCs. As one illustration, CD8+ T cells from female C57BL/6 mice specific for male-derived H-Y Uty peptide + MHC class I mediate rejection of syngeneic C57/BL6 male skin.[8] In humans, it has been appreciated for several years that minor histocompatibility antigens can be immunogenic, from observations based on organ graft rejections and bone marrow graft-versus-host reactions in cases of genetically matched HLA antigens. A few cases of donor-directed, HLA class I–restricted, cytotoxic T-cell responses have been demonstrated in such cases.[9,10] Two general families of such antigens have been identified:

1. H-Y antigens are proteins encoded on the Y chromosome. Females of the species may mount an immune response against these proteins.
2. T cells recognize peptidic antigens corresponding to polymorphisms among autosomal proteins expressed by individuals of the species. Examples include mitochondrial proteins and enzymes.

In the presence of both major and minor incompatibilities, it is clear that the alloimmune response targeted against the MHC molecules predominates.

ABO Blood Group Antigens

The A and B groups are glycosylated differentially, whereas group O lacks the enzymes necessary for glycosylation. The antigens are readily recognized by natural antibodies, termed *hemagglutinins* because they cause red cell agglutination. They are relevant to transplantation because they are expressed on other cell types, including the endothelium. Thus, they cause hyperacute rejection of vascular allografts due to preformed natural antibodies. Allograft rejection due to red blood cell type mismatching can be readily prevented by routine blood typing before transplantation. The rhesus (Rh) factor and other red cell antigens are of little concern because they are not expressed on endothelial cells.

Monocyte and Endothelial Cell Antigens

Occasionally, allografts undergo hyperacute rejection, despite appropriate ABO matching. Some of these rejection episodes have been attributed to additional non-ABO antigens expressed on endothelial cells and monocytes[11]; however, these antigen systems remain poorly understood. Pretransplant tissue typing does not currently evaluate the endothelial/monocyte antigens, owing to the apparent rarity of such antibodies and the lack of accurate reagents for typing.

CELLULAR EVENTS LEADING TO ALLOGRAFT REJECTION

In the context of allograft rejection, T cells play a central role in orchestrating the immune response as they recognize alloantigens through two distinct non-mutually exclusive pathways (see later text). Once activated, they secrete cytokines and chemokines to activate and attract various effector cells, such as CD8+ T cells and macrophages into the allograft. They are also able to interact with B cells that will secrete highly specific alloreactive antibodies. These cells in turn mediate the effector mechanisms of allograft destruction (see later text). Table 31–1 summarizes the steps leading to allograft rejection.

Allorecognition Pathways

The first step in an alloimmune response is the recognition of alloantigens by T cells (priming of alloreactive T cells). In the setting of a transplant, there is the potential for two different cellular mechanisms of allorecognition; these have been called the *direct* and *indirect* pathways of allorecognition (Figure 31–5).[12-14]

Direct refers to cell recognition of a whole intact foreign MHC molecule on the surface of donor cells. Although the specific peptide (typically derived from endogenous proteins, including MHC antigens) bound in the groove of the MHC molecule may be important in this recognition process, it does not restrict this response. The graft, which includes donor bone marrow-derived APCs, usually expresses several class I and class II MHC molecules that

Table 31–1   Steps in Allograft Rejection

1. Recognition of the alloantigen (direct and indirect pathways)
2. T-cell and B-cell activation, differentiation and expansion
3. Effector functions
4. Resolution of the response with residual memory
Figure 31–5   Allorecognition pathways and graft rejection. **A,** Graft rejection is initiated by CD4+ T cells, which recognize alloantigens. In the "direct" pathway of allorecognition, the T cell binds to a major histocompatibility complex (MHC) molecule on donor antigen-presenting cells *(left)*. In the "indirect" pathway, the foreign MHC molecule is processed into allopeptides, which are presented to the T cell by self antigen–presenting cells *(right)*. Activated CD4+ T cells proliferate and secrete a variety of cytokines that act as growth and activation factors for CD8+ cytotoxic T cells, B cells, and macrophages. **B,** Interactions among endothelial cells, T cells, and recipient antigen-presenting cells in allograft rejection. Recipient monocytes are recruited by endothelial cells to the graft tissue. They are also transformed to become highly efficient antigen-presenting dendritic cells that may need to recirculate to peripheral lymphoid organs for maturation. The dendritic cells and intragraft macrophages present donor peptides via the indirect pathway to recruited CD4+ T cells. CD8+ T cells, on the other hand, are activated by donor endothelial cells and can either directly kill endothelial cells or traverse the endothelium and kill parenchymal graft. (Adapted from Briscoe DM, Sayegh MH: A rendezvous before rejection: Where do T cells meet transplant antigens? Nature Med 2002; 8[3]:220-222.)

differ from the recipient's MHC molecules and can directly stimulate recipient T cells. In sum, donor APCs prime CD4+ and CD8+ T cells through the direct pathway. However, as these donor APCs are destroyed during the priming process, direct T-cell priming is likely to be time-limited. Thus, direct allorecognition may account for early acute cellular rejection. Consistent with this idea, direct alloreactivity was not detectable in the peripheral blood of a cohort of renal allograft recipients with chronic allograft dysfunction several years after transplantation.[15,16] In contrast, *indirect* refers to T cell recognition of nonself MHC-derived peptides (allopeptides) in the context of self MHC molecules expressed on recipient antigen-presenting cells (APCs). In this case, similar to the physiologic pathway of antigen recognition, the peptide sequence determines the response. Indirect presentation could occur through a number of mechanisms: soluble donor MHC molecules are shed from the graft and drain through the bloodstream/lymphatics to the recipient secondary lymphoid organs, where they would be processed/presented by recipient APCs to recipient T cells. Alternatively, donor graft cells that migrate to recipient secondary lymphoid organs could be endocytosed by recipient APCs. Third, recipient monocyte/macrophages entering the donor graft could endocytose donor antigens and present the peptides to recipient T cells. Other allopeptides may be derived from minor histocompatibility antigens or tissue-specific antigens. Because recipient monocytes migrating through the allograft can constantly endocytose donor antigen, priming through the indirect pathway could occur for as long as the graft is present in the host. Thus, while indirect alloreactive T cells may participate in acute rejection, they may play a predominant role in chronic rejection.[17] Consistent with this concept, several groups have now provided data correlating the indirect alloreactive T cells with the presence of chronic allograft dysfunction.[18-20] Interestingly, recent emerging data demonstrate that not only CD4+ T cells, as traditionally thought, but also CD8+ T cells can be primed through the indirect pathway of allorecognition and contribute to graft destruction.[21]

Endothelial cells of donor origin are located at the interface between the recipient's blood and the allograft and have been implicated in graft rejection (Figure 31–5).[13] Graft endothelial cells express MHC class I and class II molecules and have been shown recently to promote direct allorecognition by serving as antigen-presenting cells and as targets for T cell–mediated cytotoxicity. In addition, endothelial cells may promote indirect allorecognition by a crosstalk mechanism, which involves the recruitment and transformation of recipient monocytes by endothelial cells into highly efficient antigen presenting dendritic cells.[13]

Finally, there has been recent interest in studying where T cells meet the transplant antigens. The site of alloantigen recognition had until recently been believed to be in the allograft itself, but recent data seem to indicate that peripheral lymphoid organs are required for allograft rejection.[22] Whether unprimed T cells encounter antigens first outside of the allograft in peripheral lymphoid tissue or they migrate to secondary lymphoid organs after they encounter the alloantigens in the graft for further maturation and differentiation remains controversial. Interestingly, primed/ effector/memory cells appear to mediate graft rejection independent of peripheral lymphoid organs,

suggesting that they do get activated by alloantigens in the graft itself.[22]

T-Cell Activation

Allograft rejection is a T cell–dependent process; animals that lack T cells do not reject an allograft. In particular, CD4+ helper T cells appear to be essential orchestrators of the alloimmune response leading to allograft rejection.[23] T lymphocytes initiate the immune response, which ultimately results in graft rejection. In addition, they can function as regulators and effectors in the immune response (see later text). As discussed earlier, allorecognition is the essential initial step for initiation of the cascade of events that results in rejection of the graft (Table 31–1). The essential cell-cell interactions between T cells and APCs (donor or self) may involve five classes of receptors: the antigen-specific TCR, the CD4 or CD8 coreceptor, costimulatory molecules, accessory or adhesion molecules, and lymphokine receptors. Members of each class of receptors may present suitable targets for therapeutic and experimental manipulation and are thus discussed in the following text.

T Cell Receptor-CD3 Complex

T-cell recognition of alloantigens on APCs is the central event that initiates allograft rejection.[12,14,24] The interaction between T lymphocytes and APCs involves multiple T-cell surface molecules and their counter-receptors expressed by APCs. Antigen specificity is determined by the TCR, which recognizes processed antigen in the form of short peptides bound to an MHC molecule. Clonally restricted TCRs are made up of two chains. The major TCR is an α, β heterodimer; a less commonly expressed TCR consists of γ and δ chains. The TCR consists of constant and variable portions involved in binding to HLA and recognition of the specific alloantigenic targets. Although the TCR allows T cells to recognize antigen-MHC complexes, the cell-surface expression of TCR molecules and the initiation of intracellular signaling depend on a complex of additional peptides known as the CD3 complex. After a given TCR is engaged by alloantigen, the T cell is activated, and a signal (signal 1) is transduced through the TCR–CD3 complex. As we will discuss further in later text, full activation of T cells requires two synergistic signals (see "Costimulatory Molecules" section).

The OKT3 monoclonal antibody binds to the CD3 complex. There are at least two components to the mechanism of immunosuppression by OKT3.[25] Within hours after administration, OKT3 causes profound depletion of peripheral T cells. Because OKT3 is not cytotoxic, the depletion is attributed to sequestration of the T cells. In addition, T cells downmodulate the expression of the TCR complex. Thus, after a few days of treatment, by flow cytometry circulating CD4+ and CD8+ cells can be shown to lack detectable TCR. It is thought that the TCR is internalized by endocytosis or shedding. The modulation of TCR expression is reversible, and, after elimination of OKT3, the TCR-CD3 complex is again expressed on the cell surface. Recently, a new generation of anti-CD3 monoclonal antibodies has been generated and is currently being tested in the clinic.[26-28] These antibodies are humanized (OKT3 is a mouse antibody) and nonmitogenic, and thus may prove to be promising in minimizing some of the side effects of OKT3 mediated by its mitogenic properties.

CD4 and CD8 TCR Coreceptors

The two major subsets of T cells, cytotoxic CD8+ T cells and helper CD4+ T cells, recognize processed antigen on MHC class I and class II molecules, respectively. CD4 and CD8 molecules enhance the interaction between the TCR and APCs through the MHC. By binding class II MHC molecules, the CD4 molecule facilitates TCR-CD3 complex-mediated signal transduction and assists the actions of class II MHC-restricted T cells. Similarly, the CD8 molecule binds to class I MHC molecules and stabilizes the interaction of the class I MHC-restricted T cell with a target cell-mediating signal transduction. Thus, CD4/CD8+TCR-CD3 complex proteins function together in initiating the signals for T-cell activation. Monoclonal antibodies against CD4 or CD8 molecules inhibit T-cell activation and may be important targets for immunosuppression.

Adhesion Molecules

Immune cells gain access to the site of inflammation in the graft from nearby lymph nodes and the bloodstream. Associated with transplantation, alloantigens enter local lymph nodes. APCs, such as dendritic cells and tissue macrophages, take up foreign HLA (indirect allorecognition), or foreign HLA on donor APCs is recognized directly (direct allorecognition). Antigen-specific T cells are activated, differentiate, divide, and enter the bloodstream. Immune cells move from the bloodstream into the site of inflammation by a three-step process.

First, immune cells roll along the vessel wall through interactions between selectins on the endothelium and receptors on immune cells. Second, they adhere to vessel endothelium. Third, chemoattractant cytokines (chemokines) are released (Figure 31–6). Adhesion molecules and chemokines are important regulators of rejection and appear to be targets for immunotherapy. Adhesion molecules (integrins) are well known for their ability to facilitate adhesion between cells and between cells and the extracellular matrix. Integrins on T cells include lymphocyte function–associated antigen-1 (LFA-1), which interacts with intercellular adhesion molecules (ICAM-1 and ICAM-2); CD2, which interacts with CD58 (leukocyte function-associated antigen-3 [LFA-3]); and very-late-appearing antigen (VLA-4) (CDw49d, CD29), which interacts with vascular cell adhesion molecule (VCAM-1, CD106).These receptors are of two large structural families. The integrins, including LFA-1 and VLA-4, are made up of α, β heterodimers, whereas members of the immunoglobulin superfamily, including CD2, LFA-3, VCAM-1, and the ICAMs, are made up of disulfide-linked "receptor" domains. The inhibition of adhesion cell function has been shown to be immunosuppressive. Previous studies in murine and primate models showed increased graft survival with anti-ICAM-1 monoclonal antibodies; however, in a recent randomized multicenter trial, short-term use of the anti-ICAM-1 monoclonal antibody enlimomab for induction therapy after renal transplantation did not reduce the rate of acute rejection or delayed graft function.[29] Blockade of LFA-1 as induction treatment, on the other hand, is being studied in the context of preventing delayed graft function after transplantation.[30] Recently,

Figure 31–6   Three-step model of inflammatory cell migration from the bloodstream into the site of rejection. Rolling of mono-cytes and T lymphocytes along the vascular endothelium is mediated by selectins. Chemokines may be synthesized by the endothelial cell or produced by tissue cells and subsequently transported across the endothelium. Then they bind to gly-cosoaminoglycans on the endothelial cell surface, where they can activate leukocyte chemokine receptors causing integrin acti-vation, flow arrest, and movement across the endothelial cell barrier into the tissues following the chemoattractant gradient. (From Dong VM, McDermott DH, Abdi R: Chemokines and diseases. Eur J Dermatology 2003; 13[3]:224-230.)

efalizumab, a humanized anti-LFA-1 monoclonal antibody, was shown to be well tolerated and effective at reducing the severity of the disease in patients with psoriasis. Initial results in renal transplant patients are also promising.[31]

Costimulatory Molecules

T cells require two signals for full activation (Figure 31–7). One signal is provided by the interaction of the TCR with the MHC–peptide complex; the second costimulatory signal depends on one or more additional receptor-ligand interac-tions between T cells and APCs.[26-28] The two-signal model has gained enormous support in recent years, defining several cos-timulatory pathways and is now widely accepted (Figure 31–8).[32,33] The CD28-B7 and CD154-CD40 pathways have been described as the critical costimulatory pathways for T-cell activation. Blockade of these pathways has been reported to regulate both autoimmune and alloimmune responses in experimental models and in human disease. However, studies have indicated that inhibition of these pathways is insufficient to reproducibly induce long-lasting immunologic tolerance in some experimental autoimmunity and transplantation mod-els, indicating a role for other costimulatory pathways. The recent discovery of new members of the B7-CD28 family,[32,33] inducible costimulator (ICOS), its ligand B7h, as well as pro-grammed death-1 (PD-1) and its ligands, PD-L1 and PD-L2, have therefore been of major interest. Other molecules belonging to the tumor necrosis factor (TNF) superfamily and their receptors (TNF-R), including 4-1BB, CD30, CD134 (OX40) and CD27, and their respective ligands, 4-1BBL, CD30L, CD134L and CD70, also act as efficient costimulatory molecules for T cells.[32,33] The role of these novel costimulatory molecules is currently under intense investigation, and their role in autoimmunity and transplantation is just beginning to emerge. Thus, we will review later the role of the CD28-B7 and CD154-CD40 pathways in transplantation.

The CD28/CTLA4-B7 Pathway

Many T-cell molecules may serve as receptors for costimula-tory signals; the CD28 molecule is the best characterized of these molecules (see Figure 31–8). According to recent gene expression studies, CD28 costimulation can lead to significant augmentation of expressions of genes induced by TCR signal-ing alone. These findings are consistent with a model of cos-timulation in which CD28 signaling lowers TCR thresholds for activation of cells.[34,35] CD28 has two known ligands, B7-1 (CD80) and B7-2 (CD86), both of which are expressed pri-marily on activated professional bone marrow-derived APCs. T cells also express CTLA-4, a molecule that is highly homol-

FATE OF T CELLS DETERMINES IMMUNE RESPONSE
Figure 31–7 Stimulation of T cells through binding of a peptide-MHC complex to the T cell receptor (signal 1) in the presence of a costimulatory signal (signal two) leads to proliferation and differentiation of these cells. Apoptosis, cell cycle arrest, and active suppression are known regulators of this immune response. A few antigen-specific cells are spared and become memory cells. (From Najafian N, Khoury SJ, Sayegh MH: T cell costimulatory blockade as a novel immune intervention in auoimmune diseases. Clin Dermatol 2001; 19[5]:586-591.)

ogous to CD28 that also binds CD80 and CD86.[36] However, unlike CD28, CTLA-4 transmits an inhibitory signal that serves to terminate the immune response. Whereas CD28 is expressed by both resting and activated T cells, CTLA-4 is expressed on activated T cells only. Because CTLA-4 binds B7 molecules with a higher affinity than does CD28, its inhibitory interaction eventually predominates, leading to the termination of the immune response. The importance of CTLA-4 as a negative regulatory T-cell costimulatory molecule in the physiologic termination of T cell responses is highlighted by the observation that CTLA-4 gene knockout mice develop massive lymphoproliferation and early death. One point that needs to be emphasized is the critical role of costimulation in T-cell responses. In the absence of costimulatory signals,

sometimes the T cell simply ignores the peptide-MHC-complex presented to it. At other times, the T cell undergoes apoptotic death[37,38] or is rendered anergic for up to several weeks[37]; that is, the T cell is unable to respond to antigens, even when it is presented by APCs that express a costimulatory molecule. Precisely what determines the outcome of the stimulation of T-cell antigen receptors in the absence of costimulation (ignorance, apoptosis, or anergy) is not known. This process is considered one important factor in induction of peripheral tolerance. Thus, manipulation of CD28/B7 pathway has been envisioned as a potential strategy for achieving therapeutically useful immunosuppression or tolerance. T-cell costimulatory blockade, in the form of CTLA4Ig (LEA29Y), which blocks CD28 interaction with B7, is currently being studied as a means of immunosuppression.[36]

The CD154-CD40 Pathway

The CD154-CD40 pathway, initially described as having a role in B-cell activation, has been recognized as a key pathway for T-cell activation as well (see Figure 31–8). CD40 is expressed on APCs, such as B cells, macrophages, and dendritic cells, as well as other cell types such as endothelial cells. The ligand for CD40 (originally called CD40L and recently named CD154) is expressed on activated CD4 T cells. CD154 was later found on stimulated mast cells and basophils and, most recently, on activated platelets in vitro and in vivo and also in vivo on platelets in the process of the thrombus formation. Stimulation of CD40 provides important signals for antibody production by B cells and strongly induces B7 expression on all APCs.[39] In this manner, the CD154-CD40 system may have an important role in T-cell costimulation. Activation of APCs through CD40 also induces the expression of adhesion molecules and inflammatory cytokines that participate in T-cell activation. Therefore, CD154 may act in T-cell costimulation by directly providing costimulation, by inducing B7, or by inducing other costimulatory ligands. CD154-CD40 blockade has been shown to be efficient in preventing acute graft rejection in several small animal models. When anti-CD154 monoclonal
Figure 31–8 Overview of the main costimulatory molecules belonging to the CD28-B7 and TNF-TNF-R super families. Following ligation of the receptor-ligand pairs, the signal transduced results in a net stimulatory (+) or inhibitory (–) response. (From Salama AD, Salama AD, Sayegh MH: Alternative T-cell costimulatory pathways in transplant rejection and tolerance induction: Hierarchy or redundancy? Am J Transplantation 2003; 3:509-511.)

antibody was used as part of a strategy to induce mixed allogeneic chimerism in a renal transplant model, the primates developed donor-specific tolerance. However, some recipients developed thromboembolic complications. Such a complication was also observed in some humans entered in the phase I and phase II transplant trial with the humanized anti-CD154 (Biogen Inc., Cambridge, MA) monoclonal antibody, resulting in premature termination of trial. Thus, the plans for future development of this agent in transplantation remain unclear.

In summary, there are complex interactions between the various costimulatory pathways that influence their actions. These interactions ultimately determine the fate of the alloimmune response in vivo. A major focus of future research is thus directed at dissecting these functions to provide the rationale for developing novel therapeutic targets and strategies for induction of robust and durable transplantation tolerance.

Cytokines/Chemokines

In addition to cell–cell interactions, cell function can be directed through proteins produced by a variety of cell types. These cytokines can function as chemoattractant (chemokines, see later text), as well as growth, activation, and differentiation factors. After antigenic stimulation, CD4+ T cells differentiate into two distinct populations, each producing its own set of cytokines and mediating separate effector functions.[40,41] *Type 1* helper T cells (Th1 cells) produce interleukin-2 (IL-2) and interferon-γ (IFN-γ) and mediate activation of macrophages and induction of delayed-type hypersensitivity (DTH) responses (see later text). *Type 2* helper cells (Th2 cells) produce IL-4, IL-5, IL-10, and IL-13, which provide help for B-cell function. However, the functional segregation between the Th1 and Th2 subsets remains incompletely understood. Studies with specific Th1 or Th2 cytokine gene-knockout animals indicate the complexity of the Th1-Th2 paradigm in graft rejection and tolerance.[40-42] Data from animal and human studies showed that Th2 clones propagated from patients with stable renal transplant function, or animals tolerant to kidney transplants can regulate a proliferative response from Th1 clones isolated from patients or animals undergoing active rejection.[43,44] Except for blockade of the IL-2R, therapeutic strategies that specifically modulate lymphokines have not proved highly effective. Therefore, although manipulation of lymphokine functions may hold promise as a therapeutic modality, we will have to better understand the role of lymphokines in graft rejection and tolerance under physiologic conditions, if we are to develop effective treatments.

Chemokines are *chemoattractant cytokines*.[45] They are structurally related by amino acid homologies and, in particular, by the placement of cysteines. The nomenclature of chemokines is becoming increasingly complex. Four chemokine families are now recognized, of which the majority of members belong to the C-C chemokine family, represented by RANTES, or the C-X-C chemokine family, typified by IL-8. In general, C-C chemokines attract monocytes and T lymphocytes, and C-X-C chemokines attract granulocytes. Detection of altered chemokine mRNA in experimental models of rejection suggests that they play an important role in this process; however, because of redundancy and differences

between the function of chemokines in rodents and in humans, for the most part, the exact role that individual chemokines play in an alloimmune response remains unclear. Nevertheless, recent studies in organ transplantation models in knockout animals and with blocking antibodies indicate key roles for the receptors CXCR3 and CCR5 and selected targeting chemokines.[46,47] Mean cardiac allograft survival of 58 days in CXCR3−/− compared with 7 days in the wild-type underlines these findings. Similar effects on graft survival were obtained using an anti-CXCR3 antibody in CXCR3+/+ recipients. MHC disparate cardiac allografts transplanted into CCR5−/− mice show a tripling of graft survival. Whereas chemokine expression in the heart is primarily by EC or infiltrating mononuclear cells, kidneys have a heterogeneous population of resident cells, which express inflammatory chemokines when stimulated. Further studies of these knockout mice in studies on renal transplantation will help prove the applicability of these data to renal transplantation.

Effector Mechanisms of Allograft Rejection

Transplant rejection has both cellular (DTH responses, cell-mediated cytotoxicity) and humoral components. Once fully activated via the direct or indirect pathway (see earlier text), T cells produce cytokines and chemokines that orchestrate various effector arms of the alloimmune response. Primed CD4+ T cells can provide help for production of alloantibody and can also provide helper signals required for the induction of CD8+ CTLs,[14,23] both of which can subsequently mediate graft injury. Moreover, CD4+ T cells capable of recognizing donor antigen on donor cells can directly mediate acute graft rejection,[48] but there is some evidence that this outcome is frequency-dependent.[49] Below a certain frequency threshold, primed T cells may not reject the transplanted organ but may alternatively be capable of inducing chronic injury that results in fibrosis and vasculopathy, characteristic of chronic allograft dysfunction.[50] Furthermore, directly primed Th1 cells and macrophages can mediate delayed-type hypersensitivity (DTH) reactions and contribute to the destruction of the graft. In this setting, it is hypothesized that some of the cytokines produced by T cells and macrophages (TNF-α) may mediate apoptosis of graft cells. The pathology of a transplanted organ may also be dependent on the specific graft cell with which the primed T cells interact. It is tempting to speculate that direct recognition of donor endothelial cells by primed CD8+ T cells may participate in those acute rejections associated with pathologic evidence of vasculitis.[51] On the other hand, if intragraft donor parenchymal cells are the predominant targets of the direct alloresponse, acute rejection may appear as the classically described mononuclear cell infiltration with tubulitis. Analogous to T cells functioning through the direct pathway, indirectly primed CD4+ T cells preferentially differentiate into a pro-inflammatory type −1 cytokine-secreting phenotype[52] and provide helper signals to induce alloantibodies and cytotoxic CD8+ T cells capable of injuring the graft.[53-55] In addition, indirectly activated T cells are capable of mediating DTH, and DTH is associated with both acute and chronic graft injury.[56,57] One important question currently under investigation is whether indirectly primed, pro-inflammatory T cells can injure a graft even though they cannot interact with any antigen expressed

on the graft cells. At least in skin graft models, it is possible that recipient-derived vascular endothelial cells found on vessels feeding the graft may act as a target of the indirectly primed immune response.[58] The frequency of activated cells may also influence the eventual outcome. Higher frequencies of indirectly primed CD4+ T cells seem to be associated with acute rejection, whereas lower frequencies may mediate fibrosis and vasculopathy.[48]

In summary, the pattern of transplant rejection is not only influenced by the T-cell recognition pathway, but also by the frequency, the induced effector functions, and the specific cellular targets of the alloreactive T cells.

B lymphocytes express clonally restricted antigen-specific cell-surface receptors, called *immunoglobulins*.[59] When cell-surface immunoglobulin binds specific antigen in the context of soluble helper factors (such as IL-4, IL-6, and IL-8), B cells are activated. They differentiate, divide, and become plasma cells, which secrete soluble forms of antigen-specific antibodies displayed on their cell surface. These antibodies, in turn, can bind allogeneic target antigens and induce graft damage by binding complement or by directing antibody-dependent cellular cytotoxicity. Both immunoglobulin M (IgM) and IgG alloantibodies can be detected in the serum as well as in the graft of animals and humans undergoing allograft rejection. Preformed anti-HLA class I antibodies and, occasionally, anti-endothelial antibodies play an important role in the hyperacute rejection and accelerated vascular rejection seen in previously sensitized transplant recipients. In the case of xenotransplantation, naturally occurring xenoreactive antibodies play a critical role in the hyperacute rejection of xenografts (see Chapter 37). Finally, alloantibodies, particularly IgG, play an important pathogenetic role in the development of chronic rejection and graft arteriosclerosis.

Other soluble factors induce additional effector mechanisms, including phagocytosis by granulocytes and macrophages, and cell death by natural killer (NK) cells. NK cells express cell-surface receptors called "killer-inhibitory receptors" (KIR) that recognize HLA class I molecules.[60] When self HLA is recognized, NK cells are prevented from killing. If the killer-inhibitory receptors do not bind to a self HLA molecule, as in certain tumors or viral infections, the target cell is lysed. In addition, NK cells can lyse certain targets expressing non-self HLA (alloantigens). Although the role of NK cell–mediated cytotoxicity in allograft rejection remains controversial, NK cells appear to play a key role in mediating delayed xenograft rejection (see Chapter 37).

Resolution and Memory

Apoptosis, cell cycle arrest, and active suppression are known regulators leading to a dampening of the induced immune response (see "Tolerance" section).[61] Nevertheless, a few antigen-specific cells are spared and these become memory cells (see Figure 31–7). Memory cells have a lower activation threshold than do naïve cells and can respond rapidly to previously encountered antigens. Memory T cells not only endanger allograft survival by causing both acute and chronic rejection, but recent studies suggest that they impede the induction of transplantation tolerance.[62] Evidence that memory T cells impede tolerance induction derives from studies using costimulation blockade and mixed allogeneic chimerism strategies.

TOLERANCE

Immunologic tolerance to an allograft can be defined as normal graft function and histology in the absence of immunosuppression, associated with absence of a destructive specific alloimmune response to the graft, but with an otherwise fully functional immune system.[32] Renal transplantation has been made possible by the development of powerful immunosuppressive drugs that can prevent the rejection process but usually require lifelong administration, patient compliance, and the risk for a wide range of unwanted side effects. Although there has been great success in improving short-term allograft survival in recent years, chronic allograft nephropathy (CAN) remains the principal cause of late renal allograft failure and may even be accelerated by some immunosuppressive drugs. Immunologic tolerance would ideally prevent the side effects of immunosuppression and would hopefully prevent chronic rejection, as demonstrated in several animal models.[63] An individual is usually tolerant to self antigens. Understanding mechanisms of self tolerance has yielded important information regarding the mechanisms of immune responses and has provided the rationale to develop strategies for induction of acquired tolerance. As discussed previously, the T-cell repertoire is modified through negative and positive selection processes in the thymus to delete potentially self-reactive T-cell clones. Self tolerance is partially mediated by "negative selection" through deletion of autoreactive T-cell clones in thymus (central tolerance). On the other hand, potentially autoreactive T cells that had escaped deletion during intrathymic ontogeny are kept under control by mechanisms of peripheral tolerance. Clonal deletion through apoptosis, anergy, and immunoregulation have all been suggested as nonmutually exclusive and probably complementary mechanisms of peripheral tolerance.[61] Stimulation of lymphocytes through the antigen receptor in the absence of costimulation is not a neutral event and mediates specific inactivation through anergy, a further safeguard against self-reactivity. Thus, it has been suggested that the absence of costimulation on resting tissue APCs could serve to induce and maintain T-cell tolerance to self-antigens, and that aberrant expression of costimulatory molecules on nonprofessional APCs could activate self-reactive T cells, resulting in autoimmunity. Recent findings suggest that an additional level of regulation may be achieved by the expression of novel inhibitory molecules (CTLA4 and PD1) on T cells that can provide negative signals to terminate immune responses.[33]

Similar to self tolerance, the mechanisms of acquired tolerance are listed in Table 31–2. There are two types of acquired tolerance:

1. *Central tolerance* involves thymic deletional mechanisms analogous to self tolerance.
2. *Peripheral tolerance* is mediated by T-cell anergy and deletion, by regulatory/suppressor cells, and/or by suppressive cytokines.

The occurrence of natural tolerance was first described by Owen,[64] who showed that dizygotic twin cattle that shared a common placenta in utero would continue to have circulating blood cells of their twin specificity after birth. The resultant animals were said to be *chimeric*, and they could not reject skin grafts of the other twin in adult life. This was followed by studies by Billingham, Brent, and Medawar,[65] who

Table 31–2 Mechanisms of Transplantation Tolerance

- Central tolerance
- Peripheral tolerance
  - Anergy
  - Apoptosis
  - Regulation (regulatory cells, suppressive cytokines)

demonstrated that it was possible to induce mice to accept skin grafts from a different genetic background, if the recipient mice were injected while still in utero (or neonatally) with hematopoietic cells of donor origin. This was the first description of acquired tolerance. Neonatal tolerance is thought to be due largely to clonal deletion, whereby T cells reactive with alloantigen are deleted in the thymus, presumably by the same mechanisms that delete self reactive T cells. Other mechanisms (e.g., immune deviation to Th2 cells), however, have been described as possible mediators of neonatal tolerance.

Anergy is a state of functional inactivation in which antigen-specific T lymphocytes are present but are unable to respond (by proliferating or producing cytokines) to rechallenge with antigen. Anergy is typically induced when T cells do not receive a positive costimulatory signal, when positive costimulatory signals are blocked, or when they receive a negative costimulatory signal. Anergy can sometimes be reversed by IL-2 and thus may not be a desirable clinical approach to induce tolerance because infections may activate the immune system and reverse anergy.

Another mechanism of peripheral tolerance is through the function of antigen-specific regulatory or suppressor cells. Such cells have been demonstrated by *in vitro* assays and by adoptive transfer experiments *in vivo*. *Infectious tolerance*, whereby T cells from a tolerant animal can actively transfer specific tolerance to a naïve animal, indicates the presence of regulatory cells. Indeed, the existence of CD4+CD25+ regulatory T cells in the blood of healthy adult volunteers have been previously reported.[66] A recent study provided the first evidence that such regulatory cells appear and persist in renal transplant patients and account for indirect pathway hyporeactivity in a proportion of renal transplant patients with stable allograft function.[67] Therefore, while T-cell anergy and death are most likely the main regulatory mechanisms contributing to direct pathway hyporesponsiveness,[68] regulatory CD4+CD25+ T cells appear to play a role in regulation of indirect antidonor alloresponse in stable renal transplant patients.[67] Besides CD4+CD25+ regulatory cells, it has been recognized that CD4+ helper T cells can be subdivided into Th1 and Th2 subsets. Th2 cytokines are expressed in tolerant grafts.[69] This state of immune deviation toward predominantly Th2 cell function has been associated with tolerance in experimental models of autoimmunity and transplantation. In the case of transplantation, however, a causal relation has not been proved. Data indicating that IL-2 or IFN-γ knockout animals are capable of rejecting allografts and that IL-4 knockout animals can be "tolerized" may question the validity of the Th1 and Th2 paradigm in allograft rejection and tolerance.[41] Recently, NK1.1+ T cells have been shown to act as natural suppressor cells preventing graft versus host disease after bone marrow transplantation.[70,71] In the setting of transplantation tolerance, NKT cells also seem to be required for the induction of cardiac transplant tolerance by costimulation.

Furthermore, CD8+CD28-T cells that are capable of suppressing CD4+ T cells with allospecificity or xenospecificity could be generated by repetitive allostimulation or xenostimulation in vitro.

Novel approaches to induce transplantation tolerance in humans include T cell non-myeloablative therapy with donor bone marrow transplantation plus a solid organ transplant. One recent paper demonstrated that this is feasible in a patient with myeloma and renal failure.[72] Other strategies that may be explored in the future include T-cell costimulatory blockade, T-cell depletion protocols (thymoglobulin, Campath-1, anti-CD2, and nonmitogenic anti-CD3), and mixed allogeneic chimerism in haploidentical transplant recipients in the absence of hematologic malignancies.[32]

Finally, although the induction of immunologic tolerance remains an important clinical goal in transplantation, there are several immunologic hurdles that has made it difficult to translate animal studies to humans; these barriers include the large repertoire of alloreactive T cells in the case of transplantation, the limitations of peripheral immune regulatory mechanisms that are commonly exploited to induce tolerance (T-cell deletion, anergy, and suppression), and last, but not least, the difficult task of "tolerizing" memory T cells.[32,62]

SUMMARY

In this chapter, we have highlighted our current understanding of the cellular and molecular mechanisms involved in transplant rejection and acceptance. This information has been important in the design of current therapies and may help usher in a new generation of approaches that will result in immunologic tolerance, the ultimate goal of transplantation biologists.

Evaluation of Donors and Recipients

Colm C. Magee, M.D., M.P.H.

EVALUATION OF THE LIVING DONOR

Live kidney donation is increasingly common in the United States and in other countries. This reflects many factors, including the ongoing shortage of suitable deceased donors, the excellent results achieved with live kidney donation (even between unrelated donors and recipients), and greater physician and public awareness of its benefits. These potential benefits are summarized in Table 32–1. The number of living related and unrelated donors has increased by 68% and 100%, respectively, in the United States over the last decade.[1] In fact, the number of living donors surpassed that of cadaveric donors in 2001.

One major advantage is that preemptive transplantation (before the need for dialysis) is often feasible. Not only does this avoid complications associated with dialysis itself, but recent studies show it is associated with less acute rejection and better allograft survival.[2] This intriguing finding may reflect the avoidance of pro-inflammatory effects of advanced uremia or dialysis itself. Despite the poor matching for HLA antigens associated with unrelated donation, outcomes are excellent.[3] This emphasizes the benefits of transplanting a "healthy" kidney with minimum perioperative ischemia and reperfusion injury.

DONOR NEPHRECTOMY TECHNIQUES

Open nephrectomy is the traditional method. The advantages and disadvantages of this technique are summarized in Table 32–2. For reasons that include patient preference, surgeon preference and marketing strategy, laparoscopic nephrectomy is becoming the donor nephrectomy method of choice in the larger U.S. transplant centers.[4] This can be done as a full or hand-assisted laparoscopic procedure. The advantages and disadvantages of this technique are shown in Table 32–3. There is some evidence that the perceived advantages of laparoscopic nephrectomy have contributed to the increase in donation rates.[5] However, rates of early graft dysfunction may be higher with this technique for the following reasons: higher intra-abdominal pressures required during the procedure, longer warm ischemia times, less experience with the technique—entailing a learning curve—and more manipulation of the renal vessels.[6] One randomized trial found better donor and equivalent recipient outcomes with hand-assisted as opposed to open live donor nephrectomy.[7] It is quite likely, however, that there is a publication bias favoring the laparoscopic method. Adverse outcomes associated with this newer technique are unlikely to be submitted for publication!

CHOOSING THE POTENTIAL DONOR

The general schema for evaluation of a possible donor is shown in Figure 32–1. In general, biologically related donors are preferable to unrelated ones. ABO blood group testing is performed before HLA typing and cross-matching because ABO incompatibility traditionally precludes transplant (a limited number of ABO incompatible transplants are now being performed). When more than one family member is interested in, and suitable for, donation, the best matched donor is preferable. A two haplotype matched sibling is of course the ideal. However, older donors, such as parents, are sometimes preferred in case a subsequent transplant might be required.

Age

There is no absolute age above which donation is contraindicated; more important is whether or not there are medical contraindications (the prevalence of hypertension and type 2 diabetes mellitus, for example, increases with age). A different situation applies in the young where there are major concerns about minors' rights, the ability to freely give informed consent, and the fact that the donor will be exposed to many years of the "single kidney" state. The majority of centers do not allow donation by those less than 18 years (exceptions are sometimes made for identical twins); some centers have higher thresholds, such as 25 years. Unfortunately, there is some evidence that inappropriate donation by minors is occurring.[8]

Safety of Donation: Risks to the Donor

An important issue in the evaluation of persons for living kidney donation is balancing the professional goal of alleviating the recipient's illness with the philosophy of "first, do no harm." Four conditions must be satisfied before living donation can proceed: (1) The risk to the donor must be low, (2) the donor must be fully informed, (3) the decision to donate must be independent and voluntary, and (4) there must be a good chance of a successful recipient outcome.[9]

The risks are most easily explained to the donor as short- and long-term risks. The short-term risks are those associated with the major surgery itself, including death, thromboembolism, myocardial infarction, and wound infection. Because donors are carefully selected and the surgery is elective, major complications are rare. Of more concern to the physician evaluating the donor is the long-term risk, particularly of hypertension and kidney disease. The majority of data regarding mortality in subjects who have undergone unilateral

Table 32–1   Advantages and Disadvantages of Living Donor Kidney Transplantation

Advantages
Potential for minimum waiting time on dialysis and for pre-emptive transplantation
Close HLA matching often feasible
Expansion of total donor pool
Elective surgery
Minimal ischemic damage to allograft
Potential for less aggressive immunosuppression
Excellent graft survival and recipient survival
Psychosocial benefits to donor
Disadvantages
Psychological stress on donor and family
Perioperative donor morbidity (wound infection, thrombosis, etc.)
Perioperative donor mortality (rare)
Potential to excacerbate donor hypertension, proteinuria or kidney disease over the long term

Table 32–2   Advantages and Disadvantages of Open Nephrectomy

Advantages
Tried-and-trusted technique; long-term outcomes excellent
Risk of perioperative ischemic damage very low
Retroperitoneal approach minimizes bowel and other abdominal complications
Disadvantages
Relatively invasive surgery
Large scar with risk of hernia

Table 32–3   Advantages and Disadvantages of Laparoscopic Nephrectomy

Advantages
Less invasive surgery; postoperative recovery faster
Smaller scar
Shorter hospital stay
More acceptable to many donors
Disadvantages
Long-term outcomes not available
Learning curve
Potential for more perioperative ischemic damage and delayed graft function

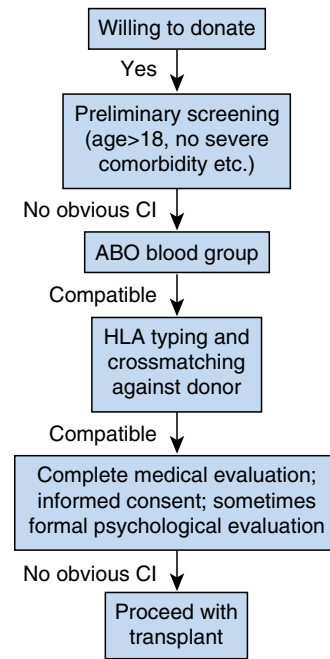
nephrectomy (for reasons including trauma, neoplasia, or donation) are very reassuring. In fact, a well-performed follow-up study of donors in Sweden found that survival was better in donors compared to that in the general population.[10] Low-grade microalbuminuria or proteinuria has been observed in up to 30% of donors; this is very rarely progressive. The majority of the evidence suggests that nephrectomy is associated with a slight increase in blood pressure. How much this reflects the natural history in a given donor is unclear; when donors were compared to siblings, a similarly high incidence was found in both.[11] Although limited data suggest that long-term renal function remains adequate in the majority of donors, there is growing concern that not enough is known about their long-


Figure 32–1   Typical steps in the evaluation of a patient for live kidney donation. *CI,* contraindication.

term outcomes.[12] Ideally, a national registry of donors would be established to allow more rigorous long-term follow-up; this has yet to be done in the United States. One recent study of the OPTN database found that 56 previous living donors had been listed for transplantation; the number of patients with less severe kidney disease could, of course, be much greater.[12]

Clinical Assessment of the Donor

To avoid conflict of interest, the proposed donor should be meticulously evaluated by a physician not involved in care of the proposed recipient. The physician must confirm that the patient's wish to donate is voluntary. This is more of a concern with nonrelated donors. The physician must also fully explain the short- and long-term consequences of donation.

The history and examination and tests (Table 32–4) should focus on excluding contraindications to donation. Many of these contraindications are shown in Table 32–5. Not all of these listed are absolute contraindications, but in general it is better to err on the side of minimizing damage to the donor. Occasionally, disagreements will arise wherein the evaluating physician will advise against donation and the patient will still want to donate, "whatever the risk." A second opinion is often of use in such cases.

Family History of Type 2 Diabetes Mellitus

Type 2 diabetes mellitus is an increasingly common cause of ESRD. Not surprisingly, when the recipient has these diseases, the risk of related donors developing diabetes later in life is a major concern. Although little is known as to whether single-kidney status would accelerate the progression of diabetic nephropathy, it seems prudent to avoid donation in those

Table 32–4 Initial Tests for Potential Live Kidney Donors*

CBC, PT, PTT
Plasma creatinine, calcium, urea, electrolytes
Fasting plasma glucose (and glucose tolerance test if patient obese or if family history of type 2 diabetes mellitus)
Chest X-Ray, EKG
Estimate of GFR (creatinine clearance or isotope)
Spot urine albumin:creatinine ratio (twice)
Urinalysis and urine culture
Tests for HIV, hepatitis B, hepatitis C, cytomegalovirus, Epstein-Barr virus

*This assumes no ABO-blood group or HLA antigen incompatibilities. Imaging studies of the renal vasculature are usually performed later.

Table 32–5 Relative or Absolute Contraindications to Live Kidney Donation

Age <18-25 or >70-75 years
Hypertension (BP >140/90 or on antihypertensive medication)
BMI >30-35 kg/m^2
Diabetes mellitus or abnormal glucose tolerance test
History of gestational type 2 diabetes mellitus
Strong family history of diabetes mellitus
Malignancy
Significant comorbidity
Microalbuminuria or overt proteinuria
Recurrent kidney stone disease
Other kidney disease
Low GFR (<70-80 ml/min)
Transmissable serious infection (e.g., HIV, hepatitis B, hepatitis C)

thought to be at high risk of developing type 2 diabetes mellitus later in life. In addition to family history (especially first-degree relative) of type 2 diabetes mellitus, the following factors increase risk: obesity, increasing age, non-white ethnicity and history of gestational diabetes. All patients with a family history of type 2 diabetes mellitus should have a glucose tolerance test; if this is abnormal, donation is prohibited due to the very high risk of developing diabetes. If the glucose tolerance test is normal and there are no other risk factors, it is reasonable to allow donation. More difficult is where the test is normal but the patient has one or both of the additonal factors mentioned. The protocol in our institution is to advise lifestyle modification for 3 to 6 months, then further review and discuss with the donor. It is sobering to note that the estimated lifetime probability of developing diabetes mellitus in the United States is now about 1 in 3.[13]

Hereditary Kidney Disease

When kidney disease in the recipient is due to an inherited disease, it is essential that the disease is excluded in related donors. This will sometimes require close consultation with a geneticist. The most common scenario is a family history of autosomal dominant polycystic kidney disease (ADPKD). If the potential donor is over age 30, the absence of cysts on a carefully performed ultrasound virtually excludes the diagnosis. If the donor is 20 to 30 years old, however, a negative ultrasound does not exclude ADPKD type II (a negative ultrasound or CT are probably adequate to exclude ADPKD type I) and genetic testing such as linkage analysis may be helpful.[14]

Alport's syndrome is a genetically heterogeneous disease with X-linked, autosomal recessive, and autosomal dominant variants. The majority of cases are X-linked. Screening of donors involves urinalysis, tests of GFR, and specialized eye and ear testing. Male siblings greater than 20 years of age are very unlikely to have the disease if hematuria is absent. Sisters of affected male recipients with X-linked diseases have a 50% chance of being carriers; a small percent of such females carrying the abnormal gene do develop renal failure. Thus, female heterozygotes (identified as having hematuria but normal renal function) should only be allowed to donate after detailed consultation with a nephrologist and geneticist.

Donor with Asymptomatic Microhematuria

Urine dipstick testing—in the absence of fever, trauma, menstruation, or vigorous exercise—should be repeated twice to confirm the presence of microhematuria. Urinary tract infection must be excluded. Urine microscopy should be performed to confirm the presence of red blood cells and to determine whether red blood cell casts are present. The presence of unexplained microhematuria at this stage does not exclude donation, but the donor must be informed that further invasive testing is required before he or she can be deemed fit to donate. The following tests may all be required: cystoscopy, imaging of kidneys and of urinary tract, and kidney biopsy. Only if these tests are normal should the hematuria be considered benign and donation be allowed.

Renal Stone Disease

A history of urinary tract stones is at least a relative contraindication to donation because stones tend to recur and obstruction of a solitary kidney could of course be catastrophic. Some centers will consider donation where all of the following apply: passage of only one stone and that at least 10 years prior to donation, no evidence of a metabolic cause (such as hypercalciuria) of stone formation, and current imaging studies showing no urinary tract stones.[15] Any such donors should be advised to continue lifelong high fluid intake.

Conclusion

Live kidney donation is likely to increase further in the United States and in other countries. It is imperative that donors are carefully selected and that the short- and long-term risks of donation are minimized. Ideally, long-term follow-up of donors will be improved; a national donor registry in the United States would be very helpful in this regard.

EVALUATION OF THE RECIPIENT

Evaluation of the patient with chronic kidney disease for transplantation should begin before initiation of dialysis. This allows preemptive (before dialysis) transplantation if a living

donor is available. Even if living donation is not an option, completion of the evaluation and testing means that the patient can be listed for cadaveric kidney transplantation as soon as dialysis is started. The initial evaluation must be thorough (Figure 32–2). Not only must the patient be extensively educated as to the risks and benefits of transplantation, but contraindications to transplant must be excluded. In addition to a thorough history and examination, a number of routine tests are required (Table 32–6). General contraindications to transplant are discussed in the following paragraph and shown in Table 32–7.

Contraindications to Transplantation

Cancer

At least 2 years disease-free status is required for almost all cancers; many programs require 5 years for breast cancer and melanoma. Close consultation with oncology colleagues is essential. Active cancer is a contraindication to transplant for at least two reasons. First, immunosuppression could accelerate progression of cancer. Second, early recurrence with associated morbidity and mortality would "waste" the transplanted organ.

Acute or Chronic Infections

Whenever possible, acute or chronic infections should be eliminated before transplant. In certain situations, complete cure is not possible and the risks and benefits of transplantation and associated immunosuppression must be very carefully considered, for instance, hepatitis C infection (response to antiviral therapy is often incomplete) or HIV infection.

Hepatitis C.

Immunosuppression can accelerate the progression of this systemic disease. This does not mean that HCV-infected patients should forego transplantation. In fact, although HCV-positive dialysis and transplant patients had poorer survival compared to HCV-positive, transplantation still conferred a survival benefit over dialysis in those with HCV infection.[16] The management of the pretransplant HCV-positive patient has not been standardized. However, most experts recommend liver biopsy in all transplant candidates to guide prognosis and therapy.[17] The goal—not always achievable—is to eliminate viral replication or, at least, slow progression to cirrhosis. An algorithm for management of the HCV-positive pretransplant patient is shown in Figure 32–3. Interestingly, the response rates to interferon-α monotherapy are probably higher in dialysis than in nondialysis patients. However, ribavirin is contraindicated in the former group because of its accumulation in renal failure and associated risk of severe anemia.

HIV.

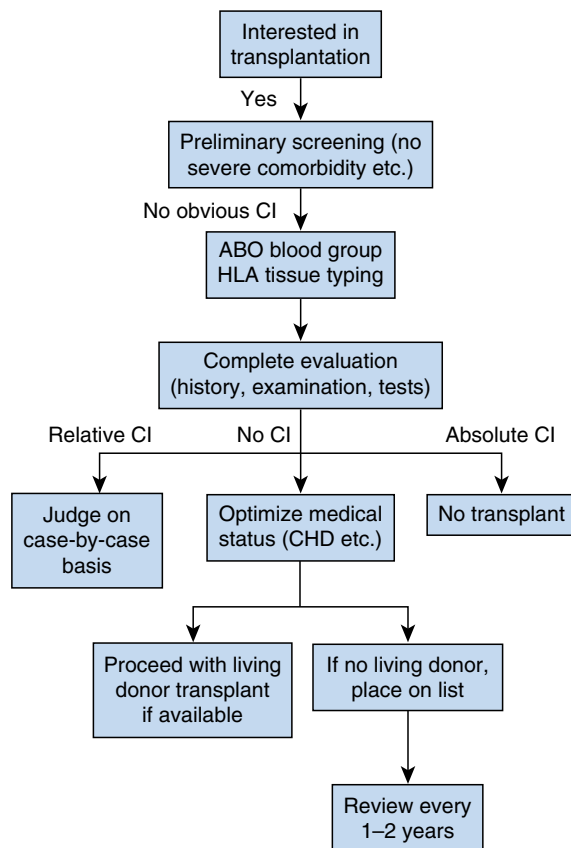
Until recently, HIV infection was considered an absolute contraindication to renal transplantation in most centers. This reflected fears that immunosuppression would facilitate progression of infection and that the short survival of


Figure 32–2   Typical steps in the evaluation of a patient for kidney transplantation. *CI,* contraindication; *CHD,* coronary heart disease.

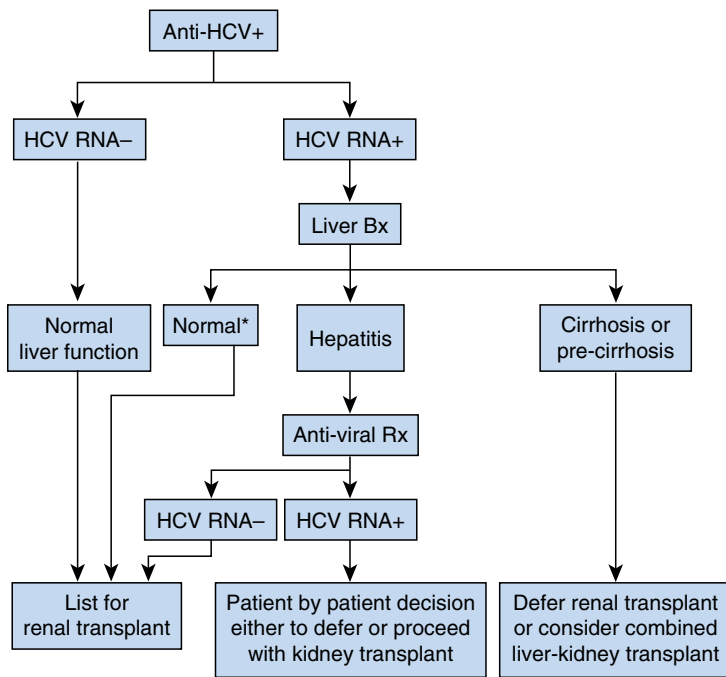
Table 32–6   Routine Tests for Potential Kidney Transplant Recipients

ABO blood typing and HLA tissue typing
CBC, PT, PTT
Plasma creatinine, urea, electrolytes, calcium, glucose, PTH
Chest X-Ray, EKG
Urinalysis and urine culture
Tests for HIV, hepatitis B, hepatitis C, cytomegalovirus, Epstein-Barr virus, syphilis
If >50 yrs: stool occult blood testing +/− colonoscopy
Women: Pap smear; mammogram if >40 yrs
Men: PSA if >50 yrs

Table 32–7   Contraindications to Kidney Transplantation

Active cancer
Active infection
Active psychiatric illness
Ongoing non-compliance with dialysis or medicine regimen
Major morbidity which would be worsened by transplant or would lead to very short posttransplant survival
High operative risk
ABO-incompatibility*
Positive T-cell crossmatch*
Severe obesity eg BMI >35 kg/m^2

*Protocols are available to facilitate transplantation across these barriers.


HIV–positive transplanted patients would waste valuable allografts. With dramatic improvements in the survival of HIV-positive patients, these premises are being reexamined.[18] These patients should be referred to centers specializing in the management of transplanted HIV-positive patients as their management is complex. One difficulty is the potential for interactions between the multiple antiviral medicines, some of which inhibit and some of which induce the cytochrome P450 system.

Tuberculosis.
Active tuberculosis, of course, requires full treatment and cure before transplant. Transplant candidates who are PPD positive and who have no clinical or radiologic evidence of active disease should receive a course of antituberculosis prophylaxis if this has not been administered before. Typically, isoniazid is prescribed for 9 months. The major adverse effect of this drug is hepatotoxicity, and monitoring of LFTs is mandatory. Ideally, the complete course of isoniazid is given pretransplant but posttransplant administration is acceptable.

Ongoing Psychiatric Illness

Psychiatric illness is only a contraindication if severe enough to impair understanding of the risks and benefits of transplantation and if severe enough to prevent normal posttransplant follow-up and compliance. Addiction to alcohol or other drugs should be successfully treated before transplantation. Mental retardation of itself is not a contraindication if adequate posttransplant support is available. The issue of informed consent for surgery can be difficult, however.

Specific Renal or Systemic Diseases that Can Recur Posttransplant

Certain renal and systemic diseases recur posttransplant and, in such cases, the recipient must be informed of this risk.

Usually transplantation is not contraindicated but a waiting period, until the disease becomes quiescent, is sometimes required.

Primary Focal Segmental Glomerulosclerosis (FSGS)

Primary FSGS has a reported recurrence rate of 20% to 40% and causes graft loss in approximately 50% of recurrent cases.[19] Risk factors for graft loss from recurrence (by analysis of registry data) include white recipient, black donor, younger recipient, and treatment for rejection.[19] Other factors thought to predict recurrence and/or graft loss are rapidly progressive FSGS in the recipient's native kidneys and recurrence of disease in a previous allograft. Treatment options include plasmapheresis or immunoadsorption, high dose glucocorticoids, high dose CNIs and cyclophosphamide but controlled studies are lacking. Those at very high risk of recurrence should be offered cadaveric rather than living donor kidneys.

Anti-GBM Disease

Before transplantation, patients with ESRD due to anti-GBM disease should be on dialysis for at least 6 months and have negative anti-GBM serology. If these criteria are fulfilled, posttransplant recurrence is very rare.

De Novo Anti-GBM Disease

De novo anti-GBM disease occasionally arises in the early posttransplant period in grafts transplanted into recipients with Alport's syndrome. Here the recipient with abnormal type IV collagen α chains produces antibodies against the previously "unseen" normal α chain in the basement membrane of the transplanted kidney. Patients with graft dysfunction should be treated with plasmapheresis and cyclophosphamide.

Those with only immunofluorescence evidence of recurrence (i.e., linear staining of GBMs by IgG) do not require therapy. Graft failure due to anti-GBM disease is more common in retransplants.

HUS/TTP

Recurrence of classical (diarrhoea associated) HUS/TTP is uncommon. In contrast, recurrence of atypical (nondiarrhoea associated) HUS/TTP, particularly if inherited, is common. In one series of patients with an autosomal recessive form of HUS/TTP, there was recurrence in six of seven cases.[20] In general, the prognosis for the graft is poor if there is recurrence. Even when ESRD is due to the classical form, transplantation should be deferred until the disease is quiescent for at least 6 months.

IgA Glomerulonephritis

Studies with longer follow-up have shown that histologic recurrence of this condition is common; in one recent series it was at least 35%.[21] On multivariable analysis, recurrence was not associated with greater risk of graft failure. IgA glomerulonephritis is not a contraindication to transplant, although it would seem prudent in very aggressive forms of this condition to allow a period of 6 to 12 months before transplant.

SLE Nephritis

Graft and patient survival overall are similar in patients with ESRD secondary to lupus nephritis compared to those with ESRD from other causes.[22] Recurrence of severe SLE, systemically or within the graft, is uncommon after transplant. This probably reflects the following: patient selection, disease activity "burning out" on chronic dialysis, and the effects of powerful posttransplant immunosuppression. After starting dialysis, patients should have clinically quiescent disease for 3 to 6 months before undergoing transplantation. Clinical criteria are a better guide to suitability for transplant than serologic criteria alone. SLE patients with anti-phospholipid antibody syndrome probably have poorer graft and patient survival because of recurrent APS after transplant. These patients should resume full anticoagulation immediately after surgery.

Wegener's Granulomatosis and Microscopic Polyangiitis

Renal and extrarenal recurrence of Wegener's granulomatosis and polyangiitis have been described after renal transplantation. It is not yet known whether current regimens incorporating MMF or tacrolimus reduce that risk. In the largest reported series, with a mean follow-up time of 44 months, ANCA associated small vessel vasculitis recurred in 17% of cases; renal involvement recurred in 10% of cases; the recurrence rate was not lower with CsA therapy.[23] This and other studies have found that positive ANCA serology at the time of transplant does not predict later relapse. Of course, patients with ESRD secondary to ANCA vasculitis should not be transplanted until the disease is clinically in remission. Relapses usually respond to cyclophosphamide.

MPGN

The primary forms of type I MPGN and type II MPGN (dense deposit disease) can recur after transplant. The risk of recurrence is unclear because these are rare conditions and some cases of "primary MPGN" may in fact have been related to HCV infection. Furthermore, type I MPGN is difficult to distinguish histologically from primary transplant glomerulopathy. One series found recurrence of type I MPGN in 33% of cases; graft survival was significantly poorer when this recurred.[24] Case reports have suggested a benefit of steroids, cyclophosphamide, and plasmapheresis.

Type II MPGN recurs, at least by histologic criteria, in most allografts. Early reports suggested that associated graft failure was unusual. However, more recent series have documented allograft loss from recurrent type II MPGN in over 20% of cases.[25]

Membranous Nephropathy

Membranous nephropathy may recur posttransplant, or more commonly, arise *de novo*. The associated clinical features vary from nonexistent (i.e., histologic evidence only) to nephrotic syndrome. In one series of 30 patients, the actuarial risk of recurrence at 3 years was 29% and recurrence was associated with poor graft survival.[26] *De novo* membranous nephropathy is often associated with chronic allograft nephropathy. As with native kidney disease, HCV infection and other causes of this glomerulopathy should be excluded.

Primary Hyperoxaluria

Primary hyperoxaluria is a rare inherited metabolic disorder characterized by hyperproduction of oxalate with resultant massive deposition in the kidney and urinary tract. Deposition can recur immediately posttransplant, leading to early graft loss. The treatment for choice is therefore often combined liver-kidney transplantation as the hepatic allograft corrects the enzyme defect.

Sickle Cell Disease

Many centers consider sickle cell disease a contraindication to transplant. Sickling may actually worsen posttransplant because of the higher blood hemoglobin. Nevertheless, some patients may be candidates for transplantation, if the disease is well controlled and if expert hematologic input (for therapies such as exchange blood transfusion) is available in the perioperative period.

Diabetes Mellitus

It is important to note that diabetics, in particular, gain a significant survival advantage with transplantation as compared to those diabetics remaining on dialysis on the waiting list.[27] Recurrence of diabetic nephropathy in the allograft has not been well studied. This reflects the poor long-term survival of diabetic transplant recipients; the duration of exposure to the diabetic milieu is often insufficient to allow development of severe diabetic nephropathy. Kim and Cheigh[28] performed a case control study of 78 patients with ESRD due to type I DM. Overall graft survival was poorer in the diabetic group; if

death were excluded as a cause of graft failure, however, graft survival would be little different. Six of 16 patients who were biopsied had histologic evidence of recurrence, but this resulted in graft loss in only one case. It is likely that with better management of risk factors for cardiovascular disease, overall survival for diabetics will improve. Thus, recurrence of clinically significant diabetic nephropathy will probably become more common.

Other Conditions that Complicate Transplantation

High Sensitization to HLA Antigens

ESRD patients can develop antibodies against HLA antigens after exposure to these antigens in previous allografts, blood products, or pregnancy. Obtaining a suitable allograft for highly sensitized patients has traditionally proved difficult—such patients may wait many years for a compatible kidney. Furthermore, rejection tends to be more common and severe. Two protocols are evolving for the "desensitization" of such patients. One involves intermittent infusions of very high dose IgG; the IgG probably has multiple immune effects. Another protocol involves pretransplant plasmapheresis, lower dose IgG, MMF, tacrolimus, and steroids. In each case, transplant is done if and when the donor-recipient cross-match turns negative. Short-term results have been very encouraging.[29,30] Longer-term results of these approaches are awaited but desensitization will likely be increasingly offered to highly sensitized patients otherwise precluded from transplantation.

Age

There is no absolute age above which transplantation is contraindicated; biologic age is more important than chronological age. Each case should be assessed on its merits. A reasonable criterion is that the patient would be expected to live for at least 5 years after transplant. Of course, many elderly patients will still need to wait several years before obtaining a cadaveric transplant. Where available, additional listing for marginal kidney transplants should be discussed.

Obesity

Obesity is associated with more transplant surgery-related complications, more DGF, higher mortality (related to cardiovascular complications), and poorer graft survival.[31, 32] Poorer long-term graft survival probably reflects the effects of DGF, nephron overwork, and more difficult dosing of immunosuppressive drugs. Nevertheless, there are some data suggesting that transplantation provides a survival benefit over remaining on the waiting list (on dialysis); no benefit was noted in those with BMI greater than or equal to 41 kg/m^2.

The question is: At what BMI are the risks of transplantation excessive? A reasonable approach is to enter all prospective recipients with BMI greater than 30 kg/m^2 into weight loss programs and, of course, to rigorously exclude/treat any cardiac disease. In those with persistent BMI greater than 30 kg/m^2 but without cardiac contraindications to surgery, eligibility for transplantation should be judged on a case-by-case basis.

Liver Disease

Hepatitis C has been discussed previously. General principles related to liver disease (of any sort) are that transplantation should not be performed where there is active hepatitis or advanced cirrhosis. Less severe forms of liver disease may not preclude transplantation, but wherever possible, treatment should be completed pretransplant.

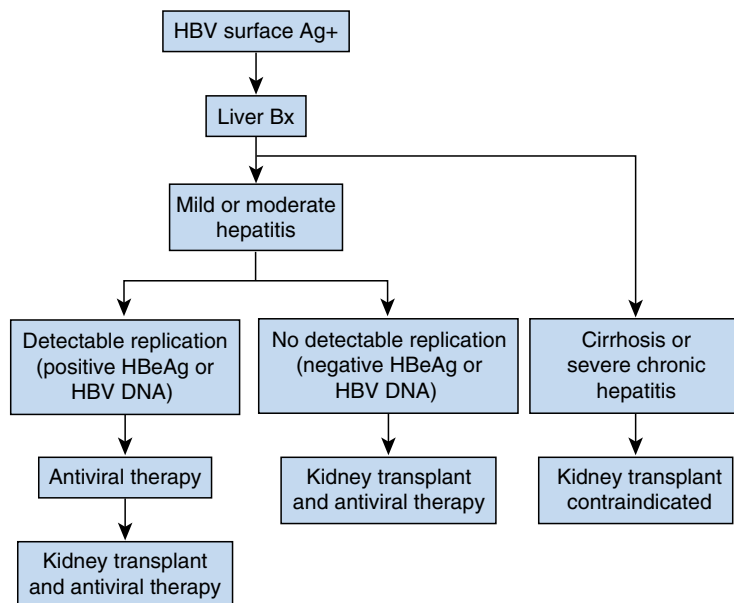
Transplantation and immunosuppression can undoubtedly worsen hepatitis B. A generally accepted strategy for the assessment of the ESRD patient chronically infected with HBV (i.e., chronically HBV surface antigen positive) is shown in Figure 32–4. Current guidelines are that all HBV surface antigen positive patients who do receive a kidney transplant should receive


Figure 32–4 Management of the HBV surface antigen positive ESRD patient being considered for kidney transplant.

lamivudine for the following 18 to 24 months.[33] Lamivudine has the major advantage over interferon-α of not promoting allograft rejection.

Cardiac Disease

The high prevalence of cardiovascular disease in ESRD patients is well known. It is very important to optimize the cardiovascular status of the transplant candidate before surgery for the following reasons: (1) The stress of surgery and anesthesia can precipitate serious cardiac events such as myocardial infarction; (2) perioperative cardiac events can contribute to delayed graft function; and (3) performing major interventions such as coronary angioplasty/stenting or coronary artery bypass grafting posttransplant could damage the allograft (whereas renal damage is not a concern in those on dialysis). Thus, all patients require careful evaluation for clinically significant coronary heart disease. A suggested schema is shown in Figure 32–5. Protocols differ substantially between centers; in some, for example, all diabetic patients undergo diagnostic cardiac catheterization. Obviously, close consultation with the candidate's cardiologist is important. The type of noninvasive test used to screen for coronary heart disease depends on center expertise and availability. In general, an exercise-based (treadmill) test is most desirable, as it best simulates the "stress" of surgery. However, many ESRD patients are not robust enough to achieve adequate heart rates or workloads on the treadmill; in such cases, pharmacologic agents can be combined with echocardiography or scintigraphy. Unless contraindicated, ESRD patients known to have coronary heart disease should receive perioperative aspirin and β-blockade.

Diseases of the Gastrointestinal Tract

These are rarely contraindications to renal transplant. Obviously, acute exacerbations of peptic ulcer disease, diverticulitis, and so forth, should be treated before transplant. Those with a history of acute cholecystitis should probably undergo cholecystectomy. Some centers perform cholecystectomy in diabetic transplant candidates with asymptomatic cholelithiasis. Sometimes partial colectomy is performed in transplant candidates with recurrent diverticulitis—the rationale again being that recurrence of the disease posttransplant would be more harmful.

Seizure Disorders

Many antiseizure medications upregulate activity of hepatic cytochrome P450 enzymes. Continuation of such medications after transplant may thus lead to difficulty obtaining therapeutic blood concentrations of the calcineurin inhibitors (and presumably other medications metabolized by this enzyme system). Transplant candidates taking antiseizure medications should be assessed as to whether such medications can be stopped or changed to less enzyme-inducing alternatives (for example, carbamazepine is less inducing than phenytoin).

MANAGING PATIENTS ON THE WAITING LIST

Waiting times in the United States and elsewhere for cadaveric grafts are increasing and are typically several years. Some patients wait more than 5 to 10 years. Thus, dialysis patients are at relatively high risk of developing new complications, particularly cardiovascular disease, while waiting for a cadaveric kidney. Ideally, all patients on the list, or at least those at highest risk of developing new complications (e.g., elderly, diabetics), should be reassessed every 1 to 2 years. This requires a lot of work! Close communication with the patient's outside nephrologist is essential.

CONCLUSION

Thorough evaluation of the candidate transplant recipient is essential. The risks and benefits of transplantation must be carefully assessed for each individual patient. As the waiting list grows longer, more attention must be paid to those on the list to ensure that they remain optimally prepared for their transplant.

Figure 32–5 Suggested evaluation for coronary heart disease pretransplant. *Hypertension, hyperlipidemia, diabetes mellitus, smoking. **Specific test will depend on patients's ability to exercise and on local expertise.

Surgical Aspects of Renal Transplantation

Nahel Elias, M.D. • Francis L. Delmonico, M.D. • Dicken S.C. Ko, M.D., F.R.C.S.C.

HISTORIC ASPECTS

The early development of renal transplantation has much of its history rooted in Boston at the Peter Bent Brigham Hospital.[1] As the chief of the Department of Surgery during those formative years, Francis D. Moore created an environment filled with energy and resources, enabling significant innovation. The careful and logical progression of the Brigham's investigative work in transplantation eventually captured the Nobel Prize, which was awarded to Joseph Murray in 1990.

Some transplant physicians may not be aware of the depth of the Brigham research that preceded Murray's accomplishments. Prior to the first successful kidney transplant between identical twins performed by Murray in 1954, a series of nine recipients of cadaveric renal allografts was published by David Hume and colleagues,[2] who were also working in Moore's department. One of Hume's patients experienced adequate renal function for nearly 6 months following transplantation. This recipient eventually suffered a rejection of the "homograft," a fate that the Brigham group had observed previously in numerous renal transplants in dogs. Hume's technique for human renal transplantation was, in retrospect, primitive; the renal allograft was placed in the thigh and a cutaneous ureterostomy was established for urinary tract drainage.[2] The patient, who enjoyed several months of renal function, wore a leg bag to collect the allograft urine, and he was able to manage the stoma without difficulty, traveling by public transportation to the hospital for follow-up on many occasions (Joseph Murray, M.D., personal communication, 1998). A total of 13 such renal transplantations were performed by the Brigham team using the upper thigh vessels for vascular anastomoses and the skin ureterostomy for drainage.[3]

Hume[4] made other contributions to transplantation that we are familiar with today, including the development of tissue typing and a network of organ sharing. His vision of an organ bank led to the formation of the Southeast Organ Procurement Foundation, the forerunner of the United Network for Organ Sharing (UNOS). The concept of removing human kidneys from cadavers was first undertaken by Hume in 1947, as he and Charles Hufnagle resolved the postpartum renal failure of a young woman by suturing the renal artery and vein of a cadaver kidney to the brachial vessels of this patient (Francis D. Moore, M.D., personal communication, 1998). The cadaver kidney provided a method of dialysis until the recovery of this patient's native kidney function permitted her survival.[4]

Had it not been for the untimely death of Hume[1] in 1973, he likely would have shared the Nobel Prize with Murray. It should be noted, however, that more than a decade before Hume's pioneering work, a Russian surgeon named Voronoy[5] attempted a renal transplantation from a cadaver (6 hours after the patient's death) (Figs. 33–1 and 33–2). Although this transplant was unsuccessful in producing urine, Hume and colleagues[2] acknowledged Voronoy in their original report of the Boston series. An informative review of the Voronoy procedure was published by Hamilton and Reid[6] in 1984.

Starzl[5] has recorded that the extraperitoneal site of renal transplantation was first considered by French surgeons prior to Murray's successful transplantation. Nevertheless, this retroperitoneal pelvic location was later chosen for the identical twin renal transplantation by Murray and colleagues[3] because it enabled implantation of a short segment of ureter into the bladder. An insufficient length of the transplanted ureter was the principal reason not to use the native renal fossa. However, performing a simultaneous nephrectomy was also viewed as an impediment. Other advantages of the heterotopic location included the following[3]:

- The kidney was placed in a "more natural environment" (versus the thigh).
- Normal physiologic conditions would be re-created by gravity drainage of the renal pelvis.

In 1954, a 24-year-old patient with malignant hypertension and a blood urea nitrogen (BUN) value of 185 mg/dL was referred to Dr. John Merrill and his colleagues at the Peter Bent Brigham Hospital.[7] The patient was disoriented and was experiencing generalized seizures. It was subsequently determined that the patient had a healthy twin brother. To confirm the genetic identity of these siblings, skin grafts were exchanged between the twins. (This approach still has a contemporary application, in the rare instances in which immunosuppression is to be withdrawn after the transplantation of a renal allograft from a sibling thought to be an identical twin.) At the time of the first transplant, no immunosuppression was available. Nevertheless, Murray concluded correctly that the kidney would not be rejected because of the genetic identity. He also anticipated that the kidney would function normally because he had established that a renal autograft had an indefinite period of normal physiologic status in experimental animals. A left donor nephrectomy was performed and the right iliac fossa was used for the recipient site of transplantation. The donor renal artery was anastomosed to the recipient's hypogastric artery in an end-to-end fashion, and the end of the renal vein was sewn to a venotomy in the side of the common iliac vein. The total ischemia time was 1 hour 22 minutes; nevertheless, the kidney made urine immediately. The ureter was tunneled through the submucosa of the bladder, and an anastomosis between mucosa of the donor ureter with mucosa of the recipient bladder was then performed.
Figure 33–1   Y. Y. Voronoy experimented with dog allografts before carrying out the first human kidney allograft in 1933 at Kherson in Ukraine. His experimental animal model is shown here. (From Hamilton D: Kidney transplantation: A history. *In* Morris PJ [ed]: Kidney Transplantation: Principles and Practice, 4th ed. Philadelphia, WB Saunders, 1994, p 4.)

Figure 33–2   David M. Hume (1917–1973) pioneered human kidney transplantation at the Peter Bent Brigham Hospital, Boston, and the Medical College of Virginia. (From Hamilton D: Kidney transplantation: A history. *In* Morris PJ [ed]: Kidney Transplantation: Principles and Practice, 4th ed. Philadelphia, WB Saunders, 1994, p 4.)

The recipient's native kidneys were subsequently removed separately at 3 and 5 months after transplantation because of (1) concern that either kidney might become the source of infection and (2) recurrent hypertension.

In awarding Joseph Murray the Nobel Prize, the committee recognized not only the first successful transplantation in 1954 but also two of his other significant accomplishments: the first successful transplantation of a renal allograft between two fraternal (nonidentical) twins in 1959 using total body irradiation as immunosuppression and, 4 years later, one of the first successful transplantations from a nontwin donor using azathioprine for immunosuppression. Although the focus of this chapter is to recount the surgical aspects of renal transplantation, the contributions of Calne[1] as a Brigham colleague of Murray's should not be overlooked. The routine use of immunosuppression for cadaver donor renal transplants soon thereafter became broadly applied by Hume, Starzl, Russell, Hamburger, and Najarian.

PREOPERATIVE EVALUATION OF RENAL TRANSPLANT RECIPIENTS

The renal disease most commonly associated today with end-stage renal disease (ESRD) is glomerulonephropathy, usually the result of diabetes mellitus. However, individuals who have lost their primary renal transplants because of rejection now constitute the next largest group of patients with renal failure being listed for transplantation. More recently, ESRD combined with another end-stage organ dysfunction necessitating double organ transplants, such as combined kidney-liver and kidney-heart, are on the increase. When there are instances in which the cause of renal failure is unknown, it remains very important to clearly establish its irreversibility before proceeding to renal transplantation.

The success of renal transplantation since the 1960s has been so favorable that it is clearly the optimal therapy for end-stage renal disease. Nevertheless, we have become victims of our own success because the number of potential recipients now far exceeds the number of donors. Thus, prospective patients must be carefully considered for renal transplantation to ensure that they are appropriate candidates for such a scarce resource. An efficient format for evaluating candidates for transplantation is to assemble a meeting of multidisciplinary representatives to assess each patient with the family in attendance. All of the pertinent medical history, laboratory data, and social information should be reviewed by the team at this family meeting to reach a clinically sound recommendation. Psychiatric assessment of a patient's compliance with the medical regimen must be determined before the patient is accepted for transplantation.

Although older age is associated with a higher incidence of other medical illnesses that may lead to a decreased life expectancy, the age of the individual is not an absolute restriction to renal transplantation. Cadaveric renal transplantation can be considered for patients older than 70 years who are otherwise in satisfactory condition for an operative procedure and who may still have a good life expectancy and, therefore, will benefit from a renal allograft.

The overall medical condition of the patient with extrarenal comorbid factors, such as cardiovascular (coronary, valvular, or peripheral vascular), pulmonary disease, hepatitis, and malignancy, also influences patient suitability. This is discussed more in Chapter 32. From a surgical perspective, assessment of arteriosclerotic peripheral vascular disease and its extent is essential. Aortoiliac disease proximal to the transplant may compromise circulation to the allograft and iliofemoral disease distally may result in steal of the lower extremity circulation by the allograft.[8] Assessment of the urinary tract is very important. In males, bladder outlet obstruction secondary to benign prostatic hypertrophy, bladder neck

contracture, or urethral strictures must be evaluated before transplant surgery. Although the presence of structural abnormalities of the urinary tract has previously precluded renal transplantation, anatomic reconstructions of the urinary tract, including continent urinary diversion, now permit affected patients to be considered for transplant. In the cases where the storage capacity of the bladder is insufficient for normal function, these bladders may be amenable to cyclic hydrodistention, augmentation cystoplasty, continent urinary diversion, or ileal conduit construction in preparation for transplant.

Ultrasonography may be useful to determine structural of the native kidneys prior to transplantation. Patients with renal failure secondary to chronic pyelonephritis are at risk for persistent urinary tract infection following transplantation; thus, a native nephrectomy prior to or at the time of transplantation may be indicated. Polycystic kidneys may also require nephrectomy prior to transplantation because of bleeding, infection, nephrolithiasis, or mass effect (compromising the space for the allograft). Renal cysts that develop in patients undergoing long-term hemodialysis are a risk factor for renal cell carcinoma.[9–11] If an abnormal mass is identified in the renal parenchyma, further anatomic definition by computed tomography (CT) is required. A native nephrectomy may be indicated to diagnose and to treat renal malignancies prior to transplantation. A renal cell carcinoma is not an absolute contraindication to transplantation, but Penn[12] has advised that an extended period of observation is necessary to rule out development of metastasis before immunosuppression is instituted.

If the patient is anuric or if obstructive/reflux uropathy is a cause of ESRD, a voiding cystourethrogram (VCUG) is often performed preoperatively. Urinary reflux and potential stagnation in a large tortuous upper tract that empties poorly may predispose to further urosepsis after transplantation. A VCUG is also useful to assess the bladder volume of patients with a history of bladder dysfunction.[13] In a large retrospective series, however, routine VCUG evaluation prior to renal transplantation found only 2.5% of 517 patients to have abnormalities.[14] A VCUG presents the potential risk of introducing infection into an otherwise sterile compartment or of causing trauma to the lower urinary tract. In the series just cited, patients with reflux alone (3 of 517) did not require intervention before transplantation.[14] Moreover, a VCUG may not distinguish reflux from a normal urinary tract in approximately 22% of patients when two consecutive VCUGs are performed successively in the same patient. The diagnostic value of a VCUG must be balanced with its risks and costs, thus making its routine use inadvisable.[13]

LIVE KIDNEY DONATION

The notion of removing an organ for transplantation is unique among major surgical procedures because it exposes the healthy donor to the risks of surgery solely for the benefit of another individual. Despite the compelling reasons for using live kidney donors, the procedure could not be justified if unacceptable morbidity or mortality were to be incurred. This concept has been critically evaluated to ensure short-term and long-term safety for the altruistic donor. In the last 50 years, live donor renal transplantation has clearly become

an accepted medical procedure using related or unrelated volunteers. Evaluation of candidate donors is discussed in detail in Chapter 32.

OPERATIVE TECHNIQUES

Open Donor Nephrectomy

The techniques of donor nephrectomy can vary among different centers; some favor a posterior rib spreading approach, whereas most now employ a mini-incision anterior flank incision. Regardless of the type of open surgical approach, there are a number of fundamental surgical principles that are of importance. One must have adequate exposure to visualize the important anatomic structures during dissection. The tissues around the renal arteries must be carefully handled to minimize vascular spasm. The vasculature to the ureter must be maintained and meticulously preserved to limit the possibility of subsequent ureteral ischemia. It is also important to maintain an active diuresis so that there will be brisk resumption of renal function after transplantation into the recipient.

Most often, the living donor patient is placed in an extended flank position so that either a supra-11th or supra-12th rib incision can be performed through the latissimus dorsi muscle posteriorly and external oblique muscle anteriorly. The internal oblique and transverse abdominis muscles are then divided with the underlying transversalis fascia to provide full retroperitoneal exposure of the kidney. The paranephric fat and Gerota's fascia, lying in the central part of the wound, are entered. The renal vein is dissected to its junction with the vena cava, the adrenal and gonadal tributaries being ligated and divided. The renal artery is skeletonized at its origin from the aorta after lifting the kidney from its bed and rotating it anteriorly. The ureter is freed, with its investing vessels and fat, down to or below the pelvic brim and then transected. Once urinary output from the skeletonized kidney is assured, the renal artery and vein are clamped and divided, taking care to leave a sufficient cuff of the retained donor vessel to allow secure repair.

The left kidney is usually preferred for transplantation because of the anatomic advantage of a longer renal vein. The left renal vein is transected just proximal to the origins of the adrenal and gonadal veins, providing sufficient length of the vein. If the right kidney is selected, the right renal vein is transected at its origin at the inferior vena cava. The excised kidney is perfused with a chilled, heparinized electrolyte solution. Increasing the osmolarity of the perfusate with mannitol is believed by some to further protect the kidney from ischemic damage. The use of more complex and thus more expensive preservation solutions is not required for living donor kidneys, which will typically be reimplanted with only a brief cold ischemic interval. The wound is closed without drains, and the patient is returned to the recovery room where a chest radiograph is obtained to exclude the possibility of pneumothorax.

Laparoscopic Nephrectomy

Minimally invasive techniques using laparoscopy have made remarkable changes in the field for surgery in the last decade.

A variation of the laparoscopic living donor nephrectomy approach using retroperitoneal endoscopy with special retractors was first reported in 1995[90]; however, the first reported case of a successful laparoscopic nephrectomy in a living donor was performed by Ratner and colleagues[91] at Johns Hopkins University. A subsequent report of 10 consecutive successful laparoscopic living donor nephrectomies performed at the same institution was evaluated against a historic control group of open nephrectomies. The renal allograft warm ischemic time was 4.2 ± 1.3 minutes during the retrieval process through a small (4 to 5 cm) infraumbilical incision. All laparoscopically procured kidneys immediately functioned upon revascularization in the recipients. Compared with the open approach, the laparoscopic procedure was associated with the following advantages[92]:

- Significantly decreased postoperative use of analgesics
- Reduced estimated blood loss
- Earlier resumption of normal diet
- Shorter hospitalization

A later study from the University of Maryland, involving 70 cases of attempted laparoscopic living donor nephrectomy, demonstrated a success rate in 94% of cases. Renal allograft survival rates were 97% in the laparoscopic nephrectomy group and 98% in the open surgery group. Similar to prior reports, this study found that narcotic requirements, length of stay, blood loss, and interval until return to normal activity were significantly less in the laparoscopic donor group.[93] These initial successes in laparoscopic living donor nephrectomies have led to further series that have demonstrated long-term safety and cost-effectiveness associated with the inherent advantages of the procedure.

Some of the initial concerns about laparoscopic donor nephrectomy included warm ischemic injury and prolonged surgical times compared to open donor nephrectomy. With the advent of many ingenious minimally invasive products over the last few years, the incorporation of endocatch and hand-assisted (Handport, LapDisc, or Pneumosleeve) devices enables shortening of ischemic times to intervals comparable to those of open donor nephrectomies. Accordingly, the results for laparoscopically removed kidneys are now quite comparable to those achieved following transplantation of organs procured via the classic open incision.[92]

Many potential live kidney donors continue to be concerned about the potential complications of open surgical approach and the resultant cosmetic appearance of a flank incision. Historically, open donor nephrectomy has been reported to have less than 1% significant morbidity.[86–89] Nevertheless, the issues of postoperative pain, hospitalization, and convalescence requiring an extended period of absence from employment have deterred potential candidates. The availability of the minimally invasive nephrectomy techniques offers a more "patient friendly" option.

Cadaveric Donor Nephrectomy

Viable organs for transplantation are also retrieved from brain dead "heart-beating" patients who are maintained in stable physiologic balance by artificial support. These donors are brought to the operating room, where organ procurement is undertaken under semi-elective conditions employing the usual sterile precautions of any aseptic surgical procedure.

There are situations in which the criteria for brain death have been fulfilled but the concept of heart-beating donation has not been culturally accepted, and in which there is irreversible brain injury but not fulfilling the criteria of brain death, these patients may be candidates for "non-heart beating" (NHBD) or donation after cardiac death (DCD). In NHBD/DCD donors, respiratory support is discontinued. After cardiac function ceases, the donor is declared dead by an independent medical professional and the surgical procurement procedure is expeditiously undertaken. The kidneys must be cooled and removed more rapidly than in the heart-beating donation procedure to minimize warm ischemic injury to the retrieved organs. The goal is to limit the warm ischemic period to, whenever possible, less than 30 minutes. To further increase the number of kidneys available for transplantation, interest has also been revived in the possible procurement of organs from donors who are dead on arrival or who die following unsuccessful cardiorespiratory resuscitation ("uncontrolled" NHBD). Several studies have confirmed that significant numbers of patients succumb either in emergency rooms or intensive care units without brain death being declared.

If only the kidneys are to be removed, bilateral nephrectomy is accomplished through a long midline incision. The peritoneum is incised around the right colon so that the bowel can be retracted upward and to the left. The proximal aorta is freed to above the celiac axis, dividing and ligating the superior mesenteric artery, tapes, or large silk sutures are passed around the distal aorta and vena cava just above the iliac bifurcations. After achieving proximal aortic, distal aortic, and distal caval occlusion, preservation of the kidneys *in situ* is begun by perfusion either with chilled University of Wisconsin (UW) solution, Euro-Collin's solution, or Ringer's lactate solution containing mannitol (18 g/L) and heparin (20,000 units/L) infused through sterile intravenous tubing that has been placed directly into the distal infrarenal aorta. The objective is to take both kidneys with the full length of the renal artery and vein, preferably on aortic and vena–caval cuffs. This approach limits the possibility of injuring accessory vessels, which are present in 12% to 15% of normal kidneys. The technique we prefer entails *en bloc* removal of both kidneys with an intact segment of aorta and inferior vena cava to allow early *in situ* cooling of the kidneys. This approach also reduces the time required for the nephrectomies, because the fine dissection necessary for identification and isolation of the artery and vein can be performed after the kidneys are removed. With this technique, the risk of damaging accessory vessels is essentially eliminated. The final mobilization of the kidneys is undertaken within the plane of Gerota's fascia in a more leisurely manner. Care is taken to free and section the ureters as far down toward the bladder as possible and to avoid dissection within the renal hilus. The distal aorta and vena cava are divided, and the entire block is lifted anteriorly to expose the lumbar vessels posteriorly. Once the proximal aorta and vena cava have been divided, the block consisting of both kidneys and ureters, aorta, and inferior vena cava can be lifted out of the abdomen and placed immediately into a basin of cooled perfusion solution.

The more typical situation involves multiple-organ procurement from the same donor. Although the details will differ, depending on the combination of organs to be removed, certain common principles prevail. These include

wide exposure, dissection of each organ to its vascular connection while the heart is still beating, and placement of cannulas for *in situ* cooling and removal of organs while perfusion continues, usually in the order of heart, lungs, liver, pancreas, and then kidneys. The aortic perfusion cannula is placed in the infrarenal aorta as described previously, then the aorta is cross-clamped at the diaphragm and the aortic flush is begun for rapid cooling of the abdominal organs. Precise coordination among the retrieval teams is required at this critical stage. The thoracic organs are removed first; the liver is next, followed by the pancreas and kidneys. The kidneys are mobilized and removed in the same process described for kidney only retrieval.

RECIPIENT OPERATION

Vascular Anastomosis

The natural orientation of the renal vein, renal artery, and ureter is the anatomic basis for transposing the kidney to the contralateral iliac fossa. The left kidney of the donor is usually transplanted to the right iliac fossa of the recipient, and vice versa. However, the donor kidney can be placed on the ipsilateral side without technical hazard. Iliac vessel anastomoses are performed through an extraperitoneal approach.

In the recipient, a modified Gibson's incision can be made in either the left or right lower quadrant of the abdomen. The curvilinear incision allows dissection through the anterior abdominal wall and medial mobilization of the peritoneum. This approach facilitates full exposure of the retroperitoneal iliac fossa, the iliac vessels, and the bladder in preparation for implantation of the renal allograft. If a ureteropyelostomy is indicated as the method of urinary reconstruction, the Gibson's incision can be extended to the tip of the twelfth rib. This enables exposure of the inferior aspects of the Gerota's fascia and permits dissection to perform a standard simple nephrectomy.

The donor renal artery can be anastomosed to the recipient's common, internal, or external iliac artery. The location of the recipient arteriotomy is influenced by the length of the donor artery, the length of the donor ureter, and the presence of atherosclerotic plaques. Although historically either the internal iliac or hypogastric artery was preferentially selected for an end-to-end anastomosis to the donor renal artery (theoretically because of better flow dynamics for the allograft), it has not been shown to be superior to an end-to-side anastomosis of the renal artery to the common or the external iliac artery. Thus, the most common anastomosis performed today is between the end of the donor renal artery and the side of the recipient external iliac artery. This position allows use of the shortest segment of donor artery. Moreover, the proximity of these vessel anastomoses to the bladder also facilitates the creation of the ureteroneocystostomy without compromising the distal ureteric blood supply (Figure 33–3).

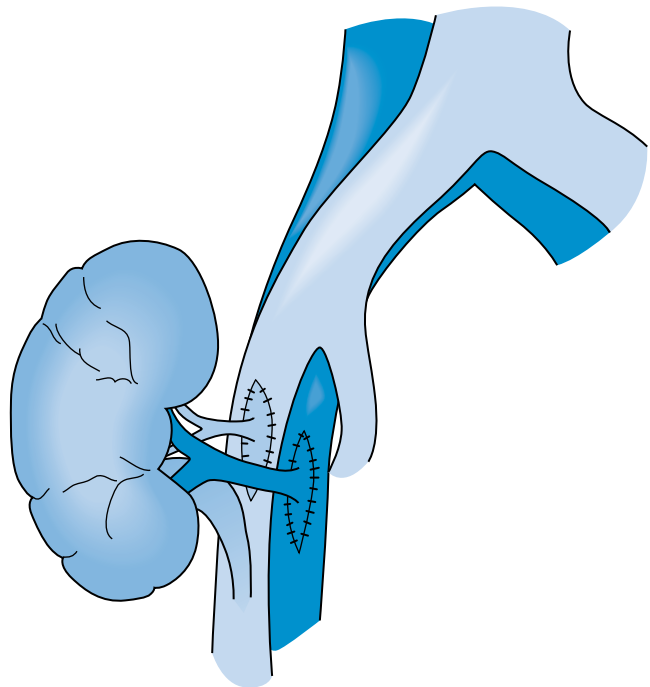
The hypogastric artery is now reserved as a last alternative to be used when the other vessels are deemed unsuitable. If the internal iliac artery is to be used, it is divided at the origin of the superior gluteal artery. However, transection of the hypogastric artery may contribute to vasculogenic impotence in males if there is significant occlusive disease of the iliac vessels.[15,16]


Figure 33–3 Use of Carrel patch on donor artery and vein end-to-side to external iliac artery and vein. (From Salvatierra O Jr: Renal transplantation. *In* Glenn JF [ed]: Urologic Surgery. Philadelphia, JB Lippincott, 1983, p 364.)

The existence of multiple donor renal arteries can be challenging for the transplant surgeon.[17] The loss of a polar vessel results in segmental infarction of the allograft. The lower pole vessel often provides blood supply to the ureter, so compromise of this artery may result in ureteral complications. Thus, during donor organ procurement, the surgical team must be cognizant of multiple renal arteries supplying either kidney. For example, the lower pole artery to the right kidney may course anterior to the vena cava, affecting the cannulation site of the vena cava during a multiorgan procurement from a cadaver donor. When a polar vessel is visualized, it can be traced to the origin of the aorta and salvaged on a Carrel patch of the aorta. Polar vessels can also be anastomosed to the main renal artery in an end-to-side manner to accommodate a single large-vessel anastomosis to the iliac arterial supply. However, very small arterial vessels may supply less than 10% of the kidney; therefore, ligation may be preferable because revascularization may not be feasible.

The placement of the renal vein anastomosis depends on the chosen site for the artery. If the external artery is selected, the renal vein is usually positioned anterior to the artery and is sewn on-end to the side of the external iliac vein. If the common iliac artery is used, the renal vein may be anastomosed to the common iliac vein posterior to the iliac artery. The posterior positioning of the renal vein on the common iliac vein prevents the possibility of poor flow when the patient is supine.

In cadaveric renal transplantation, the use of the donor vena cava to extend the short right renal vein is controversial.[18] Extension of the right renal vein enables an easier technical anastomosis and, possibly, better positioning of the kidney. However, this arrangement may theoretically cause low-flow

hemodynamics because of possible kinking of the long vessel. A study examining 305 transplanted right cadaveric kidneys demonstrated no higher rate of technical vascular complications in the 76 kidneys that had venous extensions than in those without venous extension[18]; there were no differences in 1- and 2-year graft survivals between those with and those without an extension. Some researchers have recommended that the donor procurement team provide the right kidney with the vena cava attached routinely, thus allowing the recipient surgical team to determine whether an extension is appropriate for the particular recipient's pelvic anatomy.

Urinary Drainage Reconstruction Techniques

Several strategies are employed for urinary tract reconstruction in renal transplantation. Although Hume and colleagues[2] experimented with a cutaneous ureterostomy in their pioneering series, the likely high rate of surgical complication discouraged this method of urinary drainage from gaining further acceptance. Instead, using either the bladder or ureter of the recipient offered the obvious advantage of enabling the recipient to void naturally.

Ureteroneocystostomy

The technique of ureteroneocystostomy, that is, the implantation of the donor ureter into the recipient bladder, can be classified as either an intravesical, extravesical, or combined intravesical and extravesical repair. Ureteroneocystostomy was first used for the correction of ureteral reflux in children more than 100 years ago by Witzel.[19] Intravesical repair of ureterovesical reflux gained favor in the 1940s with the Hess procedure,[20] which was designed to resolve distal ureteral stricture following reimplantation.

Historically, the most widely practiced intravesical ureteroneocystostomy was the Leadbetter-Politano technique.[21] This approach was used by Leadbetter in the early era of renal transplantation as the method of choice for urinary tract reconstruction. It involved a suprahiatal repair suitable for renal transplantation because the donor ureter was not advanced into the bladder trigone. The advantages of this procedure were (1) the elimination of ureteric kinking at the new muscular hiatus and (2) the hooking of the donor ureter by lateral placement in an expandable bladder. Nevertheless, the disadvantages of a formal cystostomy, enabling intravesical exposure and thereby necessitating prolonged bladder drainage, subsequently made the Leadbetter ureteroneocystostomy obsolete.

Extravesical ureteroneocystostomy creates an extravesical submucosal tunnel by defining a segment of detrusor bladder muscle under which the ureter passes. The most commonly used methods have been those popularized by Lich and Gregoir and by Barry.[22] Interestingly, Lich and Gregoir independently developed this technique simultaneously in the early 1960s (Figure 33–4). Gregoir's approach received much acclaim for its success in the repair of reflux in children in Europe. However, the negative experience as described by Hendren, with high reflux recurrence rates, adversely influenced its use in North America. Nevertheless, later series demonstrated its merits, which were excellent long-term results and few technical complications.[23,24] The Lich-Gregoir method of extravesical urinary reconstruction is favored in transplantation because of its simplicity. The need for minimal bladder dissection and the avoidance of complications of a formal cystostomy contribute to its effectiveness.

The concept of the Barry repair is similar to that of the Lich-Gregoir method, but the difference resides in the method of developing a submucosal tunnel. The Barry method utilizes a parallel incision in the detrusor muscle, which is followed by tunneling of the ureter submucosally between the incisions.[25] This procedure has a low complication rate, requiring reoperation in 2.1% of 1000 transplants reported.[26] Depending on the specific preferences of the treatment center and the experiences of the transplant surgeons, both methods are acceptable techniques for ureteroneocystostomy in renal transplantation.

The extravesical single-stitch technique was reviewed and compared with the Leadbetter-Politano and Lich-Gregoir

techniques at the University of Minnesota Hospital over an 8-year period in 1183 consecutive renal transplantations.[27] Overall, urologic complications occurred in 81 patients (6.8%); 68 (5.7%) of these complications occurred within 4 months of transplantation, and 13 (1.1%) were late. The complication rates for Politano-Leadbetter, Lich-Gregoir, and single-stitch techniques were 7.8%, 5.8%, and 6.7%, respectively. There was no difference among the techniques in rates of early and late complications of leakage, stricture, and hematuria in either cadaveric or living donor transplant recipients. Each technique has its inherent advantages, and every surgeon should become familiar with the different procedures to facilitate their use as dictated by individual circumstances.

Ureteropyelostomy

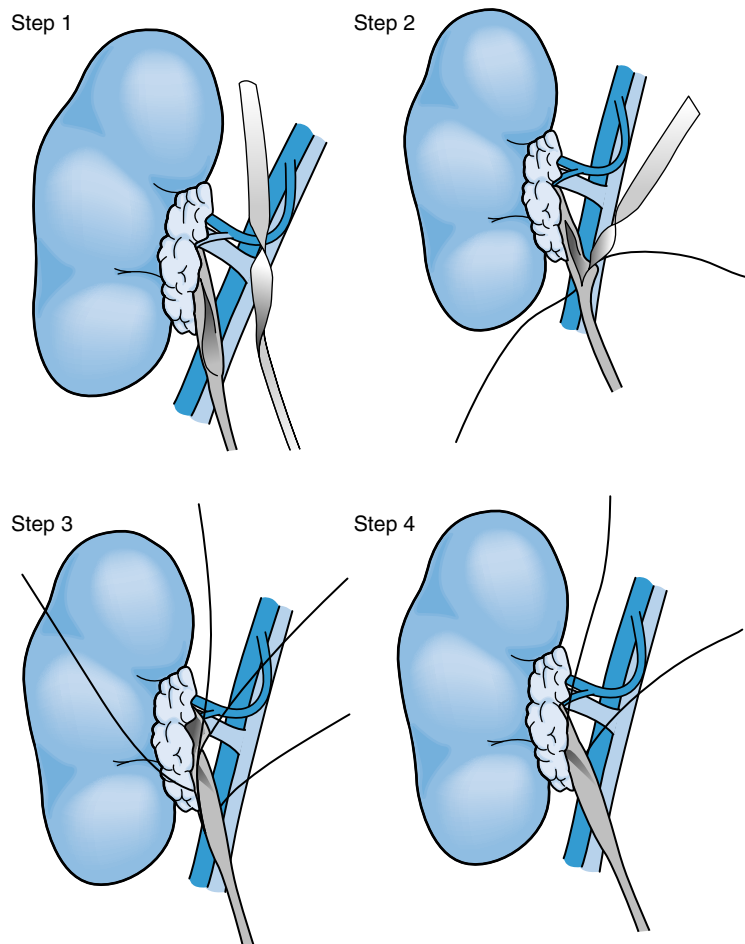
Leadbetter first described the technique of ureteropyelostomy for urinary tract reconstruction in renal transplantation 30 years ago. Updated revisions have subsequently been reported by Whelchel, Jaffers and colleagues,[28] and Hughes and colleagues[29] (Figure 33–5). The technique of ureteropyelostomy used in transplantation today employs the same surgical principles used by Foley in 1937 and by Anderson and Hynes in 1949, who earlier devised the method, that is, suturing a spatulated recipient ureter to the lowest portion of the donor renal pelvis. A ureteropyelostomy is usually accomplished after an ipsilateral native nephrectomy in which the recipient ureter is retained as a freestanding structure.

Ureteropyelostomy has distinct advantages, which include:

- Avoiding a cystostomy
- Shortening the duration of urethral catheterization
- Minimizing the complications of distal ureteral obstruction and stenosis
- Eliminating reflux in an otherwise predetermined normal ureter

In addition, a ureteropyelostomy theoretically preserves blood supply to the donor renal pelvis because the arterial supply to the native ureter is undisrupted. These technical features minimize the possibility of a poorly perfused donor distal ureter, especially after an episode of rejection. Rejection may affect ureteral blood flow and thus may contribute to the development of early ureteric leaks or late ureteric strictures.

Despite these attractive aspects, the popularity of ureteropyelostomy has been hindered historically by a high rate of urinary leaks, mainly related to the suture materials used to perform the anastomosis. With the advent of superior absorbable sutures (characterized by short duration of dissolution with good handling characteristics and appropriate needle configuration), the leak rate has become negligible. The long-term benefits of ureteropyelostomy have subsequently become more prominent compared with the uretero-

Figure 33–5 Technique of ureteropyelostomy. *Step 1*, Alignment of ureteral segments after partial transection and spatulation of the ureters. *Step 2*, Transection of the distal donor ureter after ligation of the apex stitch. Initiation of the anastomosis with direct visualization of the recipient ureter. *Step 3*, Ligation of the second corner suture with completion of the lateral suture. *Step 4*, Completion of the medial anastomosis. (From Jaffers GJ: Experience with pyeloureterostomy in renal transplantation. Ann Surg 1982; 196:588.)


neocystostomy method. The ureteropyelostomy does add time to the renal transplant procedure because the use of the ipsilateral ureter necessitates a concurrent native nephrectomy. An incidental—but important—advantage of concurrent native nephrectomy (with subsequent pathologic analysis) is that the original cause of the recipient's kidney disease can sometimes be better determined.

Ureteric Stents in Transplantation

Whether performed by ureteroneocystostomy or ureteropyelostomy, the major technical hazard of renal allograft transplantation is the reconstruction of the urinary tract. The rates of urinary leaks and obstructions in the immediate post-transplantation period range from 6% to 12%.[30] A ureteral stent can theoretically protect the urinary reconstruction through the creation of a conduit that drains the renal pelvis without exerting pressure on a healing anastomosis.

The use of ureteric stents is still controversial because of several disadvantages related to an indwelling foreign body in the immunosuppressed recipient of an allograft.[31] For example, a blood clot from the fresh anastomosis can easily obstruct the lumen of the stent. Ureteric stents may become structurally defective after urinary infection, resulting in stent breakage at the time of their removal via cystoscope. The peristaltic action of the ureter can dislodge the stent from its functional position. As a foreign body, the stent is a nidus for calculus formation, especially in a patient population predisposed to hypercalciuria because of secondary hyperparathyroidism. The distal portion of the stent may irritate the trigone of the bladder to give symptoms of irritative voiding, which is unacceptable for many patients. Because most patients undergo a meticulous urinary tract reconstruction without an increased risk of urinary leak, the use of a ureteric stent is recommended only in those circumstances in which there is a known technical hazard.[32] Such circumstances are:

1. Thin bladder secondary to disuse atrophy from chronic renal failure.
2. Anatomic outflow restriction, which may transmit elevated intravesical pressures directly onto the ureteroneocystostomy.
3. Neurogenic bladders compromised by uninhibited contractions.
4. Pediatric en bloc kidneys.[33]
5. Ureteric anastomosis into intestinal segments, such as ileal conduits or augmentation ileocystoplasties.

If a ureteric stent is required, the stent should be removed by 2 months after transplantation.

Abnormal Lower Urinary Tract

Renal failure can arise from functional abnormalities of the bladder that create high intravesical pressures leading to ureterovesical reflux. A dysfunctional bladder is associated with spinal dysraphisms and spinal cord injuries.[34,35] Such neurogenic bladders have difficulties with the storage and emptying of urine and, thus, have a propensity for urinary tract infections.[36] Patients with these conditions often require intermittent catheterization because they have lost the coordinated control of bladder function.[37] Autonomic dysreflexia associated with neurogenic bladder can cause uninhibited

bladder spasms, which may be resolved by urinary sphincterotomy and condom catheter drainage.[38] Even the most successful sphincterotomies subsequently scar and cause bladder outlet obstruction. Thus, an ileal conduit is the preferred choice of long-term urologic management for patients with dysfunctional bladder, despite the necessity of an external drainage appliance.[39,40]

The bladder with low compliance may be inadequate to perform the intended storage function. This form of bladder function predisposes to frequency and urinary incontinence. A small contracted bladder may warrant an augmentation to reconstruct the urinary tract[41–44] (Figure 33–6). This procedure provides a larger reservoir that, in combination with intermittent catheterization, may overcome the neurogenic component and allow for preservation of the native bladder.[45, 46]

Nevertheless, there are several potential problems with the ileocystoplasty. First, the intestinal mucosa is secretive in nature; thus, the presence of oliguria or anuria predisposes to accumulation of secretions, leading to outflow obstruction and subsequent bladder distention. Ileocystoplasty can be considered only in an individual with a small contracted bladder who still has satisfactory daily urine output. Second, the compliances of the ileum and bladder are dissimilar; therefore, when an ileocystoplasty is distended following successful renal transplantation, it is prone to disruption at the bladder-ileum anastomosis.[47,48] Reconstructive bladder surgery should be planned well in advance of the renal transplantation to allow for healing and appropriate maturation of the storage reservoir.[49] Third, many patients who have undergone augmentation ileocystoplasty do not void adequately and require continued intermittent catheterization. The overall problems with intermittent catheterization result in a symptomatic urinary tract infection rate of more than 40% in a nonimmunosuppressed host.[50] The development of urosepsis after transplantation may be detrimental to both patient and allograft survival.[39]

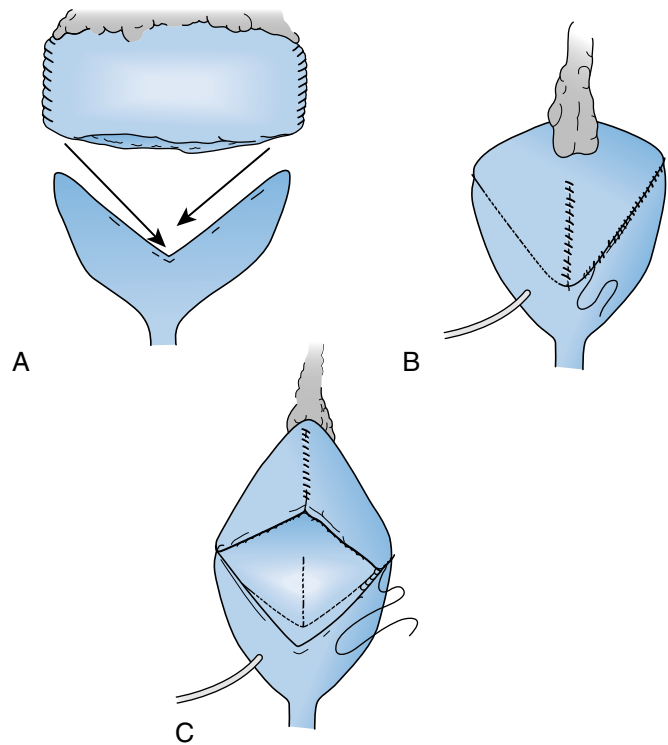
For the foregoing reasons, an ileal conduit is still the preferred treatment of choice for managing a poorly functioning lower urinary tract to reduce the potential complications associated with an abnormal lower urinary tract.

COMPLICATIONS OF RENAL TRANSPLANTATION

Vascular Complications

Thrombosis of a renal allograft can occur following hyperacute rejection; however, in the majority of cases, the cause of thrombosis remains obscure.[52–54] The associated risk factors for graft thrombosis without evidence of rejection have not been clearly established. Bakir and colleagues[55] reported the occurrence of 34 graft thromboses without pathologic evidence of rejection in 558 consecutive cadaveric kidney transplantations performed in a single center. The incidence of primary renal graft thrombosis was 6% (1.9% arterial, 3.4% venous, and 0.7% both), and this complication accounted for 45% of early (90 days) and 37% of 1-year graft losses. The multivariate analysis identified five independent risk factors for primary renal graft thrombosis:

- Use of donor's right kidney
- History of venous thrombosis (renal or extrarenal)

Figure 33–6 "Clam cystoplasty" with "cup patch" of bowel. **A,** The bladder is opened in a sagittal plane almost from anterior bladder neck to trigone. **B,** The bowel patch is reshaped to match the size of the opened bladder. **C,** Note that bowel is closed beginning at open ends, effectively disrupting peristalsis. (From Mitchell ME: Use of bowel in undiversion. Urol Clin North Am 1986; 13:352.)


- Diabetic nephropathy in the recipient
- Technical complications
- Recipient's perioperative and early postoperative hemodynamic status

There was no association between (1) primary renal graft thrombosis and recipient's age or sex; (2) number of previous transplants; (3) type of dialysis; (4) pretransplantation treatment with erythropoietin, antiplatelet agents, or oral anticoagulants; (5) donor's age or sex; (6) number of graft vessels; (7) warm and cold ischemia times; (8) site of transplantation (right or left iliac fossa); or (9) type of immunosuppressive agent used for induction.

In another series of 6153 consecutive renal transplantations, 134 index cases of graft loss from renal allograft thrombosis were reported to the Australian and New Zealand Dialysis and Transplant Registry between 1980 and 1992.[56] Renal allograft thrombosis was not associated with recipient age or sex, primary renal disease, type of dialysis, treatment with cyclosporine, extent of HLA antigen mismatch, panel-reactive antibody levels, perfusion solution and perfusion technique, or immunosuppressive therapy. However, there was a significantly higher incidence of renal allograft thrombosis in association with[56]:

- Both extremes of donor age
- Female donors
- Prolonged total ischemic time

Hematologic evaluation for hypercoagulable states is often negative in most of the patients seen for primary renal graft thrombosis. Not infrequently, the need for an anticoagulation regimen is difficult to assess because high-risk patients are not often identified preoperatively. Strategies have been developed to allow for early detection of anatomic or functional compli-cations of renal transplantation. Color flow Doppler imaging and radionucleotide scanning have been used to assess vascular integrity of renal allografts in the post-transplantation period.[57–59] When both tests are used together, they effectively differentiate delayed graft function due to acute tubular necrosis from renal allograft thrombosis.

The report from the North American Pediatric Renal Transplant Cooperative Study examined the incidence of graft thrombosis in pediatric renal transplant recipients.[60] Of 213 pediatric renal transplant failures, 27 (2.6%) were a result of thrombosis. Among recipients of living donor kidneys, the majority of graft failures occurred in patients less than 6 years old. The recipient age was not identified as a factor in cadaveric kidneys transplanted into pediatric patients. In addition, recipients of pediatric cadaveric kidneys with long cold ischemic times were observed to have a greater risk of thrombosis.

The use of kidney allografts with multiple renal arteries has been evaluated to determine its effects on survival of both renal allografts and patients. In the early experience, kidney allografts with multiple renal arteries have been associated with a higher incidence of early vascular complications. Benedetti and colleagues[17] analyzed 998 adult kidney transplantations performed between December 1, 1985, and June 30, 1993, to evaluate the complications of multiple renal arteries in donor allografts. The rate of early vascular complications in kidneys with multiple arteries was not different from that in kidneys with single arteries; however, the rate of the late complication renal artery stenosis was found to be slightly higher in kidneys with multiple arteries. Nevertheless, the overall results for kidney transplantation using allografts with multiple and single arteries are similar. The findings further suggested no significant differences in rates of posttransplantation hypertension, acute tubular necrosis, acute rejection, or creatinine levels.[17]

The outcome of renal transplantation with an arterial anastomosis to an aortofemoral vascular prosthesis was evaluated in a series of 13 cases (0.2%) from 5791 cadaveric renal transplantations performed between 1978 and 1994.[61] In six cases, the vascular reconstruction and transplant operation were performed simultaneously. In the remaining seven cases, the procedures were performed separately with a mean interval of 3.5 years. The indications for vascular reconstruction were aneurysmal disease in four cases and occlusive disease in nine. The early vascular complications of these procedures were hemorrhage (four patients) and renal vein thrombosis (one patient). Two of 13 recipients had graft loss with a mortality rate of 15%. The graft and patient survival rates were 68% and 83%, respectively, after 1 year, and 17% and 37%, respectively, after 5 years. Not unexpectedly, late mortality was mainly due to cardiovascular disease. Renal transplantation that involves an arterial anastomosis to an aortofemoral vascular prosthesis is a high-risk procedure with relatively poor short-term and long-term results. These observations should be considered in the evaluation of renal replacement therapy in this special patient population.

Urologic Complications

In our experience with the ureteropyelostomy technique of urinary tract reconstruction at the Massachusetts General Hospital, the rate of complication has been less than 2% over the past decade.

Most initial urinary tract complications after transplantation manifest as either a leak or an obstruction. For example, in the first 1000 consecutive renal transplantations performed at Oxford University, in which the Leadbetter-Politano technique was employed for all but three cases, there were 71 primary complications in 68 patients (7.1%).[62] The complications included 36 ureteral obstructions, 25 ureteral or bladder leaks, 7 bladder outflow obstructions, 2 ureteral stones, and 1 case of symptomatic vesicoureteral reflux. Although no grafts were lost as a result of urologic complications, two patients died, following septic and hemorrhagic complications despite therapeutic interventions. Induction with high-dose steroids in the early period of renal transplantation was associated with urologic complication rate of 10%. However, with later administration of low-dose steroids combined with azathioprine and cyclosporine, the incidence of complications decreased to 4%.

Urinary leaks may be the result of ischemic injury to the distal donor ureter at the site of bladder implantation. The cut end of the donor ureter must bleed sufficiently to indicate its viability prior its anastomosis to the bladder. Rejection may also cause ureteral necrosis because of renal allograft swelling and compromise of the ureteral blood supply.[63] Children are especially susceptible. If the native ureter is available, it may be used to resolve the obstruction or leak associated with distal ureteral necrosis at the site of bladder implantation. The donor ureter can be resected, and a ureteropyelostomy may be performed.

Urinary obstruction may be noted immediately after transplantation because the tunnel may compress the ureter and block its peristalsis. Placement of a stent or a revision of the ureteroneocystostomy may be indicated. If the donor ureteral blood supply is not compromised, a urinary leak of either the ureteropyelostomy or the ureteroneocystostomy can be treated by either direct operative or endoscopic placement of a stent. Percutaneous nephrostomy, with or without stenting, is not commonly used today.

Lymphatic Complications

Lymphoceles may develop following renal transplantation because (1) lymphatic channels are transected during the iliac dissection of the transplant procedure or (2) from open-ended lymphatic vessels following donor nephrectomy. Allografts undergoing rejection, which become swollen with infiltration inflammatory cells, are prone to releasing lymphatic fluid. Lymphoceles may also be associated with ureteral obstruction, venous obstruction, venous thrombosis, and infection. In a study by Khauli and colleagues,[64] univariate analysis showed a significant risk for the development of lymphoceles in transplants with acute tubular necrosis and delayed graft function, rejection, and high-dose steroids. However, multivariate analyses showed that only rejection was associated with a significant risk for lymphoceles.

The incidence of lymphoceles may be as high as 20%, but only 1 in 20 patients noted to have lymphoceles with a diameter of 5 cm or greater has symptoms that require drainage.[64] The interval for development of symptomatic lymphoceles ranges from 1 week to 3.7 years with a median of 10 months. The size and pressure of the lymphocele may cause discomfort or urinary tract obstruction or may compromise the circulation to the allograft.

Simple needle aspiration or external drainage with sclerotherapy of lymphoceles is associated with an unacceptably high incidence of recurrence and complications. Moreover, many lymphocele collections are multiloculated, thus limiting the value of percutaneous catheter drainage. The treatment of choice is a surgical approach via the retroperitoneal transplant incision or transperitoneally through an abdominal incision.

In the era of minimally invasive surgery, achieving internal drainage by laparoscopically deroofing the lymphocele and creating a peritoneal fenestration has evolved to become an alternative method of management.[65] In an early series reporting on nine patients so treated, the postoperative course was uneventful and hospitalization did not exceed 7 days; moreover, evaluation using CT scanning or ultrasonography did not demonstrate recurrence in any of the patients after a mean follow-up period of 11 months.[66] Further reports in four patients with symptomatic lymphoceles operated on laparoscopically by Boeckmann and colleagues[67] effectively demonstrated that lymphocele drainage can be achieved in 40 to 70 minutes. Most surgeons who have had extensive experience with this minimally invasive technique believe that symptomatic posttransplantation lymphocele represents an ideal indication for laparoscopic drainage.[65,67]

RETRANSPLANTATION

The number of renal allografts necessitating transplant nephrectomy because of rejection failure has declined.[68,69] The current indications for transplant nephrectomy are:

- Primary nonfunction
- Acute hemorrhage
- Uncontrolled hypertension
- Allograft infection

Otherwise, retaining the transplant kidney with low-dose immunosuppression may prevent the development of alloantibodies.[70]

Removing a failed allograft is a more challenging procedure than native nephrectomy.[71] The early removal of a nonfunctioning kidney does not pose any additional difficulty because the tissue planes from the recent procedure are preserved; they can be dissected out to expose the necessary structure for ligation and subsequent removal of the kidney.[72] The kidney being removed because of chronic rejection, however, often has significant surrounding scar tissue, thus making dissection of the kidney more difficult. The intracapsular approach was devised so that the allograft capsule is not resected and only the renal parenchyma are removed. This approach allows exposure and ligation of the main renal vessels so that the nephrectomy can be performed safely.

The choice of allograft placement for the second kidney transplant is the side contralateral from the previous allograft. When the kidney has to be placed on the same side as the previous transplant for technical reasons, an allograft nephrectomy should be performed. It is also important to exclude the possibility of an arteriovenous fistula resulting from ligated renal vessels of the previous allograft. Moreover, the new vessel anastomoses should be placed in new segments of the iliac artery and vein. If there was a previous bladder anastomosis, the use of the native ureter to perform a ureteropyelostomy should be the preferred procedure. Alternatively, if a primary ureteropyelostomy was previously performed, then a ureteroneocystostomy is indicated.

UNIQUE CONFIGURATIONS AND SPECIAL CONSIDERATIONS

Horseshoe Kidneys

Horseshoe kidneys develop after the embryologic fusion of a portion of the renal blastema across the midline at 4 to 8 weeks of gestation (Figure 33–7). The normal medial rotation and upward migration of the kidney to an anatomic location cephalad to the inferior mesenteric artery is prevented by the isthmus of the fused kidney. Horseshoe kidneys are considered to be at high risk for complication after transplantation.[73] Most transplant surgeons are reluctant to utilize horseshoe kidneys because of their unpredictable arterial and venous anatomy. In addition, other congenital anomalies may be associated with this abnormality, including ureteral duplications, ureteropelvic junction obstructions, and vesicoureteral reflux.

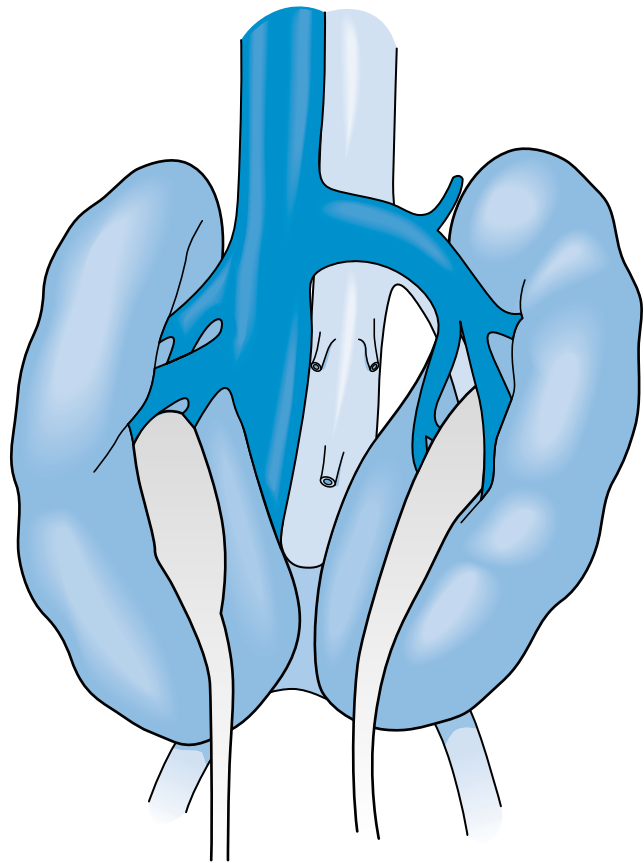
Nevertheless, horseshoe kidneys have been used for transplantation either as an en bloc engraftment into a single recipient[74] or following an isthmectomy that divides the kidneys for transplantation into two recipients.[75–81] Although isthmectomy may theoretically lead to urinary fistula formation and parenchymal hemorrhage, these complications have not been reported thus far in the literature. The use of horseshoe kidneys is driven by the shortage of cadaveric donor organs and by the fact that the fused kidneys are histologically normal. Thus, if the isthmectomy is performed successfully and if other anatomic considerations, such as ureteropelvic junction obstruction, can be overcome by a ureteropyelostomy for urinary tract reconstruction, horseshoe kidneys may be appropriate for transplantation.


Figure 33–7 Classic features of horseshoe kidney. Fusion of lower poles produces an isthmus and shifts the axis of the kidneys toward the lumbosacral vertebrae. (From Koff SA: Anomalies of the kidney. *In* Gillenwater JY [ed]: Adult and Pediatric Urology. St. Louis, Mosby-Year Book, 1987, p 1820.)

Pediatric En Bloc Kidney Transplantation

Pediatric kidneys are an important source of cadaveric renal allografts for transplantation.[82–84] Sustained and significant hypertrophy of such a single kidney does occur. The decision whether to retain kidneys recovered from a pediatric donor is influenced by the donor's age and body weight and the cortical dimensions of the kidneys. If the donor is older than 3 years and weighs more than 15 kg (30 lb), and if the polar length of the donor kidneys exceeds 8 cm, the kidneys can safely be divided and transplanted even to two adult recipients because they provide enough nephron mass to maintain normal renal function.

The reported surgical complication rate (~5%) is not sufficient to discard pediatric kidneys because of vascular thromboses; however, these pediatric allografts are also susceptible to failure because of rejection.[83,84] Nevertheless, there is no statistical difference in allograft survival between single pediatric kidneys and cadaveric kidneys from donors older than 50 years.

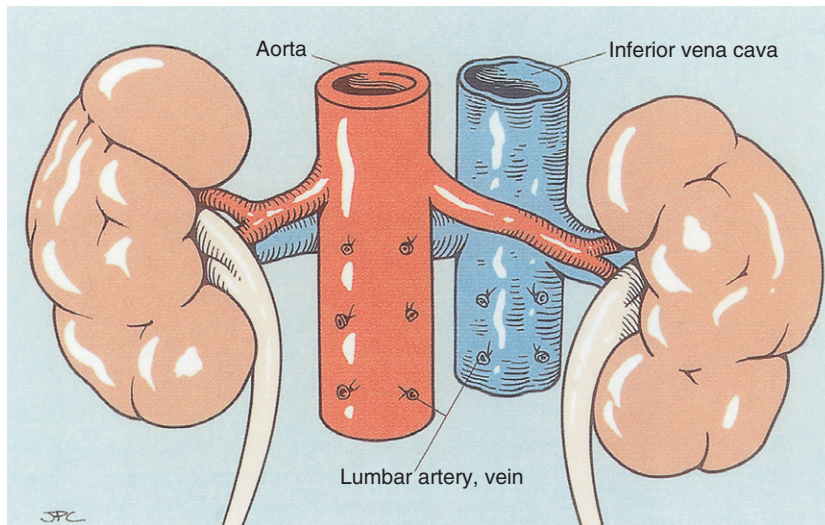
The use of en bloc cadaveric kidneys from younger pediatric donors (<3 years) is more controversial. The overall long-term results have not paralleled those of kidneys from


Figure 33–8 Pediatric en bloc kidneys. (From Shapiro R: Renal transplantation. *In* Starzl TE [ed]: Atlas of Organ Transplantation. Philadelphia, JB Lippincott, 1992, p 4.11.)
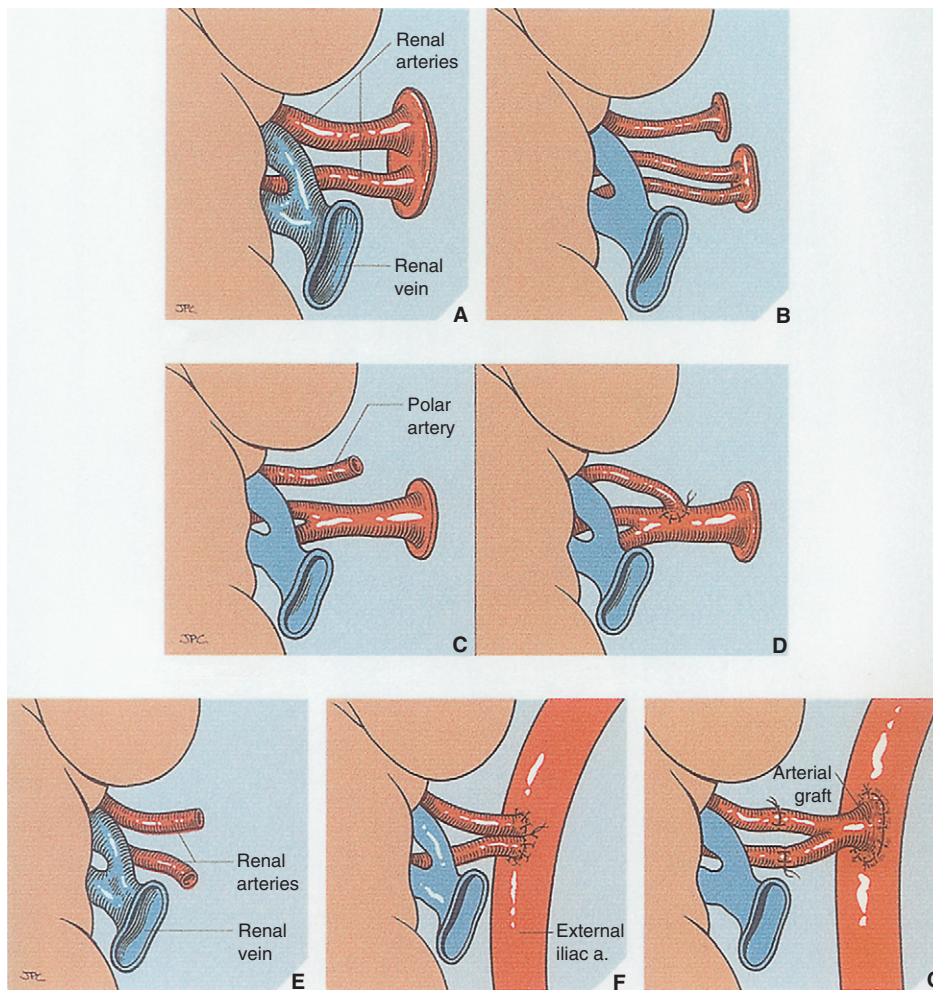

Figure 33–9 Multiple renal artery and reconstruction. (From Shapiro R: Renal transplantation. *In* Starzl TE (ed): Atlas of Organ Transplantation. Philadelphia, JB Lippincott, 1992, p 4.7.)

adult donors. The factors that have been implicated in failure of kidneys from younger pediatric donors include:

1. Reported higher incidences of technical complications.
2. Observed severe renal dysfunction secondary to rejection.
3. The inadequate nephron mass provided to adult recipients, despite the en bloc preparation.

Several technical alternatives have been developed for en bloc transplantation of pediatric kidneys.[85] All of the options are designed to overcome the anatomic impediments of small renal vessels and short double ureters (Figure 33–8; see Color Figure). Most surgeons place the kidneys in a retroperitoneal position using iliac sites of arterial and venous anastomoses that allow the shorter pediatric ureters to reach the recipient bladder. The superior cut ends of the donor aorta and the vena cava above the renal vessels are oversewn, and the inferior aorta and vena cava complete the vascular reconstruction.

Our preferred procedure for ureteric implantation of en bloc pediatric allografts is to create separate tunnels for two cystostomy sites, anastomosing each ureter extravesically by the Lich-Gregoir technique. This approach avoids a formal Leadbetter-Politano cystostomy and implantation. The major advantage of a double cystostomy site is the preservation of renal function of the contralateral renal unit if a complication does occur with one of the ureteroneocystostomies. Alternatively, others have favored joining the ureters together distally and constructing a single ureteroneocystostomy, reducing the potential for a complication by another ureteric anastomosis. Because ureteral leaks can result in a technical failure and loss of both kidneys, stents may be advisable.

We have performed renal transplantations using an en bloc pediatric preparation since 1993 without technical complications. All of our recipients continue to display normal renal function. Thus, en bloc pediatric transplants are a suitable source of kidneys.

Multiple Renal Arteries

Multiple renal arteries can be challenging because they present a diverse arterial supply that must be restored.[17] The loss of an accessory polar artery results in a segmental infarction of the kidney. The donor surgical team must search for the aberrant distribution of additional renal arteries. For example, the lower pole artery to the right kidney usually crosses anterior to the inferior vena cava. The presence of urologic anomalies, such as double ureters, may alert the donor surgeon to the possibility of additional renal vessels.

Polar vessels are preserved by dissecting each artery to its aortic origins (Figure 33–9; see Color Figure). The accessory artery may be in close proximity to the main renal artery, thus allowing for a single Carrel patch to be used for the recipient vascular anastomosis. The polar circulation can also be restored by anastomosing the accessory artery to the side of the main renal artery. Rarely, the inferior epigastric artery may be used for separate anastomosis to the accessory renal artery, if there is significant atherosclerotic plaque in the donor renal artery that precludes a satisfactory vascular reconstruction. However, when the accessory renal artery supplies less than 10% of a kidney, revascularization may not be feasible, given the small caliber of the artery.

Two-for-One Kidney Transplantation from Older Donors

The shortage of cadaver organ donors has prompted organ procurement organizations, such as the New England Organ Bank (NEOB), to expand the pool of acceptable cadaver donors by recovering organs from cadavers of ever-increasing age.[94] The data from the NEOB reveal a significant change in the characteristics of the donor pool.[95] Less than 40% of the NEOB donor population are trauma victims, and the largest category now represents individuals dying of cerebral vascular accidents (55%). These patients are much older and frequently have additional medical complications. The rate of survival for renal allografts obtained from older donors is not as good as that for kidneys procured from younger donors.[96] In an effort to provide a better estimate of immediate and long-term function of an allograft procured from an older donor, the NEOB has performed routine postrecovery biopsies on all such kidneys. The decreased survival of kidneys transplanted from older donors may be a result of an insufficient renal mass to support the recipient.[97] Thus, when a single kidney from an older donor is transplanted, and the kidney has a smaller number of functioning nephrons as a result of obsolescence, the kidney may suffer chronic dysfunction.

One approach to improve utilization of a source of allografts that otherwise might be discarded is to offer two allografts from an older age donor to a single recipient (a two-for-one approach). The reason for allocating both kidneys from an older donor to a single recipient is that the literature suggests that offering only one obsolescent allograft is not likely to provide a sufficient nephron mass to enable normal long-term renal function in the recipient.[98–104] This clinical concern is the principal reason that treatment centers have declined single kidneys from such older donors. The donor inclusion criteria to establish an automatic two-for-one allocation are:

- Age 60 or greater
- Creatinine clearance less than 65 mL/min
- 20% or greater glomerulosclerosis of both kidneys as determined by frozen-section biopsy

Most of the experience with the two-for-one approach has been reported by the University of Maryland and Stanford University Medical Centers.[105] This allocation scheme was established only after all UNOS (United Network of Organ Sharing) centers throughout the country had declined the kidneys offered singly. The NEOB procedure mandates a two-for-one allocation if the donor inclusion criteria are met. To delay and permit centers to consider transplanting only one of these kidneys before considering transplanting two would increase the ischemic time for these allografts, thereby compromising their function.[96]

A 1998 review of the NEOB experience regarding the transplantation of a single older donor kidney reveals the following data:

1. The preservation time for kidneys transplanted from 60-year-old donors was 23.4 ± 11 hours, versus 20.2 ± 10 for kidneys transplanted from donors younger than 60 years ($P < .01$).
2. A reduction in the duration of preservation was associated with immediate allograft function from all NEOB donors.

For kidneys from 60-year-old donors that had immediate function, the preservation time was 22.2 ± 9 hours (for those with delayed function, preservation time 25.4 ± 13 hours; $P = .1$ NS); for kidneys from donors younger than 60 years of age that had immediate function, the preservation time was 18.8 ± 9 hours (for those with delayed function, preservation time 24.9 ± 11 hours; $P < .01$).

3. A preservation time of less than 12 hours was associated with a reduction in the dysfunction rate of the kidneys from the 60-year-old donors (<12 hours, 23.1%; >12 hours, 43.5%; $P = .19$). Thus, centers appear to delay in deciding whether to accept a single older kidney. This increase in preservation time may influence immediate function of the allograft.

The two-for-one concept does not suggest that two kidneys will immediately function better than one. The risk factors that might influence immediate allograft dysfunction must be considered; these factors include maintaining the hemodynamic stability of the donor (especially in older donors, maintaining normovolemia and good urine output) and minimizing the preservation time.

The NEOB has developed a separate recipient selection list to reduce the ischemic time while we identify potential recipients. The patients on this list give informed consent to accept two-for-one kidneys well in advance of the potential allocation. The informed consent procedure is needed because of ethical concerns not only regarding acceptance of the marginal kidneys but also because the operating time, as well as the risk of technical complications, may be doubled.

Induction Therapy in Kidney Transplantation

Flavio Vincenti, M.D.

Induction therapy with polyclonal and monoclonal antibodies (MAbs) has been an important component of immunosuppression dating back to the 1960s as demonstrated by Starzl and colleagues in 1967 on the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection in renal transplant recipients. Over the past 40 years, several polyclonal antilymphocyte preparations have been used in renal transplantation; however, only two preparations are currently FDA approved, Atgam and Thymoglobulin.[2-4] Another important milestone in biologic therapy was the development of monoclonal antibodies (MAbs) and the introduction of the murine anti CD3 MAb, OKT3 for the treatment of acute rejection.[5] Table 34–1 lists the currently used biologic agents in renal transplantation. Horse antithymocyte globulin (Atgam) and OKT3 (Orthoclone OKT3) were introduced in the 1980s and rabbit antithymocyte globulin (Thymoglobulin) was approved in the United States for use in the late 1990s. While the registered indication of these three biologic agents is to treat acute rejection or steroid resistant acute rejection, they have been used extensively as induction agents in the prophylaxis of rejection.[6] The anti-interleukin-2 receptor (IL-2R) MAbs (frequently referred to as anti-CD25) were the first biologics that were proved to be effective as induction agents in pivotal randomized double-blind prospective trials.[7-10] Over the past 7 years, the use of biologic agents for induction therapy in the prophylaxis of rejection has increased (Fig. 34–1). The popularity of induction therapy has been propelled by several factors, including the introduction of the anti IL-2R antibodies, the emergence of Thymoglobulin as a safer and more effective alternative than Atgam or OKT3 and the increased popularity of drug minimization regimens that spare calcineurin inhibitors or steroids but require coverage with biologic induction.[11]

Biologics for induction can be divided into two groups: the depleting agents and the immune modulators. The depleting agents consist of Atgam, Thymoglobulin, and OKT3 (the latter also produces immune modulation); their efficacy is derived from depleting the recipients of CD3 positive cells at the time of transplantation. The second group of biologic agents, the anti IL-2R MAbs do not result in depletion but block IL-2 mediated T-cell activation by binding to the α chain of IL-2R.

The benefits of induction therapy with the anti IL-2R MAbs were conclusively demonstrated in phase III clinical trials that showed that therapy with either daclizumab (humanized anti-IL2R) or basiliximab (chimeric anti-IL2R) resulted in significantly lower rejection rates than placebo.[7-10]

The decision to use induction therapy is often based on the clinical evaluation of the immunologic risks of transplant recipients. Although all patients can benefit from induction therapy, cost considerations tend to limit induction to the following category of patients:

1. Patients at high immunologic risk of rejection (i.e. blacks, sensitized patients, patients with delayed graft function, retransplant patients)
2. Patients that require or are being considered for calcineurin inhibitor sparing regimens
3. Patients in whom corticosteroids are completely avoided or withdrawn within days after transplantation.

The next important decision in induction therapy is the selection of the desired type of biologic agent, depleting antibody (Thymoglobulin, Atgam, or OKT3) or a nondepleting anti-IL2R. The regimens, benefits, and side effects of these two groups of biologic agents are shown in Tables 34–2 and 34–3. The choice of the specific antibody within each class is often arbitrary but may be based on a number of factors.

Thymoglobulin has displaced both Atgam (because of efficacy) and OKT3 (because of the cytokine release syndrome and excessive toxicity) as the depleting antibody of choice. The anti-IL-2R antibodies, daclizumab and basiliximab, are used interchangeably, although differences can exist between these two agents. Basiliximab is a chimeric antibody and thus could potentially elicit more side effects than daclizumab. Because basiliximab retains the variable domains from the parent murine antibody it has higher affinity to the IL-2Rα than the fully humanized daclizumab. The dose and regimen of basiliximab is fixed at 20 mg at day 0 and day 4 after transplantation. Daclizumab is approved for use in a prolonged five-dose regimen of 1 mg/kg administered at 2 weekly intervals after transplantation. However, increasingly daclizumab is being used in a two-dose regimen similar to basiliximab.[12]

POLYCLONAL ANTILYMPHOCYTE SERA

Polyclonal antilymphocyte agents are produced by immunizing animals with human lymphoid cells. The most frequent immunogen is a thymocyte. The sera from immunized animals are harvested and processed to obtain purified globulin. The final product, however, contains many antibodies that react against a variety of other targets, including red blood cells, neutrophils, and platelets. Within hours of administration polyclonal agents result in lymphocyte depletion secondary to a number of mechanisms, including complement dependent and Fc-dependent opsonization and lysis. The polyclonal agents also contain antibodies to a wide variety of cell surface antigens, including the IL-2R adhesion molecules and costimulatory molecules. The role of these targets in the overall effectiveness of the polyclonal agents is supported by the findings of a recent study showing that administration of Thymoglobulin intraoperatively as opposed to postoperatively resulted in a decrease of delayed graft function presumably by preventing ischemia reperfusion injury.[13]

Table 34–1 Antibodies in Current Use in Renal Transplantation

- **Polyclonal Antibodies**
  Atgam (horse derived globulin)
  Thymoglobulin (rabbit derived globulin)
- **Monoclonal Antibodies**
  OKT3 (murine anti CD3)
  Basiliximab (chimeric anti-IL-2R)
  Daclizumab (humanized anti-IL-2R)

Polyclonal agents are xenogeneic proteins and therefore elicit a number of side effects including fever and chills. Less commonly they can also induce a serum sickness-like syndrome and rarely ARDS. Anaphylaxis is extremely rare even upon reexposure.

ANTI-CD3 MONOCLONAL ANTIBODIES

OKT3 was approved in 1986 for the treatment of acute rejections. OKT3 is a murine IgG2 monoclonal antibody targeting the CD3 complex adjacent to the T cell receptor. Soon after the injection of OKT3, T cells disappear from circulation as a result of opsonization and their removal from circulation by mononuclear cells in the liver and spleen. In addition, initially OKT3 can activate T cells and result in release of several cytokines including IL-2, interferon γ, IL-6, and TNF.[14] These
Figure 34–1 Percent of de novo patients receiving induction therapy (1997–2003).

Table 34–3 The Dose and Regimen of Currently Available Induction Agents

- Thymoglobulin
  1-2 mg/kg IV up to 14 doses or until renal function improves
- Atgam
  10-20 mg/kg IV up to 14 doses or until renal function improves
- OKT3
  5 mg IV 7-14 days
- Basiliximab
  20 mg IV at days 0 and 4 after transplantation
- Daclizumab

Phase III regimen: five doses of 1 mg/kg at day 0 and every 2 weeks thereafter transplantation. Increasingly used regimen: one (2 mg/kg) or two doses (second dose 1 mg/kg)

cytokines cause a syndrome that has been referred to as the cytokine release syndrome and consists of fever, chills, headache, gastrointestinal complaints and, less commonly, ARDS, aseptic meningitis, and encephalopathy. The availability of other induction agents and the severity of the side effects associated with the cytokine release syndrome have resulted in a marked reduction in the use of OKT3 in the past several years. Furthermore, OKT3 is immunogenic in humans, and approximately 50% of patients will make antibodies to it following a course of treatment.[15] Many of these patients will develop high titer anti-mouse antibodies that preclude retreatment with OKT3.

There are several humanized nonactivating anti-CD3 MAbs that offer clear-cut advantages over the murine OKT3 but have yet to be developed for use in renal transplantation.

ANTI IL-2R MONOCLONAL ANTIBODIES

The successful introduction of two monoclonal antibodies (MAb), daclizumab (Zenapax, Roche Laboratories) and basiliximab (Simulect, Novartis Pharmaceuticals Inc.), targeting the α chain of the IL-2R, can be attributed to the extensive investigative efforts performed on the IL-2R in the early 1980s.[16] The α chain was the first of the three IL-2R subchains to be fully characterized and was initially identified as Tac (for T-cell activation) protein. The IL-2R β and γ chains are required to transduce the IL-2 signal inside the cell, while the addition of the α chain leads to the expression of the high-affinity IL-2R. A MAb with the ability to block the interaction

Table 34–2 The Pros and Cons of Depleting and Nondepleting (Anti IL-2Ra MAbs) Biologics

Depleting Antibodies	Nondepleting Antibodies
- Rejection rare during use	- Rejection occurs during use
- Calcineurin inhibitors can be used sequentially (i.e., delayed)	- Calcineurin inhibitors should not be delayed
- Acute side effects with administration	- No acute side effects
- Associated with increased infections and malignancies	- Very safe and not associated with complications of over-immunosuppression

between IL-2 and the α chain of the high-affinity IL-2R αβγ has the potential to block the amplification of the immune response and the prevention of rejection. Promising clinical trials of murine or rat anti IL-2R MAbs followed soon thereafter and were published in the late 1980s and early 1990s.[17,18] The chimerization and humanization of rodent antibodies resulted in more humanized constructs that had prolonged half-life and lacked immunogenicity. The phase III trials with daclizumab and basiliximab provided convincing and conclusive proof that blockade of the IL-2 pathway can result in significant reduction in acute rejection.[7-10]

The exact mechanism of action of the anti-CD25 MAbs is not completely understood. There is no evidence that long-term tolerance occurs with therapy with anti-CD25 MAb. Significant depletion of T cells does not appear to play a major role in the mechanism of action of these MAbs. Studies with the anti-IL-2R MAbs suggest that the main mechanism of action of these antibodies is through saturation and blockade of the IL-2Rα.[7,19] However, other mechanisms of actions may mediate the effect of these antibodies. In a study of daclizumab-treated patients, there is approximately a 50% decrease in circulating lymphocytes staining with 7G7, a fluorescein-conjugated antibody that binds on the α chain to an epitope distinct from the epitope that is recognized and bound by daclizumab.[7] Similar results were obtained by Amlot and colleagues[19] in studies with basiliximab. These findings indicate that therapy with the anti-IL-2R MAbs results in a relative decrease of the expression of the α-chain either from depletion of coated lymphocytes and/or modulation of the α-chain secondary to decreased expression or increased shedding. There is also recent evidence that the β-chain may be downregulated by the anti-CD25 antibody.

CLINICAL ADMINISTRATION AND MONITORING IN TRANSPLANTATION

There are two anti-IL-2R preparations for use in clinical transplantation. Daclizumab was approved by the FDA in December of 1997, and basiliximab was approved in May of 1998. Daclizumab was administered in the phase III trials in five doses starting immediately preoperatively, and subsequently at biweekly intervals.[7,8] The dose of daclizumab used was 1 mg/kg given intravenously over 15 minutes in 50 to 100 cc solution of normal saline. This regimen was shown to result in saturation of the IL-2R α on circulating lymphocytes for up to 120 days after transplantation. The half-life of daclizumab was 20 days. Daclizumab blood concentrations of about 5μg/mL persisted in circulation for up to 70 days after transplantation. A higher concentration of daclizumab is required to block IL-2-mediated biologic responses than just to saturate IL-2R. While 1μg/mL of daclizumab saturates the IL-2R on circulating lymphocytes, concentrations of about 5μg/mL are required to block IL-2–mediated biologic responses.[12] In the phase III trials, daclizumab was used with a maintenance immunosuppression regimen that consisted of cyclosporine, azathioprine and steroids, or double-therapy, cyclosporine and steroids. Subsequently, daclizumab was successfully used with a maintenance triple-therapy regimens either with cyclosporine or tacrolimus, steroids and mycophenolate mofetil (MMF) substituting for azathioprine.[20,21]

In the phase III trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on day 4 after transplantation.[9,10] This regimen of basiliximab was shown to result in a concentration of greater than or equal to 0.2 μg/mL, sufficient to saturate IL-2R on circulating lymphocytes, for 25 to 35 days after transplantation. Concentrations of basiliximab required to block IL-2-mediated biologic responses are about 1μg/mL. The half-life of basiliximab was 7 days. In the phase III trials, basiliximab was used with a maintenance regimen consisting of cyclosporine and prednisone. In a recently reported randomized trial, basiliximab was shown to be safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone.[22]

At present, there is no marker or test to monitor the effectiveness of anti-IL-2R therapy. Saturation of α chain on circulating lymphocytes, although important as a determinant of minimal blood concentrations, is not predictive of rejection that occurs during anti-IL-2R MAb therapy. Kovarik and colleagues[23] analyzed the influence and duration of IL-2R blockade on the incidence of acute rejection episodes in patients who participated in the phase III basiliximab trials and who had detailed disposition analysis of basiliximab.[23] Duration of receptor blockade was similar in patients with rejection and without rejection (34 ± 14 days vs. 37 ± 14 days, mean + SD). In another daclizumab trial, patients with acute rejection were found to have circulating as well as intragraft lymphocytes with saturated IL-2R.[24] A possible explanation is that those patients who reject on anti-IL-2R blockade do so through a mechanism that bypasses the IL-2 pathway due to cytokine–cytokine receptor redundancy (i.e., IL7, IL15).

THE CHOICE OF INDUCTION: DEPLETING VERSUS ANTI-IL2R MABS

Several studies have compared the effectiveness and safety of Thymoglobulin to the anti-IL-2R MAbs antibodies.[25,26] The first study is an open label randomized multicenter French trial comparing the efficacy and tolerability of Thymoglobulin versus basiliximab.[25] The protocol compared basiliximab plus immediate (within the first 24-hours post transplantation) cyclosporine therapy versus Thymoglobulin plus delayed (initiated when the serum creatinine is less than 2.8mg/dL) cyclosporine therapy. All patients also received corticosteroids and MMF at standard doses beginning on the day of transplantation. Fifty predominantly low immunologic risk patients were randomized to each treatment group. The incidence of acute rejection and overall outcome was similar between the two treatment groups, but patients in the Thymoglobulin arm had a higher incidence of side effects (Table 34–4). In contrast, Brennan and colleagues[26] performed a prospective, randomized, multicenter study of Thymoglobulin compared with basiliximab for induction immunosuppression in high immunologic risk patients. High immunologic risk patients were defined as recipients of kidneys likely to have delayed graft function, retransplants, patients with high levels of panel reactive antibodies (PRA) greater than 20%, six antigen mismatch and patients of African descent. Maintenance immunosuppression consisted of cyclosporine, MMF, and prednisone. Table 34–5 shows that patients treated with Thymoglobulin as compared with basiliximab had significantly lower composite endpoints as well as

Table 34–4 Outcomes During the 6-Month Posttransplantation Period (Intention-To-Treat Analysis)

Variable	Basiliximab (n=50)	Thymoglobulin (n=50)
First biopsy-confirmed rejection episode	4 (8%)	4 (8%)
First acute rejection episode treated with antibody therapy	0	1 (2%)
First acute rejection episode treated with tacrolimus	1 (2%)	0
Graft loss*	2 (4%)	0
Death	1 (2%)	0
Treatment failure†	7 (14%)	4 (2%)

*Need for regular postoperative dialysis or nephrectomy or retransplantation.
†Acute rejection, graft loss, or death ? whichever occurred first.

biopsy proven rejection. Taken together these two studies suggest that for lower immunologic risk patients the anti-IL2 MAbs may be the safer choice while for the higher immunologic risk patients, the depleting antibodies such as Thymoglobulin are likely to be the more effective therapy.

BIOLOGIC AGENTS IN DRUG MINIMIZATION TRIALS

As mentioned earlier, induction with biologic agents has been used predominately to enhance the effectiveness of immunosuppression at the time of antigen presentation and increased antigen load. Recently, however, induction therapy has been utilized to leverage drug minimization protocols, especially steroid avoidance or very rapid steroid discontinuation strategies. Table 34–6 details the various steroid-sparing regimens that have utilized different induction regimens to either completely eliminate corticosteroids or withdraw them very rapidly after transplantation. In a single center open label trial at Stanford University, 43 pediatric patients were treated with an extended regimen of daclizumab (6 months) after transplantation as a replacement for corticosteroids with patients maintained on tacrolimus and MMF.[27] With a mean follow-up of 16 ± 9 months, acute rejection occurred in approximately 5% of patients. In a Canadian multicenter, single arm open label trial, patients were also treated with cyclosporine, MMF, and a corticosteroid avoidance protocol but with a shorter course of daclizumab (the conventional five doses, given 1 mg/kg every 2 weeks). The acute rejection rate at 1 year was 25% with the majority of rejections being mild.[28] The other three studies (Table 34–6) utilized steroids only during the perioperative period followed by early discontinuation with induction therapy with either an anti IL-2R MAb or Thymoglobulin and

were associated with low acute rejection rates. However, longer-term follow-up will still be required to determine whether this approach is, in fact, safe and beneficial.

INDUCTION THERAPY IN CALCINEURIN INHIBITORS (CNI) SPARING REGIMENS

Induction therapy is also being utilized to facilitate a CNI free regimen combining the two anti-proliferative agents, sirolimus, and MMF in conjunction with steroids. Flechner and colleagues[32] treated 61 patients randomized to either cyclosporine or sirolimus with induction therapy with basiliximab. All patient were treated with MMF and steroids. At 1 year, patient and graft survival were not significantly different between the two treatment groups. The sirolimus-treated patients had a rejection rate of 6.4% compared with 16% in the cyclosporine treatment group. At 12 months following transplantation, the sirolimus treated patients had a significantly lower mean serum creatinine than the cyclosporine treated patients (1.3 mg/dL vs. 1.78 mg/dL, p=.004). These results were appreciably better than those obtained by Kreis and colleagues[33] in a multicenter European study in patients treated with the same maintenance regimen but without biologic induction. The incidence of biopsy-proven acute rejection was 27% with the majority of rejection being moderate in severity. Thus, the superior results obtained by Flechner and colleagues are likely due to the addition of induction therapy to their maintenance regimen. Larson and colleagues[11] treated a randomized group of patients with Thymoglobulin induction and maintenance with either sirolimus, MMF, and prednisone; or tacrolimus, MMF, and prednisone. At 6 months the overall rejection rate in the CNI free treatment arm was 17% with the majority of rejections being subclinical and mild. In

Table 34–5 Efficacy Results: Interim Analysis

	Interim Patients Analyzed (n=212)		
	Thymoglobulin (n=106)	Basiliximab (n=106)	P value
Composite (AR/GL/death)	10.4%	23.6%	.017

summary, induction therapy appears to be useful both in corticosteroid sparing as well as in CNI sparing regimens.

EMERGING BIOLOGIC INDUCTION REGIMENS

Two additional biologic agents are being used in novel immunosuppressive regimens to achieve drug minimization. The first agent is CAMPATH 1H, a humanized anti-CD52 monoclonal antibody approved for use for chronic lymphocytic leukemia. A single dose of anti-CD52 results in prolonged depletion of lymphocytes (6 months or greater) and has been used in several trials to eliminate CNI, steroids or both.[34,35] These trials have been investigator-initiated and at the present time no pivotal study is planned with anti-CD52. The long-term safety of prolonged lymphocyte depletion remains unresolved, although early and intermediate follow-up has not witnessed the emergence of PTLD or opportunistic infections.

The most promising area for biologic induction is blockade of the costimulatory pathway in an attempt to induce tolerance or the very least, graft acceptance with minimal maintenance immunosuppression. This represents a new paradigm in terms of biologic induction as these agents are being developed to be used chronically, intermittently, and indefinitely. The prototype is LEA29Y, a second generation CTL4Ig, which binds with enhanced affinity to CD80 and CD86, thus preventing their binding to CD28 and the subsequent necessary signaling for T-cell activation. In a large multicenter, prospective randomized study, costimulatory blockade is being tested for its efficacy and safety in a regimen consisting of intermittent LEA29Y intravenous therapy (initially every 2 weeks, then either every 4 or 8 weeks) and maintenance immunosuppression consisting of MMF and prednisone versus a standard regimen of cyclosporine, MMF, and prednisone.[36]

While the results of these trials are yet to be reported, in a recently published study in nonhuman primates, a regimen of LEA29Y and sirolimus was successful in producing prolonged engraftment of islet cells without the use of CNI or corticosteroids.[37]

SUMMARY

Biologic induction therapy is currently an important component of immunosuppression therapy, and, in the future, it is more likely to replace rather than be replaced by maintenance oral immunosuppressive drugs.

Current and Emerging Maintenance Immunosuppressive Therapy

Simin Goral, M.D. • J. Harold Helderman, M.D.

This chapter reviews current immunosuppressive management in kidney transplantation while emphasizing the emerging features that have led to a more individualized approach to each patient.

The dictum of accommodation between host and graft drives the construction of renal transplantation immunosuppressive management strategies. It has been observed that the technical, drug toxicity-related, and immunologic graft loss rates are highest within the first several months after engraftment. Certainly, after 1 year of allograft survival, loss rates become nearly linear over time, permitting construction of graft half-life survival curves with high confidence.[1] Corollary to the law of graft half-life accommodation is the rule that heightened immunosuppression is required early, with progressive reduction in the amount and stringency over time. Until highly allospecific immunity or even alloantigenic tolerance can be achieved, this strategy of "more early and less late" will continue to define the role of immunosuppression, regardless of the agents employed.

Pursuant to the dictum of accommodation, three distinct periods of transplantation immunosuppression have been defined:

1. The perioperative *induction* period
2. *Early maintenance,* characterized by progressive taper of the individual drugs in the regimen
3. *Chronic maintenance,* characterized by a relatively fixed package of agents used at the lowest, effective doses until an intervening event occurs, such as late acute rejection, infection, or neoplasm

In this chapter, induction therapy will be discussed briefly, followed by the agents used in the early and late maintenance phases of immunosuppression. Since they are similar, they are discussed together.

INDUCTION IMMUNOSUPPRESSION

In the perioperative period, steroids are given initially at high doses; rapid tapering is then instituted to achieve the levels used in the early maintenance phase. The rapidity of the tapering varies from center to center. Usually, the patient receives a 250-mg to 500-mg pulse of IV methylprednisolone during surgery. Cytotoxic drugs such as azathioprine or mycophenolate mofetil (MMF) are frequently used. Azathioprine is typically given as an intravenous dose of 3 to 5 mg/kg, followed by a rapid taper to the induction dose of 150 mg/day for 5 days, and leading into the early maintenance dose of 100 mg/day or 2 mg/kg/day, whichever is lower, adjusted by marrow toxicity. Initial doses of MMF are typically 2 to 3 g/day in divided doses.

The greatest differences in induction strategies involve the decisions: (1) whether or not to use a calcineurin inhibitor (CI) such as cyclosporine or tacrolimus or (2) whether or not to provide a T cell–directed polyclonal or monoclonal antibody for a defined period before introducing the calcineurin inhibitor to enter the early maintenance phase of immunosuppression. The development of the *antibody-induction approach* stemmed from the recognition that cyclosporine and tacrolimus are nephrotoxic, thus potentially compromising early graft function.

A sequential induction approach, which was developed to avoid early cyclosporine use, employs anti–T cell antibodies that are extraordinarily effective at forestalling acute rejection when used early.[2] A short overlap period follows, during which cyclosporine or tacrolimus is introduced. The achievement of target blood levels of calcineurin inhibitor is determined empirically at rejection prophylaxis.[3] When these target levels are achieved, the antibody is discontinued, the induction phase is considered complete, and the recipient enters the early maintenance phase of immunosuppression.

Testing the role of antibody induction requires carefully constructed, large trials (which have been rare) or an approach to the data that employs statistical tools of meta-analysis. A combined group of investigators from the Vanderbilt Transplant Center and the Brigham and Women's program in Boston performed a meta-analysis of data in the published literature.[4] When taken together, statistically significant graft survival outcomes in the United States improved in cases in which polyclonal or monoclonal antibodies were used. More recently, Shield and colleagues[5] analyzed the large United Network for Organ Sharing (UNOS) database and reached the same conclusion. In another study, Szczech and colleagues[6] looked at the combined individual patient-level data from published trials to examine the effect of induction therapy on allograft survival. They showed a benefit of induction therapy at 2 years, particularly among presensitized patients. Although the benefit of this therapy subsequently waned, presensitized patients continued to have benefit at 5 years. Induction antibodies are discussed in more detail in Chapter 34.

MAINTENANCE PHASE

Therapeutic Approach

Following the accommodation dictum, the transplant recipient enters early and then late maintenance with progressive graft survival. In the next part of this chapter, we review each agent available for use for immunosuppressive maintenance

individually, with a focus on newer approaches. It is appropriate to first provide a general framework for the therapeutic approach in these next two immunosuppressive periods.

The bedrock of maintenance immunosuppression since the early 1980s has been a calcineurin inhibitor with some form of adjunctive immunosuppression. In most programs, steroids were added as a second immunosuppressive drug ("double therapy"), or a cytotoxic agent was also used ("triple therapy"). Azathioprine was the predominant cytotoxic agent used until the early 1990s, when it was superseded in most programs by mycophenolate mofetil (MMF), based on evidence from three large randomized, prospective, blinded cooperative treatment trials conducted worldwide.[8] No clear graft survival advantage has been shown with azathioprine-based triple therapy over double therapy.[9,10] The important reduction in early acute rejection rates with MMF-based triple therapy drives the popularity of that regimen.

Immunosuppressive Agents

Steroids

Although not an emerging maintenance therapeutic agent, steroids remain a basic element in almost all protocols; thus, a brief discussion of standard uses and attempts at steroid withdrawal is in order. Corticosteroids have been used for prevention as well as for treatment of acute allograft rejection since the early 1960s. They block the expression of several cytokine genes and the synthesis and action of several chemoattractants and vasodilators as part of their anti-inflammatory properties. In some transplantation centers, steroids are administered in the perioperative period as part of induction therapy (e.g., methylprednisolone, 250–500 mg, given intravenously), followed by prednisone, 30 mg/day in two or three separate doses. The dose is gradually tapered over 3 months to a maintenance dose of 5 to 10 mg, or to lower doses in some centers.

The long-term use of steroids causes numerous and diverse complications, including growth retardation in children, osteoporosis, avascular necrosis, hyperlipidemia, hypertension, cataracts, and diabetes. To minimize or eliminate the occurrence of these complications, studies have been undertaken and are in progress at a number of transplantation centers. The potential benefits of eliminating steroids from the immunosuppressive regimens must be weighed against the risk of acute or chronic rejection and eventually early loss of the allograft. A meta-analysis by Hricik and colleagues[11] suggested that the elimination of steroids is associated with an increased short-term risk of acute rejection, with no statistically significant adverse effect on long-term patient or allograft survival. These studies, however, had a great deal of heterogeneity in their designs and outcomes as well as short follow-up periods. Moreover, the experience of the Canadian Multicentre Transplant Study Group[12] with steroid withdrawal revealed that statistically significant differences in outcomes can be seen only after prolonged follow-up (more than 3 years), raising caution and potentially explaining the results of the Hricik study. Two randomized trials studied the potential risks and the benefits of late steroid withdrawal (3 months after transplantation) while patients are on cyclosporine and MMF.[13, 14] The investigators concluded that for recipients on cyclosporine, mycophenolate mofetil, prednisone with no acute rejection at 90 days, the chance of developing subsequent acute rejection is small. When prednisone was

tapered and withdrawn, the risk of acute rejection increased but withdrawal patients had a lower cholesterol level, less need for antihypertensives, and increased lumbar spine bone density. Of note, acute rejection risk was higher in blacks (39.6%) versus non-blacks (16%). There have been recent studies favoring immunosuppressive regimens in which steroids are withdrawn very early (usually in the 1st week) after transplantation or completely avoided.[15,16] Although there are many benefits of withdrawing steroids from the maintenance immunosuppressive regimens, we believe that clinicians should be cautious when considering steroid minimization because of the unresolved issues such as the timing of steroid discontinuation, concerns over the lack of long-term follow-up, infrequent use of controls in most of the trials, and the other immunosuppressive drugs included in the protocol, allowing the safest steroid minimization protocol.

Randomized, controlled studies are in progress to assess the risk of rejection and graft loss with the newer immunosuppressive agents, including MMF and rapamycin, which may facilitate withdrawal of steroids in the future.

Cyclosporine

Before the discovery of the antirejection properties of cyclosporine, the graft and patient survival rates after kidney transplantation were barely acceptable, and transplantation of other solid organs remained highly experimental. The introduction of cyclosporin A into the clinical arena of transplantation in 1978 revolutionized medical management after transplantation and improved early graft survival significantly. Because of its profound impact on transplantation, a cyclosporine-based immunosuppressive regimen had become the gold standard of medical maintenance immunosuppression.

Cyclosporine is a small polypeptide of fungal origin. It binds to cyclophilin, a cytoplasmic receptor protein and creates an active complex. By binding to calcineurin, a calcium-regulated enzyme, the cyclosporine-cyclophilin complex inhibits the expression of several critical T-cell activation gene transcription factors, thus forestalling the activation and proliferation of lymphocytes (Figure 35–1). The form of this drug initially available, Sandimmune, has pharmacokinetic properties that have made it difficult to use. There is a great deal of interpatient and intrapatient variability in exposure to drug with standard dosing, whereas 12-hour trough blood levels are poorly reflective of drug exposure. Both gut motility and bile are required for adequate gastrointestinal absorption. Certain groups of patients (e.g., children, African-Americans, and diabetic patients) absorb drugs poorly and are thus vulnerable to rejection.

A microemulsion formulation of cyclosporine (Neoral) entered the clinical arena of transplantation in 1995. This formulation is a preconcentrate that, on contact with gastrointestinal fluids, rapidly forms a microemulsion, resulting in increased absorption of cyclosporine that is unaffected by food intake or the presence of bile. Neoral has shown increased bioavailability and decreased intrapatient and interpatient variability. Area under the curve (AUC) 0 to 4 hours represents the period of greatest variability among transplant recipients. Adequate absorption is very important for effective rejection prophylaxis. It has been shown previously that although the correlation between cyclosporine trough blood concentrations and total systemic exposure measured by the AUC is improved with Neoral, C0 trough level does not correlate well with AUC.[17, 18] Recent studies indicated that 2-hour

post dose sample, C2, is the best single time-point predictor of AUC 0 to 4 in all solid organ transplants.[19, 20] Dose reduction depending on C2 levels in many overexposed patients may lead to improvements in renal function and blood pressure and a decrease in the incidence of chronic allograft nephropathy as well. Further studies are required to confirm the long-term benefits of this strategy. Replication of these studies in patient groups with different absorptive characteristics such as children and diabetics with gastroparesis would also be necessary.

No significant difference has been demonstrated in safety and tolerability between the standard oil-based cyclosporine (Sandimmune) and the new formulation.[21] The absorption of cyclosporine has been markedly improved by conversion of even stable patients from Sandimmune to Neoral, especially poor absorbers, such as diabetic recipients of simultaneous kidney and pancreas allografts.[22] Indeed, a meta-analysis of a global database of worldwide studies of conversion showed the most dramatic improvement in the worst absorbers.[23] Finally, Kahan and colleagues[24] revealed an association between variable oral bioavailability of cyclosporine and risk of chronic rejection, which theoretically can be reduced by switching patients from Sandimmune to Neoral.

New patients are started on Neoral at a dose similar to that of Sandimmune, with adjustments in dosing made to achieve the same target blood levels. In several studies, 1:1 dosage conversion from Sandimmune to Neoral was safe for most stable patients.[25,26] However, it is strongly recommended that serum creatinine and cyclosporine blood levels be closely monitored, with the first time point at 7 days after conversion, to capture any cyclosporine-related toxic events because a 10% to 20%

dose reduction is frequently required. Neoral is available in the same oral dosage strengths and forms as Sandimmune (25 and 100 mg, capsules, and 100 mg/mL, oral solution).

Table 35–1 reviews the toxicity profile of cyclosporine. Similar adverse effects have been reported with Neoral. Long-term studies should help determine whether the improved bioavailability and higher peak concentrations of Neoral will lead to reduced chronic rejection and longer graft survival or to increased chronic nephrotoxicity.

Another major development in transplantation therapeutics involving the cyclosporine molecule is the advent of generic formulations for study; these have already triggered discussion,

even before market availability. The type of the generic formulations (the old formulation of cyclosporine versus the newer microemulsion), their success in clinical trials, and their cost will have a major impact on their future use. Using an open-label, three-period design, Roza and colleagues[27] studied 50 renal transplant recipients taking stable doses of Neoral. Subjects switched from Neoral on a milligram-for-milligram basis to Gengraf. The pharmacokinetics of Gengraf were equivalent and indistinguishable from those of Neoral. Gengraf was well tolerated and interchangeable with Neoral in these stable renal transplant recipients. To gain wide acceptance in the transplantation community, the generic cyclosporine formulations must be held to a higher standard than is usually applied by the U.S. Food and Drug Administration (FDA) censure of generic drugs. In this medical arena, in which survival of the organ transplant is at stake, mere bioequivalence (within 30%) after single-dose comparisons in young healthy volunteers is an inadequate criterion for acceptance. In the least, especially because this molecule has a complex pharmacokinetic profile, different patient populations and perhaps even efficacy data should be the standards on which approval is based.

Because of the significant long-term side effects of calcineurin inhibitors including nephrotoxicity, cardiovascular diseases and malignancy, there are new trials on the way to minimize the use these agents. The introduction of newer and potent agents in the recent years has prompted interest in CI-sparing (the initial use of a standard or low dose CI with subsequent withdrawal) and CI-avoidance (completely avoiding the use of CI) protocols. The physicians should be aware that these strategies are not safe for all patients. The studies are in progress.

Tacrolimus

Tacrolimus (FK-506; Prograf) is an immunosuppressive agent that was approved by the FDA in 1994 for use in liver transplant recipients and in 1997 for use in kidney transplant recipients based on trials in which FK-506 was used either as the primary immunosuppressive agent or as rescue therapy in steroid-resistant rejection.[28,29] Tacrolimus is a macrolide antibiotic that was isolated in 1985 from a soil actinomycete. It blocks T-cell activation genes by a mechanism similar to that of cyclosporine (see Figure 35–1). By binding to a ubiquitous, highly conserved cytosolic protein (FK-506–binding protein [FKBP]), the class of which has been labeled the *immunophilins,* FK-506 blocks the activation of calcineurin, a calcium-activated serine-threonine phosphatase, and inhibits the calcium-dependent signal transduction pathway in T lymphocyte activation. In open-label phase III studies, acute early transplant rejection rates, antirejection medication use, and the histologic severity of rejection were all reduced by FK-506, as compared with Sandimmune.[30] In these trials, the toxicity profile favored cyclosporine. The target range of trough blood level that optimizes efficacy and minimizes toxicity appears to be 5 to 15 ng/mL. The corresponding recommended initial dose of FK-506 is 0.1 to 0.2 mg/kg/day.

The toxicity profile of FK-506 is similar to that of cyclosporine (Table 35–2). The characteristics of nephrotoxicity include new arteriolar hyalinosis, degeneration or necrosis of smooth muscle cells of the media of the afferent and efferent arteriolar walls, and vacuolization of the proximal tubule. Neurotoxicity and diabetes occur more frequently with FK-506 than with cyclosporine.

Although the pathogenesis of diabetes due to FK-506 is not well understood, it has been reported that FK-506 decreases glucose-induced insulin release at high concentrations in animal and human pancreatic cells. Obesity, a family history of diabetes, a history of glucose intolerance, positive hepatitis C status, and the use of high steroid doses are some of the risk factors for diabetes in patients taking FK-506. A recent retrospective study by First and colleagues[31] showed that the incidence of post-transplant diabetes mellitus (PTDM) was 4.9% in tacrolimus-treated patients compared to 3.3% in cyclosporine-treated patients ($p=.453$). In this particular study, the absence of an antiproliferative agent correlated with the development of PTDM. In another study, using data from the United States Renal Data System, Kasiske and colleagues[32] identified 11,659 Medicare beneficiaries who received their first kidney transplant from 1996 to 2000. The cumulative incidence of PTDM was 9.1%, 16.0%, and 24.0% at 3, 12, and 36 months posttransplant, respectively. Using Cox's proportional hazards analysis, they demonstrated that risk factors for PTDM included age, African-American race, Hispanic ethnicity, male donor, increasing HLA mismatches, hepatitis C infection, body mass index greater or equal to 30 kg/m^2, and the use of tacrolimus as the initial maintenance immunosuppressive medication. Tremors, headache, seizures, and insomnia are also reported with use of this drug. Diarrhea, nausea, and anorexia are relatively common in patients receiving FK-506. The incidence of hyperlipidemia as well as hypertension is lower with FK-506 than with cyclosporine. Gloor and colleagues[33] also demonstrated that subclinical rejection episodes were much lower in patients treated with tacrolimus, MMF, and steroids (2.6%) compared to historic controls treated with cyclosporine (30%).

There is tantalizing evidence that FK-506 is a potent and useful immunosuppressive agent for the prevention of acute rejection and reversal of steroid-resistant rejection. Recently, in a 5-year follow-up study, Vincenti and colleagues[34] demonstrated that tacrolimus-based therapy resulted in significantly reduced risk of graft failure, without an increase in the incidence of adverse events associated with long-term immunosuppression.

Prospective, randomized studies are underway looking at the incidence of chronic allograft nephropathy, long-term renal function, steroid withdrawal, and cardiovascular risk factors comparing cyclosporine and tacrolimus, as well as testing the long-acting FK-506 molecule.

Azathioprine

Azathioprine is a purine analogue with a complex mechanism of action. It is metabolized in the liver to 6-mercaptopurine

Table 35–2 Potential Adverse Effects of FK-506

and 6-thioinosinic acid. Azathioprine can inhibit both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis by preventing interconversion among the precursors of purine synthesis and by inhibiting the initial steps of the de novo purine synthesis pathway through suppression of the enzyme glutamine phosphoribosyl pyrophosphate aminotransferase. It was widely used with steroids for maintenance immunosuppression before the introduction of cyclosporine to clinical transplantation.

The usual maintenance dose of azathioprine is 1 to 3 mg/kg/day as a single oral dose. One can adjust the dosage by monitoring the hematologic side effects, not by assessing blood level measurements. The most important side effect of azathioprine is bone marrow suppression, which can usually be reversed by decreasing the dose or temporarily discontinuing the drug. Hepatitis, pancreatitis, and hair loss have also been reported. There is an important drug interaction with allopurinol, which by inhibiting the enzyme xanthine oxidase, can increase the toxicity of azathioprine. Therefore, simultaneous administration of azathioprine and allopurinol should be followed closely, and the dose of allopurinol may need to be reduced to 25% to 50% of the usual dose.

In two separate meta-analyses of triple therapy (cyclosporine, prednisone, azathioprine) versus double therapy (cyclosporine, prednisone) no graft outcome advantage could be statistically discerned for azathioprine in cyclosporine-based maintenance regimens.[9,10] The new immunosuppressive agent MMF, which has decreased marrow toxicity, has entered the clinical arena of transplantation and gained popularity as part of the triple-drug regimen (cyclosporine or tacrolimus, MMF, and steroids). In one way, MMF has reduced acute rejection episodes by half compared with triple-therapy regimens that include azathioprine; however, the molecule is much more expensive.

Mycophenolate Mofetil

MMF is a semisynthetic derivative of mycophenolic acid produced by the fungus *Penicillium*. It was approved by the FDA in 1995 for use in rejection prophylaxis in kidney transplantation and has already replaced azathioprine in many centers around the world. Mycophenolic acid is poorly absorbed after oral administration; the use of MMF, the pro-drug, improves the drug's bioavailability. After oral administration, MMF is rapidly and completely converted to mycophenolic acid, which functions as a noncompetitive inhibitor of the rate-limiting enzyme inosine monophosphate dehydrogenase in the de novo purine biosynthesis pathway (Figure 35–2). Because lymphocytes are highly dependent on the de novo pathway of purine synthesis and cannot efficiently use the salvage pathway, MMF, in theory, selectively inhibits the proliferation of T and B lymphocytes. A second action to inhibit intracellular glycosylation of peptides may prove equally important because many growth factors and their receptors require the addition of glycosyl residues to traffic from the endoplasmic reticulum to the cell surface.

The efficacy and safety of MMF in renal transplantation have been evaluated in three large multicenter studies.[35-37] These studies indicated that MMF reduces the incidence of acute rejection significantly compared with azathioprine or placebo when combined with cyclosporine and steroids. Side effects were greater in patients who received 3 g/day of MMF in all studies and included diarrhea, esophagitis, gastritis, leukopenia, and anemia. Nephrotoxicity, neurotoxicity, and hepatotoxicity have not been reported with MMF (Table 35–3).

Although MMF is a promising agent for both induction and maintenance therapy, it has also been used successfully as rescue therapy for biopsy-proven rejection refractory to treatment with high-dose steroids, OKT3, or both.[38] Its long-term graft survival advantage as well as effects on decreasing the

risk of late acute rejection over azathioprine have also been shown in several recent studies.[39,40]

In addition, experimental animal data suggest that MMF may directly inhibit many mechanisms thought to be involved in chronic rejection. Although many authorities believe that MMF is an important adjunct to steroids and to some IL-2–blocking agents for early maintenance therapy, the duration of treatment with this relatively expensive agent is unclear. Trials to address this issue, especially in light of the impact on preventing rather than reversing chronic rejection, are being initiated. Ongoing trials are also looking at steroid withdrawal in patients taking MMF and at the use of MMF in combination with rapamycin and steroids in patients receiving marginal donor kidneys. Use of enteric-coated formulation of MMF allowing more therapeutic mycophenolic acid exposure is also underway.

Sirolimus

Sirolimus (rapamycin) is a macrolide antibiotic produced by *Streptomyces hygroscopicus* that has demonstrated potent immunosuppressive activity in a number of studies in both animals and humans. It has been approved in 1999 by the FDA for prophylaxis of acute rejection in renal transplant recipients after a series of clinical trials from Europe and United States demonstrated that, when used in combination with cyclosporine and steroids, it decreased the incidence of acute rejection episodes in the early posttransplant period, compared with either azathioprine or placebo. Another indication to withdraw cyclosporine when used in combination with sirolimus and steroids has also recently been approved by the FDA. Although it is structurally related to FK-506 and binds to FKBP, sirolimus has a distinct mechanism of action.[32] It forms a complex with the FKBP that binds with high affinity to the mammalian target of rapamycin (mTOR). This interaction causes dephosphorylation and inactivation of p70S6 kinase, which, when activated, stimulates the protein synthesis and cell cycle progression. This activity effectively blocks cytokine-driven (IL-2, IL-4, IL-15) T-cell proliferation by inhibiting G1 to S phase of the cell cycle. A clear synergistic effect with cyclosporine has been shown.

Although antagonistic to FK-506 in vitro, the intracellular pool of FKBP is so large that the two agents have been effectively used in renal transplant recipients *in vivo*. It has been demonstrated that simultaneous dosing of tacrolimus and sirolimus after transplantation is safe and that trough level monitoring is adequate to control therapy.

Sirolimus is a potent immunosuppressive drug. It has a relatively long half-life. It is metabolized by the same P450 enzyme system involved in the metabolism of CIs. It can be used both with and without a CI. Recent trials using sirolimus in combination with MMF and steroids demonstrated that

sirolimus may be safely and effectively used as primary therapy for the prevention of acute rejection in kidney transplantation.[42] In another study, Oberbauer and colleagues[43] showed that early cyclosporine withdrawal followed by a sirolimus-steroids maintenance regimen resulted in long-term improvement in both renal function and blood pressure, without increased risk of graft loss or late acute rejection.

The drug is relatively safe and well tolerated.[44] Reported side effects include headache, leukopenia, thrombocytopenia, hyperlipidemia, diarrhea, delayed wound healing, and lymphocele (Table 35–4). Nephrotoxicity does not occur when the drug is used without a CI but it can exacerbate CI nephrotoxicity. Animal studies showed that rapamycin also inhibits smooth muscle cell proliferation and migration as well as chronic graft vessel disease in rat transplant models of chronic rejection, which raises hope that this agent may have a role in the prevention of clinical chronic rejection as well.[45]

Interestingly, in a recent study, Morice and colleagues[46] showed that a rapamycin-eluting coronary stent compared to a standard stent showed considerable promise for the prevention of neointimal proliferation, restenosis and associated cardiac events in patients with coronary artery disease.

There is also evidence from animal studies that sirolimus can block regional tumor growth and metastatic progression of the tumor by showing an antiangiogenic effect linked to a decrease in production of vascular endothelial growth factor (VEGF) and to markedly inhibited response of vascular endothelial cells to stimulation by VEGF, as well as increasing the expression of E-cadherin.[47,48] In another animal model, sirolimus inhibited the growth of EBV-associated B-cell lymphomas.[49] Thus, the use of sirolimus may be of value for the management of posttransplant malignancy. Future trials as well as the long-term results of current trials with sirolimus can shed light to this issue.

Since it probably has no adverse effects on renal function (when used without a CI), sirolimus has been used in patients with delayed graft function. By using a CI-free protocol of antibody induction, sirolimus, mycophenolate mofetil, and prednisone in recipients with marginal donor kidneys or delayed graft function, Shaffer and colleagues[50] recently demonstrated low rates of acute rejection and excellent early patient and graft survival. Conversely, there are concerns that, when used with a CI, sirolimus could exacerbate delayed graft function; this requires further study. Sirolimus use has also

been reported in hemolytic-uremic syndrome, in steroid-free regimens, as a rescue agent in severe acute rejection, and as a substitute for CI in patients with chronic rejection.

Everolimus or SDZ RAD is a derivative of sirolimus. Its half-life is shorter than that of sirolimus. Trials are in progress in which it is being tested in combination with calcineurin inhibitors in renal transplant recipients.

Leflunomide

Leflunomide is a synthetic isoxazole derivative with anti-inflammatory and antiviral properties, which inhibits pyrimidine nucleotide synthesis with secondary effects on IL-2, transforming growth factor alpha and antibody production. It has been reported to prevent acute rejection and delay progression of chronic allograft nephropathy as well as prolong graft survival in different animal models. Interestingly, it has inhibitory effects on herpes virus replication. Side effects include anemia, gastrointestinal toxicity, elevated liver enzymes, and weight loss. Studies using leflunomide and its analogue, FK778, are being tested in phase II trials.

SUMMARY

For many years, the mainstay of immunosuppressive therapy in kidney transplantation has been the combination of Sandimmune, azathioprine, and prednisone. In recent years, the introduction of cyclosporine microemulsion, tacrolimus, mycophenolate mofetil, sirolimus, and leflunomide for maintenance therapy has provided transplant physicians with a wide variety of choices in order to be able to pick and choose the best individual immunosuppressive regimen for the individual patient.

Numerous potent immunosuppressive agents are in the design stage or undergoing trial. The questions such as whether these new agents are providing more specific immunosuppression, or what would be the best combination to achieve maximum efficacy and minimum harm, or whether these agents would prevent chronic rejection and improve long-term graft survival, and, finally, whether these agents affect tolerance induction still remain unanswered.

ACKNOWLEDGMENT

Diagnosis and Therapy of Graft Dysfunction

Important advances in immunosuppressive therapy and refinement in surgical techniques have allowed renal transplantation to become the preferred treatment modality for virtually all suitable candidates with end-stage renal disease. Ideally, a renal allograft recipient receives a high quality donor kidney, undergoes a smooth surgical grafting, develops an immediate post-transplantation diuresis with a steady improvement in renal function, and achieves excellent renal function with long-term stability. Although such idealized course is realized for many patients, graft dysfunction is an incessant threat throughout the graft lifetime for many others. The etiology and management of graft dysfunction vary over time. In this chapter, graft dysfunction will be discussed in three arbitrarily defined phases:

1. *Delayed graft function* (DGF), occurring in the immediate post-transplantation period
2. *Early graft dysfunction,* occurring in the first 2 to 3 months post-transplantation months
3. *Late graft dysfunction,* occurring thereafter

DELAYED GRAFT FUNCTION

Definition

Despite the exponential growth in renal transplantation, no universally defined criteria for delayed graft function have been established. Nevertheless, various indices, including urine volume, dialysis requirement, and serum creatinine, have been used by transplant nephrologists to diagnose "delayed graft function."

In general, a urine output greater than 20 mL/kg/day in the immediate postoperative period is a good clinical indicator of adequate renal function. Using urine output as an indication for early allograft function, however, is limited in cases where large urine volume is still being produced by the native kidneys. A large urine output from the native kidneys in the immediate postoperative period may be mistaken for an early functioning allograft. Similarly, in these same patients, no increase in urine output postoperatively does not necessarily indicate delayed graft function.

In studies evaluating the causes and management of DGF, a modified definition of "the need for more than one dialysis" is sometimes applied to take into account the need for a single postoperative dialysis for the management of hyperkalemia or fluid overload or the safe administration of blood products.[1] Using the need for dialysis alone to define DGF, however, may lead to underdiagnosis, particularly if there is some residual native kidney function. It has been proposed that an elevated serum creatinine concentration (>400 mmol/L) 1 week after transplantation should be used as a more sensitive and specific measure of DGF.[2]

Differential Diagnosis

The differential diagnosis of DGF is shown in Table 36–1. Although most cadaveric kidneys with DGF are afflicted with the clinicopathologic entity of acute tubular necrosis (ATN), it is important to not use the term loosely lest other causes of DGF not be considered. Post-transplantation ATN, like ATN in the nontransplant setting, is essentially a diagnosis of exclusion, and the diagnostic algorithms in the transplant and nontransplant settings have much in common. A systematic approach to the evaluation of DGF may be divided into prerenal (or preglomerular type), intrinsic, and postrenal. Although uncommon, vascular causes of DGF must be excluded, particularly in the early postoperative period (see Table 36–1). The term *primary nonfunction* should best be applied to kidneys that never function, and allograft nephrectomy is usually indicated.

Prerenal Causes of DGF

Severe intravascular volume depletion or significant fall in blood pressures is usually suggested by a careful review of patients' preoperative history and intraoperative report. Knowing patients' dialysis dry weight and their preoperative weight may be invaluable in the assessment of their volume status in the immediate postoperative period. Intraoperative Swan-Ganz placement for continuous monitoring of central venous or pulmonary artery wedge pressure may be useful in assessing the volume status of patients with cardiomyopathy and/or coronary artery disease.

Both calcineurin inhibitors (CNI) cyclosporine and, to a lesser extent, tacrolimus have been shown to cause a dose-related reversible afferent arteriolar vasoconstriction and "preglomerular type" allograft dysfunction that manifests clinically as delayed recovery of allograft function. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, Amphotericin B, nonsteroidal anti-inflammatory drugs (NSAIDs), and radiocontrast dye are commonly used drugs that may potentially precipitate or exacerbate acute preglomerular type allograft dysfunction. A thorough chart review should focus on the recent use of nephrotoxic medications and perioperative blood pressure curves.

Intrinsic Renal Causes of DGF

Intrinsic renal causes of DGF typically include acute tubular necrosis (ATN), acute rejection, infection, thrombotic

Table 36–1   Differential Diagnosis of Delayed Graft Function (DGF)

Prerenal (or Preglomerular Type)
Volume contraction
Nephrotoxic drugs (see text)
Vascular Complications
Arterial or venous thrombosis
Renal artery stenosis
Intrinsic Renal
Acute tubular necrosis
Accelerated acute or acute rejection
Thrombotic microangiopathy
Recurrence of primary glomerular disease (particularly FSGS)
Postrenal
Catheter obstruction
Perinephric fluid collection (lymphocele, urine leak, hematoma)
Ureteral obstruction:
Intrinsic (blood clots, poor reimplantation, ureteral slough)
Extrinsic (ureteral kinking)
Neurogenic bladder
Benign prostatic hypertrophy

microangiopathy, or recurrence of glomerular disease affecting the native kidneys.

Acute Tubular Necrosis

Post-transplant acute tubular necrosis is the most common cause of DGF. The two terms are often used interchangeably, although not all cases of DGF are caused by ATN. Its incidence varies widely among centers and has been reported to occur in 20% to 25% of patients (range 10% to 60%).[3–8] The difference in the incidence reported may, in part, be due to the more liberal use of organs from marginal donors by some centers but not by others and/or the difference in the criteria used to define DGF. Unless an allograft biopsy is performed, post-transplant ATN should be a diagnosis of exclusion. Both donor and/or recipient factors are important determinant(s) of early allograft dysfunction (Table 36–2).

Pathogenic Mechanisms

ATN found in the post-transplant setting is essentially an ischemic injury that may be synergistically exaggerated by both immunologic and nephrotoxic insults.[1] All transplanted kidneys are subject to injury at various steps in the transplantation process—from donor death to organ procurement, surgical reanastomosis, and postoperative course. Understanding, identifying, and addressing the potential for injury at every step of this complex process are critical to the prevention of post-transplant ATN. Some degree of ischemic injury is invariably unavoidable in cadaveric renal transplantation.

Table 36–2   Risk Factors for Delayed Graft Function (DGF) Due to Acute Tubular Necrosis (ATN) in Cadaveric Renal Transplantation

Donor Factors	Recipient Factors
Premorbid Factors	**Premorbid Factors**
Age (<10 or >50)	African American (compared to Caucasians)
Donor hypertension	Peripheral vascular disease
Donor macrovascular or microvascular disease	Presensitization (PRA>50)
Cause of death (cerebrovascular vs. traumatic)	Reallograft transplantation
Preoperative Donor Characteristics	**Perioperative and Postoperative Factors**
Brain–death stress	Recipient volume contraction
Hypotension, shock	Early high dose calcineurin inhibitors
Prolonged use of vasopressors	+/− Early use of OKT3
Preprocurement ATN	
Non–heart beating donor	
Nephrotoxic agents	
Organ Procurement Surgery	
Hypotension prior to cross-clamping of aorta	
Traction on renal vasculatures	
Cold storage flushing solutions	
Kidney Preservation	
Prolonged warm ischemia time (+/− contraindication to donation)	
Prolonged cold ischemia time	
Cold storage vs. machine perfusion	
Intraoperative Factors	
Intraoperative hemodynamic instability	
Prolonged rewarm time (anastomotic time)	

(Adapted from Pham PT, Pham PC, Wilkinson AH: Management of the transplant recipient in the early postoperative period. *In* Davidson (ed): Oxford Textbook of Clinical Nephrology, 3rd ed. New York, Oxford University Press [In press]).

Much can be inferred about the cellular and molecular mechanisms of post-transplant ATN from observations in nontransplant animal models and ATN in native kidneys. Readers are referred to extensive reviews of this topic.[9–13] In essence, during ischemia, cellular metabolism continues and the resulting shift to anaerobic metabolism leads to accumulation of lactic acid, failure of sodium-potassium-ATPase pumps, loss of cell polarization, cell swelling, and subsequent lysis with release of cytotoxic oxygen-free radicals.

Because of the unique sequence of events leading to organ transplantation, the transplanted kidney is particularly

susceptible to reperfusion injury. The reintroduction of oxygen into tissues with a high concentration of oxygen-free radicals leads to the production of superoxide anion and hydrogen peroxide leading to lipid peroxidation of cell membranes. This process may be responsible for the commonly occurring clinical sequence, where an early post-transplantation diuresis is followed by oliguria within hours.

Damage to the vascular epithelium leads to the release of vasoactive molecules that may be responsible for the hemodynamic changes typical of ATN.[11] The term *vasomotor nephropathy* may be more appropriate than ATN because it describes a physiologically altered state that may not be necessarily accompanied by tubular necrosis histologically.[12] As a result of increased renovascular resistance and decreased glomerular permeability, the glomerular filtration rate (GFR) falls. In ATN, tubules obstructed with cellular debris further reduce the GFR and the increased intrarenal pressure due to edema further reduces blood flow.[13] Although blood flow to the renal cortex is reduced, there is a relatively greater reduction in GFR and tubular function, which accounts for the common findings of "good flow and poor excretion" on scintigraphic studies.[14] The alterations in vascular resistance and increased intracapsular pressure result in the increased resistive index and reduced or reversed diastolic blood flow observed on Doppler ultrasound.

Although ischemic injury has been regarded as a major risk factor for the development of post-transplant ATN, several lines of evidence suggest that immunologic factors may be equally important. The former is suggested by the observation that the incidence of DGF was significantly higher among recipients of cadaveric kidneys than for living-donor transplants and the latter by the observation that DGF is more prevalent in recipients of re-allograft transplants compared to those of primary transplant, particularly if they have high levels of preformed panel-reactive antibodies.[3,15] A positive flow cytometry cross-match in the absence of a positive standard complement-dependent cytotoxicity cross-match has also been shown to be associated with a greater incidence of ATN and delayed lowering of the post-transplant plasma serum creatinine level.[16] Presumably, the immunologic factors make the newly transplanted kidney more susceptible to ischemic injury.

The Effect of ATN on Host Immunogenicity

Some but not all evidence suggest that ATN may contribute to the upregulation and exposure of histocompatibility antigens and increase the immunogenicity of the transplanted kidney, hence enhance its susceptibility to both acute and chronic rejections.[17–18] The stress of brain death itself likely has a similar effect. In a rat study, explosive brain death has been shown to be associated with upregulation of macrophage (IL-1, IL-6, and TNFα) and T-cell–associated products (IL-2 and IF-α) in the peripheral organs, rendering them more susceptible to subsequent host inflammatory and immunologic responses.[19] Nitric oxide produced by the inducible nitric oxide synthase (iNOS) enzymes in response to ischemic cell injury has been suggested to a play a key role in the link between ischemic reperfusion injury and graft rejection.[20] Renal epithelial regeneration after ischemic damage is mediated by growth factors and cytokines, such as epidermal growth factors (EGF) and transforming growth factor β (TGF-β), which may facilitate the development of the low-grade inflammation and

fibrosis that occurs in chronic rejection.[21] Injury, in the form of ATN, leads to inflammation, which, in turn, facilitates an immune response that causes further injury.[15,17] A number of studies have shown that in the long-term, ATN kidneys that do not develop rejection do as well as non-ATN kidneys that do not develop rejection, lending support to the theory that it is the immunologic consequences of ATN that are responsible for its prognostic significance.[22] Yet studies on the impact of DGF (presumably due to ATN) with or without early acute rejection on long-term graft survival have yielded conflicting results (discussed in a later section).

Histology

ATN in the allograft is similar to that in the native kidney. Tubular epithelial cells show necrosis, often with sloughed, degenerated, or apoptotic epithelial cells in the tubular lumina, a feature more prominent in ATN involving transplanted kidneys.[23] Proximal cell brush border staining is focally absent with flattening of tubular cells, and there may be regeneration in the form of mitotic figures (Figure 36–1).[24] The interstitium is variably edematous, with a minimal or patchy interstitial lymphocytic infiltrate; however, there is no associated inflammation in the walls of tubules. No specific changes of glomeruli or the vasculature are found in ATN.

Prediction and Prevention

Kidneys from living, related, or biologically unrelated donors rarely suffer from DGF, whereas the incidence of DGF in recipients of cadaveric transplants varies from 10% to 60%.[3–8] Living donors undergo an extensive evaluation process to ensure their health and that of their kidneys, and the circumstances of live donor organ harvesting permit minimalization of ischemic damage to the organ. On the contrary, the circumstances of sudden death are always, in varying degrees, detrimental to renal function, and some degree of ischemic damage is inevitable, considering the complexities of the cadaveric organ procurement process.
Figure 36–1 Acute tubular necrosis. Tubular cells show flattening and necrosis and focally are desquamated into the tubular lumina. The central tubule contains calcium oxalate in the lumen, a product of cellular debris. (Jones methenamine silver × 250)

Donor factors before the procurement of cadaveric organs are important predictors of early and late graft function. Kidneys from older donors have a higher incidence of ATN,[25] a finding that is reminiscent of the clinical observation that older patients in the nontransplantation setting are also more susceptible to ATN when faced with ischemic or nephrotoxic insult.[26] The common factor linking older age to ATN is probably diminished capacity of the aging vasculature to vasodilate adequately to protect the transplant from anoxic damage.

In this respect, donor death from traumatic injury is less likely to be associated with ATN than death from cerebrovascular causes because the trauma victim is more likely to have been younger and healthier than a stroke victim.[27] Even the "ideal" trauma victim is likely to have experienced an episode of hypotension, and a history of fluctuating or deteriorating renal function is not uncommon. Kidneys from young donors typically recover from pre-transplantation injury, whereas the prognosis for kidneys from older donors with pre-transplantation impairment of function is often poor, and it has previously been suggested that such kidneys should not be routinely transplanted.[28] However, with the ever-increasing disparity between supply and demand for cadaveric donor kidneys, expanded criteria donor kidneys (ECD) have been increasingly used by some centers. These kidneys are defined by donor characteristics that are associated with a 70% greater risk of kidney graft failure when compared to a reference group of nonhypertensive donors of ages 10 through 39 years whose cause of death was not cerebrovascular accident (CVA) and whose terminal creatinine was less than or equal to 1.5 mg/dL. The donor factors associated with this increased relative rate of graft failure include age 60 or older, or ages 50 to 59, with at least 2 comorbid factor. The latter may include CVA as a cause of death, hypertension, and/or terminal creatinine greater than 1.5 mg/dL (Table 36–3). To optimize allograft outcome using these "marginal" kidneys, the United Network of Organ Sharing (UNOS) has implemented a system to minimize cold ischemia time and to expedite ECD kidney placement. Currently, the allocation of ECD kidneys is based on prior identification of and consent by ECD waitlisted candidates, pre-procurement tissue typing of ECD kidneys, and abbreviated time period (2 hours) for placement of zero mismatched ECD kidneys. If no zero antigen mismatch transplant candidate is identified, the ECD kidney will be allocated to all other "pre-identified" candidates by waiting time alone, first locally, then regionally, and then nationally.

Despite the efforts to decrease cold ischemia time, the use of ECD kidneys inevitably increases the incidence of post-transplantation ATN. Similarly, attempts to bolster the cadaveric donor supply by the use of non–heart-beating donors (NHB) that are, by definition, susceptible to warm ischemia resulted in an elevated DGF rates.[28] Analysis of the U.S. Renal Data System database revealed that recipients of NHB donor organs experienced nearly twice the incidence of DGF compared with heart-beating donors (42.4% vs. 23.3%, respectively). Nonetheless, NHB donor transplants experienced comparable allograft survival when compared with cadaveric transplant at 6-year follow up (73.2% vs. 72.5%, respectively: P=NS). Interestingly, patient survival was greater at 6 years for NHB compared with cadaveric renal transplant recipients, although this did not reach statistical significance. Significant factors for allograft loss for NHB donor organ recipients include repeat transplant, DGF, donor age older than 35 years, and

Table 36–3 Factors that Determine Expanded Criteria Donors (Adapted from UNOS)

Donor Condition	Donor Age Categories	
	50–59	≥60
CVA + HTN + Creat >1.5	X	X
CVA + HTN	X	X
CVA + Creat >1.5	X	X
HTN + Creat >1.5	X	X
CVA		X
HTN		X
Creat >1.5		X
None of the above		X

X, expanded criteria donor; *CVA,* cerebrovascular accident (as the cause of death); *HTN,* hypertension; *Creat,* creatinine.

head trauma as a cause of initial injury.[29] Acknowledging these risk factors may maximize the use of cadaveric donor organs while minimizing the risk of accepting kidneys with primary nonfunction.

In selected cases, dual transplant of ECD kidneys have been offered to older recipients with excellent short-term allograft outcome, comparable to that of recipients of single non-ECD control kidneys.[30] It has been suggested that the salutary effect of dual kidney transplant is due to increasing viable nephron mass. Experimental studies in rats have shown that increasing the number of viable nephron mass by dual kidney transplantation prevented the progressive deterioration in renal function that occurred in control rats receiving single kidney.[31] Studies on long-term graft function and survival in human recipients of ECD kidneys are currently limited. In a single center retrospective study consisting of 10 dual renal transplant recipients and 10 age matched single cadaver kidney recipients, allograft function and the incidence of graft loss at 4-year follow-up were comparable between the two groups.[32]

Organ Procurement and Preservation

Early ischemic injury adversely affects both short- and long-term allograft function and/or survival. In cadaveric kidneys the earliest injury begins with organ procurement and preservation. The technical aspect of donor management and organ procurement in the era of multiorgan harvesting are beyond the scope of this chapter. The purpose of donor management is to maintain adequate organ perfusion before rapid cooling and flushing of the kidneys to minimize warm ischemia. The warm ischemia time refers to the period between circulatory arrest and the commencement of cold storage.[33] Ischemia at body temperature can be tolerated for only a few minutes, after which irreversible cellular injury begins to occur such that within about 30 minutes, the organ becomes nonviable. The cold ischemia time refers to the period of cold storage or machine perfusion. Fortunately, for the purposes of transplantation, anaerobic metabolism can maintain renal cellular energy requirements for up to 48 hours, provided the organ is cooled to about 4°C with an appropriate preservation solution.[34] Increasing both the warm and cold ischemia times leads to a progressive decline in graft survival rates and an increase in the incidence of DGF.[33] Ideally, kidneys are

transplanted without significant warm ischemia and with cold ischemia time of less than 24 hours, although longer cold ischemia may be acceptable.

Organ Preservation: Collins Solution versus University of Wisconsin Solution

Although the method of kidney preservation differs between centers, simple cold storage is currently the most widely used technique. The goal of preservation is to maximize ischemic tolerance during anaerobic metabolism and to minimize ischemic reperfusion injury. Collins solution was used for many years for flushing and for organ preservation until the 1990s, when University of Wisconsin solution started to gain popularity. University of Wisconsin solution has been shown to be superior to Collins solution in reducing the rate of DGF and in extending cold ischemia time.[8,35] Both solutions have high potassium content and are hyperosmolar. UW solution contains lactobionate, raffinose, and hydroxyethyl starch as osmotic component, whereas Collins solution contains glucose. UW solution also contains glutathione, adenosine, and the free-radical scavenger allopurinol, and it has a higher viscosity than that of Collins solution. Although the higher viscosity of Wisconsin solution may impede a sufficient initial flush, glutathione content in UW solution may serve to facilitate regeneration of cellular adenosine triphosphate (ATP) and to maintain membrane integrity, whereas during reperfusion, adenosine may provide the substrate for regeneration of ATP. Newer solutions with increasing chemical stability, lower potassium content, and lower viscosity are currently in the investigational stages. Although controversies remain regarding the relative benefits of cold storage versus pulsatile perfusion of the newly procured organ during the period of cold ischemia, pulsatile preservation is preferred by some centers.[36] A number of studies have shown that pulsatile perfusion is associated with a lower incidence of DGF and an improvement in early and long-term allograft function.[36,37] Pulsatile perfusion may also permit identification of kidney(s) that will likely result in primary nonfunction, hence sparing a recipient of the morbidity associated with the transplant operation and of the potential for the development of allosensitization.[36] In this respect, pulsatile perfusion of kidneys may aid in optimizing the use of marginal kidneys.

Rewarm time refers to the period between the removal of the kidney from cold storage and the completion of the vascular anastomosis.[33] The length of this period is strongly correlated to the incidence of DGF. Minimalization of this time period is, to a large extent, a reflection of surgical technical expertise. Ischemic damage can be minimized, if the kidney is kept cool with cold packs during this period. Before, during, and after recipient surgery, compulsive attention to the volume status helps minimize post-transplant dysfunction. If recipients require dialysis preoperatively, care should be taken to ensure that at the completion of the dialysis, the patient is at or above, but not below, his or her "dry weight" en route to the operating room. During the surgery, a state of mild volume expansion should be maintained, as permitted by the cardiovascular status of the patient. Central venous pressure should be maintained at about 10 mmHg with the use of isotonic saline and albumin infusions, and systolic blood pressure should be kept above 120 mmHg.[38]

Prevention Using Drug Therapy

Various pharmaceutical agents and protocol modifications have been made to encourage postoperative diuresis and to reduce the incidence or severity of ATN.[39] The use of diuretics is discussed in the section on management. Some immunosuppressive protocols do not permit the use of intravenous cyclosporine in the early postoperative period. Some programs use routine induction therapy with antilymphocytic agents in all patients, thereby obviating the vasoconstrictive effect of both cyclosporine and tacrolimus. More commonly, however, induction therapy is used selectively in patients with anticipated or established DGF. As ATN may render the allograft more susceptible to immunologic injury, the use of antilymphocyte antibodies in this setting may also be beneficial due to their potent immunosuppressive effect. Dopamine infusions at renal dose levels of 1 to 5 mcg/kg/min are used routinely at some centers to promote renal blood flow and to counteract cyclosporine-induced renal vasoconstriction.[39] The benefits of dopamine have not been proved in randomized trials, although its use has become institutionalized. Fenoldopam, a selective agonist of dopamine-1 receptors with both systemic and renal vasodilator properties, has been shown to reverse cyclosporine-mediated renal vasoconstriction in stable renal transplant recipients.[40] However, its role in reducing the incidence or severity of post-transplant DGF remains to be determined. Administration of calcium channel blockers to the donor or recipient, or at the time of the vascular anastomosis, has become routine in many transplant centers largely as a result of randomized clinical trials showing improved initial function with their use.[41] The presumed mechanism of action is by virtue of a direct vasodilatory effect. The kidney is often observed to "pink-up" when verapamil is injected into the renal artery during surgery.[38]

Randomized trials of allopurinol and other oxygen-free radical scavengers have not shown convincing benefit in graft function.[42] Although prostaglandins have been shown in animal models to minimize ischemic injury,[43] no benefit was found in a blinded trial of the prostaglandin E analogue enisoprost.[44] Similarly, although pretreatment with an antibody preparation against the intercellular adhesion molecule 1 (anti-ICAM-1) has been shown in experimental rat models to alleviate ischemic reperfusion injury, no benefit was found in a randomized multicenter trial of the anti-ICAM-1 monoclonal antibody enlimomab.[45] Blinded trials of atrial natriuretic factor administration have shown only marginal benefit in native kidney ATN,[46] and it is unlikely that this agent will find a place in the transplantation setting. In renal transplant recipients with DGF, it has been shown that neither renal vasoconstriction nor hypofiltration is alleviated by a progressive elevation of endogenous plasma atrial natriuretic peptide levels.[47]

Management of Delayed Graft Function

The differential diagnosis of DGF (see Table 36–1) must be considered before a patient is labeled with the most likely explanation—post-transplantation ATN. Most patients with DGF are oliguric or anuric. Knowledge of the patient's native urine output is critical to assess the origin of the early post-transplantation urine output. From the previous discussion on the etiology of DGF, it is clear that information about the

donor kidney itself is critical. When the transplant is from a living donor, postoperative oliguria is rare because of the short ischemia time, and if it occurs, it must raise immediate concern regarding the vascularization of the graft. However, when a patient receives a cadaveric kidney from a nonideal donor, DGF may be anticipated. The mate kidney from a cadaveric donor often behaves in a similar manner, and information on its function can be useful.[1]

Anuria is easy to define. Oliguria in the peri-transplantation and early post-transplantation period usually refers to a urine output of less than about 50 mL/hr. Before the low urine output is therapeutically and diagnostically addressed, the patient's volume status and fluid balance must be assessed and the Foley catheter irrigated to ensure patency. If clots are present, the catheter should be removed while gentle suction is applied in an attempt to capture the offending clot. Thereafter, a large catheter may be required. If the Foley catheter is patent and the patient is clearly hypervolemic, up to 200 mg of furosemide should be given intravenously. If the patient is judged to be hypovolemic or if a confident clinical assessment cannot be made, a judicious isotonic saline should be given, followed by a large dose of furosemide. A suggested algorithmic approach to postoperative fluid management in an oliguric patient is shown in Figure 36–2.

Indications for dialysis in the transplant recipient with DGF are essentially the same as in any patient with postoperative renal dysfunction. Hyperkalemia is a persistent danger and must be monitored repeatedly and treated aggressively. It is usually safest to dialyze patients once the potassium level reaches the "high fives." Other treatment modalities, such as intravenous calcium, and glucose with insulin, are valuable temporizing measures but do not obviate the need for dialysis. Sodium polystyrene sulfonate (Kayexalate) should not be administered rectally in the early post-transplant period because it may induce colonic dilatation and predispose to perforation.[48]

Patients with DGF often become volume overloaded in the early post-transplantation period because they are frequently subjected to repeated volume challenges. It is not infrequent for such patients to be several kilograms over their dialysis dry weight, and this fluid gain may not be always clinically obvious. Ultrafiltration with or without dialysis may be required. When dialyzing post-transplantation patients who have DGF, one must take particular care to avoid hypotension, which may perpetuate the graft dysfunction. A bicarbonate bath and a biocompatible dialyzer should be used. In patients with established DGF, the dialysis requirement should be assessed daily until graft function improves.[1]

Diagnostic Studies in Persistent Oliguria or Anuria

Failure to respond to volume challenge and furosemide administration warrants further evaluation with diagnostic imaging studies to determine the cause of the early post-transplant oliguric state. The urgency of this evaluation partially depends on the clinical circumstances. If diuresis is anticipated, such as after a living donor kidney transplantation, diagnostic studies should be performed immediately—in the recovery room if necessary. If oliguria is anticipated, studies can usually be safely delayed by several hours.

Diagnostic studies are used to confirm the presence of blood flow to the graft and the absence of a urine leak or obstruction. Blood flow studies are performed scintigraphically or by Doppler ultrasound.[49] The typical scintigraphic finding in ATN is relatively good flow to the graft compared with poor excretion. If the flow study reveals no demonstrable blood flow, a prompt surgical reexploration is necessary to attempt to repair any vascular technical problem and diagnose hyperacute rejection. These kidneys are usually lost, however, and are removed during the second surgery. If adequate blood flow is visible with the scintiscan or Doppler studies, the possibility of ureteral obstruction or urinary leak needs to be considered and can be evaluated by the same imaging studies. In the first 24 hours after transplantation, as long as the Foley catheter has been providing good bladder drainage, the obstruction or leak is almost always at the ureterovesical junction and represents a technical problem that needs surgical correction.[38]

Other Causes of Graft Dysfunction During the First Week After Transplantation

Early Acute Rejection

Hyperacute Rejection

Rejection occurring immediately after transplantation or hyperacute rejection is due to presensitization and is mediated by antibodies to donor human leukocyte antigens (HLA). The rejection occurs after an anamnestic response, and a critical level of antibodies is produced that results in an irreversible vascular rejection. Hyperacute rejection may be evident before wound closure or it may be "hidden" and manifest itself as primary nonfunction of the kidney allograft.[50] Patients are usually anuric or oliguric and often have fever and graft tenderness. The renal scan shows little or no uptake, a finding that differentiates this cause of graft dysfunction from the much more frequent ATN. There may be evidence of intravascular coagulation. Prompt surgical exploration of the allograft is often indicated, and when in doubt, an intraoperative biopsy is performed to determine viability. Because of assiduous attention to the pretransplantation cross-match, it occurs rarely in modern transplantation practice.

Because hyperacute rejection is due to preformed antibodies, it is characterized morphologically by arterial and glomerular thrombi, which often contain neutrophils or may have accumulation of intravascular neutrophils as the initial event. The interstitium is edematous and variable parenchymal necrosis or infarction is observed, depending on the length of time from thrombosis to nephrectomy. There is no significant vascular or tubulointerstitial inflammation. Immunofluorescence microscopy reveals fibrin within the intravascular thrombi, and immunoglobulin M (IgM), IgG, C3, and fibrin may be found lining portions of the arterial and capillary lumens. In this setting, most allografts need to be removed.[51]

Accelerated Acute Rejection

Accelerated acute rejection or delayed hyperacute rejection occurs within 24 hours to a few days after transplantation and may involve both humoral and cellular immune mechanisms. Accelerated acute rejection probably represents a delayed amnestic response to prior sensitization and may be seen after donor-specific transfusions in recipients of living-donor transplant due to a primed T-cell response.[52] HLA allosensitization through repeat transplants, multiple pregnancies, or multiple transfusions are well-substantiated risk factors for hyperacute or accelerated acute rejection. However, with the current sensitive cross-matching techniques, such as flow cytometry or antihuman globulin augmentation tests, hyperacute rejection has virtually been nonexistent.

Early Cell-Mediated Acute Rejection

Early cell-mediated rejection, with a typical interstitial infiltrate or vasculitis, can also be detected in the latter part of the first week after transplantation, although it typically occurs somewhat later. It may develop in an allograft already suffering from ATN and may be difficult to recognize clinically because the patient is anuric or oliguric. An allograft with DGF, presumably due to ATN, should undergo serial biopsies at intervals of about 10 days to detect the covert development of rejection. The prognosis for long-term function of these grafts is poor, although adequate function may be achieved, if the ATN reverses and the rejection responds to intensification of immunosuppression (see Chapters 29 and 30).

Nonimmunologic Causes

Nonimmunologic causes of DGF (other than ATN) of various etiologies may occur in the first post-transplant week or any time thereafter and are discussed under graft dysfunction in the early post-transplant period.

Long-Term Impact of Delayed Graft Function

Studies on the impact of DGF on long-term graft function have yielded conflicting results.[3,4,6,7,53] Data from the UNOS Scientific Renal Transplant Registry revealed that DGF reduced 1-year graft survival from 91% to 75% ($p <.0001$) and graft half-life from 12.9 to 8.0 years, independent of early acute rejection. The deleterious effect of DGF with or without acute rejection on graft half-life remained significant after adjusting for discharge serum creatinine of less than 2.5 mg/dL. Interestingly, in the presence of DGF with or without acute rejection, the survival advantage of well-matched kidneys (0–1 mismatch) over those of poorly matched (5–6 mismatch) kidneys was no longer seen.[54] Some group of investigators showed that DGF, when combined with rejection had an additive adverse effect on allograft survival, whereas others suggested that DGF is deleterious to graft outcome only when associated with reduced renal mass and hyperfiltration injury.[53,55] The harmful effect of DGF may also be more pronounced when marginal donor kidneys are used. It should be noted that in most studies reported transplant biopsies were not performed and DGF was presumed to be due to ATN. This, along with the difference in the criteria used to define DGF may explain, in part, the conflicting results between various studies.

GRAFT DYSFUNCTION IN THE EARLY POST-TRANSPLANT PERIOD

The early post-transplantation period usually refers to the time span following discharge from the hospital until the second or third month, at which time most patients have achieved stable graft function and a stable immunosuppressive regimen. Although the differentiation, at this stage, between the early and late post-transplantation is clearly somewhat arbitrary, it is based on the finding that most acute rejection episodes occur within the first few months. In randomized trials that have used episodes of acute rejection as their end points, more than 90% of acute rejection episodes occur during the first year.[56,57] Similarly, most episodes of cyclosporine or tacrolimus toxicity occur during this period, as do most cases of surgery-related graft dysfunction.

By the second week, graft function of most patients with DGF due to ATN begins to improve, although some patients remain oliguric for several weeks. In all patients who have become independent of dialysis, measurement of the serum creatinine (SCr) concentration is a simple yet invaluable marker of kidney transplant function, and the universal

availability of this test greatly facilitates post-transplantation management. In clinical transplantation management, it is generally not necessary to measure renal function by more accurate and sophisticated techniques, such as creatinine clearance and isotope filtration rates, although these techniques may be valuable in assessing the significances of changes in SCr with time and in providing a more accurate baseline value for follow-up. The level of SCr reached by the second week is an important determinant of long-term graft function, and any baseline level greater than the "low twos" is a source of concern necessitating evaluation. The relationship between SCr and adverse outcome in renal transplantation remains the most robust predictor of graft survival at all time points.[2] Recent analysis of the UNOS database involving 105,742 adult renal transplant recipients performed in the United States between 1988 and 1998 revealed that post-transplant serum creatinine greater than 1.5 mg/dL at 1 year significantly decreased graft half-life regardless of whether or not patients had an episode of acute rejection[58] (discussed in further details under graft dysfunction during long-term follow up).

Elevations in SCr of greater than 25% from baseline almost always indicate a significant, potentially graft-endangering event. Smaller elevations may represent laboratory variability, and if there is any question regarding a small asymptomatic rise in SCr, the test should be repeated within 48 hours. The clinical algorithm in approaching SCr elevations (or failure to reach a low baseline value) is similar, in principle, to that used in the nontransplant setting in that "prerenal," "renal," and "postrenal" causes need to be considered. In the early post-transplantation period, acute rejection and nephrotoxicity are constant threats to graft function; anatomic or surgical problems must be considered, however, before medical diagnoses are made to explain deteriorating graft function.

Acute Rejection

Clinical Presentation

Acute rejection is the term conventionally used to describe the cellular immune response to the transplant that produces enough inflammation and destruction to cause recognizable graft dysfunction, as measured by an elevation of the SCr. More recently it has been suggested that humoral immune response or more specifically, donor specific anti-HLA antibodies can also cause direct graft injury and acute allograft dysfunction. Although using the SCr to define the occurrence of rejection is highly convenient it is insensitive in detecting subclinical pathogenic allograft inflammation or "subclinical rejection." Up to 30% to 80% of protocol biopsies performed in the first 3 months post-transplantation in patients with stable allograft function have been shown to meet Banff criteria for type I rejection.[59] More importantly, untreated subclinical rejection has been suggested to be a precursor to chronic rejection and chronic allograft nephropathy.[59,60] Conversely, treatment of subclinical rejection in the first 3 months post-transplantation has been shown to prevent both late clinical rejections and the development of chronic rejection.[61,62]

The classic symptoms and signs of acute rejection are fever, malaise, graft tenderness, and oliguria. Acute rejection can present with a seemingly innocuous influenza-like illness, and transplant recipients should be warned of the potential significance of these symptoms. These symptoms consistently and rapidly resolve when the rejecting patient receives pulse steroids, presumably as a result of the blockade of interleukin-1 by corticosteroids.[63] Since the advent of cyclosporine and of potent immunosuppressive agents in general, these findings are seen less frequently, and many rejections present as asymptomatic elevations of the SCr. In the presence of fever, graft tenderness, and/or oliguria, a search for alternative causes of graft dysfunction is warranted.

Fever may indicate either rejection or infection and should never be presumed to be due to the former without considering the latter. Infection during the first few weeks usually results from bacterial pathogens in the wound, urinary tract, or respiratory tract and may be associated with an elevated SCr level as a result of vasodilatation or volume contraction.[64] A thorough history, physical exam, standard laboratory tests, and a chest radiograph must, therefore, precede the diagnosis and treatment of rejection. An elevated white blood cell count is frequently seen in the post-transplantation period, particularly in patients still receiving high baseline doses of corticosteroids, and is often unhelpful in the differential diagnosis. Fever due to infection with opportunistic organisms usually does not occur in renal transplant recipients until several weeks after transplantation. Cytomegalovirus (CMV) infection may mimic acute rejection, and its possible presence always needs to be considered, particularly in CMV-negative recipients of kidneys from CMV-positive donors.[64]

Many patients comment on incisional tenderness in the first few days and can be reassured that this is of little clinical significance. The new onset of graft tenderness in a previously pain-free patient, however, is a significant symptom that needs to be evaluated. A tender, swollen graft in a patient with a rising SCr concentration and fever usually indicates rejection, although the possibility of acute pyelonephritis must also be considered.[64] Cyclosporine and tacrolimus toxicity and CMV infection do not produce graft tenderness. Excruciating localized perinephric pain is usually a result of a urine leak.[65]

Both rejection and cyclosporine toxicity may produce weight gain and edema as a result of impaired graft function and avid tubular sodium reabsorption. Mild peripheral edema is common in stable patients receiving cyclosporine. Acute rejection, cyclosporine toxicity, and tacrolimus toxicity can all produce graft dysfunction in the absence of oliguria. Oliguria is common in severe acute rejection; its occurrence makes a diagnosis of drug toxicity less likely and makes the necessity to exclude an anatomic cause all the more critical.

Imaging Studies

The morphologic findings in acute rejection are nonspecific and somewhat subjective, and imaging studies are performed to exclude alternative causes of graft dysfunction. In mild acute rejection episodes, ultrasonographic and nuclear medicine study results may be normal.[14,49] Ultrasonographic abnormalities include graft enlargement, obscured corticomedullary definition, prominent hypoechoic medullary pyramids, decreased echogenicity of the renal sinus, thickened uroepithelium, and scattered heterogenous areas of increased echogenicity. The resistive index is also elevated as it is in other causes of graft dysfunction that produce increased vascular resistance to the kidney.[14]

Acute rejection may appear on nuclear medicine technetium 99m DTPA and MAG-3 scans as delayed visualization

(decreased perfusion) of the transplant in the first-pass renal scintiangiogram.[49] Poor parenchymal uptake with high background activity (poor kidney function and clearance) may be seen in the second and third phases of the three-phases imaging study. However, it should be noted that neither renal Doppler ultrasound nor radioisotope flow scan is sufficiently sensitive or specific in the diagnosis of acute rejection. Although invasive, tissue diagnosis remains the most accurate means of differentiating acute rejection from other causes of acute deterioration of allograft function.

Histopathologic Diagnosis

Percutaneous renal biopsy is the gold standard diagnostic tool for acute rejection. Although readily accessible and less invasive, allograft fine needle aspiration has significant diagnostic limitations, and its use has lost popularity. The timing and frequency of kidney biopsies vary among centers. One clinical approach to graft dysfunction is to base a therapeutic intervention empirically on the clinical presentation and laboratory values. A favorable response confirms the diagnosis, but a lack of response requires tissue diagnosis. It is probably wise to obtain tissue diagnosis of rejection before embarking on a course of OKT3 or polyclonal antibodies because occasionally CMV infection may present as fever and graft dysfunction,[64] in which case potent immunosuppressive therapy could be catastrophic. A more aggressive approach to graft dysfunction is to perform a kidney biopsy whenever the SCr level rises 25% over the baseline value. Therapy is then based on the morphologic findings.

Types of Acute Rejection

Acute rejections occur, most typically, between the first week and the first 3 months after transplantation. In unsensitized patients with low levels of preformed antibodies, acute rejections rarely occur in the first week, while very early rejections (or accelerated acute rejection) may occur in sensitized patients (as previously described). On the basis of the underlying immunopathogenic mechanisms, acute rejection can be divided into cell-mediated and humoral immunity. Approximately 90% of the episodes of acute rejection are predominantly cell-mediated, whereas 20% to 30% of all acute rejection episodes have a humoral component.[66] The histologic diagnostic criteria are different for these two types of rejection and are discussed separately. It should be noted, however, that the histopathologic findings of acute cellular rejection can be seen in allograft biopsies with acute humoral rejection or vice versa.

Acute Cellular Rejection

Acute cellular rejection generally occurs after the first posttransplant week and most commonly occurs within 3 months after transplantation. It has been suggested that CD4+ T cells play an important role in the initiation of rejection, whereas CD8+ T cells are critical at a later stage.[52] There has been accumulating evidence indicating that the effector pathway of cytotoxicity T lymphocytes killing (CTL) leading to acute renal allograft rejection involves the perforin/granzyme degranulation pathway.[67] Urinary perforin mRNA and granzyme B have been shown to be elevated in acute allograft rejection. It has been suggested that measurement of urine perforin mRNA and granzyme B messenger RNA may offer a noninvasive means of diagnosing acute renal allograft rejection with a sensitivity of 79% to 83% and a specificity of 77% to 83%.[68] Nonetheless, whether measurement of these cytotoxic proteins may be beneficial in monitoring or in the diagnosis of acute cellular rejection awaits further studies.

Acute Humoral Rejection

Acute humoral rejection generally occurs within the first 1 to 3 weeks after transplantation.[69] Its incidence has been difficult to determine in part due to the lack of well-defined diagnostic criteria. Although the detection of the complement degradation product C4d deposition in peritubular capillaries (PTC) of renal allograft biopsies has been regarded as a footprint of a humoral response, focal PTC C4d staining has also been found to be present in ischemic injury. More recently, Mauiyyedi and associates[69] suggested that a definitive diagnosis of AHR requires demonstration of circulating donor specific antibodies (DSA). Yet other investigators speculated that non-HLA, anti-endothelial antibodies or subthreshold levels of DSA may account for the C4d(+) DSA(−) cases of AHR? hyperacute rejection as a result of antibodies to endothelial cells has been reported.[69,70] The currently suggested histologic and immunopathologic criteria for AHR is shown in Table 36–4.

Core Biopsy

Biopsy evaluation for acute changes should be performed in unscarred portions of the renal cortex. Cell-mediated acute rejection occurs in two forms, including the tubulointerstitial and vascular types. Tubulointerstitial acute rejection is characterized by lymphocytes in the walls of tubules (tubulitis) with associated interstitial edema and inflammation, including lymphocytes, activated lymphocytes, monocytes, and occasional scattered eosinophils or plasma cells. Variable degrees of tubular cell flattening, necrosis, and regenerative

Table 36–4 Pathologic Criteria for Acute Humoral Rejection*

- C4d deposition in peritubular capillaries[†]
- At least one of the following[‡]:
  - Neutrophils in peritubular capillaries
  - Arterial fibrinoid necrosis
  - Acute tubular injury
- Circulating donor-specific antibodies

*Cases that also meet the criteria of type I or II acute cellular rejection (Banff) are considered to have both processes.
†Bright and diffusely positive staining (at least 2/4+ by immunofluorescence) for C4d in peritubular capillaries (PTCs).
‡Neutrophils in PTCs, on average, two or more neutrophils per high power field, in PTC, in 10 consecutive 40 × (500 μm diameter) fields; fibrinoid necrosis in an artery larger than an arteriole; acute tubular injury, loss of brush borders, flattened epithelium, apoptosis. If only two of the three numbered criteria are present, the term "suspicious for acute humoral rejection" is recommended (for example, when donor-specific antibodies are not tested). (Adapted from Racusen LC, Colvin RB, Solez K, et al: Antibody-mediated rejection criteria: An addition to the Banff '97 classification of renal allograft rejection. Am J Transplant 2003; 3:708-714.).

change are also present (Figure 36–3). Vascular cell-mediated rejection is characterized by lymphocytes, monocytes, or both extending under the endothelial lining into the intima (endothelialitis), with endothelial cells appearing swollen and often detached from the vascular wall (Figure 36–4). Infrequently in severe cases, the inflammatory cells are found in the arterial media and may be associated with smooth muscle cell necrosis.[71] This process involves small and medium-sized intrarenal arteries and tends to be present focally, so it may be missed on biopsy. Therefore, a minimum of two arteries within the biopsy and at least 12 sections of the tissue are required for an adequate assessment of vascular rejection. Vascular rejection is usually accompanied by the tubulointerstitial form and may be associated with interstitial hemorrhage due to increased permeability of peritubular capillaries. The finding of interstitial hemorrhage suggests the presence of vascular rejection even in the absence of diagnostic arteries, if other causes of hemorrhage, such as prior biopsy site and infarction, have been excluded.[72] Glomeruli may display a form of capillary rejection termed *acute transplant glomeru-lopathy*, in which capillary lumens contain mononuclear leukocytes.[73]
Humoral antibody-mediated rejection in its classic form is a vascular process wherein neutrophils infiltrate artery walls, with fibrin deposition inducing fibrinoid necrosis, often accompanied by mononuclear leukocytes.[70] There may be associated intravascular thrombosis, glomerular inflammation, and foci of renal parenchymal necrosis or infarction. Another type of antibody-mediated rejection is associated with C4d deposition around PTC, best demonstrated by immunofluorescence microscopy (Figure 36–5).[74] This may be associated with only minor tubular cell necrosis, with neutrophil infiltrates or in the setting of arterial fibrinoid necrosis. The currently suggested histologic and immunopathologic criteria for AHR are shown in Table 36–4.

Attempts are underway to provide standardized morphologic definitions of acute rejection. The Banff ’97 working classification[75] includes separate categories for cell-mediated and antibody-mediated rejection. The former requires as a minimum greater than 25% of the interstitium to contain inflammation and greater than four mononuclear leukocytes in a tubule, and the category is subdivided into tubulointerstitial and vascular forms of rejection. The antibody-mediated rejection category was recently revised[76] and now is reflected in Table 36–4. More than one form of rejection may be present simultaneously. The borderline category, characterized by inflammation less than that required for a diagnosis of cell-mediated acute rejection, remains controversial as to its immunologic significance. Further study is required, possibly with the application of cytokine analysis, to determine accurately the meaning of low grade inflammation within the allograft.

Cyclosporine and Tacrolimus Toxicity

Although biochemically distinct, cyclosporine and tacrolimus are two potent immunosuppressive agents with similar mechanism of action as well as clinical and pathologic patterns of nephrotoxicity. Their potential for impairment of graft function, particularly in the early post-transplant period should be included in the differential diagnosis of the elevated serum creatinine level. It is important to note that there are various

Figure 36–3 Acute cell-mediated tubulointerstitial rejection. There are interstitial edema and lymphocytes with lympho-cytes in the walls of most tubules. (Periodic acid-Schiff × 250)

Figure 36–4 Acute cell-mediated vascular rejection. The artery contains swollen endothelial cells that are focally detached from the artery wall with undermining lymphocytes. The adjacent interstitium has edema and a lymphocytic infiltrate. (Hematoxylin and eosin × 250)

clinical and histologic manifestations of cyclosporine and tacrolimus toxicity; in the early post-transplant period, the most important are the frequently occurring functional decrease in renal blood flow and GFR and the infrequently occurring thrombotic microangiopathy.

Functional Decrease in Renal Blood Flow and Filtration Rate

Cyclosporine and tacrolimus produce a dose-related, reversible, renal vasoconstriction that particularly affects the afferent arteriole.[39] The glomerular capillary ultrafiltration coefficient (Kf) also falls, possibly because of increased mesangial cell contractility. Clinically, this condition is reminiscent of prerenal dysfunction, and in the acute phase, tubular function is intact. The mechanism of the vasoconstriction is discussed in Chapter 38. Cyclosporine- and tacrolimus-induced renal vasoconstriction may manifest clinically as delayed recovery from ATN and as transient, reversible, dose-dependent and blood level-dependent elevation in SCr concentration that may be difficult to distinguish from other causes of graft dysfunction.

Cyclosporine and Tacrolimus Blood Levels

The use of blood levels of cyclosporine and tacrolimus in clinical immunosuppressive management is discussed in Chapter 38. High blood levels of cyclosporine and tacrolimus do not preclude a diagnosis of rejection, although they may make it less likely, particularly in the case of tacrolimus.[57] Nephrotoxicity may develop at apparently low levels of both drugs, and some degree of toxicity may be intrinsic to their use.[77] Nephrotoxicity and rejection may coexist. In clinical practice, particularly when SCr elevation is modest, it is fair to initially presume that a patient with a very high cyclosporine or tacrolimus level is probably suffering from nephrotoxicity and that a patient with deteriorating graft function and very low drug level is probably undergoing rejection. If the appropriate clinical therapeutic response does not have a salutary effect on graft function, the clinical premise needs to be reconsidered. Cyclosporine toxicity usually resolves within 24 to 48 hours of a dose reduction, whereas tacrolimus toxicity may take longer to resolve. Progressive elevation of the plasma creatinine level, even in the face of persistently high drug levels, suggests rejection.

Patients may detect somatic manifestations of toxicity, and these symptoms may suggest the diagnosis. Tremor and headache are produced by both drugs but are particularly marked with tacrolimus.[77] Compared to Sandimmune, the Neoral formulation of cyclosporine produces higher peak levels and a more consistent pharmacokinetic profile with a magnified area under the curve (AUC) in some patients.[78] The high peak level may be detected by patients as headache and flushing, whereas the magnified AUC may predispose to nephrotoxicity at a time that trough levels are deemed not elevated. More recently, Neoral cyclosporine monitoring using the 2-hour postdose (C2) has been suggested to correlate better with the risk for acute rejection and cyclosporine-induced nephrotoxicity compared with trough (C0) monitoring.[79] We are currently conducting a pilot study to assess whether improved renal function can be achieved at 6 and 12 months post-transplant in de novo renal transplant recipients receiving Neoral using C2 for dosing determination as compared to historical controls using trough monitoring. Adoption of C2 monitoring as a new tool to monitor Neoral dose adjustment awaits further studies. Prospective randomized trials are needed.

Drug Interactions

Well-substantiated potentiation of renal impairment has been described when amphotericin, aminoglycosides, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, and/or angiotensin receptor antagonists are used in patients receiving calcineurin inhibitor therapy. More recently, exacerbation of nephrotoxicity has been observed in renal transplant recipients receiving the newer immunosuppressant sirolimus and cyclosporine combination therapy.[80,81]

Sirolimus is a potent immunosuppressant with a mechanism of action and a side effect profile distinct from that of the calcineurin inhibitors. When used as base therapy without a calcineurin inhibitor sirolimus has been shown to be devoid of nephrotoxicity.[82,83] However, in two phase III clinical trials (The Global and U.S. Rapamune Study Group) concomitant administration of cyclosporine and sirolimus has been shown to potentiate cyclosporine-induced nephrotoxicity.[80,81] There has been substantial evidence suggesting that cyclosporine exposure is increased by a pharmacokinetic interaction with sirolimus. In rat animal models sirolimus has also been shown to increase partitioning into renal tissue to a greater extent than it increases whole blood concentrations.[84] When combination therapy is used, a reduction in therapeutic cyclosporine level is desirable, particularly when there is an unexplained rise in SCr level. The pharmacologic interaction between sirolimus and tacrolimus has been less rigorously studied. Co-administration of tacrolimus and sirolimus has been shown to result in reduced exposure to tacrolimus at sirolimus doses of greater than or equal to 2 mg/day.[85] However, cases of acute allograft failure following sirolimus-tacrolimus therapy have been reported.[86] Caution should be exercised when combination immunosuppressive agents are used.

Thrombotic Microangiopathy (TMA)

Use of both cyclosporine and tacrolimus may be associated with drug-induced thrombotic microangiopathy. Although the exact pathogenic mechanism of cyclosporine-induced TMA remains speculative, multiple prothrombotic effects of cyclosporine have been implicated in the pathogenesis of cyclosporine-associated TMA. These include a direct cytotoxic effect on endothelial cells, a reduction of prostacyclin synthesis, and alterations in the thromboxane A2 to prostacyclin ratio, leading to vasoconstriction, platelet aggregation, and thrombus formation.[87] Cyclosporine has also been found to reduce the generation of activated protein C from endothelial cells and to increase thromboplastin expression from mononuclear and endothelial cells. More recently, deficiency in the activity of von Willebrand factor cleaving metalloprotease ADAMTS13 and the presence of its inhibitory antibodies has been reported to cause TMA in a renal allograft transplant recipient receiving cyclosporine-based immunosuppression. However, whether cyclosporine or calcineurin inhibitor plays a role in the formation of autoantibodies to ADAMTS13 remains to be determined.[88] As is the case

with cyclosporine, it is suggested that endothelial cell damage may be the inciting event in tacrolimus-induced TMA. However, tacrolimus has mixed effects on the synthesis of prostaglandins.

TMA may develop as early as 4 days postoperative to as late as 6 years post-transplantation. It may be evident clinically by virtue of the typical laboratory findings of intravascular coagulation (e.g., thrombocytopenia, distorted erythrocytes, elevated lactate dehydrogenase levels) accompanied by an arteriolopathy and intravascular thrombi on transplant biopsy. Unlike the primary form of thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome, however, cyclosporine- or tacrolimus-associated TMA may be covert, and the laboratory findings may be inconsistent. In recipients of renal allograft, renal dysfunction is the most common manifestation. Thrombocytopenia and microangiopathic hemolysis are often mild or absent and the diagnosis is often made on graft biopsies performed to determine the cause of DGF or to rule out acute rejection.[87] Although there have been no controlled trials comparing the different treatment modalities of this condition, dose reduction or discontinuation of the offending agent appears to be pivotal to management. Adjunctive plasmapheresis with fresh frozen plasma replacement may offer survival advantages. In transplant recipients with cyclosporine-associated TMA, successful use of tacrolimus immunosuppression has been reported. However, recurrence of TMA in renal transplant recipients treated sequentially with cyclosporine and tacrolimus has been described, and clinicians must remain vigilant for signs and symptoms of recurrence of TMA in patients who are switched from cyclosporine to tacrolimus or vice versa.[87] There have been anecdotal reports of the successful use of sirolimus and/or mycophenolate mofetil in transplant recipients with calcineurin inhibitor associated TMA.[89,90] However, recently sirolimus has also been reported to cause TMA in recipients of renal allografts.[91] The use of the monoclonal antibody muromonab-CD3 OKT3 has also been associated with the development of post-transplant TMA, although infrequently.

Other potential causative factors of post-transplant-associated TMA include the presence of lupus anticoagulant and/or anticardiolipin antibody, cytomegalovirus infection, and, less frequently, systemic viral infection with parvovirus B19 or influenza A virus.[92] An increased incidence of TMA has also been described in a subset of renal allograft recipients with concurrent hepatitis C virus infection and anticardiolipin antibody positivity.[93]

Histologic Features

Cyclosporine and tacrolimus nephrotoxicity have similar appearances in renal allografts. The most common form of acute toxicity is a variant of ATN, with scattered individual necrotic tubular cells, considerable dilatation of tubular lumina and epithelial cell flattening without extensive loss of brush border staining.[94] The characteristic feature, often not present, is isometric vacuolization of proximal tubular cell cytoplasm, which tends to involve all tubular cells in few tubular profiles (Figure 36–6).[95] There is mild interstitial edema without significant inflammation or with focal aggregates of inactive lymphocytes often in perivenous locations; tubulitis is absent. There are no specific glomerular abnormalities, but arterioles have muscular hypertrophy and may contain rounded plasma protein collections (insudates) in the outer aspect of the muscular walls and individual smooth muscle cell necrosis. The juxtaglomerular apparatus is enlarged.

Thrombotic microangiopathy has an identical morphologic appearance regardless of the underlaying pathogenetic cause. Therefore, TMA associated with the calcineurin inhibitors has the usual features, including glomerular capillary, arteriolar, and occasionally arterial thrombosis (Figure 36–7).[96] Vascular walls have muscular hypertrophy, loose mucoid intimal thickening, and fibrin deposition with luminal narrowing. This process may be patchy and subtle or widespread and associated with cortical infarction. The histologic features of chronic cyclosporine and tacrolimus toxicity are discussed in the section on chronic rejection and chronic allograft toxicity.

Infection

The most common infections in the early post-transplantation period that are associated with graft dysfunction are uri-
Figure 36–6   Acute calcineurin-inhibitor nephrotoxicity. Isometric vacuoles are in the cytoplasm of all epithelial cells in the center proximal tubular profile. (Jones methenamine silver × 300)
Figure 36–7   Thrombotic microangiopathic form of acute calcineurin-inhibitor nephrotoxicity. The arteriole has swollen endothelial cells and nuclear fragments entrapped in a luminal thrombus. The adjacent juxtaglomerular apparatus is enlarged. (Jones methenamine silver × 250)

nary tract and CMV infections. Uncomplicated urinary tract infections do not usually lead to graft dysfunction, unless they are complicated by pyelonephritis or urosepsis. Clinical CMV infection may mimic acute rejection and is discussed in Chapter 40.

Vascular Complications: Renal Artery Stenosis

Transplant renal artery stenosis may occur as early as the first week but is usually a late complication and is discussed under allograft dysfunction during long-term follow-up. Arterial or venous thrombosis generally occurs within the first 2 to 3 postoperative days but may occur as long as 2 months post-transplant. In most series reported, the incidence of graft thrombosis ranges from 0.5% to as high as 8% with arterial accounting for one third and venous thrombosis for two thirds of cases.[38,97] Thrombosis occurring early after transplantation is most often due to technical surgical complications, whereas the later onset is generally due to acute rejection.[38] In patients with initial good allograft function, thrombosis is generally heralded by the acute onset of oliguria or anuria associated with deterioration of allograft function. Abnormal laboratory findings may include thrombocytopenia, hyperkalemia, and a rising lactate dehydrogenase level. Clinically, the patient may present with graft swelling or tenderness, and/or gross hematuria. In patients with DGF and good residual urine output from the native kidneys there may be no overt signs or symptoms, and the diagnosis rests on clinical suspicion and prompt imaging studies. The diagnosis is usually made by Doppler ultrasound or isotope flow scan. Confirmed arterial or venous thrombosis typically necessitates allograft nephrectomy. In recipients of kidneys with multiple arteries, thrombosis may occur in a single branch, and depending on the extent of renal parenchymal supplied, adequate functioning tissue may remain.

Suggested predisposing factors for vascular thrombosis include arteriosclerotic involvement of the donor or recipient vessels, intimal injury of graft vessels, kidney with multiple arteries, history of recurrent thrombosis, thrombocytosis, younger recipient and/or donor age, and the presence of antiphospholipid antibody (anticardiolipin antibody and/or lupus anticoagulant).[92] There has been no consensus on the optimal management of recipients with abnormal hypercoagulability profile, such as abnormal activated protein C resistance ratio or factor V Leiden mutation, antiphospholipid antibody positivity, protein C, or protein S deficiency or antithrombin III deficiency. However, unless contraindicated, perioperative and/or postoperative prophylactic anticoagulation should be considered, particularly in patients with a prior history of recurrent thrombotic events. Transplant of pediatric en bloc kidneys into adult recipient with a history of thrombosis should probably be avoided. The duration of anticoagulation has not been well defined, but lifelong anticoagulation should be considered in high-risk candidates.[92]

Ureteral Obstruction

Ureteral obstruction occurs in 2% to 10% of renal transplants[98] and is usually manifested by painless impairment of graft function due to the lack of innervation of the engrafted kidney. Hydronephrosis may be minimal or absent in early obstruction, whereas low-grade dilatation of the collecting system secondary to edema at the ureterovesical anastomosis may be seen early post-transplantation and does not necessarily indicate obstruction. A full bladder may also cause mild calyceal dilatation due to ureteral reflux, and repeat ultrasound with an empty bladder should be carried out. Persistent or increasing hydronephrosis on repeat ultrasound examinations is highly suggestive of obstruction. Renal scan with furosemide washout may help support the diagnosis, but it does not provide clear anatomic detail.[14,99] Although invasive, percutaneous nephrostomy tube placement with antegrade nephrostogram is the most effective way to visualize the collecting system and can be of both diagnostic and therapeutic value.

Blood clots, a technically poor reimplant, and ureteral slough are the common causes of early acute obstruction after transplantation.[38,65,92] Ureteral fibrosis secondary to either ischemia or rejection can cause an intrinsic obstruction. The distal ureter close to the ureterovesical junction is particularly vulnerable to ischemic damage due to its remote location from the renal artery and hence its compromised blood supply. Ureteral fibrosis associated with polyoma BK virus is a newly recognized cause of ureteral obstruction in the setting of renal transplantation.[100] Ureteral kinking, lymphocele, pelvic hematoma or abscess, and malignancy are potential causes of extrinsic obstruction. Calculi are uncommon causes of transplant ureteral obstruction.[38]

Definitive treatment of ureteral obstruction due to ureteral strictures consists of either endourologic techniques or open surgery. Intrinsic ureteral scars can be treated effectively by endourologic techniques in an antegrade or retrograde approach. A stent is left indwelling to bypass the ureteral obstruction and can be removed cystoscopically after 2 to 6 weeks.[38] Routine ureteral stent placement at the time of transplantation has been suggested to be associated with a lower incidence of early postoperative obstruction.[101] Extrinsic strictures or strictures that are longer than 2 cm are less likely to be amenable to percutaneous techniques and are more likely to require surgical treatment, as do strictures that fail endourologic incision.[38] Obstructing calculi can be managed by endourologic techniques or by extracorporeal shock wave lithotripsy.

Perinephric Fluid Collections

Symptomatic perinephric fluid collections in the early postoperative period can be due to lymphoceles, hematoma, urinoma, or abscesses. Lymphoceles are collections of lymph caused by leakage from severed lymphatics. They typically develop within weeks after transplantation. Most lymphoceles are small and asymptomatic. Generally, the larger the lymphocele, the more likely it is to produce symptoms and to require treatment, although very small but strategically placed lymphoceles can result in ureteral obstruction. Lymphoceles may also compress the iliac vein, leading to ipsilateral leg swelling or deep vein thrombosis, or they may occasionally produce urinary incontinence due to bladder compression.[38]

Lymphoceles are usually detected by ultrasound either as an incidental finding or during evaluation of allograft dysfunction. They appear as a roundish, sonolucent, septated mass.[49] Hydronephrosis may be present, and the ureter may be seen

adjacent to and compressed by presentation, and ultrasound appearance distinguish a lymphocele from other types of perinephric fluid collections, such as a hematoma or urine leak. Needle aspiration reveals a clear fluid with a creatinine concentration equal to that of the serum.

No therapy is necessary for the common, small, asymptomatic lymphocele. Percutaneous aspiration should be performed if a ureteral leak, obstruction, or infection is suspected. The most common indication for treatment is ureteral obstruction. If the cause of the obstruction is simple compression resulting from the mass effect of the lymphocele, percutaneous drainage alone usually resolves the problem. The ureter is often narrowed and may need to be reimplanted because of its involvement in the inflammatory reaction in the wall of the lymphocele. Repeated percutaneous aspirations are not advised because they seldom lead to dissolution of the lymphocele and often result in infection. Infected or obstructing lymphoceles can be drained externally. Sclerosing agents, such as povidone-iodine, tetracycline, or fibrin-glue, can be instilled into the cavity with variable results.[38] Lymphoceles can also be marsupialized into the peritoneal cavity, where the fluid is reabsorbed.

An obstructed hematoma is best managed by surgical evacuation. Urinoma or evidence of a urine leak should be treated without delay. A small leak can be managed expectantly with insertion of a Foley catheter to reduce intravesical pressure. This maneuver may occasionally reduce or stop the leak altogether. Persistent allograft dysfunction, particularly in a symptomatic patient, often necessitates early surgical exploration and repair. Infected perinephric fluid collections should be treated by external drainage or open surgery in conjunction with systemic antibiotics.

GRAFT DYSFUNCTION DURING LONG-TERM FOLLOW-UP

The causes of graft loss after the first year are listed in Table 36–5. Both immunologic and nonimmunologic factors have been suggested to play an interactive role in the development of chronic allograft dysfunction. Hence, the term "chronic rejection" has been replaced by the less specific but more accurate term *chronic allograft nephropathy*. Graft loss from recurrent diseases is discussed in Chapter 35.

Table 36–5 Causes of Chronic Allograft Failure

Alloantigen-Dependent	Alloantigen-Independent
Acute rejection	Delayed graft function
Poor HLA matching	Nephron "dose"
Prior sensitization	Donor age
Inadequate immunosuppression	Ischemia-reperfusion injury
Poor adherence to medications	Hypertension
	Hyperlipidemia
	Calcineurin inhibitor nephrotoxicity
	Cyto-megalovirus infection

HLA, human leukocyte antigen.

Chronic Rejection and Chronic Allograft Nephropathy

Chronic allograft nephropathy (CAN) usually occurs months or years after transplantation and can be loosely defined as progressive deterioration of graft function in the absence of any other causes, such as rejection, recurrent or de novo glomerular diseases, or structural abnormalities. Similar to chronic kidney disease of the native kidneys, CAN may be accompanied by hypertension and/or proteinuria. The characteristic histopathologic changes of CAN are provided in detail below. The development of CAN is multifactorial in etiologies and include both alloantigen-dependent and alloantigen-independent factors.

Alloantigen-Dependent Factors

Acute rejection episodes, poor HLA matching, prior sensitization, inadequate immunosuppression, and noncompliance have all been implicated in the development of CAN.

Acute Rejection Episodes
Numerous retrospective studies have shown that the most significant predictive factor for the development of CAN and late graft loss is the incidence of acute rejection episodes.[102–105] In some studies, even a single episode occurring within the first 2 months has a negative predictive effect, although multiple episodes and late episodes are more powerful predictors. It should also be noted that treatment of acute rejection episodes after the first year is often followed by incomplete recovery of graft function and expedited graft loss. It has been estimated that the half-life of allografts with no rejection episodes is 13 years, compared with 6 years for allografts with more than one episode.[104]

In addition to the frequency and timing of occurrence, the severity and histopathologic type of rejection have also been shown to be predictive of subsequent development of CAN. In this respect, early cell-mediated vascular rejections are more likely than tubulointerstitial rejections to herald CAN.[106] Interestingly, however, untreated subclinical rejections have also been suggested to result in the early appearance of chronic graft pathology and impaired graft function at long-term follow-up.[59, 61]

More recently, humoral immune mechanisms have also been suggested to have an important role in the pathogenesis of CAN.[107] In a retrospective study consisting of 152 renal allograft biopsies performed for evaluation of chronic allograft nephropathy, 23 of 38 (61%) of chronic rejection cases had peritubular capillaries staining for C4d, compared with 1 of 46 (2%) of controls (the former include allograft biopsies showing either glomerular basement membrane duplication in the absence of de novo or recurrent glomerulonephritis or arterial intimal fibrosis with intimal mononuclear cell infiltration, and the latter include allograft biopsies that showed chronic cyclosporine toxicity or nonspecific interstitial fibrosis, and native kidneys with end-stage renal disease). It was further demonstrated that circulating anti-donor HLA antibody was present in the majority of C4d-positive chronic rejection cases, whereas it was absent in C4d-negative chronic rejection cases (antidonor HLA positivity: 88% vs. 0% $p <.0002$, respectively). Whether complement C4d deposits in peritubular capillaries found on

biopsy samples from patients with CAN represents an ongoing immunologic process and merits intervention remains to be determined.

Histocompatibility

Well-matched kidneys tend to last longer than less well-matched kidneys. This observation is true for both living donor and cadaveric transplants.[108] Among living donor transplants, the half-life for two-haplotype–matched transplants has been estimated to be 22.7 years compared with 13.1 years for one-haplotype–matched transplants, which, in turn, tend to function longer than zero-haplotype–matched and transplants from living, unrelated donors.[27,109] The importance of matching is particularly evident for cadaveric transplants: six-antigen–matched or zero-mismatched cadaveric transplants have a 5-year survival rate approaching 80% and a half-life approaching 13 years, compared with about 50% and 8 years, respectively, for completely mismatched transplants.[110] For many years, the improved long-term prognosis of living, related donor transplant over cadaveric donor transplants was presumed to be due largely to better histocompatibility matching. Although matching is important, the excellent short-term and long-term results of living, unrelated transplants suggest that the condition of the kidney at the time of transplantation is a critical, nonalloantigen-dependent factor.[109]

Noncompliance and Suboptimal Immunosuppression

The importance of alloantigen-dependent factors is clearly illustrated by the ongoing necessity to maintain adequate immunosuppression for the life span of the graft[111]; the definition of "adequate immunosuppression," however, remains controversial, and long-term prospective randomized trials comparing immunosuppressive regimens of varying intensity have not been performed. The discontinuation of corticosteroid in patients receiving triple therapy with cyclosporine, azathioprine, and prednisone has variably been shown to result in an unacceptable increased risk of acute and chronic rejection.[63,112,113] An increased incidence of rejection following steroid withdrawal was also seen in recipients receiving triple therapy with cyclosporine, prednisone, and mycophenolate mofetil, even among recipients who had been rejection free prior to steroid cessation.[114] More recent studies have shown that adequate immunosuppression can be achieved with regimens consisting of tacrolimus and mycophenolate mofetil or sirolimus (with or without antibody induction), hence allowing safer discontinuation of corticosteroids.[115,116] However, long-term follow-up data is currently lacking.

Noncompliance is a potent cause of late graft loss, and although occasional long-term, stable patients may "get away" with discontinuation of immunosuppression, such a policy is fraught with danger and should be discouraged, unless there is specific overriding indication, such as malignancy. The development of an acute rejection episode in a previously stable patient should prompt suspicion of noncompliance or inadequacy of the immunosuppressive regimen.

Alloantigen-Independent Factors

Nephron Dose and Hyperfiltration

The concept of nephron dose is based on the presumption that circumstances associated with an unfavorable ratio between the supply of functioning nephrons transplanted and the demands of the recipient make the allograft more susceptible to chronic loss of function.[117] The supply of functioning nephrons may be an absolute feature of the allograft (young or old age, female sex, African-American race, all of which are associated with a reduced nephron supply) or a feature of perioperative events, such as prolonged ischemia times and ATN. Limited data have shown that dual transplant of marginal kidneys have resulted in excellent short- and long-term allograft outcome, presumably due to increased viable nephron mass.[30] In a rat model of chronic rejection, the transplanted kidney appeared to be protected from progressive damage by the presence of a retained, functioning, recipient native kidney.[118] This finding supports the hypothesis that hyperfiltration in the remaining nephrons makes them susceptible to chronic damage in a manner similar to that proposed to explain the inexorable loss of function of the diseased nephrons of patients with chronic kidney disease. Interestingly, in a single center retrospective study, baseline glomerular hypertrophy (identified on intraoperative biopsies after vascular anastomosis) was shown to be an important determinant of late allograft dysfunction.[119] In addition to nephron "dose," perioperative damage to the allograft may also contribute to nonspecific tissue injury, cytokine release, upregulation of cell-surface markers and adhesion molecules, and chemoattraction of neutrophils, with further cycles of injury and repair.[120]

Recently, renal function in the first post-transplant year has been shown to serve as a predictor of renal allograft survival regardless of whether or not patients had prior episodes of acute rejection. For recipients of cadaveric renal allografts who had no clinical evidence of acute rejection within 1 year post-transplantation and who had a serum creatinine of less than 1.5 mg/dL at 1 year and a change in serum creatinine of less than 0.3 mg/dL between 6 months and 1 year post-transplant, the estimated median graft half-life is 17 years compared with 5 to 6 years for those who had no acute rejection episodes within 1 year but who had a serum creatinine at 1 year post-transplant of greater than 1.5 mg/dL and a change in SCr of greater than 0.3 mg/dL between 6 months and 1 year post-transplant.[58]

Other Factors

Systemic hypertension may exaggerate and perpetuate the vascular injury associated with allograft nephropathy, which has pathologic features in common with hypertensive nephrosclerosis.[106] One mechanism by which hypertension could lead to progressive renal allograft dysfunction is by increasing shear stress in renal vessels. It has been suggested that shear stress could promote atherosclerosis and hypertension by causing an upregulation of endothelin-1, PDGF, and other growth factors within the endothelium and by reducing NO secretion.[121] In rat orthotopic renal transplant models, it has been shown that hypertension increases the expression of growth factors and MHC class II.[122] In essence, hypertension may act in concert with or synergistically with immunologic factors to cause progressive graft dysfunction. Dyslipidemia, calcineurin inhibitor nephrotoxicity, number of transplants, proteinuria, CMV infection, and donor age and gender are other suggested risk factors for chronic allograft dysfunction. In a recent retrospective study consisting of 40,289 primary solitary Caucasian adult renal transplants, older donor and recipient age were shown to have an independent, yet equally detrimental effect on renal allograft survival.[123]

Histopathologic Features

The term *chronic allograft nephropathy* is used when it is uncertain which immunologic and nonimmunologic factors have contributed to the chronic changes, although it may be used synonymously with chronic transplant rejection.[124] CAN has characteristic morphologic features, including focal tubular atrophy and/or tubular dropout with interstitial fibrosis and variable degrees of associated mononuclear inflammation. When chronic transplant rejection is present there is intimal fibrosis of arteries with entrapped mononuclear leukocytes in the thickened vascular wall, disruption of the internal elastic lamina, and narrowing of the lumens.[125] Lymphocytes are frequently present in the scarred interstitium and in atrophic tubules. Glomeruli may be normal or ischemic or may show chronic transplant glomerulopathy, a lesion consisting of capillary wall double contours, mesangial widening with mild hypercellularity, mesangiolysis and leukocytes in capillary lumens; segmental glomerulosclerosis may also be present (Figure 36–8).[6] These glomeruli have variable deposition of IgM, complement, and fibrin focally in capillary walls identified by immunofluorescence. Ultrastructurally, mesangial migration and interposition, and subendothelial flocculent material are present, whereas peritubular capillaries have been reported to contain multilayered basement membranes.[127] Chronic transplant glomerulopathy confirms that chronic rejection is present, even in the absence of a diagnostic artery. The arterial and glomerular lesions, although diagnostic, tend to be focal and may not be present in a biopsy specimen. In this event, it may be difficult to differentiate between nephrosclerosis, chronic cyclosporine and tacrolimus nephrotoxicity, and chronic rejection, and the term *chronic allograft nephropathy* should be used. Active cell mediated and/or antibody-mediated acute rejection may occur simultaneously with CAN.

Chronic cyclosporine and tacrolimus toxicity is characterized by focal "striped" interstitial fibrosis, thought to be cortical medullary rays,[128] with associated tubular atrophy and little inflammation.[129] Arteries are normal, but arterioles may show muscular hypertrophy and rounded insudates in the walls, particularly the outer portion (Figure 36–9). The glomeruli are unremarkable or show mild ischemic change. The chronic toxicity of cyclosporine and tacrolimus cannot be differentiated histologically.[129,130]
Clinical Course

Chronic rejection typically occurs in patients who have suffered episodes of acute rejection, particularly when these episodes are multiple or late or when recovery of graft function, as judged by the return of the serum creatinine level to baseline is incomplete.[131] It presents clinically as deterioration of graft function, typically with proteinuria of varying degrees and hypertension. The time course to allograft failure is extremely variable, ranging from months to years. In most cases, the loss of graft function is inexorable, although spontaneous reduction and arrest of the rate of decline may occur. Proteinuria is usually moderate (1 to 3 g/day), but nephrotic-range proteinuria may occur. Chronic rejection is the most common cause of transplant nephrotic syndrome.[132,133]

Renal function in chronic rejection is typically monitored by the rise of the serum creatinine. The creatinine clearance, however, may overestimate the true GFR in the presence of chronic renal failure and proteinuria. As a result, the early stages of graft dysfunction may be associated with apparently minor rises in the SCr level, whereas small changes in GFR produces big changes in creatinine levels as the graft approaches end-stage failure.[134]

Differential Diagnosis

Chronic rejection needs to be differentiated from other causes of late graft dysfunction. The absence of a history of rejection, hypertension, and proteinuria should arouse diagnostic skepticism.[132,133] A renal ultrasound should be performed at least once to exclude obstructive causes of graft dysfunction, and the possibility of renal artery stenosis should be considered, particularly if hypertension is severe or the hemoglobin/hematocrit is high. Kidney biopsy provides a definitive diagnosis and may allow an estimate of the severity of the lesion

Figure 36–8 Chronic rejection. Arterial intimal fibrosis, tubular atrophy with interstitial fibrosis, interstitial lymphocytes and chronic transplant glomerulopathy are present. (Jones methenamine silver × 125)
Figure 36–9 Chronic calcineurin-inhibitor nephrotoxicity. There is "striped" tubular atrophy with interstitial fibrosis without a significant lymphocytic infiltrate. The intervening tubules are unremarkable as are the majority of glomeruli. The small glomerulus has mild ischemic features. (Jones methenamine silver × 125)

and show the presence of coexisting acute rejection or de novo or recurrent glomerular lesions.

Treatment

The optimal management of immunosuppression for the chronically failing allograft has yet to be defined. If an element of acute rejection is suspected, a steroid pulse should be given, but this therapy should not be repeated if it is ineffective. Monoclonal and polyclonal antibodies should not be given in the presence of chronic rejection. Intensification of calcineurin inhibitor therapy often merely exaggerates nephrotoxicity. In contrast, a reduction or cessation of CNI in conjunction with either the addition, continuation, or increase in the dose of mycophenolate mofetil may slow the rate of decline of renal function in patients with biopsy-proven CAN and deteriorating allograft function.[135,136] There has been some evidence suggesting that Neoral C2 monitoring is superior to trough monitoring in detecting cyclosporine underexposure or overexposure.[137] In the latter dose reduction has been reported to result in stabilization or improvement of allograft function. More recently, conversion from cyclosporine or tacrolimus to sirolimus has been shown to preserve graft function in patients with biopsy-confirmed CAN.[138] Although a number of studies have demonstrated that CNI dose reduction or withdrawal in conjunction with MMF or sirolimus treatment may improve or slow the progression of CAN, manipulation of immunosuppressive therapy may be of little beneficial effect when SCr is 3.0 to 3.5 mg/dL or higher at the time of therapeutic intervention (unpublished observation).

The relative contribution of nonimmune mechanism(s) to the development of progressive allograft dysfunction is difficult to define, and the management of CAN should be targeted at risk factor modification. Blood pressure control and aggressive management of dyslipidemia are mandatory. The use of angiotensin converting enzyme inhibitor (ACEI) and/or angiotensin receptor blocker (ARB) has also been advocated due to its well-established antiproteinuric and cardioprotective effects. However, these drugs should be used with care because of their potential to cause or exacerbate anemia, hyperkalemia, and renal dysfunction. A rising serum creatinine should alert clinicians to the possibility of renal artery stenosis.
