Chronic Kidney Disease, Dialysis, & Transplantation

COMPANION TO BRENNER & RECTOR'S THE KIDNEY

SECOND EDITION

Chronic Kidney Disease, Dialysis, and Transplantation ISBN: 1-4160-0158-1
A Companion to Brenner and Rector's The Kidney
Second Edition

NOTICE

Nephrology is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the licensed prescriber, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the author assumes any liability for any injury and/or damage to persons or property arising from this publication.

Contributors

Stuart Abramson, M.D., M.P.H.
Maine Nephrology Associates, Portland, Maine

Miriam J. Alter, Ph.D.
Associate Director for Epidemiologic Science, Division of Viral Hepatitis, Centers for Disease Control and Prevention, Atlanta, Georgia

Matthew J. Arduino, M.S., Dr.P.H.
Supervisory Research Microbiologist, Division of Healthcare Quality Promotion, Centers for Disease Control and Prevention, Atlanta, Georgia

George R. Aronoff, M.D., F.A.C.P.
Professor of Medicine and Pharmacology; Chief, Division of Nephrology, Department of Medicine, University of Louisville School of Medicine, Louisville, Kentucky

Vaidyanathapuram S. Balakrishnan, M.D., M.R.C.P.
Assistant Professor, Tufts University School of Medicine, Division of Nephrology, Department of Medicine, Tufts-New England Medical Center, Boston, Massachusetts

Joanne M. Bargman, M.D., F.R.C.P.C.
Professor of Medicine, University of Toronto; Staff Nephrologist, University Health Network, Toronto, Ontario, Canada

Peter G. Blake, M.B., F.R.C.P.C., F.R.C.P.I
Professor of Medicine, University of Western Ontario, Chair of Nephrology, London Health Sciences Center, London, Ontario, Canada

Joseph V. Bonventre, M.D., Ph.D.
Professor of Medicine, Harvard Medical School; Division Chief, Renal Section, Brigham and Women's Hospital, Boston, Massachusetts

Marilia Cascalho, M.D., Ph.D.
Director, Transplantation Biology, Departments of Surgery, Immunology and Pediatrics, Mayo Clinic, Rochester, Minnesota

Vimal Chadha, M.D.
Assistant Professor of Pediatrics, Virginia Commonwealth University Medical Center, Chair, Section of Pediatric Nephrology, Richmond, Virginia

Christopher T. Chan, M.D., F.R.C.P.C.
Medical Director-Home Hemodialysis, Division of Nephrology, Toronto General Hospital, University Health Network; Assistant Professor–Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada

Anil Chandraker, M.D., C.H.B., M.R.C.P.
Transplant Research Center, Brigham and Women's Hospital, Boston, Massachusetts

Glenn M. Chertow, M.D., M.P.H.
Associate Professor, Division of Nephrology, Department of Medicine, University of California, San Francisco, School of Medicine, San Francisco, California

William R. Clark, M.D.
Clinical Assistant Professor of Medicine, Indiana University School of Medicine; Baxter Healthcare, Indianapolis, Indiana

Allan J. Collins, M.D., F.A.C.P.
Professor of Medicine, University of Minnesota, Minneapolis, Minnesota

Josef Coresh, M.D., Ph.D., M.H.S.
Professor, Departments of Epidemiology and Biostatistics, Johns Hopkins University School of Hygiene and Public Health; Professor, Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland

Bryan M. Curtis, M.D., F.R.C.P.C.
Kidney Foundation of Canada Research Fellow, Division of Nephrology and Clinical Epidemiology Unit, Patient Research Centre, Health Sciences Centre, Memorial University of Newfoundland Faculty of Medicine, St. John's, Newfoundland, Canada

Gabriel M. Danovitch, M.D.
Professor of Medicine and Medical Director, Kidney Transplant Program, University of California, Los Angeles, David Geffen School of Medicine, Los Angeles, California

Simon J. Davies, M.D., F.R.C.P.
Professor, Institute of Science and Technology in Medicine, Keele University, Keele, England; Clinical Director, Department of Nephrology, University Hospital of North Staffordshire, Stoke-on-Trent, England

Francis L. Delmonico, M.D.
Professor of Surgery, Harvard Medical School; Director of Renal Transplantation, Massachusetts General Hospital, Boston, Massachusetts

Laura M. Dember, M.D.
Associate Professor of Medicine, Boston University School of Medicine; Director of Dialysis, Boston University Medical Center, Boston, Massachusetts

Thomas A. Depner, M.D.
Professor, Department of Internal Medicine, University of California, Davis, School of Medicine; Medical Director, University Dialysis Clinic, Sacramento, California

Rita De Smet, M.Sc., Ing.
Renal Division, Department of Internal Medicine, University Hospital Ghent, Ghent, Belgium

Bradley S. Dixon, M.D.
Associate Professor, Department of Internal Medicine,
University of Iowa, Iowa City, Iowa

Jeremy S. Duffield, M.R.C.P., Ph. D.
Renal Fellow/NKRF Senior Fellow, Harvard Institutes of
Medicine (BWH), Boston, Massachusetts

Nahel Elias, M.D.
Department of Surgery, Harvard Medical School;
Massachusetts General Hospital, Boston, Massachusetts

Joseph A. Eustace, M.B., M.H.S., M.R.C.P.I.
Assistant Professor, Departments of Medicine and
Epidemiology, Johns Hopkins University School of Medicine;
Medical Director, Bond Street Dialysis Unit, Johns Hopkins
University Hospital, Baltimore, Maryland

Martin S. Favero, Ph.D.
Director, Scientific and Clinical Affairs, Advanced
Sterilization Products, Johnson & Johnson, Irvine, California

Steven Fishbane, M.D.
Associate Professor of Medicine, State University of New
York (SUNY) at Stony Brook School of Medicine, Stony
Brook, New York; Director of the Dialysis Network, Associate
Chairman of Medicine, and Associate Director of
Nephrology, Winthrop-University Hospital, Mineola,
New York

Jay A. Fishman, M.D.
Director, Transplant Infectious Disease & Compromised
Host Program, Massachusetts General Hospital; Associate
Professor of Medicine, Harvard Medical School, Boston,
Massachusetts

Dayong Gao, Professor
UK Alumni Professor of Mechanical Engineering,
University of Kentucky, College of Engineering,
Department of Mechanical Engineering, Lexington,
Kentucky

John S. Gill, M.D., M.S.
Assistant Professor of Medicine, University Of British
Columbia, St. Paul's Hospital, Vancouver, B.C., Canada;
Adjunct Assistant Professor, Division of Nephrology,
Department of Medicine, Tufts-New England Medical
Center, Boston, Massachusetts

Griet Glorieux, M.Sc., Ph.D.
Renal Division, Department of Internal Medicine, University
Hospital Ghent, Ghent, Belgium

Simin Goral, M.D.
Associate Professor of Medicine, Division of Nephrology,
University of Pennsylvania Medical Center, Philadelphia,
Pennsylvania

William E. Harmon, M.D.
Division of Nephrology, Department of Medicine, Harvard
Medical School; Department of Nephrology, Children's
Hospital, Boston, Massachusetts

Olof Heimbürger, M.D., Ph.D.
Division of Renal Medicine, Department of Clinical Science,
Karolinska Instituet, and Senior Physician, Department of
Renal Medicine, Karolinska University Hospital at Huddinge,
Stockholm, Sweden

J. Harold Helderman, M.D.
Professor of Medicine, Microbiology, and Immunology;
Chief, Renal Transplant Program; Medical Director,
Vanderbilt Transplant Center, Vanderbilt University Medical
Center, Nashville, Tennessee

Lee W. Henderson, M.D., F.A.C.P.
Renal Division, Baxter Healthcare Corporation, McGaw
Park, Illinois

Jonathan Himmelfarb, M.D.
Clinical Professor of Medicine, University of Vermont College
of Medicine, Burlington, Vermont; Director of Nephrology
and Transplantation, Maine Medical Center, Portland, Maine

Michelle Hladunewich, M.D.
Assistant Professor of Medicine, University of Toronto
Hospitals, Toronto, Ontario, Canada

Zhongping Huang, M.D.
Department of Mechanical Engineering, University of
Kentucky, Lexington, Kentucky

Bertrand L. Jaber, M.D.
Assistant Professor, Tufts University School of Medicine;
Vice-Chairman, Department of Medicine Caritas-
St. Elizabeth's Medical Center, Boston, Massachusetts

Dicken S.C. Ko, M.D., F.R.C.S.(C.), F.A.C.S.
Assistant Professor of Surgery, Departments of Surgery and
Urology, Harvard Medical School; Massachusetts General
Hospital, Boston, Massachusetts

Holly Kramer, M.D., M.P.H.
Department of Preventive Medicine and Epidemiology,
Loyola University Medical Center, Maywood, Illinois

Alan M. Krensky, M.D.
Stanford University, Stanford, California

Richard Lafayette, M.D.
Associate Professor of Medicine; Associate Chairman,
Clinical Affairs, Department of Medicine, Stanford University
School of Medicine; Clinical Chief, Division of Nephrology,
Stanford University Medical Center, Stanford, California

Norbert Hendrik Lameire, M.D., Ph.D.
Professor of Medicine, Renal Division, Department of Internal
Medicine, University Hospital Ghent, Ghent, Belgium

James P. Lash, M.D.
Associate Professor of Clinical Medicine; Program Director,
Nephrology Fellowship, Section of Nephrology, Department
of Medicine, University of Illinois at Chicago College of
Medicine; University of Illinois at Chicago Medical Center,
Chicago, Illinois

Adeera Levin, M.D., F.R.C.P.C.
Professor of Medicine, Division of Nephrology, University of British Columbia Faculty of Medicine; St. Paul's Hospital, Vancouver, British Columbia, Canada

John K. Leypoldt, Ph.D.
Research Professor of Medicine and Adjunct Professor of Bioengineering, Dialysis Program, University of Utah; Veterans Affairs Salt Lake City Health Care System, Salt Lake City, Utah

Philip Kam-Tao Li, M.D., F.R.C.P., F.A.C.P.
Chief of Nephrology and Consultant Physician, Department of Medicine & Therapeutics, Prince of Wales Hospital; Chinese University of Hong Kong, Hong Kong

Orfeas Liangos, M.D.
Clinical Research Fellow, Division of Nephrology, Tufts-New England Medical Center, Boston, Massachusetts

Colm C. Magee, M.D., M.P.H.
Instructor in Medicine, Harvard Medical School, Staff Physisican Renal Division, Brigham and Women's Hospital, Boston, Massachusetts

Naveed Masani, M.D.
Attending Nephrologist, Winthrop-University Hospital, Mineola, New York

Tahsin Masud, M.D.
Assistant Professor of Medicine, Department of Medicine, Renal Division, Emory University School of Medicine, Atlanta, Georgia

Philip McFarlane, M.D., F.R.C.P.C.
Associate Professor of Medicine, University of Toronto Faculty of Medicine; Medical Director, Home Dialysis, Division of Nephrology, St. Michael's Hospital, Toronto, Ontario, Canada

Ravindra L. Mehta, M.B.B.S., M.D., F.A.C.P.
Professor of Clinical Medicine, Associate Chair for Clinical Affairs, Department of Medicine, Division of Nephrology, University of California, School of Medicine, San Diego, California

David C. Mendelssohn, M.D., F.R.C.P.C.
Associate Professor of Medicine, University of Toronto Faculty of Medicine, Toronto, Ontario, Canada; Head, Division of Nephrology, Medical Director of Dialysis, Humber River Regional Hospital, Weston, Ontario, Canada

William E. Mitch, M.D.
Edward Randall Distinguished Professor of Medicine; Department of Medicine, University of Texas Medical Branch at Galveston, Galveston, Texas

Sharon M. Moe, M.D.
Associate Professor of Medicine, Associate Dean for Research Support, Indiana University School of Medicine; Director of Nephrology, Wishard Memorial Hospital, Indianapolis, Indiana

Anupama Mohanram, M.D.
Renal Fellow, UT Southwestern Medical Center, Dallas, Texas

Donald A. Molony, M.D.
Professor of Medicine, Department of Internal Medicine, Division of Renal Diseases and Hypertension, University of Texas Houston Medical School, Houston, Texas

Bhamidipati V.R. Murthy, M.D., D.M.
Assistant Professor, Department of Internal Medicine, Division of Renal Diseases and Hypertension, University of Texas Houston Medical School, Houston, Texas

Nader Najafian, M.D.
Instructor of Medicine, Harvard Medical School; Renal Division, Brigham and Women's Hospital; Transplantation Research Center, Brigham and Women's Hospital and Children's Hospital, Boston, Massachusetts

Cynthia Nast, M.D.
Professor of Pathology, Department of Pathology, David Geffen School of Medicine at UCLA and Cedars Sinai Medical Center, Los Angeles, California

Gihad E. Nesrallah, M.D., F.R.C.P.C., F.A.C.P.
Staff Nephrologist, Division of Nephrology, Department of Internal Medicine, Humber River Regional Hospital, Toronto, Ontario, Canada

Daniel Norman, M.D.
Division of Pulmonary, Critical Care and Sleep Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts

Brenda M. Ogle, Ph.D.
Director, Transplantation Biology, Departments of Surgery, Immunology and Pediatrics, Mayo Clinic, Rochester, Minnesota

Yvonne M. O'Meara, M.D.
Department of Nephrology, Mater Hospital, Dublin, Ireland

Dimitrios G. Oreopoulos, M.D., Ph.D., F.R.C.P.C., F.A.C.P.
Professor of Medicine, Toronto Western Hospital, Toronto, Ontario, Canada

Brian J.G. Pereira, M.D., M.B.A.
Professor of Medicine, Tufts University School of Medicine, President and Chief Executive Officer, NEHCF, Tufts-New England Medical Center, Boston, Massachusetts

Phuong-Chi T. Pham, M.D.
Associate Professor of Medicine, Division of Nephrology, Department of Medicine, David Geffen School of Medicine at UCLA and Olive View–UCLA Medical Center, Sylmar, California

Phuong-Thu T. Pham, M.D.
Assistant Professor of Medicine, Nephrology Division, Kidney and Pancreas Transplantation, Department of Medicine, University of California, Los Angeles, David Geffen School of Medicine, Los Angeles, California

Andreas Pierratos, M.D., F.R.C.P.C.
Associate Professor of Medicine, University of Toronto Faculty of Medicine, Toronto, Ontario, Canada; Humber River Regional Hospital, Weston, Ontario, Canada

Jeffrey L. Platt, M.D.
Director, Transplantation Biology, Departments of Surgery, Immunology and Pediatrics, Mayo Clinic, Rochester, Minnesota

Sarah Prichard, M.D., F.R.C.P.C.
Professor of Medicine, Division of Nephrology, Department of Medicine, McGill University Faculty of Medicine, Montreal, Quebec, Canada

Emilio Ramos, M.D.
University of Maryland School of Medicine, Division of Nephrology, Baltimore, Maryland

Madhumathi Rao, M.D., F.R.C.P. (U.K.)
Instructor of Medicine, Division of Nephrology, Department of Medicine, Turfts University School of Medicine; Tufts-New England Medical Center, Boston, Massachusetts

Denise Sadlier, M.B., M.R.C.P.I.
Department of Medicine and Therapeutics, Mater Misericordiae University Hospital, Conway Institute of Biomolecular and Biomedical Research, University College Dublin; Dublin Molecular Medicine Centre, Dublin, Ireland

Mark J. Sarnak, MD
Associate Director, Research Training Program, and Assistant Professor, Division of Nephrology, Department of Medicine, Tufts University School of Medicine; Tufts-New England Medical Center, Boston, Massachusetts

Robert C. Stanton, M.D.
Assistant Professor in Medicine, Harvard Medical School; Chief, Nephrology Section, Joslin Diabetes Center, Boston, Massachusetts

Rita Suri, M.D., F.R.C.P.C.
Staff Nephrologist, London Health Sciences Centre and Assistant Professor of Medicine, University of Western Ontario, London, Canada

Cheuk-Chun Szeto, M.D., M.R.C.P.
Department of Medicine & Therapeutics, Prince of Wales Hospital, Shatin, Hong Kong

Geoffrey S. Teehan, M.D., M.S.
Division of Nephrology, Department of Medicine, Tufts-New England Medical Center, Boston, Massachusetts

Elias D. Thodis, M.D.
Assistant Professor of Nephrology, Demokritus University of Thrace, Alexandroupolis, Greece

Robert Thomas, MD
Division of Pulmonary, Critical Care and Sleep Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts

Jerome Tokars, M.D., M.P.H.
Medical Epidemiologist, Division of Healthcare Quality Promotion, Centers for Disease Control and Prevention, Atlanta, Georgia

Robert D. Toto, M.D.
Professor of Medicine; Director, Patient-Oriented Research in Nephrology, University of Texas Southwestern Medical Center, Dallas, Texas

Kathryn Tuohy, M.D.
Division of General Internal Medicine, Brown Medical School; Rhode Island Hospital, Providence, Rhode Island

Raymond Camille Vanholder, M.D., Ph.D.
Professor of Medicine, Renal Division, Department of Internal Medicine, University Hospital Ghent, Ghent, Belgium

Vassilis Vargemezis, M.D.
Department of Renal Medicine, Democritus University of Thrace, University Hospital, Alexandroupolis, Greece

Flavio Vincenti, M.D.
Professor of Clinical Medicine, Kidney Transplant Service, Department of Medicine, University of California, San Francisco, School of Medicine, San Francisco, California

Bradley A. Warady, M.D.
Professor of Pediatrics, University of Missouri-Kansas City School of Medicine; Associate Chair of Pediatrics, Chief, Section of Pediatric Nephrology; Director, Dialysis and Transplantation; The Children's Mercy Hospital, Kansas City, Missouri

Daniel E. Weiner, M.D., M.S.
Division of Nephrology, Department of Medicine, Tufts-New England Medical Center, Boston, Massachusetts

Mark E. Williams, M.D., F.A.C.P.
Associate Clinical Professor in Medicine, Harvard Medical School; Nephrology Section, Joslin Diabetes Center, Boston, Massachusetts

Jane Y. Yeun, M.D.
Associate Professor, Director, Nephrology Fellowship Program, University of California Davis Health Center, Department of Medicine, Sacramento, California; Staff Nephrologist, Sacramento Veterans Administration Medical Center, Department of Medicine, Mather, California

Preface

For the past two decades, *The Kidney,* by Drs. Barry M. Brenner and Floyd Rector, has been the central resource for authoritative and current information in the field of nephrology. However, the continuing expansion in the understanding of the pathophysiology and management of kidney diseases, dialysis, and transplantation and rapid advances in technology led to the need for more focused accompaniments to *The Kidney.* Consequently, a series of companion textbooks emerged; the first edition of our textbook, *Dialysis and Transplantation,* was the second in this series. The intent of our initial venture was to provide readers with a seamless flow of information regarding the management of the patient with end-stage renal disease (ESRD), including hemodialysis, peritoneal dialysis, and transplantation. In pursuit of this goal, we sought to provide an overview of the principles of management of the patient with ESRD as well as a more focused examination of the physiologic principles and clinical application of the different modes of kidney replacement therapy.

Since the release of the first edition of our textbook, there have been tremendous advances in the field of kidney disease. The publication of the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI) guidelines has led to a new nomenclature and staging of patients with chronic kidney disease (CKD) and has focused the nephrology community on the magnitude of the problem. Since most of the comorbidity and complications of CKD begin early in the course of the disease, we have chosen to expand the scope of this textbook to include the entire spectrum of CKD, including the period prior to dialysis or transplantation. Hence the new title, *Chronic Kidney Disease, Dialysis, and Transplantation.* We undertook this revision with the understanding that the treatment of patients with ESRD is complex, and the field is rapidly changing. The past few years have witnessed new frontiers in the understanding of the pathophysiology, prevalence, and possible interventions with respect to cardiovascular disease, other comorbidity, and complications of CKD. Likewise, there has been considerable progress in the study of the physiologic basis of dialysis and its complications and the immunologic basis of allograft tolerance and rejection. Advances in pharmaceutical technology and biotechnology have brought new and effective therapies into clinical use, and the results of several pivotal clinical trials have challenged established concepts in patient management. Finally, the continuing efforts of professional societies to improve the quality of patient care have resulted in the development of new evidence-based clinical practice guidelines and clinical performance measures. These developments have mandated a new look at the management of the patient with CKD. Consequently, we invited distinguished scientists and educators in the field of kidney disease to provide an in-depth review—from the laboratory to the clinic. Each author was challenged to discuss the fundamental concepts behind the management of the patient with ESRD, to provide a comprehensive critique of clinical trials, and to present rational recommendations for clinical treatment.

Our strategy was to cover the most clinically relevant issues in dialysis and transplantation and to classify them under the broad sections of CKD, complications of CKD, hemodialysis, peritoneal dialysis, transplantation, acute renal failure, and economic issues. Each section was overseen by a section editor. Each chapter is self-contained and provides the reader with a thorough review of the subject along with a complete list of key references. Diagnostic and treatment algorithms have been used whenever possible. With an eye on the future, our contributors were encouraged to identify major unanswered questions, to suggest future clinical trials, and to highlight promising experimental strategies. We have applied a strong editorial policy to ensure that chapters remain balanced and that they conform to these principles. The editorial team has changed; Dr William Owen has departed and Dr. Peter G. Blake has joined us. In addition, we have had the privilege of working with an extraordinary team of section editors, Drs. Bertrand L. Jaber, V. S. Balakrishnan, Annamaria T. Kausz, and Colm Magee, who have brought additional rigor and vitality to the process

In summary, we endeavored to significantly revise the first edition of out textbook, *Dialysis and Transplantation,* and substantially expanded the scope in this edition, *Chronic Kidney Disease, Dialysis, and Transplantation.* Readers are encouraged to refer to *The Kidney* or other companions in this series for a detailed discussion of other issues in nephrology. We intend to maintain this textbook as a work in progress and to update it periodically as the relentless advances in the field mandate. During the coming years, we welcome comments, critiques, and suggestions from our readers as we strive to deliver a comprehensive and contemporary textbook on dialysis and transplantation.

Chronic Kidney Disease

Chapter 1

Chronic Kidney Disease: Definition and Epidemiology

Joseph A. Eustace, M.B., M.H.S., M.R.C.P.I. •
Josef Coresh, M.D., Ph.D.

The developed world is suffering from an epidemic of kidney disease, the full spectrum of which is only beginning to be understood. Figure 1–1 illustrates the "pyramid" of chronic kidney disease (CKD), including estimates of the number of individuals at each stage in the United States. Kidney failure is the most visible aspect of this spectrum, but it represents only a minority of the total population affected by kidney disease. In the United States the age, race, and gender adjusted incidence of kidney failure requiring maintenance renal replacement therapy (that is, who have end-stage renal disease, ESRD) has increased over threefold in the last two decades, to a current rate of 334 persons per million population (pmp).[1] Although the annual rate of increase in the incidence rate has slowed to less than 1% for the last 2 years, given the expected demographic trends in the general population, by 2030 there are projected to be 2.2 million Americans who will require maintenance dialysis or kidney transplantation.[1] Similar trends, though of lesser magnitude, have been reported worldwide. In different national registries the rate of increase in incidence has uniformly been highest in the elderly. The U.S. race and gender adjusted incidence rates in subjects older than 75 years is 100-fold higher than those of individuals younger than 20 years, while globally the burden of kidney disease is disproportionately borne by the socially disadvantaged and by racial minorities.[1]

In addition to those patients with ESRD, at least 8.0 million Americans were estimated to have moderately or severely decreased kidney function, CKD stages III–IV.[2] The extent to which changes in the prevalence of CKD parallel the increase in ESRD over the last decade is unknown. The presence of CKD is clinically important, not only because such patients are at increased risk of progressing to kidney failure, but also because CKD is independently associated with complications that are likely to directly contribute to poor health-related outcomes, the most important of which is increased cardiovascular disease morbidity and mortality. As a result, a person over age 65 with severe CKD is several times more likely to die than to progress to requiring dialysis.[1] Increasing evidence suggests that some of the increased mortality risk is the result of CKD and that some of this attributable risk is amenable to intervention.

In recognition of the current health crisis associated with kidney failure, with its ever increasing prevalence, morbidity, mortality, and great cost ($20 billion for the U.S. ESRD program in 2000), the most recent U.S. Public Health strategy, "Healthy People, 2010," has for the first time devoted a separate chapter to CKD. Unfortunately, despite the evident importance of CKD we have very limited data on its epidemiology within the general population. Renal failure registry data is unlikely to be representative of the broader spectrum of CKD, while clinical reports, by necessity, emphasize forms of kidney disease that more readily come to clinical attention. The epidemiology of CKD is, therefore, incompletely described and much of the available data is not generalizable. What is known is that there is a wide degree of variability both within and between countries in the occurrence, clinical characteristics, and outcomes of patients with kidney failure and that there has been substantial changes in these parameters over time.

DEFINITION OF CHRONIC KIDNEY DISEASE

Terminology

Investigation of the epidemiology of CKD has to date been hampered by the lack of a uniform terminology. Traditionally, a wide and confusing combination of expressions, in English, Latin, and ancient Greek, have been used interchangeably to describe a persistent decrement in kidney function.[3] To help introduce a uniform terminology the National Kidney Foundation (NKF) in its Kidney Disease Outcomes Quality Initiative (KDOQI) has recently proposed a formal definition for CKD (Table 1–1).[2] This definition provides a necessary and essential foundation to help standardize current medical

Stage

	Glomerular Filtration Rate, ml/min/1.73m²
5 — Kidney Failure (300,000)	<15
4 — Severely Decreased Filtration (400,000)	15–29
3 — Moderately Decreased Filtration (8 million)	30–59
2 — Kidney Damage with Mildly Decreased Filtration (5 million)	60–89
1 — Kidney Damage with Normal Filtration (6 million)	Normal ~120
Figure 1–1 The spectrum of chronic kidney disease in the United States. *From USRDS (1988), includes approximately 230,000 patients treated by dialysis, and assuming 70,000 additional patients not on dialysis. Other estimates are from NHANES III (1988–1994): 15,600 individuals representing a U.S. population of 177 million age greater than age 20. Percentages total to greater than 100% because NHANES III may not have included dialysis patients. GFR estimated from serum creatinine using MDRD Study equation based on age, gender, race, and calibration for serum creatinine. For Stages 1 and 2, CKD is based on the persistence of positive spot albumin-to-creatinine ratio greater than or equal to 17 mg/g in men or greater than or equal to 25 mg/g in women. Persistence of microalbuminuria estimates are based on a subsample (54% of those with GFR>90, N= 102; 73% of those with GFR 60–90, N= 44).

Table 1–1 Definition of Chronic Kidney Disease

1. Kidney damage for ≥3 months, as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, manifest by *either*:
   - Pathological abnormalities; or
   - Markers of kidney damage, including abnormalities in the composition of the blood or urine, or abnormalities in imaging tests
2. GFR <60 mL/min/1.73 m² for ≥3 months, with or without kidney damage

(From the National Kidney Foundation KD: Clinical Practice Guidelines for Chronic Kidney Disease: Evaluation, Classification, and Stratification. Am J Kidney Dis 2002; 39 (suppl 1): S1-S266. Copyright 2002, with permission from the National Kidney Foundation.)

Table 1–2 Stages of Chronic Kidney Disease

Stage	Description	GFR (mL/min/1.73 m²)
1	Kidney damage with normal or ↑ GFR	≥90
2	Kidney damage with mild ↓ GFR	60–89
3	Moderate ↓ GFR	30–59
4	Severe ↓ GFR	15–29
5	Kidney failure	<15 (or dialysis)

Chronic kidney disease is defined as either kidney damage or GFR <60 mL/min/1.73 m² for ≥3 months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies. (From the National Kidney Foundation KD: Clinical Practice Guidelines for Chronic Kidney Disease: Evaluation, Classification, and Stratification. Am J Kidney Dis 2002; 39 (suppl 1): S1-S266. Copyright 2002, with permission from the National Kidney Foundation.)

communication as well as to help make such communication more readily intelligible to the patient. It further serves to help identify and focus formal research in areas where it has traditionally been lacking, to facilitate appropriate population-based screening, and to encourage the timely prevention and treatment of kidney disease, as well as support formal quality improvement initiatives.

The NKF guidelines support the uniform use of the expression "chronic kidney disease" (CKD) to represent the entire spectrum of disease that occurs following the initiation of kidney damage. The severity of the resulting syndrome is denoted by a staging scheme that extends from occult kidney damage, with well-preserved function (stage I) down to the level of kidney failure requiring renal replacement therapy (stage V) (Table 1–2). As the English word *kidney* lacks a ready adjectival form, in this chapter we will continue to use the expression

"renal" in this setting. We use the term *azotemia* to mean the overall toxicity state that accumulates with kidney dysfunction, without any implication at the overall severity of this state, and *uremia* to refer to the constellation of frequently subjective complications that develop with advanced azotemia and which necessitate the initiation of renal replacement therapy. Because the expression "end-stage renal disease" (ESRD) is widely used in regulatory and administrative circles, and it is codified in U.S. law, the KDOQI guidelines continue to use this expression to represent those subjects receiving or eligible for renal replacement therapy either by some form of dialysis or by transplantation.

NKF Definition of Chronic Kidney Disease

CKD is defined as *the presence of objective kidney damage and/or the presence of a glomerular filtration rate of 60 mL/min/1.73 m² body surface area, or less, for at least 3 months, irrespective of the underlying etiology of the kidney damage* (Table 1–1). Evidence of kidney damage may be either structural or functional in nature and may derive from renal histology or from the results of appropriate urine, blood, or renal imaging studies. The commonest and most readily available marker of kidney damage resulting in glomerular dysfunction is the presence of proteinuria. Similarly, the presence of abnormal sediment on urine microscopy or the demonstration of multiple cysts on renal imaging in a patient with a family history of polycystic kidney disease would meet the requirement for objective kidney damage. Because the relationship of hypertension to kidney disease is complex and varied, hypertension by itself is not included in the above definition; instead the presence or absence of hypertension is noted separately in conjunction with the presence or absence and the severity of CKD (Table 1–3).

In accordance with the KDOQI definition, a documented GFR of below 60 mL/min/1.73 m² fulfills the definition of CKD without requiring any additional evidence of underlying kidney damage. This cutoff in GFR was selected because it represents over a 50% reduction in kidney function as compared to the level for young healthy adults, and it is supported by accumulating evidence demonstrating the presence of complications as the glomerular filtration rate falls below 60 mL/min/1.73 m².[2] Patients with a GFR between 60 and 89, without evident kidney disease, are not defined as having CKD but are instead referred to as having a decreased GFR, either with or without the associated presence of high blood pressure (Table 1–3). This approach avoids potentially misclassifying the renal function in otherwise healthy elderly patients with a decreased glomerular filtration rate as a consequence of aging without any other evidence of kidney damage, while at the same time recognizing the increased risk of such patients for actually developing CKD as a consequence of their lower baseline GFR.

Change in Glomerular Filtration Rate with Age

The glomerular filtration rate is known to vary substantially with age, as well as with pregnancy,[4] dietary protein intake,[5] and certain medications, such as angiotensin converting enzyme inhibitors. Glomerular filtration rate increases during early infancy, reaching normal adult levels at approximately age 2 years. The glomerular filtration rate subsequently declines with increasing age. Although the changes in early infancy are clearly physiologic, the nature and consequences of the decrement that occurs with old age are not fully understood. In a cross-sectional study mean (sd) extrapolated GFR among 72 healthy adults males, as measured by iothalamate clearance, varied from 128 mL/min/1.73m² at ages 20 to 29 to 58 mL/min/1.73m² for 80 to 89 years old.[2] More recently a similar relationship was described in a study of 159 subjects, whose GFR was measured using urinary insulin clearance (Figure 1–2).[6]

Autopsy studies have shown a decrease in kidney weight and volume that occurs between the 5th and 9th decades of life. This is predominantly the result of a loss of renal mass from the outer cortex.[7] This results from a decrease in cortical capillary mass with resulting glomerular tuft collapse and eventual hyalinization of the tuft.[6] This capillary loss leads to a decrease in the total glomerular filtration surface area, thereby leading to a reduced glomerular ultrafiltration capacity, as measured by the glomerular ultrafiltration coefficient (K_f) and, consequently, reduced renal plasma flow.[8] Histologically, these changes are represented by the presence
Figure 1–2 Glomerular filtration rate plotted as a function of age, in women *(circles)* and men *(triangles)*. (From Hoang K, Tan J, Derby G, et al: Determinants of glomerular hypofiltration in aging humans. Kidney Int 2003; 64:1417–1424.)

Table 1–3 Definition and Stage of Chronic Kidney Disease

GFR (mL/min/1.73 m²)	With Kidney Damage*		Without Kidney Damage*	
	With HBP[†]	Without HBP[†]	With HBP[†]	Without HBP[†]
≥90	1	1	"High blood pressure"	"Normal"
60–89	2	2	"High blood pressure with ↓ GFR"	"↓ GFR"[‡]
30–59	3	3	3	3
15–29	4	4	4	4
<15 (or dialysis)	5	5	5	5

Shaded area represents chronic kidney disease; numbers designate stage of chronic kidney disease.
*Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.
[†]High blood pressure is defined as ≥140/90 in adults and >90th percentile for height and gender in children.
[‡]May be normal in infants and in the elderly.

of glomerulosclerosis, the prevalence of which increases in a linear fashion after the 5th decade of life,[9,10] reaching 10% to 40% of glomeruli in patients older than 60 years.[9,11] In the cortex, glomerulosclerosis is eventually accompanied by obliteration of arteriolar supply and subsequent absorption of the obsolescent glomeruli. As a consequence, there is an absolute reduction in the number of glomeruli with age. The mean number of glomeruli, estimated by a stereological technique, was 560×10^3 in subjects older than 55 years as compared to 695×10^3 for subjects younger than 55 years ($p < .001$).[12] Whether these age-related changes represent a true physiologic effect or are instead the result of occult pathology is unknown; however, this issue has developed considerable importance with the increasing use of elderly living transplant donors and of extended criteria allografts of cadaveric origin.

Glomerular Filtration Rate and Gender

GFR levels have frequently been reported to be lower in any given age group in women as compared with men, the average difference after adjustment for body surface area being approximately 8%.[2] Women also develop treated ESRD at a lower rate than men, and female animals often show protection against progressive kidney disease compared to male animals.[13] GFR is known to increase substantially during and immediately following pregnancy, reaching 140% to 165% of nonpregnant levels by the second trimester.[4] This elevation persists until approximately gestational week 36, and thereafter starts to decrease but may not return to the previous baseline until several weeks postpartum.[14] As a consequence, the accurate diagnosis of CKD is particularly challenging during pregnancy.

SEVERITY OF CHRONIC KIDNEY DISEASE STAGE

Diagnostic Schema

Traditionally CKD has been classified using a variety of different schema that are based on clinical-pathologic features; these include:

1. The degree of proteinuria/albuminuria (normal, microalbuminuria, subnephrotic, nephrotic).
2. The rate of progression, which we arbitrarily define as stable (GFR: <1.0 mL/min/1.73 m^2/year), slow progression (GFR: 1.0-3.9 mL/min/1.73 m^2/year), fast progression (GFR: 4+ mL/min/1.73 m^2/year), or rapidly progressive (progressing to kidney failure within several weeks or months of clinical onset).
3. The underlying diagnostic category (e.g., vascular, glomerular, tubulointerstitial) or specific diagnosis (e.g., diabetic glomerulosclerosis).
4. The presumed pathogenic mechanisms (e.g., autoimmune, lysosomal storage disease, allergic).
5. The basis of specific tests (e.g., ANCA positive vasculitis).

The utility of the above schema varies in different clinical circumstances. They all focus on the underlying primary cause of the kidney dysfunction and, as such, are typically used by nephrologists primarily in a diagnostic context and to help determine disease specific management and prognosis.

Rationale for a Severity Staging System in CKD

The diagnostic schema ignore the fact that as patients pass through the continuum of progressive kidney damage, there are predictable complications, such as the development of anemia and an elevated parathyroid hormone level, and predictable management issues, such as dialysis access preparation and pre-ESRD vaccination, which are common to progressive kidney disease in general, regardless of the specific underlying etiology. Increasing evidence documents the development of prognostically important complications that are associated with the degree of kidney dysfunction and that begin long before the occurrence of terminal kidney failure.[2] Traditionally, the clinical recognition and management of these complications, which often don't impact kidney disease progression itself, has not been systematic. Failure to focus on these issues has resulted in patients initiating dialysis with multiple inadequately controlled, CKD-related complications.[15] While the level of awareness for these complications has greatly increased over the last decade, there has traditionally been no standardized framework upon which to base relevant clinical practice. The NKF KDOQI staging system for CKD was developed in part to help address this need. This staging system may in some way be considered as representative of the "azotemic burden" that results from a given degree of kidney damage and the associated complications that may typically be expected to occur given the severity or "stage" of an individual's CKD. The staging system is based on the glomerular filtration rate, using this as the best single measure representative of global kidney function. Although the division of what is a continuum of change into specified categories is by nature arbitrary, from a practical standpoint, this simplification facilitates the recognition and management of CKD, which may otherwise be neglected if the primary focus is aimed exclusively at the underlying etiology and cause-specific management.

NKF Stage of Chronic Kidney Disease

CKD is divided into five stages, with the higher stage being associated with worse kidney function. Stage I represents subjects who do not have a clear filtration deficit and is defined as a normal or elevated kidney function (GFR > 90 mL/min/1.73 m^2) in association with evidence of kidney damage; this latter is defined broadly but is most often represented by the presence of persistent albuminuria. Stage II is a mild reduction in kidney function (GFR 60–89 mL/min/1.73 m^2) that occurs in association with kidney damage. CKD stages III and IV correspond to moderately and severely decreased kidney function (GFR of 30–59 and 15–29 mL/min/1.73 m^2, respectively). This large a decrement in kidney function is classified as CKD regardless of the presence of additional evidence of kidney damage. Stage V represents kidney failure, defined by either a GFR of below 15 or the need for dialysis therapy (Table 1–2). This staging system focuses on the severity of kidney dysfunction rather than on diagnostic considerations; as such, this complements and in no way replaces traditional classification schemes based on etiology. It is important to recognize the distinction between chronic stage of kidney disease and markers of etiology and progression of kidney disease. As shown in Table 1–4, CKD stage is an excellent measurement of severity

Table 1–4 Importance of CKD Stage, Type of Kidney Disease and Level of Proteinuria in Determining Outcomes in CKD

Outcome	Importance for Different Outcomes		
	CKD Stage	Type of Kidney Disease (Diagnosis)[†]	Proteinuria
Concurrent complications*	+++	+	+
Prognosis (next 10 years)			
Risk of CVD or mortality	+++	+	++
Risk of kidney failure	+++	++	+
Rate of decline in GFR	+	+++	+++

* Concurrent complications include hypertension, anemia, malnutrition, bone disease, neuropathy and decreased quality of life.
† For example, diabetic kidney disease, glomerular diseases, vascular diseases (such as hypertensive nephrosclerosis), tubulointerstitial diseases (including disease due to obstruction, infection, stones, and drug toxicity or allergy), and cystic disease (including polycystic kidney disease).

and a predictor of the risk of comorbidity and complications. However, the underlying diagnosis and the presence of proteinuria are better predictors of the rate of decline in GFR.

Chronic Kidney Disease and Transplantation

In keeping with the NKF definition, nearly all patients who undergo kidney transplantation continue to be defined as having CKD, the stage of which is determined by the level of allograft function. Only those patients with an allograft function of less than 15 mL/min/1.73 m^2 would be classified as having kidney failure (CKD stage V). The majority of allografts would be expected to result in CKD stages II to IV, which appears appropriate given the azotemic burden associated with failing allograft function and the often suboptimal management of the associated complications.[16] It is unknown whether the occurrence of complications is the same regardless of whether the residual GFR arises from a single functional kidney (as with a failing allograft) or from two kidneys.

CKD EPIDEMIOLOGY: DATA SOURCES

ESRD Registries

The available evidence suggests that throughout the 1980s and 1990s there was a sustained global increase in the number of new (incident) and established (prevalent) patients with treated kidney failure. The most reliable data demonstrating this increase comes from ESRD registries, such as the United States Renal Data System (USRDS), which tracks most patients in the United States who are treated with either maintenance dialysis or transplantation. Data from Western Europe is collated by the European Renal Association/ European Dialysis and Transplant Association (ERA/EDTA) registry based on several national and regional registries. These European registries track renal replacement therapy from the first day of treatment and are voluntary, however, on validation studies they have shown patient registration levels in excess of 95%. Registries of kidney failure treatment are also available in other countries, including Japan and Australia/New Zealand. However, although the NKF definition of CKD stage V includes all patients with a GFR of below

15 mL/min/1.73 m^2, the available data from renal replacement registries only include those who have progressed to the need for requiring dialysis, who are offered and accept renal replacement therapy at that time, and, in the case of the USRDS, for some analyses those who have been on a stable modality for at least 60 days; ESRD registry data therefore is not representative of even the entire spectrum of patients with CKD stage V.

In view of the above-mentioned limitations particular caution is required in comparing ESRD registry data from different regions and countries. Sources of variation may result from true differences in the incidence of CKD (either biologic or environmental in origin), differences in the rate of progression of the renal injury, differences in patient survival with CKD (in part due to differential competing mortality rates), and differences in the recognition, referral, and acceptance (by either the dialysis program or by the patient) for renal replacement therapy, as well as administrative differences in the registration and classification of patients within the individual dialysis registry.

CKD Stages I to IV

Unfortunately, data on the epidemiology of the earlier stages of CKD within the general population are still limited. It is likely that only a minority of patients with CKD actually progress to treatment by renal replacement therapy and so end up being identified in the ESRD registries; instead the majority of subjects die with CKD. In addition, some patients may maintain stable, though reduced, GFR and suffer complications of CKD without ever progressing to renal failure. As a result, ESRD trends provide only limited insights into the total morbidity and mortality associated with CKD. Several factors hinder the ready description and investigation of the epidemiology of early stages of CKD. As early CKD is typically clinically silent, both patients and physicians often fail to recognize its occurrence.[17] The symptoms that do occur are usually nonspecific and are typically not appreciated until late in the natural history of the condition. Complications of CKD are often attributed to preexisting comorbid disease or to old age rather than to kidney disease. Part of this failure to detect CKD relates to the widespread use of unadjusted serum creatinine as a screening test for the measurement of kidney function, despite the fact that in many cases of substantial kidney disease, especially in elderly subjects, the serum creatinine fails to

rise above the population-derived reference range. Further compounding this has been a long-standing mistaken clinical tendency to interpret modest elevations in serum creatinine as representing only a minor clinically insignificant degree of kidney damage, and so systematically underestimate the severity of CKD even when its presence is recognized. Due to the lack of formal screening programs and inadequate recognition of CKD, most hospital and clinic based series of CKD are by necessity limited to diseases that do come to clinical attention, either as a result of the rapid rate of progression, advanced kidney disease or the development of associated features such as a frank nephrotic syndrome. As a consequence such case series are unlikely to be representative of the true burden of CKD, especially nonproteinuric forms. The most generalizable data come from population surveys for prevalence of CKD and its complications. Progression data require prospective follow-up, but the relatively slow progression of CKD requires a large sample size and long duration of follow-up. Administrative data on Medicare patients with diagnosed CKD as well as data from health care organizations are often less detailed but provide a powerful source for following large groups of individuals.

U.S. Prevalence Estimates

The Third National Health and Nutritional Examination Survey (NHANES III) has provided a valuable source of data to estimate the prevalence of CKD and associated complications in the United States.[2] Between 1988 and 1994, this program used a complex multistage sampling scheme to quantitate the state of health and health related behaviors, with inferences that are applicable to the general noninstitutionalized U.S. population. Subgroups at the extremes of age, as well as racial minorities, were over-sampled to provide more reliable estimates within these populations among surveyed adults. A serum creatinine level was measured on 16,589 study participants, thus allowing estimation of their GFR, calculation of the point prevalence of CKD, and examination on a cross-sectional basis of the various complications associated with different stages of kidney disease. Calibration of the serum creatinine assay to the laboratory where the MDRD equation was developed allows for a reliable estimate of GFR.[18] Additional data will be available from the continuation

of NHANES, the next wave of which will provide data from 1999 to 2000. Valuable population-based data are available from other large cross-sectional surveys in the United States and internationally, although they don't use national probability samples, thus limiting their generalizability.

KIDNEY FAILURE (CKD STAGE V)

### Incidence of Renal Replacement Therapy for ESRD in the United States

Relatively precise data regarding the use of renal replacement therapy to treat end-stage renal disease within the United States are available from the annual data report of the U.S. Renal Data System (USRDS), which tracks data on the vast majority of subjects within the United States who have a functioning renal allograft or are treated with maintenance dialysis. Throughout the 1980s and 1990s the incidence of ESRD treated by renal replacement therapy in the United States increased exponentially; the incidence rate (adjusted for age, race, and gender) in calendar years 1981, 1991, and 2001 increased from 91 per million population (pmp) to 223 pmp and to 334 pmp, respectively. However, in the 2 most recent years for which data are available, the adjusted incidence rate, although still increasing, has started to slow; the increases in the adjusted incidence rate for years 2000 and 2001 were both approximately 1% (Figure 1–3). The actual number of incident U.S. patients in 2001 was 93,327 patients, up from 91,449 patients the previous year.

Gender

The race and age adjusted incidence of ESRD is significantly higher in males (404 per million population) than in females (280 per million population), and the gender specific incidence rate has similarly tended to increase at a faster rate for males.

Age

The incidence of ESRD varies dramatically with age; the 2001 race and gender adjusted rates per million for those over age 75 is 100 times higher than for those less than age 20
Figure 1–3 Age, race, and gender adjusted incidence of end-stage renal disease within the United States *(bars)*, and annual percent change relative to the previous year. (From U.S. Renal Data System: USRDS 2003 Annual Data Report: Atlas of end-stage renal disease in the United States. Bethesda, MD, National Institutes of Health, 2003, pp 1–560.)

(Figure 1–4). The rate of increase in incidence has also been much higher in the older categories; over the last decade the adjusted incidence rates for those age 75 and above has almost doubled (from 782 pmp to 1542), the adjusted rate among those age 65 to 74 increased by almost 50% (from 938 pmp to 1402 pmp), with only a slightly lower rate of increase (45%) among those age 45 to 64 (from 432 pmp to 625 pmp). The rate of increase for those younger than 45 years has been much lower; the incidence rate among those age 20 to 44 increased by 15% (from 104 pmp to 120 pmp), while the increase among those younger than 20 years was only 7% (from 14 pmp to 15 pmp). The increase in the oldest age category as compared with the 65- to 74-year-olds is likely to be a consequence of both increased intake into the ESRD program of very old subjects as well as the increased incidence of ESRD arising from diseases that increase in frequency with aging. The trends seen in the 45- to 65-year-old category are possibly more representative of changes in actual incidence of ESRD because they are potentially less influenced by secular trends in accepting patients for renal replacement therapy. It is very likely that the great increase in ESRD incidence within the United States is not simply the result of increased acceptance of subjects into treatment programs but also represents a substantial increase in the number of subjects at risk for ESRD, although this effect has not been adequately quantified.

Race

Although Caucasians have the lowest absolute age and gender adjusted incidence rate of treated ESRD, the rate of increase in incidence over the decade from 1991 to 2001 has been greatest in Caucasians (56%) and Asians (54%) as compared to African-Americans (40%) and Native Americans (20%). The reasons for these differentials are likely to be complex and cannot be explained purely by the better longevity of Caucasians as the

results persist following adjustment for age. Some of these may be related to differences in access to or quality of health care delivery or trends in diabetes incidence and care.

Geographic Variation

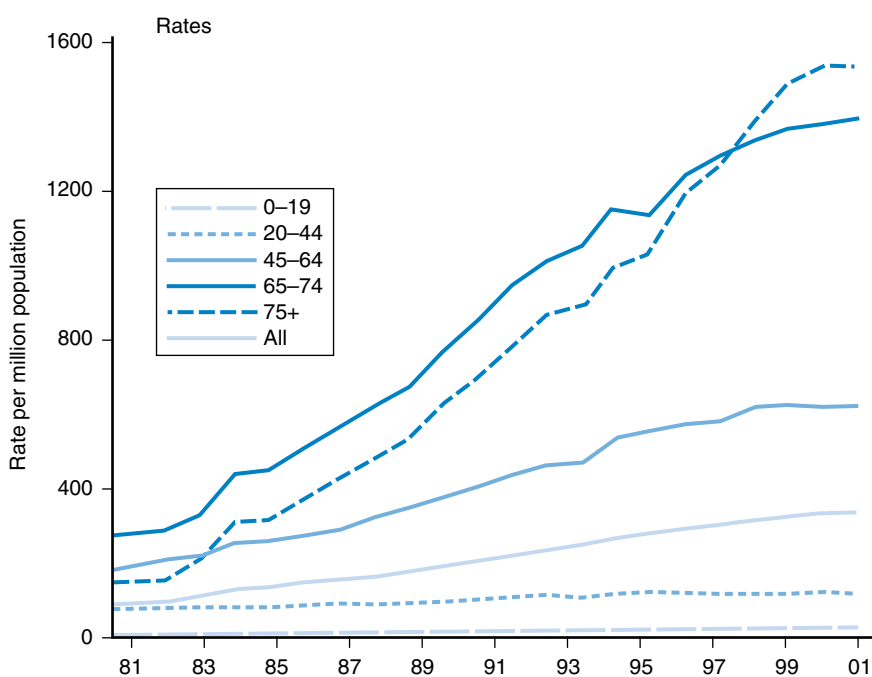
Although the incidence of ESRD is high throughout the United States, there is nevertheless substantial geographic variation across states (Figure 1–5). In 2001 the state specific incidence rates varied by 2.7-fold despite adjusting for the age, race, gender, and population of the state; the adjusted rate was lowest for Montana at 143 per million population and highest for West Virginia at 387 per million population. Some of this variability is likely to relate to differences in geographic availability of renal replacement therapy as well as clinical practice patterns.

Modality

According to USRDS data, in 2001, 86,289 patients were initially treated with hemodialysis, 6991 patients initiated peritoneal dialysis, and 2412 underwent preemptive renal transplantation without prior dialysis. Between 1997 and 2001, the incidence rates of hemodialysis increased 3.3% per year, incidence rates for preemptive transplantation increased 8.9% per year, and in contrast the rate for peritoneal dialysis decreased by 4% per year. Of those treated with peritoneal dialysis, approximately half were treated with a cycler, a proportion that has steadily increased over time.

Incidence of Renal Replacement Therapy for ESRD in Europe

Similar to the U.S. experience, there has been a dramatic increase in the incidence of patients treated with renal replacement therapy throughout much of Europe; whether

Figure 1–4 Race and gender adjusted incidence rate of end-stage renal disease by age category. (From U.S. Renal Data System: USRDS 2003 Annual Data Report: Atlas of end-stage renal disease in the United States. Bethesda, MD, National Institutes of Health, 2003, pp 1–560.)


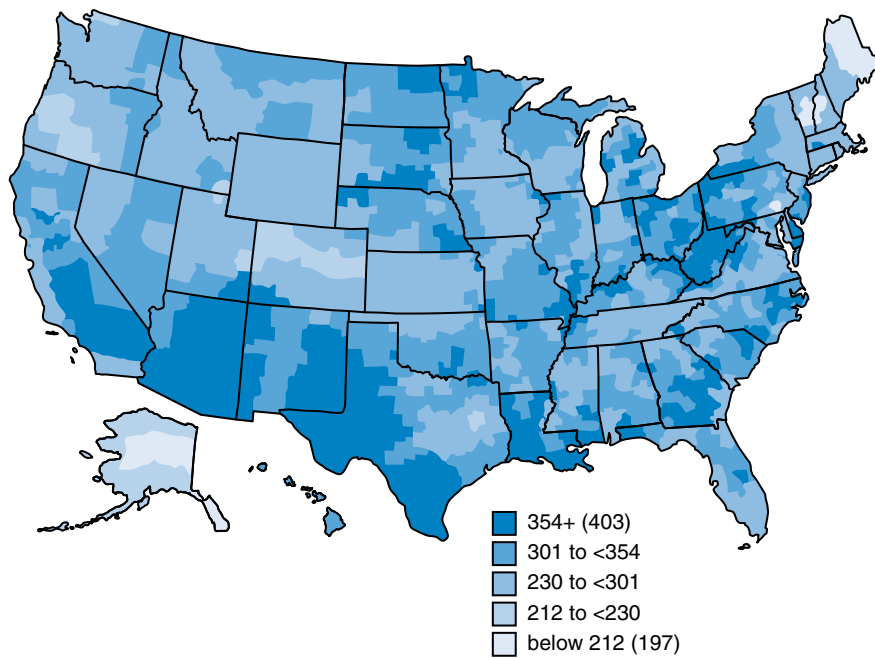


Figure 1–5 Geographic variation in age, race, and gender adjusted incidence rates for ESRD, per million population. (From U.S. Renal Data System: USRDS 2003 Annual Data Report: Atlas of end-stage renal disease in the United States. Bethesda, MD, National Institutes of Health, 2003, pp 1–560.)

this trend is also starting to slow in Europe is unclear. Stengel and colleagues[19] reported the change in incidence rates between 1990 and 1999 in nine Western European national ESRD registries (Austria, Belgium, Denmark, Finland, Greece, The Netherlands, Norway, Spain, UK [Scotland]). The age and gender adjusted incidence rates were calculated over this time period by Poisson regression using the mid-year census population estimates to calculate the population at risk. Analysis shows that the age and gender adjusted incidence rate increased 47% from 79.4 per million population (pmp) for 1990 to 1991 up to 117.1 pmp from 1998 to 1999. Thus the age and gender adjusted incidence rate in Europe remains about one-third that of the United States. The incidence rate of renal replacement therapy in Western Europe increased in an approximately linear fashion, at an overall mean rate of 4.8% per year (range between countries: 2.1% – 6.4%). In the United States incidence rates increased faster for men than for women, with overall increases of 5.2% versus 4% per year, respectively. Adjusted incidence rates were relatively stable for patients less than 45 years old but increased by 2.2% per year in the 45- to 64-year-old age group (from 135.3 to 203.1 pmp); by 7.0% in the 65- to 74-year-old age group (from 290.9 to 490.1 pmp), and over threefold (from 140.9 to 540.4 pmp) in those over age 75. Although the trend in adjusted incidence in all of the constituent registries was toward a significant increase, there was substantial variation between countries, especially for older patients; the rate of increase in incidence for patients above 75 years over the decade examined increased by a factor of 2.1 in The Netherlands, 6.6 in Scotland, 9.3 in Denmark, and 30.6 in Finland.

Incidence of Renal Replacement Therapy for ESRD in Asia and Australia/New Zealand

The unadjusted annual incidence rate for renal replacement therapy in the treatment of ESRD in Japan increased approxi-

mately threefold from 81.3 pmp in 1982 up to 252 pmp in 2001. Despite the relatively homogenous Japanese population and uniform health care, as in the United States there are substantial variations in ESRD incidence rates across regions; the incidence and rate of increase varied from 140 pmp and 9.1 pmp per year up to 179 pmp and 12 pmp per year across different regions.[20] The unadjusted incidence rate in Taiwan (331 pmp) is similar to that in the United States, and it has increased at almost double the U.S. rate (15%) over the last 4 years.

The unadjusted incidence rates in Australia and New Zealand are considerably less than that described above with unadjusted incidence rates of 92 and 107 pmp, respectively. As in other countries, there has been a substantial, in the Australian case twofold, increase in the annual incidence rate. As seen elsewhere the increase in overall incidence has largely been the result of an increase among those over age 65, with rates being relatively steady for those younger than 65, while racial minorities and people of native descent, such as Australian Aboriginals or New Zealand Maori Islanders, bear a disproportionate degree of the overall burden of ESRD.[21]

Cumulative Lifetime Risk of ESRD

Using a Markoff model, it has been estimated that the cumulative lifetime risk for requiring maintenance renal replacement therapy was approximately 1 in 40 for Caucasian males, slightly under 1 in 50 for Caucasian females, and approximately 1 in 13 for African-Americans of either gender.[22] By age 56, the estimated cumulative risk of ESRD in black men and women already exceeds the lifetime risk among their white American counterparts.

Prevalence of Stage V CKD

Trends in the prevalence of ESRD have shown an even larger increase than the incidence trends discussed above because survival on dialysis has improved over time. As reported by

USRDS, the age, race, and gender adjusted point prevalence count, as of December 31, 2001, was 405,081 persons, equivalent to an adjusted prevalence rate of 1392 per million population. This rate is 1.7-fold higher than in 1991 and 5.6-fold higher than in 1981. Currently, approximately 60% of the ESRD population is Caucasian, 31% is African-American, 4.1% is Asian, and 1.5% is Native-American, revealing a substantial overrepresentation of racial minorities in the burden of ESRD. Although the highest incidence of ESRD is seen in patients older than 74 years, the highest prevalence occurs in the 65- to 74-year-old group (4791 pmp) as compared to 4098 pmp for those greater than age 74 and 2905 pmp for 45 to 64 year olds. This difference results from differential incidence rates as well as differential survival rates on dialysis. Because of the age structure of the general population, the largest number of ESRD patients is between the ages of 45 and 64 years (41% of ESRD patients). The adjusted prevalence for 20 to 44 year olds was 813 and for those less than 20 years old it was 78 pmp. As in the incidence statistics, the prevalence is higher for males than for females, with adjusted prevalence rates of 1670 and 1163 pmp, respectively. Of the prevalence U.S. ESRD population, currently 65% of patients are treated with hemodialysis, 28% by renal transplant, and 7% by peritoneal dialysis, the latter being evenly split between noncycler and cycler-based techniques. More recent data suggest that the proportion of patients treated by a cycler-based therapy is even higher than this.

Although the prevalence rate of ESRD in the United States is extremely high, it is not unique. In 2001 the total Japanese prevalence count of ESRD was 209,036, equivalent to an unadjusted rate of 1642 pmp, a rate that exceeds the unadjusted prevalence rate for the United States. The 2001 unadjusted prevalence rate for Taiwan, 1423 pmp, was similar to the U.S. rate. The point prevalence as of December 31, 2000, in Australia was 334 pmp and in New Zealand it was 247 pmp. In Western Europe Luxemburg and Germany have the highest prevalence rates, while in central Europe the Czech Republic has the highest rate (Figure 1–6). Some of these lower observed rates correspond to lower availability of treatment. Thus the rates are likely to represent an underestimate of the true burden of disease.

Projected U.S. Prevalence Rates

Adjusting for the expected change in population demographics and growth, it is estimated that by the year 2030 the number of patients with ESRD in the United States is likely to increase to 2.24 million subjects, with half of the subjects being over age 65 and the majority of them being non-Caucasian (Figure 1–7).

CKD STAGES I TO IV

Prevalence data are available from national probability samples and large screening efforts. Earlier reports focused on urine dipstick and serum creatinine. Later reports focus on estimating GFR and application of the CKD staging system.

Prevalence of Kidney Damage: Albuminuria and/or Hematuria

The precise prevalence of kidney damage in the general population is unknown. From an epidemiologic perspective, the
Figure 1–6 International comparison of the unadjusted prevalence of ESRD. (From U.S. Renal Data System: USRDS 2003 Annual Data Report: Atlas of end-stage renal disease in the United States. Bethesda, MD, National Institutes of Health, 2003, pp 1–560.)

best studied marker of kidney damage has been albuminuria. Other potential markers of kidney damage such as urinary sediment and renal imaging have not been studied as systematically.[2,23]

U.S. Prevalence

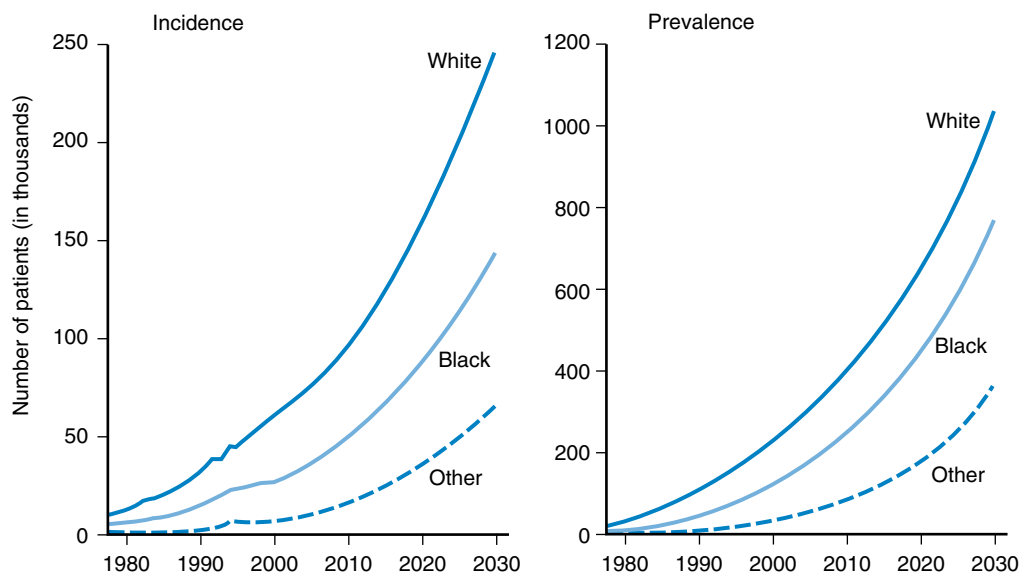
Data from the NHANES III Survey revealed that at the time the study was conducted (1988–1994) approximately 11.7% of


Figure 1-7   Projected growth of the incidence and prevalence ESRD population, by race. (From U.S. Renal Data System: USRDS 2003 Annual Data Report: Atlas of end-stage renal disease in the United States. Bethesda, MD, National Institutes of Health, 2003, pp 1–560.)

the noninstitutionalized U.S. population had an abnormal urinary albumin to creatinine ratio.[24] This equates to approximately 20.2 million adults with microalbuminuria. In a subsample from this study that underwent repeated testing, clinical macroalbuminuria always persisted, while only 61% of those with microalbuminuria had a positive result on the repeated test. Whether this reflects initial false positive results or alternatively the presence of intermittent proteinuria and if the latter, the significance of this finding relative to the risk of progressive kidney disease is unknown; however, it is notable that even the presence of albuminuria below the traditional definition of microalbuminuria is associated with increased cardiovascular risk.[25] The presence of albuminuria varies by age and the presence or absence of diabetes. Using nongender specific cutoffs, among adults older than 70 years 26.6% had microalbuminuria (<30 mg/day) and 3.7% had frank albuminuria (>300 mg/day); in those aged 60 to 69, the prevalence was 16.2% and 2%; and in those aged 40 to 59 years it was 9.1% and 1%, respectively. As expected, the prevalence was higher in diabetics; in diabetics over age 70 the prevalence of microalbuminuria was 43.2% and of frank albuminuria it was 8.4%, in nondiabetics it was 24.2% and 3.0%, respectively.[24] It is noteworthy that when gender-specific cutoffs are used, which attempt to estimate the spot albumin-to-creatinine ratio which would correspond to 30 and 300 mg/day of albumin excretion, the cutoffs are lower (17 and 255 mg/g for men and 35 and 350 mg/g for women) and the prevalence estimates are somewhat higher.[26] However, the current consensus is in favor of using nongender-specific cutoffs to maintain simplicity and consistency with American Diabetic Association guidelines.[27,28]

Cardia Study

In a study of 2582 healthy black and white young adults enrolled in the Cardia Study, using the average of the albumin to creatinine ratios obtained at 10 and 15 years of follow-up, the prevalence of microalbuminuria was 6.4% and of macroalbuminuria it was 0.7%. Levels tended to be higher in African-Americans than in Caucasians and in males compared to females, and for those with impaired baseline fasting glucose levels.[29]

AusDiab Kidney Study

The population prevalence of kidney damage in Australia has been estimated in the AusDiab Kidney Study[30]; 11,247 noninstitutionalized Australians, aged 25 years or older, were randomly surveyed using a stratified clustered selection method, and examined for indicators of CKD including the presence of proteinuria, dipstick hematuria, or an estimated creatinine clearance below 60 mL/min using the Cockcroft-Gault equation. The study sample comprised 92.9% Caucasians and 5.5% Asians. Overall, 2.4% of participants were found to have a urinary protein to creatinine ratio of 200 mg/g or higher (approximately 250 mg/day). The prevalence was similar in men and women and increased eightfold with age, from 0.8% for 25 to 44 year olds to 6.6% in the 65 and older group. Almost half a percent (0.4%) of subjects had proteinuria in excess of approximately 1 g/day. The prevalence of dipstick positive hematuria of "+1" or greater was approximately 1 in 20 (4.6%) and was more common in women than in men, especially in younger age groups. Over 1 in 10 participants (11.2%) had a Cockcroft Gault creatinine clearance of less than 60 mL/min/1.73 m^2; the risk of reduced renal function was higher in women than in men and increased significantly with age, from 0.01% in the 25- to 44-year-old group to 54.8% for those 65 years and older; 6.4% of the population had all three findings of hematuria, proteinuria, and reduced renal function. Of the patients with proteinuria, in approximately half (46.8%) it was an isolated finding, in a third (34.8%) it was associated with a creatinine clearance of less than 60

mL/min/1.73 m^2 and in an eighth (12%) it was associated with hematuria. Of those with hematuria 1 in 8 (12.1%) had a reduced GFR, 1 in 20 (5.7%) had proteinuria and 1 in 50 (2.1%) had both. Most (87%) patients with a GFR of less than 60 mL/min/1.73 m^2 had neither proteinuria nor hematuria, 7% had proteinuria, and 5% had hematuria, while 1% had both. These results show that reduced GFR is related to but by no means synonymous with either hematuria or proteinuria in the general population.

Okinawa Screen Study

In 1983 107,192 Japanese on the island of Okinawa underwent a population-based kidney disease screening program. Similar to the findings in the AusDiab study the prevalence of hematuria increased linearly over a ninefold range with age in men, from 0.9% at ages 18 to 29, to 8.2% in those 80 years and older; hematuria was more common in women, especially at younger ages (7.3% at 18–29 years and 15.3% at age 80 and older). The prevalence of proteinuria, defined as +1 or greater proteinuria by dipstick, was high in both men (4% for 18–29 year olds, 6% for those over 80) and women (3% and 7%, respectively). The prevalence of proteinuria and hematuria combined was less than 2% in all age groups for both genders.[31]

Prevalence of Elevated Serum Creatinine

The majority of studies have defined the presence of CKD in terms of an elevated serum creatinine. This approach has several important limitations. Because there is no universal standard for the calibration of the serum creatinine assay, serum creatinine results may differ substantially between different laboratories.[18,32] Furthermore, as the serum creatinine level is dependent on both the daily creatinine production rate as well as its excretion rate, individuals with lower muscle mass and thus lower creatinine generation rates will have a lower serum creatinine at any given level of kidney function. Thus an elderly individual may have a serum creatinine within the population reference range despite substantially reduced kidney function, while, in general, women will have lower levels of kidney function as compared to men at a given serum creatinine level.[18] These limitations are demonstrated in a cross-sectional study of 2781 unselected outpatients in British Columbia who had serum creatinine measurements arranged by their community physician.[33] Subjects had a mean (standard deviation) age of 57[18] years and were defined as having hypercreatininemia if their serum creatinine was greater than 1.5 mg/dL (130 Umol/L) and an abnormal creatinine clearance if their Cockcroft Gault estimated creatinine clearance of below 50 mL/min. Of the population examined 6.5% had abnormal serum creatinine, whereas an additional 13.9% of the population had an estimated creatinine clearance below 50 despite having a serum creatinine that was within the assay reference range. The proportion of subjects with an abnormal Cockcroft Gault, despite creatinine within the normal range, increased from 0.8% for those aged 40 to 49, to 1.6% for those aged 50 to 59, to 12.6% for those aged 60 to 69, and to 47.3% for those aged greater than 70 years. Given the above limitations, studies based on serum creatinine assessments alone often underestimate the true prevalence of CKD.

NHANES III

An early analysis of NHANES III data reported the prevalences of serum creatinine at or above 1.5, 1.7, and 2.0 mg/dL to be 5%, 1.9%, and 0.6% for men, and 1.6%, 0.7%, and 0.3% for women.[34] Applying these percentages to the 1990 U.S. Census population results in the estimates of 6.2, 2.5, and 0.8 millions of Americans having serum creatinine levels at or above these cutoffs, respectively.

Reykjavik Study

A much lower prevalence of CKD has been reported in Iceland, a country where the prevalence of end-stage renal disease (approximately 55 per million population) is much lower than in the United States. This study examined the initial prevalence of an elevated serum creatinine above 1.7 mg/dL (150 Umol/L) and the subsequent renal outcome among 18,912 people who were living in Reykjavik, Iceland, as of 1967.[35] The estimated GFR at the time of study entry was between 30 to 35 mL/min/1.73 m^2, confirming that the above creatinine cutoff was representative of patients with CKD stage IV. The overall survey response rate was approximately 70%, with participation being lower in older age groups; the response rate among 75- to 79-year-olds was 53%. At baseline, 45 patients were found to have confirmed elevations in serum creatinine; of these the elevations were transient in three individuals, 39% of the subjects had proteinuria, 12% had diabetes, and 67% had hypertension. The crude prevalence of creatinine above 1.7 mg/dL was 0.22%, which was substantially higher for men (0.28%) than among women (0.15%). Some of this gender-related effect is likely to have resulted from the use of a gender independent cutoff for creatinine despite the typically greater muscle mass and consequent creatinine generation rate in men as compared to women. The prevalence of elevated serum creatinine increased with age. Over a median follow-up of 7.5 years, 27% of subjects maintained a relatively stable function with a yearly decline in estimated GFR of less than 1 mL/min/1.73 m^2, while two-thirds had progressively decreasing kidney function. These historic prevalence estimates from Iceland are therefore considerably less than those identified more recently within the United States in NHANES III, even when using results specific to non-Hispanic whites in the latter study. However, the degree to which these differences relate to methodologic differences in the design and conduct of the studies, to secular trends, or to true biologic effects or variation in clinical practice is unknown. Of note, in sharp contrast to the current U.S. experience, in the Reykjavik study only 1 person out of almost 19,000 subjects had kidney damage attributed to diabetes.

Prevalence of CKD in a Southwestern U.S. Health Maintenance Organization

The prevalence of elevated serum creatinine in the Southwestern United States has been reported from 199,065 enrollees in a health maintenance organization, using gender-specific creatinine cutoffs (serum creatinine of >1.2 mg/dL for women and >1.4 mg/dL for men). At least one gender-specific elevation in serum creatinine level was found in 7.1% of subjects and a sustained elevation, on at least two occasions at least 90 days apart, was found in 1.7%. Applying these

proportions to the 1990 census data, they estimated a prevalence of 9.1 million Americans in 1990 who would have at least one elevated serum creatinine and 4.2 million Americans with at least two elevated creatinines.[36]

Framingham Study

The prevalence of hypercreatininemia has also been reported from the Framingham cohort. A creatinine cutoff of 1.36 mg/dL (120 Umol/L) for men and 1.54 mg/dL (136 Umol/L) for females were derived from the 97.5 percentile of the serum creatinine distribution in a subgroup of 3241 study subjects, with a mean (sd) age of 47 (13.7) years and who were free of known renal, cardiovascular, and hypertensive disease or diabetes. Eight percent of women and 8.9% of men had elevated serum creatinine levels above these levels.[37]

Okinawa Screening Study

In the Okinawa Screening Study, 1.1% of women and 3.1% of men had serum creatinine levels above 1.4 mg/dL (124 Umol/L) and 1.5 mg/dL (133 Umol/L), respectively. However, this assay was only performed on 14,607 members of the original cohort who were discovered on initial screening to have either an abnormal urinalysis or an elevated blood pressure.[31]

Prevalence of CKD Stages

The initial NKF Guidelines for CKD apply the CKD definition and stages to NHANES III data to obtain overall U.S. population-based prevalence estimates, and subsequent publications detail the methods and the prevalence in high- and low-risk subgroups.[18,30,38] This approach, which relies on an estimated GFR derived from the calibrated serum creatinine assay overcomes most of the limitations of using serum creatinine levels alone. This analysis estimates that during 1988 to 1994 approximately 8 million Americans had glomerular filtration rates of below 60 mL/min/1.73 m^2 and 19 million had CKD stages I to V. Table 1–5 shows the absolute number of subjects and the proportion of the general noninstitutionalized U.S. population with the different stages of CKD. The AusDiab study used the presence of either proteinuria or hematuria on a dipstick, rather than persistent microalbuminuria, as markers of kidney damage, which resulted in low estimates of CKD

stages I and II of 0.9% and 2%.[30] In contrast, the prevalence of CKD stage III was 10.9%, higher than the 4.3% estimate in the United States. However, the numbers are not directly comparable because different equations and serum creatinine methods were used. The prevalence of CKD stage IV was 0.3%, similar to the U.S. estimate of 0.4% at this lower GFR range, where creatinine calibration has a smaller impact. The prevalence of stage V in AusDiab was 0.003% but individuals on dialysis may be less likely to participate in population surveys. Therefore, the prevalence of stage V in the K/DOQI report is based on USRDS data, rather than NHANES data.

ETIOLOGY OF KIDNEY DISEASE

A detailed review of the epidemiology, natural history, and management of the specific conditions that give rise to kidney disease is beyond the scope of this chapter, but we review below some of the salient epidemiologic aspects of the more notable conditions. Information on population-based epidemiology of many of these conditions is extremely limited, most notably by the lack of any widespread or uniform registry of CKD patients. Registries do exist for ESRD, which track the attributed etiology of kidney failure, however, by definition these registries only include patients who progress to and are accepted for renal replacement therapy, and as such they reflect the most progressive forms of diseases causing CKD. The distribution of etiologies in the ESRD registries is similarly influenced by the natural history of the underlying condition, the efficacy of available treatment and practice patterns regarding disease recognition and management, as well as by potential referral and selection biases. Furthermore, in many cases recognition of CKD is often delayed until late in the disease course, when the patient has already developed advanced kidney damage, making it difficult to accurately establish the underlying cause and rendering the attributed diagnosis essentially a matter of speculation. The attributed etiology of kidney failure in the USRDS registry is collected on a regulatory form, completion of which may default in whole or in part to administrative or clinical support staff, while alternatively the physician certifying the patient as starting ESRD is often not the same physician who managed the patient's CKD, and thus even the physician may have incomplete knowledge of the pre-ESRD diagnostic workup.

Table 1–5 Prevalence of GFR Category: NHANES III 1988–1994, U.S. Adults (Age =20)

Stages and Prevalence of Chronic Kidney Disease (Age ≥ 20)				
		GFR	Prevalence*	
Stage	Description	(mL/min/1.73 m^2)	N (1000s)	%
1	Kidney damage with normal or ↑ GFR	≥90	5,900	3.3
2	Kidney damage with mild ↓ GFR	60–89	5,300	3.0
3	Moderate ↓ GFR	30–59	7,600	4.3
4	Severe ↓ GFR	15–29	400	0.2
5	Kidney failure	<15 (or dialysis)	300	0.1

*Data for Stages 1–4 from NHANES III (1988–1994)[1]. Population of 177 million adults age ≥20 years. Data for Stage 5 from USRDS (1998)[2] include approximately 230,000 patients treated by dialysis, and assume 70,000 additional patients not on dialysis. GFR estimated from serum creatinine using MDRD Study equation based on age, gender, race and calibration for serum creatinine. For Stages 1 and 2, kidney damage estimated by spot albumin-to-creatinine ratio >17 mg/g in men or >25 mg/g in women on two measurements. (Copyright 2002, with permission from the National Kidney Foundation.)

Alternatively, clinical studies reporting the etiology of kidney disease are typically based on case series or biopsy series conducted in a single hospital or unit, often a tertiary referral center, and as such are heavily influenced by referral and selection biases, while in most cases the catchment area and population at risk can only be roughly approximated.

Diabetes

There has been a dramatic and global increase in the incidence and prevalence of diabetes over the last 2 decades. Distinguishing the relative contribution of type I versus type II diabetes to the incidence of kidney failure is difficult because many ESRD databases do not reliably make this distinction and, in addition, the diagnostic criteria have changed over time. However, the natural history of diabetic glomerulosclerosis appears to be similar for both type I and type II diabetes, if subjects are matched for an equal duration of diabetes. In clinical practice the duration of type II diabetes prior to clinical diagnosis is less predictable.

Nephropathy from Type I Diabetes

The incidence of type I diabetes has progressively increased over last several decades,[39] despite that the incidence of renal disease in type I diabetics appears to have either declined,[40] or at least been held steady.[41] The prime determinants of the rate of progression appears to be the degree of hypertensive and glycemic control.[42] In a cohort of 1075 subjects diagnosed with type I diabetes in Allegheny County, Pennsylvania, the cumulative incidence of ESRD was 11.3% at 25 years of diabetes, with an unadjusted incidence rate of 521/100,000 person years (95% CI: 424–629). The 20-year cumulative incidence rate for ESRD significantly declined in consecutive cohorts with regard to year of diagnosis from 9.1% for 1965 to 1969, 4.7% for 1970 to 1974 and 3.6% for 1975 to 1979.[43]

Nephropathy from Type II Diabetes

There has proportionately been a far greater increase over the last 2 decades in the incidence of type II diabetic nephropathy. This has paralleled the increased prevalence of type II diabetes, which itself has been associated with increased rates of obesity and sedentary lifestyles.[44] The increase in type II diabetic renal disease has occurred despite the proven benefit of secondary prevention with tight glycemic and antihypertensive control,[45,46] as well as potential primary preventative measures with lifestyle modification and pharmacotherapy.[47, 48] The implementation of these preventative strategies remains markedly suboptimal. In one survey the prevalence of diabetes in the United States increased by over a third, from 4.9% in 1990 to 6.5% in 1998, while the percentage of subjects with a BMI greater than 30 kg/m^2 increased from 11.1% to 18%.[49] In a prospective study of 155,774 patients in the Netherlands followed between 1998 to 2000, the age and gender adjusted prevalence rates of type II diabetes increased from 2.2% to 2.7%, and patients over 70 years of age accounted for over half of these subjects.[50]

In keeping with this dramatic increase in the prevalence of type II diabetes over the last 2 decades and the underutilization of preventative management strategies, there has been a dramatic increase in ESRD rates attributed to diabetic kidney disease. This increase has been one of epidemic proportion, and it has substantially contributed to the overall increased rates of ESRD. In the United States the age, race, and gender adjusted incidence rate of ESRD attributed to diabetes has doubled over the last decade, to a current adjusted rate of 148 pmp in 2001. The adjusted incidence rate peaks in the 65- to 74-year-old age group and is almost threefold higher in African-Americans than in Caucasians. Comparing data from NHANES III with NHANES II, between 1978 and 1991 the self reported prevalence of diabetes among 30 to 74 year olds increased 59%, and this increase was estimated to be responsible for 28% of the increase in incidence of ESRD over this period.[51] These trends are likely to have been further accentuated over the last decade. Similar trends, though of a lower magnitude, have been reported in Europe, though with substantial variability between countries, the 1999 age and gender adjusted incidence rate being 10.2 pmp in Norway and 39.3 pmp in Austria. That the incidence of diabetic kidney disease plays a major role in explaining the variability in ESRD rates was shown in Austria, where the age adjusted overall incidence rate of ESRD in the Tyrol region is 97.9 pmp/year (95% CI, 86.9–109.1), as compared to 120.9 pmp/year (95% CI, 116.9–124.5) for the rest of the country. On examining the cause-specific ESRD rates, most of these differences between regions are explained by differences in the rates of diabetic nephropathy and vascular nephropathy; the distribution of other etiologies for renal failure being similar. These differences are not obviously explained by differential rates of selection for dialysis or by available access to renal replacement programs in the Tyrol as compared to the rest of Austria. However, compared to the rest of Austria, the population in Tyrol has lower average body mass indices, a higher percentage who take regular physical exercise, and a lower overall rate of diabetes.[52]

Hypertension/Ischemic Kidney Disease

Hypertension is the second most common attributed etiology of ESRD in the United States, and from 1990 to 2001 the adjusted incidence rate of ESRD attributed to hypertension increased by almost 50%, although in the last 3 years this rate of increase appears to be slowing. The 2001 age, gender, and race adjusted incidence rate was 89 per million U.S. population. The reported incidence increases with age, while the age and gender adjusted incidence rate is over three times higher in African-Americans than in Caucasians. In Europe the incidence of ESRD attributed to hypertensive renovascular disease has also increased, though this increase has been predominantly limited to subjects over age 65. Its incidence varies widely between countries, with an adjusted rate of 5.8 pmp in Finland and 21 pmp in Norway.

The accuracy with which hypertension is attributed as the cause of ESRD has been widely questioned. Indeed, even whether nonmalignant hypertension can cause de novo kidney disease at all, especially in Caucasians, is controversial.[53] In contrast, there is abundant evidence that hypertension, especially systolic hypertension, is a powerful promoter of kidney damage, which may exacerbate the renal injury and rate of renal decline that occurs from a given disease.[54] There is also clear evidence that hypertension predates an increased risk of ESRD.[55–57] In addition, control of blood pressure clearly decreases the risk of CKD progression. A causal relationship

between hypertension and CKD is difficult to establish because hypertension is a frequent consequence of CKD and thus is likely to be present in a large proportion of subjects with CKD regardless of their initial etiology. This is especially problematic given the large proportion of CKD patients who present with advanced CKD at the time of nephrology referral. In addition, the clinical definition of hypertensive kidney failure has been relatively loose and has not typically required demonstration of supportive evidence in the form of hypertensive damage at other nonrenal vascular beds.

Some of the recent increased incidence in ESRD is likely to have resulted from decreasing competing mortality rates as a consequence of improved stroke and/or myocardial infarction survival, with such survivors subsequently developing kidney disease as a renal manifestation of their diffuse atherosclerosis. However, in an analysis comparing the potential effect of stroke and heart attack survival on the incidence of ESRD between 1978 and 1991, the effect was relatively modest, and improved survival following stroke and/or myocardial infarction explained only 4.8% of the increase in incidence of ESRD over the examined period. Nevertheless it remains intuitive, if unproven, that a decrease in competing mortality, in the continued presence of diffuse atherosclerosis, is likely to increase the prevalence of ischemic renal vascular disease and to have contributed to the observed increase in ESRD attributed to hypertension. In addition, the aggressive management of large vessel atherosclerosis, with repeated endovascular cannulation for diagnostic or therapeutic purposes, is likely to predispose to cholesterol embolization with resultant renal injury. In a study of 1786 consecutive Japanese patients 40 years of age and older undergoing left heart catheterization, the incidence of definite cholesterol emboli was 0.66% and that of possible cholesterol emboli was an additional 0.73%.[58] In addition, radiologic contrast agents cause acute kidney damage and may contribute to an increased risk of ESRD.[59]

Glomerulonephritis

With the exception of some rare diseases such as Goodpasture's disease and ANCA associated pauci-immune vasculitis, most forms of glomerulonephritis cannot be readily diagnosed by serologic tests alone; therefore, the accuracy with which the occurrence of different forms of glomerulonephritis are estimated will vary directly with the timing and frequency with which kidney biopsies are performed. The increased utilization and demonstrated safety of percutaneous kidney biopsy, especially with the assistance of real-time sonographic guidance, had led to increased rates of biopsy and diagnosis of patients with less overt forms of glomerulonephritis and increasing recognition of the spectrum of findings associated with glomerulonephritis. However, kidney biopsy rates vary widely; for example, they are reported to be several times higher in Australia than in Italy.[60, 61] Similarly, in response to a questionnaire, 21% of nephrologists from Australia and New Zealand said they would perform a kidney biopsy in a patient with less than 1 gm of proteinuria/day, as compared to 14% of nephrologists from Europe and 0% from the United States.[62] Patients with isolated hematuria are more likely to undergo renal biopsy in many areas of Asia than in either the United States or Europe.[63] Given this great degree of variability, it is almost impossible to make comparisons either over time or between different sites. Given the high frequency of patients who present late to nephrology clinics, who may have established CKD and resulting small kidneys and thus do not, undergo kidney biopsy, the true incidence of the various forms of glomerulonephritis remains uncertain. In distinction to the overall spectrum of glomerulonephritis, those patients who develop frank nephrotic syndrome typically do present for medical evaluation and often are biopsied if they do not have long-standing diabetes. Changes in the identified etiology of the nephrotic syndrome therefore are more likely to be revealing of true changes in prevalence over time and less influenced by referral practices. Mindful of these limitations, it is interesting to note that in Europe the incidence of glomerulonephritis reported by the Danish National Kidney Biopsy Registry has remained relatively constant over the time period from 1985 to 1997; the incidence of biopsy proven glomerulonephritis overall was 39.2 cases per million population per year, the incidence peaked in the 60- to 70-year-old group, which was over twice that for patients in the 20- to 40-year-old group.[64] A similar estimate of the incidence of glomerulonephritis comes from Italy, where the rate was calculated as being 47 cases per million population per year.[65]

IgA Nephropathy

IgA nephropathy is the most common overall primary form of glomerulonephritis found on kidney biopsy worldwide. It is uncommon in children, rare in African-Americans, and may on occasion be familial. It is a particularly common diagnosis among Asians and is responsible for almost 50% of biopsy-proven glomerulonephritis from Japan.[66] The overall prevalence of IgA nephropathy varies substantially, in part related to varying practice patterns with regard to biopsy of patients with nonnephrotic proteinuria or isolated hematuria. Thus, the prevalence is substantially higher in Japan where there is routine screening of patients for proteinuria than, for example, in Canada or in the United States, where in the absence of formal screening program patients typically present later in their disease course. In comparing outcomes between different countries, it is important to note that countries with screening programs are more likely to identify patients with mild disease—and thus a potentially better prognosis—as well as demonstrate a substantial lead time bias effect on kidney survival. In a study from Singapore examining the frequency of glomerulonephritis over the last two decades, IgA nephropathy remained the single most common form of glomerulonephritis, representing 56% of biopsies. However, over time, there has been a decrease in the frequency of IgA nephropathy and an increase in the frequency of minimal change disease, which is now the most common underlying diagnosis found in patients with nephrotic syndrome in that country.[67]

FSGS and Membranous

Traditionally, membranous nephropathy has been the most common primary cause of adult nephrotic syndrome in both the United States and Europe. Over the last 20 years, however, there has been a significant increase in the frequency of idiopathic Focal Segmental Glomerulosclerosis (FSGS), which has now become the most common cause of idiopathic nephrotic syndrome among adults in the United States. This increased frequency is especially evident in African-Americans but is also present in Caucasians. The frequency of FSGS among

patients undergoing biopsy for nephrotic range proteinuria increased from 29% between 1975 and 1985 to 38% between 1985 and 1994.[68] Barisoni and colleagues[69] noted that the frequency of all forms of FSGS diagnosed by kidney biopsy increased sevenfold between 1974 and 1993, while Haas and colleagues[70] confirmed a similar increase in the Midwestern United States. The frequency of idiopathic FSGS increased from 4% to 12% over a 20-year period; during this time frame, the proportion of patients with membranous glomerulopathy, approximately 9%, did not change, whereas the proportion with minimal change nephropathy declined. In the study, the proportion of patients presenting with frank nephrotic syndrome and the racial characterization of the population remained relatively constant over the study period, arguing against changes in the demographic makeup of the population or changes in kidney biopsy rates as being the primary cause for the observed increased incidence of FSGS. The incidence of FSGS is four times higher in African-Americans than in Caucasians.[68] In an analysis of the changing incidence of glomerulonephritis as the cause of ESRD, Braden and colleagues[71] confirmed FSGS to be the most common cause among black subjects and its increasing incidence among white subjects, among whom it has replaced membranous nephropathy as the most common cause of nephrotic syndrome. There has similarly been an increased incidence of FSGS in Hispanic patients, among whom this is noted to be the second most common cause of primary glomerulonephritis after IgA nephropathy. FSGS is also common in areas of the Middle East, present in 41% of kidney biopsies for nephrotic syndrome in Saudi Arabia; intermediate frequencies are described in Europe (6%–15%); and the lowest frequencies are described in Asia (2%–11%).[63]

HIV-Associated Nephropathy and Collapsing Glomerulopathy

The incidence of secondary FSGS due to HIVAN (HIV associated nephropathy) initially mirrored the prevalence of the HIV epidemic among African-Americans. More recently, these rates have leveled off, presumably due to the more widespread use of effective, highly active antiretroviral therapy. While the histologic appearance of HIVAN has typically shown collapsing features, an idiopathic form of this histologic finding had not been described prior to 20 years ago but is now increasingly recognized, especially in HIV negative African-American patients. This entity has more than doubled in frequency, from 11% of all cases of idiopathic FSGS between 1979 and 1985 to 24% between 1990 and 1993.[69] The pathogenesis with this variant of FSGS and the reason for this increased frequency over time remains unclear, but it has been speculated that it may be the result of an infectious agent, for example parvovirus B19 infection,[72] or an interaction of environmental factors such as the increased frequency of obesity in genetically predisposed individuals.

Vasculitides

Comparison of the occurrence of vasculitis is particularly susceptible to selection and referral biases, with the majority of the limited number of reports coming from single tertiary referral centers with relatively small and often poorly defined source populations. Different diagnostic criteria, for example,

the 1990 American College of Rheumatology vasculitis criteria, as compared to the Chapel Hill Consensus Conference definitions, further complicates the examination of trends over time. Furthermore, the introduction in the mid-1980s of relatively specific antineutrophil cytoplasmic antibodies (ANCA) associated with Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome have allowed for more ready identification of cases, especially those with atypical features.

An examination of the incidence of systemic vasculitis from two regional referral centers, one in Norfolk, England, and the other in Lugo, Spain, using Chapel Hill consensus conference definitions, found similar overall incidence of primary systemic vasculitis in the two regions. The incidence in Norfolk was 18.9 cases per million population (pmp) while in Spain it was 18.3 pmp. The incidence of Wegener's granulomatosis in Norfolk (10.6 pmp) was greater than in Spain (4.9 pmp). This has been interpreted as being in keeping with anecdotal trend for higher incidence of Wegener's granulomatosis at northern latitudes, a similar predisposition having been proposed for giant cell arteritis. In both the English and the Spanish centers, there was a marked increase in the incidence with advancing age, with peak incidence at ages 65 to 74 (52.9 pmp).[73]

A study from northern Norway over a 15-year period, based on hospital discharge records from all 11 hospitals in the region as well as from two renal pathology services, and using American College of Rheumatology 1990 criteria, found an incidence per million population for Wegener's granulomatosis of 5.2 (95% confidence interval (CI) 2.7–9.0) between 1984 and 1988, which had risen to 12.0 (95% CI 8.0–17.3) between 1994 and 1998. The respective point prevalence increased from 30.4 pmp (95% CI 16.6–51.0) to 95.1 pmp (95% CI 96.1–129.0). The incidence was higher in men than in women, with again a peak incidence in the 65- to 74-year-old group. However, it is impossible to determine how much of that increased incidence over time relates to improved diagnosis secondary to the widespread introduction of ANCA testing.

The incidence of vasculitis has been estimated based on all hospital and outpatient unit records as well as pathology and immunology results within a five million population, living within two large mixed rural and urban areas of north and south Germany. Over a 2-year period (1998–1999), 473 individuals were diagnosed as having incident primary systemic vasculitis. The unadjusted incidence rates in north Germany for all primary systemic vasculitides were 54 cases pmp/year in 1998 and 48 pmp/year in 1999, compared to rates in the south of 48 pmp in 1998 and 41 pmp in 1999. The incidence rates for ANCA associated vasculitis were 11 and 9.5 pmp in 1998 and 1999, respectively, in the north and 9 and 7 pmp in the south. Overall, Wegener's granulomatosis was the most frequent type of ANCA associated vasculitis diagnosed. There was no significant difference in the type of vasculitis identified between northern and southern Germany, or between urban or rural areas.

Tubulointerstitial Kidney Disease

The diagnosis of chronic tubulointerstitial kidney disease is especially difficult to make because it is often clinically silent: Patients usually lack substantial proteinuria and have a bland urinary sediment. Primary tubulointerstitial disease may occur as a consequence of allergic reaction, toxic exposures, or

more rarely due to autoimmune mechanisms. The incidence of chronic interstitial nephritis is unknown. The increased use of exotic herbal preparation for a variety of purported reasons, including slimming regimens, has resulted in the increased recognition of an aggressive form of tubulointerstitial disease, referred to as Chinese herb nephropathy, characterized by minimal glomerular findings and a rapid, often irreversible decline in renal function.[74] Balkan nephropathy has been a long recognized form of severe tubulointerstitial disease; endemic to the Balkans, its etiology is unknown but is believed to result from an environmental exposure, the leading candidate being contamination of cereals or pork products by Ochratoxin A.

The association between analgesic use and renal failure remains complex and controversial and raises a variety of issues that demonstrate the potential limitations of observational epidemiology, especially retrospective studies.[75–77] While the nephrotoxic consequences of some agents such as phenacetin is well established, the association between currently used analgesics, such as nonsteroidal anti-inflammatory preparations or the Cox-2 inhibitors,[75] with long-term kidney dysfunction has been demonstrated in several studies but remains unproven. Lead has long been recognized as a potential nephrotoxin and cause of interstitial kidney disease, though the population-related renal consequences of lead exposure have been poorly defined. In a recent analysis based on NHANES III data, higher lead levels in the general population were associated with higher prevalence of CKD.[78] The highest population quartile of lead exposure as compared to the lowest quartile was associated with a 2.6 (95% CI: 1.5–4.5) higher odds of CKD, suggesting the possibility that prolonged exposure to even low environmental lead levels may contribute to kidney damage.

PATIENT OUTCOMES

Treatment with renal replacement therapy continues to be complicated by extremely high morbidity and mortality, though these have slowly improved over time. The 1-year, all modality (transplantation and dialysis) survival rate, adjusted for age, race, gender, and ESRD etiology increased from 73.8% in 1980 to 79.8% in 2000; the 5-year survival rate increased from 31.2% to 38.8%, respectively. Examining dialysis specific survival rates, 1-year survival improved between 1980 and 2000 from 74.8% to 79.2% and the 5-year survival rate increased from 29.5% to 34.4%. This improvement has occurred despite a marked increase in the degree of comorbidity among incident patients during this time. Among prevalent dialysis patients the overall age, race, and gender adjusted mortality rates fell by approximately 10% over the last decade. However, this improvement is the result of a decrease in mortality for patients who have been treated with dialysis for less than 3 years; the mortality rate for those dialyzed for 3 or more years has steadily increased (Figure 1–8).[79] The latter increase may reflect sicker patients surviving the first years on dialysis. The decline in prevalent mortality rates since 1980 has been less impressive for African-Americans, a 12.3% reduction, as compared to 13.5% for Caucasians, 18.2% for Native-Americans, and 29% for Asians.

The comparison of survival among transplant recipients as compared to dialysis treated patients is inherently biased because it does not take into account the selection bias that results from the screening of potential transplant candidates and the exclusion of high-risk subjects. A fairer comparison is to examine outcomes between transplant recipients and those individuals who are successfully wait-listed but who continue on dialysis while waiting for a transplant. This analysis continues to show approximately threefold lower mortality for transplanted as compared to wait-listed subjects.[80]

ESRD Hospitalization rates

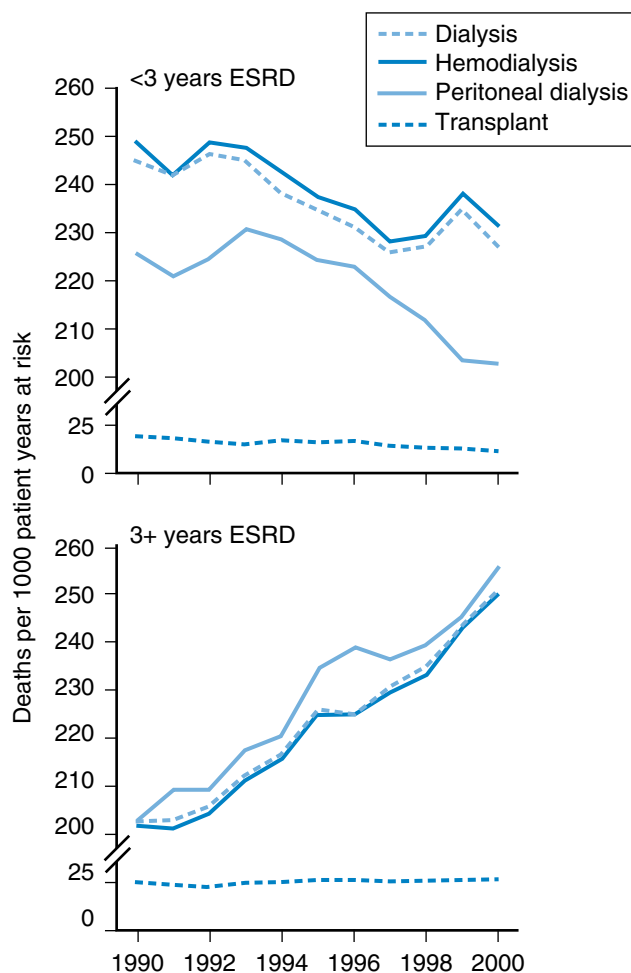
Hospital admission rates have remained relatively constant within the dialysis population over the last decade in the United States.[1] Hospitalization rates are highest for patients with primary diagnosis of diabetes (2.4 admissions per patient year in 2001) and lowest for glomerulonephritis (1.7 admission per patient year, in 2001). Hospitalization days per patient year have steadily decreased over the last decade, by 19% for those with a primary diagnosis of glomerulonephritis and 21% for those with a primary diagnosis of


Figure 1–8 Prevalence mortality rates by duration of ESRD and modality. (From U.S. Renal Data System: USRDS 2003 Annual Data Report: Atlas of end-stage renal disease in the United States. Bethesda, MD, National Institutes of Health, 2003, pp 1–560. Copyright 2002, with permission from the National Kidney Foundation.)

diabetes (to 10 and 18 days a year, respectively, in 2001). Similar trends have been seen in the transplant population (1.26 and 0.76 hospitalizations for a total of 10 and 5 days a year in 2001 for ESRD attributed to diabetes and glomerulonephritis, respectively).

Outcomes in CKD Stages I to IV

Data from population-based studies and clinical populations are increasingly showing the gradual increase in kidney related complications at lower levels of GFR. These relationships are discussed in detail in subsequent chapters. Cross-sectional analyses indicate that many complications are noticeably more common at a GFR below 60 mL/min/1.73 m[2].[2] In addition, prospective data showing a higher risk of cardiovascular disease and mortality at lower kidney function are increasing.[81]

Expected Remaining Years of Life

The limitations of our current strategies for managing CKD are clearly evident in the limited expected remaining years of life for patients treated with dialysis, which are only one-third to one-sixth that of the age matched general U.S. population. The lowest ratios are found for white females. Thus, for a white 45-year-old on maintenance dialysis, the remaining years of life are 6.3 for a male and 6.0 years for a female, as compared to the general population remaining years of life of 32.4 and 36.6 years, respectively. The equivalent figures for an African-American male and female are 7.7 and 7.3 years of life on dialysis, as compared to 27.8 and 33 years in the general population.[1]

SUMMARY

The epidemiology of CKD is becoming better understood. In addition to the epidemic increase of treated kidney failure, the large burden of earlier stages of CKD is now better appreciated. A standardized definition and staging system complements the exiting etiologic classification of disease and focuses on complications common to all types of CKD. Management of CKD complications are important to prevent not only further CKD progression but also the associated morbidity and mortality that precede the onset of kidney failure and often result in mortality prior to initiation of dialysis. Improved understanding of the epidemiology (distribution and determinants) of CKD will be important in devising and tracking the implementation of strategies for improved diagnosis and treatment of all stages of CKD.

Measurement of Kidney Function

Anupama Mohanram, M.D. • Robert D. Toto, M.D.

The accurate measurement of kidney function is essential for the evaluation and management of kidney disease. This is especially important because early kidney disease is silent. Furthermore, staging by level of kidney function facilitates determination of not only kidney disease but also associated risks, such as cardiovascular disease, bone disease, and anemia. By measuring kidney function over time, one can monitor the course of kidney disease and the effects of therapies directed at slowing the progression of kidney disease. The National Kidney Foundation (NKF) recommends estimation of glomerular filtration rate (GFR) for staging the severity of chronic kidney disease (CKD), as shown in Table 2–1.[1]

GLOMERULAR FILTRATION RATE

Glomerular filtration rate is a standard measure of kidney function; it is the clearance by filtration of a marker from plasma by the kidneys and represents renal excretory function. Level of GFR correlates with structural kidney damage; however, in certain disease processes GFR may be normal or even elevated in the presence of significant kidney disease. Consequently, a normal GFR alone does not exclude kidney disease. GFR should be used in conjunction with other clinical parameters for diagnosis and management.

There is a great deal of variability in GFR for normal subjects,[2] and factors such as exercise and protein intake can influence GFR. Normal ranges for GFR are age and gender dependent. Table 2–2 demonstrates the mean GFR from the Third National Health and Nutrition Survey by age[3] and levels of kidney function in the Scandinavian population by age and gender. GFR is generally higher among men compared to women: mean adult values for GFR are 130 mL/min/1.73 m^2 for men and 120 mL/min/1.73 m^2 for women. Kidney function is expected to decline with advancing age, and the rate of decline of creatinine clearance, estimated from 24-hour urine collections, increases with advancing age.[4] Despite these factors, GFR is very useful for following kidney function over time for a given individual.

There are a variety of methods for estimating or measuring GFR, ranging from prediction equations based on serum creatinine (SCr) to complicated repeated measures of urine and serum samples, and each method has its own advantages and disadvantages.

Clearance Methods

Renal Clearance

The basic formula for measuring renal clearance of any substance is the product of the urine concentration of marker and the urine flow rate in mL/min divided by the plasma concentration of marker. For optimal GFR measurement, a marker is given via continuous infusion in order to achieve and maintain a stable plasma level of the marker. The marker may be given intravenously or subcutaneously and is followed by repeated collections of urine samples approximately every 30 to 45 minutes (Figure 2–1). The plasma concentration of the marker is usually measured at the midpoint of the urine collection period or as the log mean of two measures taken before and after each urine collection period. Urine is optimally collected with a properly positioned bladder catheter. However, in most instances bladder catheters are not employed to measure renal clearance; consequently, errors in measurement may occur due to incomplete bladder emptying, particularly in diabetics and children.

Plasma Clearance

The advantage of plasma clearance methods is that urine collection is not required. To measure plasma clearance, the marker may be given as a continuous injection or as a single bolus injection. If the marker is given as a continuous injection, plasma concentration is determined at steady-state. When the marker's distribution space and the marker's plasma level are constant, the rate of infusion and the rate of elimination will be the same. However, steady-state may not be achieved for 3 to 24 hours, which may limit use of this test. The basic formula for plasma clearance for a continuous infusion is the infusion rate of marker in mL/min divided by the plasma concentration of marker in mg/dL.

When a marker is given as a single injection, plasma clearance can be modeled as a two-compartment model (Figure 2–2) or as a single-compartment model (Figure 2–3) in order to measure GFR. The two-compartment model requires multiple measures of plasma concentration of marker over time. These measured concentrations of marker over time are then modeled as two phases of plasma clearance. Phase one is a slow elimination phase and represents movement of the marker from the intravascular space to the extravascular space. Phase two is the rapid elimination phase and represents plasma clearance of the marker, which is assumed to be the same as the renal clearance of the marker. This assumption is incorrect for some markers, such as Chromium ethylenediamine tetra-acetic acid (^{51}Cr-EDTA). Extra-renal clearance of such markers leads to overestimation of glomerular filtration rate by up to 10%.

For most markers, the two-compartment model accounts for all plasma clearance of marker. Two lines are determined in order to calculate GFR by the two-compartment model. The first line is a best fit regression of the terminal elimination phase (depicted by slope k_1 and intercept A in Figure 2–2). The second line is the best fit of the difference between actual

Table 2–1   Stages of Chronic Kidney Disease

Stage of CKD	Description	Glomerular Filtration Rate (mL/min/1.73 m²)
1	Kidney damage (such as proteinuria) with normal or increased GFR	>90
2	Kidney damage with mildly decreased GFR	60–89
3	Moderately decreased GFR	30–59
4	Severely decreased GFR	15–29
5	Kidney failure	<15 or dialysis

Staging for chronic kidney disease based on glomerular filtration rate as defined by the National Kidney Foundation. (From Eknoyan G, Levin NW: K/DOQI clinical practice guidelines for chronic kidney disease: Evaluation, classification, and stratification. Am J Kidney Dis 2002; 39[2]:S14-S266.)

values and values calculated from the line fitted to the terminal elimination phase (depicted by slope k_2 and intercept B in Figure 2–2). Glomerular filtration rate (two-compartment method) is calculated as follows:

$$GFR = [Marker] \times k_1 \times k_2 / (Ak_2 + Bk_1)$$

where [Marker] is the amount of marker given.

One can also determine GFR for a one-compartment model based on these regression analyses. Glomerular filtration rate (one-compartment method) is calculated as follows[5–7]:

$$GFR = [Marker] \times k_1/A$$

Figure 2–3 shows a single-compartment model after a single injection. When plasma clearance is modeled as a single compartment, the area below the dotted line is used as the area under the curve (AUC) and corresponds to the rapid elimination phase. This model assumes total excretion of the marker. Because the slow elimination phase is not included, the AUC by the one-compartment method is slightly lower than the actual AUC, leading to overestimation of plasma clearance.[8]

MARKERS FOR MEASURING GLOMERULAR FILTRATION RATE

An ideal marker should be freely filtered, not protein bound, eliminated solely by the kidney and not metabolized, reabsorbed, or secreted by the renal tubules. One should be able to measure the marker by a reproducible and accessible laboratory assay without interference from other compounds. In addition, an ideal marker is one that is safe, readily available, and inexpensive. Less ideal markers may impart radiation exposure, require intravenous access for infusions, and require multiple sampling of blood and/or urine, via bladder catheterization. Although there is no ideal marker, inulin has been considered the gold standard. The major markers are discussed in this section and summarized in Table 2–3.

Exogenous Clearance Markers

Inulin

Inulin is the gold standard among markers because it allows for the most accurate measure of glomerular filtration rate. However, it is not practical for clinical use because it is expensive, in short supply, and it must be given intravenously.[9] It remains useful as a research tool given its accuracy.

Inulin (MW 5200 daltons [Da]) is an inert plant-derived fructose polymer. It does not bind to plasma proteins, is freely filtered and excreted by the kidney, and it is not reabsorbed or secreted by the tubule. There is no extra-renal metabolism of inulin. It can be measured in urine and plasma with the caveat that high glucose levels can interfere with the anthrone assay used to measure inulin.

There are several methods for measuring clearance with inulin; one such method is explained here. The patient begins the day by drinking water (10–15 mL/kg) after an overnight fast and is encouraged to continue drinking water in order to attain a urine flow rate of 4 mL/min. An intravenous loading dose of inulin is administered prior to beginning an inulin infusion in order to achieve steady-state (typically 45–60 minutes). After inulin is given, urine is collected every 30 minutes by bladder catheterization in order to avoid variability in measurement. Plasma inulin levels are also measured. Clearance is then calculated from an average of 3 to 5 measures based on the steady-state assumption that when the volume of distribution stabilizes, then infusion is equal to elimination.

This technique is considered cumbersome for clinical practice because it requires intravenous access for a constant infusion, oral water loading and need for bladder catheterization, and a prolonged time (more than 6 hours) to complete the procedure. Another caveat is that if the patient does not keep up with water loading, inulin elimination is decreased. Given these difficulties, newer techniques use an inulin bolus and no infusion. Bolus dosing without infusion results in lower levels of inulin that can now be measured by high pressure liquid chromatography. Inulin clearance with continuous intravenous infusion remains the gold standard for estimating GFR; however, due to the inconveniences mentioned, other markers have been used as described below.

Iothalamate

Iothalamate is convenient to administer both in clinical as well as in research settings. The radioiodinated form has advantages compared to using inulin since the radioiodinated iothalamate, ^{125}I-iothalamate, can be administered as a single subcutaneous injection for renal clearance measurement, making it an attractive method for estimating GFR.

Sodium iothalamate (MW 614 Da) is a derivative of tri-idobenzoic acid. It is a high osmolar ionic radiocontrast agent that is slightly protein bound.[10] Clearance measurements using sodium iothalamate are reasonably accurate, but overestimate inulin clearance by about 7% because of a constant rate of proximal tubular secretion. It can be given subcutaneously as the ^{125}I-nuclide and is relatively convenient for clinical management as well as for research purposes. A small amount undergoes extra-renal metabolism via the liver, biliary tract, and small intestine, which is more pronounced for patients with advanced CKD.[11] However, the nuclide is very expensive, requires special handling and

Table 2–2 Glomerular Filtration Rate, Plasma Creatinine, and Creatinine Excretion in Adults by Increasing Age

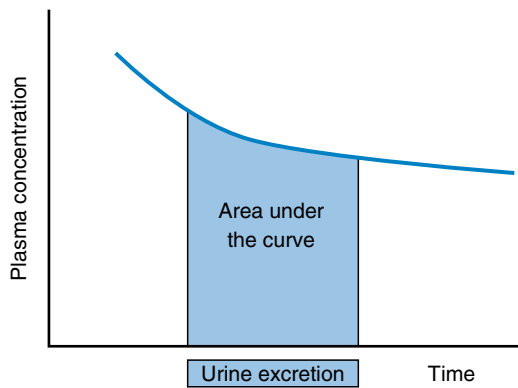
Second column shows population mean GFR from the Third National Health and Nutrition Survey (NHANES III), calculated by the Modification of Diet in Renal Disease formula. The remainder of this table shows creatinine concentrations and clearance by age and gender for a Scandinavian population of hospitalized patients with normal serum creatinine. Note that for these patients with normal creatinine, with advancing age, the trend is for decrease in urinary creatinine and decrease in measured creatinine clearance. Also note that overall, women tend to have lower urinary creatinine and clearance than men. (From Coresh J, Astor BC, Greene T, et al: Prevalence of chronic kidney disease and decreased kidney function in the adult U.S. population: Third National Health and Nutrition Examination Survey. Am J Kidney Dis 2003; 41[1]:1-12; and Kampmann J, Siersbaek-Nielsen K, Kristensen M, Hansen JM: Rapid evaluation of creatinine clearance. Acta Med Scand 1974; 196(6):517-520. Used with permission.)


Figure 2–1 Renal clearance. This cartoon shows plasma concentration of a marker versus time. To calculate renal clearance of a marker, divide the amount of the marker that is excreted in the urine by the area under the curve (AUC): Clearance = [Urine excretion]/AUC. (Adapted from Horio M, Orita Y, Fukunaga M: Assessment of renal function. *In* Johnson RJ, Feehally J [eds]: Comprehensive Clinical Nephrology. London, Mosby, 2000, pp 3.1–3.6.)
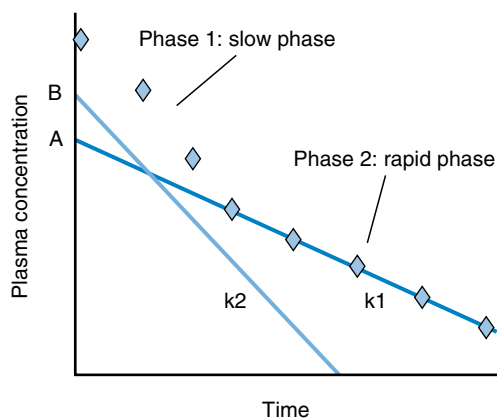

Figure 2–2 Plasma clearance curve after single injection—two-compartment model. In this cartoon, diamonds depict measured plasma concentration over time for a marker. Phase 1, the slow elimination phase, represents movement of the marker from the intravascular space to the extravascular space. Phase 2, the rapid elimination phase, represents renal elimination of the marker. The two-compartment model accounts for all plasma clearance of marker. The first line (slope k_1 and intercept A) is the best fit of the terminal elimination phase, the rapid phase, by least squares method. The second line (slope k_2 and intercept B) shows the best fit of the difference between actual values and values calculated from the line fitted to the terminal elimination phase. Glomerular filtration rate (two-compartment method) is calculated as follows: GFR = [Marker]$k_1 k_2$ /(Ak_2 + Bk_1), where [Marker] is the amount of marker given.
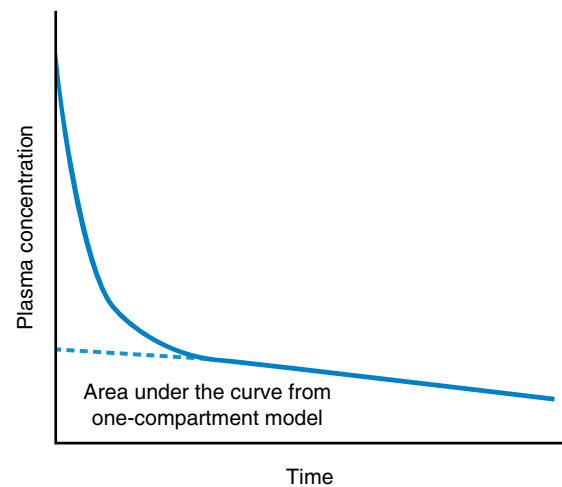
Glomerular filtration rate (one-compartment method) is calculated as follows: GFR = [Marker]k_1 /A. (Adapted from Silkensen JR, Kasiske BL: Laboratory assessment of kidney disease: Clearance, urinalysis, and kidney biopsy. *In* Brenner BM [ed]: The Kidney. Philadelphia, WB Saunders, 2004, pp 1107-1137.)


Figure 2–3 Plasma clearance after single injection—single-compartment model. When plasma clearance is modeled as a single compartment, the area below dotted line is used as the AUC and corresponds to the rapid elimination phase, as shown here. This model assumes total excretion of the marker. Because the slow elimination phase is not included, the AUC by the one-compartment method is slightly lower than the actual AUC, leading to overestimation of plasma clearance. (Adapted from Horio M, Orita Y, Fukunaga M: Assessment of renal function. *In* Johnson RJ, Feehally J [eds]: Comprehensive Clinical Nephrology. London, Mosby, 2000, pp 3.1–3.6.)

documentation, exposes the patient to radiation, and therefore cannot be made widely available to practice or research environments.

Although the amount of radiation used for GFR studies is lower than the amount used for radiologic procedures, these markers are concentrated in the urinary system, and exposure is a safety concern.[12] Furthermore, there is some risk of thyroid uptake, but this can be prevented with pretreatment of oral iodine (Lugol's solution). Radiation exposure is an even greater concern in pregnant women and in children. Alternative markers should be considered in patients who are allergic to iodinated compounds or contrast media. We recommend use of creatinine or cystatin C or, if possible, inulin to measure GFR in those at risk for allergic reaction to iodinated compounds, although there is some evidence that pretreatment with corticosteroids and antihistamines may reduce this risk.[13]

Continuous I.V. infusion and subcutaneous methods are available for cold iothalamate.[14–16] The cost of cold iothalamate is low, making this marker an attractive alternative to radionuclide management. Subcutaneous injection of cold iothalamate can be employed to measure GFR but requires access to high performance liquid chromatography (HPLC) or capillary electrophoresis to measure accurately low blood and urine levels of the marker. Whether using cold or hot iothalamate, GFR is overestimated when compared to inulin.[17]

Table 2–3   Advantages and Disadvantages of Clearance Markers for Measuring Glomerular Filtration Rate

Markers and Characteristics	Exogenous					Endogenous

GFR compared to inulin	NA	O	O	Ur, Op	S	O	S

This table shows the major advantages and disadvantages of the clearance markers for GFR discussed in the text.
HPLC, high performance liquid chromatography; *Y*, yes; *N*, no; *NA*, not applicable; *L*, little (<10%); *I*, iodinated compound; *R*, radioactive; *S*, similar; *Ur*, underestimates by renal clearance method; *Up*, overestimates by plasma clearance method; *O*, overestimates;
*May need to preadminister Lugol's solution.
† Anthrone method: high glucose concentration can interfere, leading to false positive; alternate enzymatic assay less available than anthrone assay.
‡ Jaffe method: high glucose, fructose, pyruvate, acetoacetate, uric acid, ascorbic acid, plasma proteins, bilirubin and cephalosporins can interfere; enzymatic method: high glucose, ethamsylate and metamizol can interfere.
§ Lacks FDA approval.

Chromium Ethylenediamine Tetra-Acetic Acid (⁵¹Cr-EDTA)

Plasma clearance of ⁵¹Cr-EDTA has been studied extensively and is widely used in Europe to measure GFR. It is an impractical method for routine estimation of renal function because it is time-consuming; however, it is frequently employed for clinical studies. Because it is a radio-labeled marker, it exposes the patient to radiation and its associated risks. Also, this agent is not approved by the Food and Drug Administration, thus limiting its application in the United States.

⁵¹Cr-EDTA (MW 292 Da) is freely filtered and not metabolized by the renal tubule. It is slightly protein bound,[18] and 10% may be subject to extra-renal metabolism.[19–21] Early studies demonstrated good agreement between renal clearance of inulin and plasma clearance of a single injection of ⁵¹Cr-EDTA.[22,23] More recent studies have shown that renal clearance of ⁵¹Cr-EDTA underestimates inulin clearance, and that plasma clearance of ⁵¹Cr-EDTA overestimates it.[9] It should be noted that plasma clearance and not renal clearance is the preferred method for estimating GFR with Cr-EDTA. Despite the slight overestimate of GFR by plasma clearance, the precision of this technique is superior to that of most other markers. A single sampling of ⁵¹Cr-EDTA is preferred because the single-sample method is associated with fewer errors compared to two samples.[24]

Iohexol

Iohexol is popular in Europe and Australia.[25,26] Clearance of iohexol can be calculated after 3 hours with a single measurement for patients with normal renal function. The linear model is similar to that of inulin,[27] and iohexol clearance is an accurate marker of GFR[28] not affected by level of renal function or gender.[29] However, iohexol is generally not available in clinical practice because it is time-consuming and requires access to advanced assay methods.

Iohexol (MW 821 Da) is a low osmolar nonionic radiocontrast agent. Iohexol is usually given intravenously and can be measured by X-ray fluorescence, chemical detection of iodine,

or HPLC.[27] HPLC is more precise and more accurate.[30] A single measurement has been shown to be adequate for patients with GFR ranging from 4 to 139 mL/min/1.73m^2.[28,31] Iohexol has been studied in diabetics and is a reasonable marker for GFR in this population.[25] In a pediatric population, Iohexol was superior to several methods of estimating GFR, including serum creatinine-based equations and serum cystatin C.[32] In patients with gynecologic cancer, iohexol was equivalent to ^{51}Cr-EDTA and superior to creatinine for measuring GFR.[33]

Endogenous Clearance Markers

Serum Creatinine and Blood Urea Nitrogen

The two most commonly employed endogenous markers of kidney function are serum creatinine and blood urea nitrogen (BUN). A major advantage of endogenous markers of renal function is their safety, unlike potential contrast allergy or radiation exposure with certain other methods. However, there are numerous limitations to these markers.

Serum creatinine (MW 113 Da) is commonly used to assess kidney function, and it is incorporated into a variety of equations to estimate GFR. Serum creatinine is not protein-bound and is freely filtered. The production of serum creatinine depends on muscle mass, which is influenced by age, weight, and gender.[34] Serum creatinine is also influenced by diet and kidney filtration and secretion, which can result in a variation on a daily basis.[35] Creatinine is secreted in the proximal tubule, and its secretion can be inhibited by medications such as cimetidine, probenecid, and trimethoprim.[36] It is this tubular secretion that contributes to overestimation of GFR with serum creatinine. Because serum creatinine is not linearly related to GFR, its measurement alone is not recommended to assess kidney function accurately (i.e., GFR).

Blood urea (MW 60 Da) is a function of urea production, renal excretion, and breakdown by gut bacteria. Urea production depends on protein intake and breakdown, which, in turn, depends on diet, liver function, and kidney function. Urea is reabsorbed in the tubules. Other factors that influence BUN are diuretic use and sodium depletion.[37,38] Other issues to consider are reduced production of BUN and creatinine in the setting of liver disease and reduced muscle mass in the elderly or chronically ill; both patient types might still have chronic kidney disease despite normal appearing BUN and/or creatinine. Both examples illustrate that reliance on level of BUN or creatinine alone or together for estimation of kidney function may be misleading. The consequences include both misdiagnosis of kidney disease and potential harm from overdosing medications that are dependent upon renal excretion.

Creatinine Clearance: 24-Hour Urine Collection

Obtaining a 24-hour urine collection is a common method for measuring creatinine clearance. Typically, urine collection is started in the morning, following the first void, and continues all day and overnight, and ends with collection of the first void the following morning.[39] There may be errors in timing and collecting urine, both in the inpatient and outpatient setting. Properly collected urines can yield reasonably accurate estimates, but the method remains imprecise. This method lacks precision as a predictor of GFR.[34] Creatinine clearance overestimates GFR due to tubular secretion of creatinine. Fractional overestimation of GFR increases with more advanced CKD. Table 2–2 shows serum creatinine, 24-hour urine creatinine, and creatinine clearance for a series of hospitalized Scandinavian patients with serum creatinine in the normal range, categorized by age group and gender.[40] Note that men tend to have higher urinary creatinine and clearance compared to women, and with advancing age, urinary creatinine decreases as does clearance. These findings are likely a reflection of differences in body composition, that is, muscle mass. The accuracy and precision of creatinine clearance are highly dependent on patient compliance with urine collection procedures. That is, under-collection or over-collection of the sample markedly influences both accuracy and precision. In fact, the precision of serum creatinine based estimates of GFR are better than 24-hour urine creatinine clearance.[39]

Tubular secretion contributes to overestimation of GFR with serum creatinine; blockade of tubular secretion with cimetidine (1200 mg/day) improves accuracy of creatinine clearance such that it approaches inulin clearance.[34] However, this method requires careful timing of both cimetidine dosing and creatinine measurement.[36] Furthermore, with more advanced stages of CKD, there is more extra-renal breakdown of creatinine in the small bowel, leading to further imprecision of the assessment of kidney function, using urine collection methods.[9]

Creatinine clearance tends to overestimate GFR, whereas urea clearance tends to underestimate GFR. Taking advantage of this fact, the average of the creatinine clearance and urea clearance has been shown to correlate more closely with actual GFR in individuals with chronic kidney disease.[41,42]

Given the problems with 24-hour urine collection for estimation of creatinine clearance or GFR, the National Kidney Foundation has recommended estimating GFR or creatinine clearance from regression equations based on serum creatinine (see later text).

Creatinine Clearance During Water Loading

Creatinine clearance can also be measured during acute water loading. The protocol is similar to that used for renal clearance of inulin or iothalamate, except that endogenous creatinine in blood and urine is the marker for estimating GFR. This method is inexpensive because the creatinine assay is widely available, reproducible, and not costly. However, like other renal clearance techniques, it is time-consuming. It can be done concomitantly with iothalamate or inulin methods.[43]

Serum Cystatin C

Serum cystatin C (cysC) is an endogenous protein that was first proposed as a marker for GFR in 1985.[44] CysC (MW 13 kilodaltons [kD]) is a positively charged cysteine proteinase inhibitor that has a pH of 9.0. It is filtered freely and completely reabsorbed and catabolized in the proximal tubule, resulting in its complete elimination.[45] Even though it is a safe marker, factors limiting its current use include reduced access and higher cost of laboratory methods for measuring cysC as compared to SCr, which may make it a less attractive alternative for clinical use.

CysC shows great promise as a novel marker for GFR because it does not have the same limitations as serum

creatinine. CysC is produced constitutively at a constant rate in all nucleated cells, and, unlike creatinine, several studies have shown that it is not affected by muscle mass, gender, or diet. Furthermore, CysC is not altered by inflammatory states. Past the age of 50 years, and again past the age of 70 years, patients have an increase in serum cysC due to age-related decrease in GFR.[46,47] Another advantage of CysC is that it may be useful for detecting renal impairment in advance of elevation of serum creatinine.

The methodology for measuring cysC has improved. The initial method for detecting cysC was a radioimmunoassay, followed by fluorescent and enzymatic immunoassays. Newer studies are based on latex immunoassay, by particle-enhanced turbidimetric immunoassay (PETIA), and by particle-enhanced nephelometric immunoassay (PENIA). The newer studies have improved precision and speed compared to older studies. The nephelometric assay has improved precision compared to other techniques, and cysC values are similar for men and women as well as for African-Americans and whites.[48]

Although some studies have shown that cysC is superior to serum creatinine for assessing kidney function or estimating GFR, others have shown equivalence of the two markers. Some studies evaluated correlation between 1/cysC and a standard marker, whereas other studies evaluated the receiver operating characteristic (ROC) for cysC versus serum creatinine. Some of the studies that did not show a difference between the two did show a trend for superiority of cysC. Reasons for non-superiority of cysC may have been due to type II error secondary to small sample size,[49] the chosen reference standards for GFR, use of earlier methods of measuring cysC, and the use of different units for GFR (not including body surface area). Because of these points, a meta-analysis of studies comparing cysC and creatinine correlation coefficients (54 studies) and ROC (11 studies) was conducted,[50] which demonstrated that cysC was significantly better for both of these parameters (Table 2–4). This study also showed that nephelometric assays exhibited significantly higher correlation coefficients than other methods for measuring cysC.

Although prior studies have shown that cysC is related to GFR without the limitations of serum creatinine (it is unrelated to age, body mass, gender), a more recent cross-sectional study suggests otherwise. In this study of 8058 individuals (mostly Caucasian), factors that were related to cysC were determined through multivariate linear regression, after adjusting for creatinine clearance. The factors independently associated with higher cysC levels were older age, male gender, height, weight, current cigarette smoking, and higher serum C-reactive protein.[51] This study also found that although cysC was a better predictor of creatinine clearance by 24-hour urine, it was not a better predictor than serum creatinine when factors such as age, weight, and gender were also considered. This study demonstrates that further studies of cysC are needed and in more heterogeneous populations. Whether cysC is better than serum creatinine at detecting smaller and earlier changes in GFR remains controversial.[48]

Pediatric populations may benefit from GFR estimation using cysC, because cysC after the age of 1 year is comparable to adults. The assay for serum creatinine is less accurate because children have lower serum creatinine due to their lower muscle mass. In a review of five pediatric studies evaluating different parameters, two showed that cysC was significantly superior to serum creatinine, whereas the other three showed equivalence. Few children below the age of 4 were included in these studies, and it is hypothesized that this group would benefit the most from the use of cysC versus serum creatinine.[48]

Patients with cirrhosis of the liver also tend to have lower serum creatinine and lower muscle mass as well as increased tubular secretion of creatinine, making serum creatinine a problematic marker for GFR. In a study of 44 cirrhotics without evidence of renal disease (normal urinalysis and no proteinuria), patients with more advanced liver disease by Child-Pugh criteria had higher levels of cysC. There was correlation between 1/serum creatinine and 1/cysC. Only cysC correlated with GFR,

Table 2–4 Results of Meta-Analysis of Cystatin C Studies

Comparison	Parameter	1/Cystatin C	N	1/Serum Creatinine	N	p
Correlation coefficient	Mean r (95%CI)	0.816 (0.804, 0.826)	3703	0.742 (0.726, 0.758)	3101	<.001
		Cystatin C		**Serum Creatinine**		
ROC-plot AUC	Mean (95%CI)	0.926 (0.892, 0.960)	997	0.837 (0.796, 0.878)	997	<.001
		Nephelometric Assay		**Other Assays**		
Correlation coefficient	Mean r (95%CI)	0.846 (0.832–0.859)	1698	0.784 (95%CI, 0.766–0.801)	1953	<.001

This table shows three different comparisons related to studies of cystatin C. The first comparison shows correlation coefficients for the inverse of cystatin C (versus a variety of markers as reference standards, including serum creatinine) and the inverse of serum creatinine. The second comparison is between the receiver operating characteristic curves (ROC) that plot sensitivity by 1-specificity, measured as area under the curve (AUC) for cystatin C (versus reference standard such as inulin or other exogenous marker, and not serum creatinine) and for serum creatinine. The third comparison shows correlation coefficients for the nephelometric assay for cystatin C versus all other assays for cystatin C. There were too few studies in this meta-analysis to compare ROC plots of AUC for assays. (From Dharnidharka VR, Kwon C, Stevens G: Serum cystatin C is superior to serum creatinine as a marker of kidney function: A meta-analysis. Am J Kidney Dis 2002; 40[2]:221-226.)

and cysC had a higher sensitivity for detecting reduced GFR.[52] Further studies of cysC are needed in this population.

More studies are needed to determine the utility of cysC as a marker in chemotherapy patients. One study showed decreased GFR by cysC, however, a second methodology was not used for comparison.[53] Theoretically, certain malignancies may have elevated levels of cysC from cell death or tumor burden. One study has shown that tumor burden does not affect cysC levels.[54]

There have been numerous studies of cysC in the transplant population ranging from detecting the return of renal function in the immediate post-transplant period[55] to detecting graft failure. Although some studies have shown superiority of cysC, the results have been mixed, and most studies do not include a comparative gold standard. Several studies suggest that cysC underestimates GFR by 10% to 25% in renal transplant patients.[56,57] Elevated cysC levels could be due to assay interference by immunosuppressive drugs, backleak of cysC due to renal damage, increased protein binding, or increased cell turnover. The potential interaction between steroids and cysC has not been determined. Studies of asthmatic patients[58] and renal transplant patients treated with steroids have shown that treatment with steroids increases cysC,[59] whereas a study of patients with nephrotic syndrome treated with steroids did not show increased cysC.[60] On the other hand, cyclosporine has been shown to decrease cysC.[58]

Further studies are needed to evaluate the utility of using cysC as a marker for GFR in specific populations such as children, kidney transplant recipients, chemotherapy patients, and cirrhotics. It is certainly reasonable to follow patients over time with GFR determined by serum creatinine, given the higher cost of the cysC assay. However, in order to detect early disease, prior studies have shown that cysC is superior to serum creatinine as an endogenous marker for GFR.

FORMULAS FOR ESTIMATING GLOMERULAR FILTRATION RATE

In clinical practice and in research environments it is often impractical or impossible to truly measure GFR. Consequently, several mathematic models based on serum creatinine have been developed in order to estimate glomerular filtration rate. For this reason, various methods utilizing serum markers of renal function have been developed to provide indirect estimates of GFR without the inconvenience of time commitment and repeated collections of blood and urine. Two of the most commonly used equations are the Cockcroft-Gault equation and the Modification of Diet in Renal Disease (MDRD) equation. These two equations are recommended by the clinical practice guidelines in the National Kidney Foundation Kidney Disease Outcomes Quality Initiative Clinical Practice Guidelines for Chronic Kidney Disease for estimating GFR in adults.[1]

Cockcroft-Gault Equation

The Cockcroft-Gault equation was developed to estimate creatinine clearance and is subject to the same limitations as creatinine.[61]

$$\text{Creatinine clearance (mL/min)} = \frac{(140 - \text{age}) \times \text{Body weight (kg)}}{72 \times \text{serum creatinine (mg/dL)}}$$

For females, multiply by 0.85.

This formula has been evaluated in different patient populations (e.g., diabetics, critically ill patients) and has been shown to be accurate and more precise than creatinine clearance by 24-hour urine, especially between 20 to 100 mL/min.[34] An online calculator for GFR estimated by the Cockcroft-Gault equation is available through the NKF Web site: *http://www.kidney.org/professionals/kdoqi/gfr_page.cfm*, but this calculation is easily done on paper or with a standard hand-held calculator.

Modification of Diet in Renal Disease (MDRD) Equation

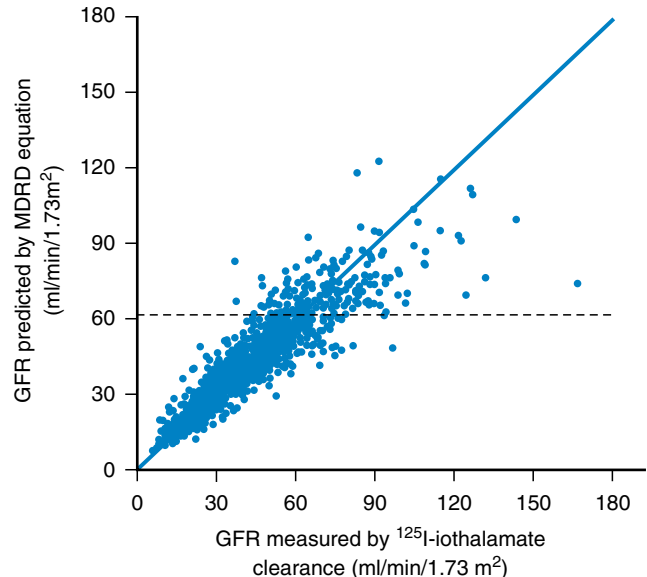
Levey and colleagues[62] developed a prediction equation for estimated GFR (eGFR) based on serum creatinine and demographic and serum variables obtained for the Modification of Diet in Renal Disease (MDRD) study. In the MDRD study, 1628 mostly nondiabetic patients had GFR measured by ^{125}I-iothalamate and estimates based on creatinine clearance and prediction equations. Serum creatinine and other measures at baseline were used to develop the final MDRD study prediction equation by a stepwise regression analysis that included independent predictors of GFR. The formula was developed initially in data from a subset of patients and then tested in the remainder of MDRD subjects. Figure 2–4 depicts the relationship between GFR predicted by MDRD and GFR measured by ^{125}I-iothalamate. Figure 2–5 shows the improved fit of MDRD versus other equations, compared to GFR.


Figure 2–4 Relationship between GFR predicted by MDRD equation and GFR measured by 125-I-iothalamate.[62] This graph shows the relationship between GFR as predicted by one of the MDRD equations (calculated from demographic and serum variables, no urine variables) and GFR as measured by inulin clearance. Each point shows the relationship at baseline in the study. The solid line is the line of identity.[62] There is a strong correlation between predicted and mean GFR. However, as seen here, there is considerable variability. For a predicted GFR of 60 mL/min/1.73 m², the measured GFR ranges from 40 to 95 mL/min/1.73 m², as shown by the dashed line.
Figure 2–5 MDRD predicted and measured GFR by different prediction equations.[62] The R^2 values show percentage of variance of the log of GFR accounted for in the MDRD validation sample (n= 558) by equations derived from the training sample (n= 1070). The values of 1 to R^2 indicate the percentage of variance in log GFR that is unexplained by each equation. Note that this value is decreased by 50% from $100/P_{cr}$ to the multiple regression models. Although the multiple regression model that includes urine measurements has the closest values to measured GFR, this model does not add much to the multiple regression model that does not include urine measurements. C_{cr}, creatinine clearance; C_{urea}, urea clearance; P_{cr}, serum creatinine concentration.

The four variable MDRD equation includes age, race, gender, and serum creatinine,[62] as shown here:

$$\text{GFR (mL/min/1.73 m}^2) = 186 \times (\text{serum creatinine}^{(-1.154)}) \times (\text{age}^{(-0.203)})$$

For females, multiply by 0.742.
For African-Americans, multiply by 1.21.

This formula is not one that can be calculated easily by hand at the bedside like the Cockcroft-Gault equation. Rather, a calculator or personal digital assistant may be used at the bedside to determine GFR from the MDRD equation. An estimated GFR calculator for adults based on MDRD is available at the NKF Web site: *http://www.kidney.org/professionals/kdoqi/gfr_page.cfm.*

The MDRD formula is not without limitations, however. It has not been validated in specific populations such as children, the elderly, diabetics, and patients with liver disease. Only 12% of MDRD enrollees were African-American.[62] This equation, like others, is modeled after a steady-state model.

Therefore, these equations should not be applied to patients with changing kidney function. Given the impact of dietary intake on creatinine, a fasting creatinine is preferred. The MDRD equation can overestimate and underestimate true GFR. Most importantly, the MDRD equation has not been validated in a prospective study directly comparing it to a renal clearance marker. In the African-American Study of Kidney Disease and Hypertension (AASK) study ad hoc analysis, overall estimated GFR (MDRD equation) and measured GFR (iothalamate clearance) provided similar results in terms of the outcome of rate of decline in GFR. However, there were subtle differences in some of the other GFR based outcomes. These findings suggest that additional prospective studies are needed to provide further validation of the MDRD equation.[63] At this time, the MDRD equation is widely used to estimate glomerular filtration rate and to stage chronic kidney disease. In the future, better estimation equations using serum creatinine and other factors known to influence kidney function should be developed. This is an important priority of ongoing research in this field.

Children

The Schwartz and Counahan-Barratt formulas are the two most convenient and practical formulas for estimating GFR in children.[64] The Counahan-Barratt formula is as follows[65]:

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 0.43 \times \text{Height (cm)} \div \text{serum creatinine (mg/dL)}$$

The Schwartz formula estimates creatinine clearance as follows[66-68]:

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 0.55 \times \text{Height (cm)} \div \text{serum creatinine (mg/dL)}$$

For children younger than 1 year of age, the constant is 0.45, and for adolescent boys, the constant is 0.7. Pediatric GFR calculators are available at the NKF Web site: *http://www.kidney.org/professionals/kdoqi/gfr_page.cfm.*

CONCLUSION

GFR is the preferred method for assessing kidney function and staging CKD for the purpose of diagnosis, prognosis, and management. There are several methods for measuring and estimating GFR. Each method has particular strengths, weaknesses, and limitations. Inulin clearance remains the gold standard. For clinical purposes, creatinine and cysC are good markers for measuring GFR. For clinical management, serum creatinine-based estimates of GFR, including the Cockcroft-Gault and MDRD equations, are the preferred methods. For research purposes, inulin and iothalamate clearances are accurate, reliable, and reproducible measures of GFR. Although cysC appears to be a promising new endogenous marker for measuring GFR, further studies are needed.

Diabetic Kidney Disease

Mark E. Williams, M.D., F.A.C.P. • Robert C. Stanton, M.D.

According to the annual health report from the U.S. Department of Health and Human Services, the epidemic of diabetes mellitus in the United States continues to get worse. The percentage of Americans diagnosed with diabetes increased 27% between 1997 and 2000, and the percentage of Americans diagnosed with diabetes in 2002 rose to 6.5%, up from 5.1% in 1997.[1] The number of Americans diagnosed with diabetes mellitus has increased 61% over the last decade and will more than double by 2010. The incidence of diabetic nephropathy has more than doubled in the past decade,[2] due largely to increasing prevalence of type II diabetes.[3] Diabetic nephropathy now accounts for nearly 45% of new cases of end-stage renal disease (ESRD) in the United States,[4,5] with hypertension and glomerulonephritis being the second and third most common causes, respectively. The percentage of new cases of ESRD due to diabetes has been rising steadily for 25 years and is expected to continue to rise, largely contributing to the expected doubling of the number of patients with ESRD in the United States. This is considered to be due to the epidemic of type II diabetes that is occurring in the United States and throughout the world. Between 1992 and 2001, the size of the Medicare chronic kidney disease (CKD) population increased by 53%[5] (Figure 3–1). Results from the NHANES III study, published in 2002, documented that one third of diabetics demonstrated either microalbuminuria (MA) or macroalbuminuria.[6]

Proteinuria and progressive loss of kidney function are the clinical hallmarks of diabetic CKD. In the natural history of the disease.[7] Proteinuria is preceded by stages of excessive glomerular filtration and of microalbuminuria, which signals an increased risk of progression to overt nephropathy. A progressive increase in proteinuria subsequently leads to a variable decline in renal function. Proteinuria signifies evidence of glomerular damage and may be viewed as a measure of the severity of diabetic glomerulopathy. Early clinical reports noted nephrotic syndrome in 87% of type I and 70% of type II diabetic patients, and end-stage renal failure in up to 75% of diabetic patients within 15 years of developing proteinuria.[4] Factors that cause progression of kidney disease continue to be actively investigated and include glomerular hypertension and hypertrophy, activation of coagulation pathways, biochemical damage from hyperglycemia, and lipid deposition.

Two decades of progress in retarding the progression of renal disease were recently reviewed.[8] Until the mid-1970s, it was generally accepted that no treatment could slow the progression of diabetic nephropathy.[9] There is current agreement that the course of diabetic nephropathy can be impacted when interventions are implemented at the earliest possible time.[10] Current challenges in the management of the diabetic patient at risk for chronic kidney disease include nephropathy screening, early interventions to delay progression, and modification

of disease comorbidities[11] (Figure 3–2). Later in the course, priorities become prevention of complications of uremia and preparation for renal replacement therapy. Diabetes is a chronic illness and diabetes care is complex.[4] This chapter reports on the complexity of diabetic nephropathy, its clinical hallmarks, proteinuria and loss of kidney function, and its primary therapy, renin-angiotensin blockade. It details the current approaches to management and describes potential new treatment strategies under current investigation.[12]

EPIDEMIOLOGY AND GENETICS

It is generally accepted that 25% to 40% of patients with either type I or type II diabetes will develop diabetic nephropathy.[13–16] There are certain subgroups that have a higher incidence and prevalence of diabetic nephropathy. Young and colleagues[17] showed that in the United States, African-Americans, Hispanics, Asians, and Native Americans all have a higher likelihood of developing diabetic nephropathy as compared to Caucasians, even when correcting for socioeconomic status, age, and gender. There may even be gender differences within racial groups. Crook and colleagues[18] reported a twofold increase in ESRD in African-American women as compared to African-American men.

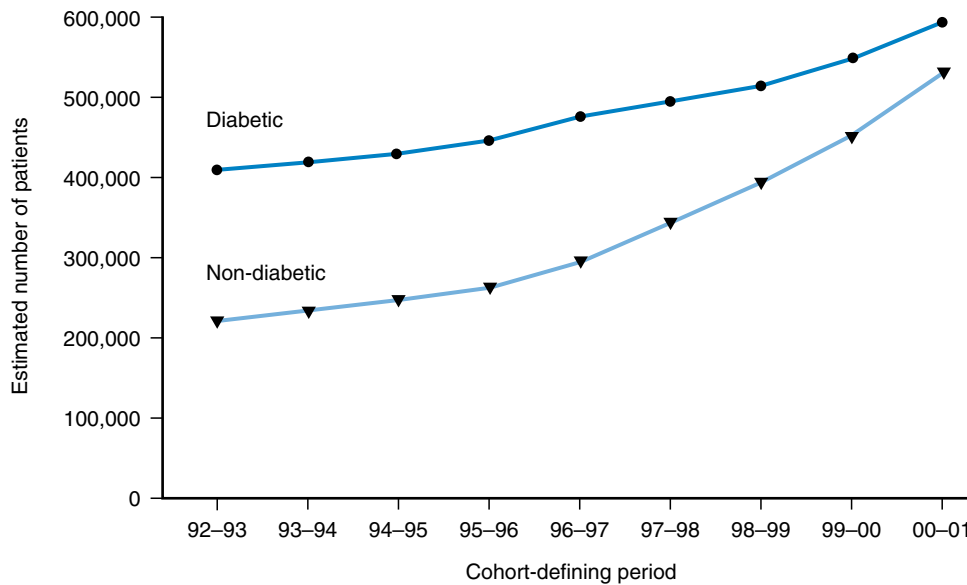
The typical initial manifestation of diabetic nephropathy is detection of urinary albumin above normal levels (microalbuminuria, 30–300 mg/24 hr). It had been thought that microalbuminuria was present in 100% of the cases of diabetic nephropathy, but recent studies show that the initial pattern of expression is changing, with patients presenting with increased creatinine and normoalbuminuria.[14] This changing pattern might be due to changes in therapy, as over the past 10 years there has been increasing recognition of the importance of achieving tight control of blood sugar[19] and of maintaining ever lower targets for optimal blood pressure.[20] Importantly, not all patients who develop microalbuminuria will progress.[14] Caramori and colleagues[14,21,22] reviewed this a few years ago, noting that the prior estimate that 80% or more of patients with microalbuminuria will progress to proteinuria, and ever worsening renal function is contradicted by a number of studies, suggesting that only 30% to 40% will progress. This is still a highly significant number of patients and, as discussed later, comprise an ever growing proportion of the ESRD population.[23] Cases of diabetic nephropathy are typically not seen before 5 years of diabetes in type I patients, and the incidence then rises over the ensuing 10 years. This suggests that a relatively long exposure to the pathophysiologic processes associated with diabetic complications is required to cause kidney damage. In contrast, patients with type II diabetes might have diabetic nephropathy at the time of diagnosis, but true duration of diabetes in type II patients


Figure 3–1 Trends in the size of the Medicare chronic kidney disease population, by diabetic status, from 1992 to 2001. Estimated from patients enrolled in any 2 consecutive calendar years. (From U.S. Renal Data System: USRDS 2003 annual data report. Bethesda, MD, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2003.)
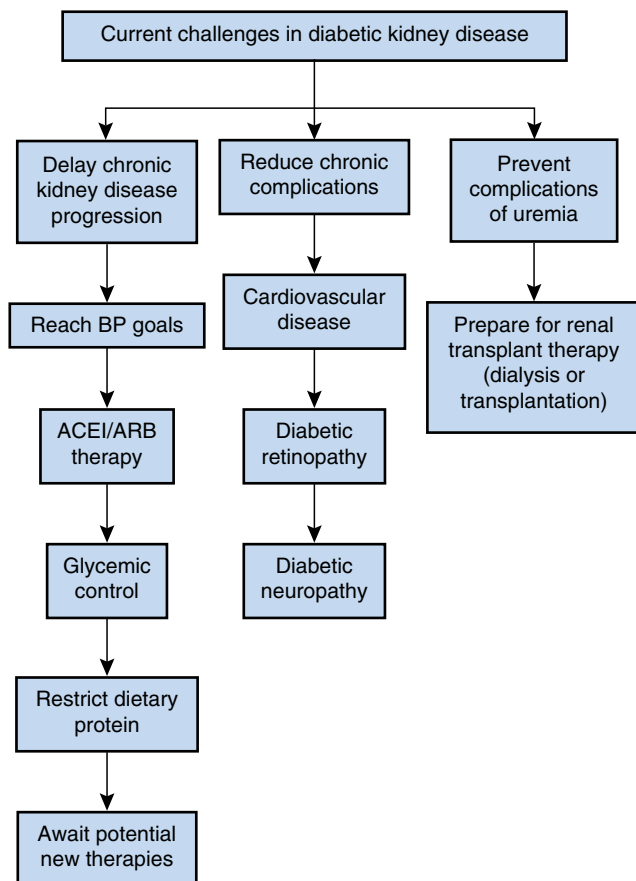

Figure 3–2 Current challenges in management of diabetic kidney disease.

is unknown in most cases. There may also be changing patterns of the incidence and prevalence of diabetic nephropathy. Bojestig and colleagues[15] reported that patients who developed diabetes between 1961 and 1965 had a cumulative incidence for diabetic nephropathy of 28%, whereas those who developed diabetes between 1971 and 1975 had a cumulative incidence of only 5.8%. Hovind and colleagues[24] recently reported similar findings for diabetic nephropathy and diabetic retinopathy. Although no specific reasons are given for these changes, one might surmise that improved blood sugar and blood pressure control might play a significant role.

In addition to treatment effects, there may be a genetic predisposition to develop diabetic nephropathy. Genetic determinants and their impact on the initiation and progression of diabetic nephropathy continue to be actively investigated.[25] Several observational studies have suggested that the ACE genotype may influence progression of diabetic nephropathy. The D allele of the insertion (I)/deletion (D) polymorphism of the ACE gene (ACE/ID) is strongly associated with progressive loss of kidney function.[26] In a recent study of type I diabetic nephropathy patients, the D allele of the ACE ID polymorphism was associated with accelerated progression of nephropathy.[27] Analysis of the clinical course of 168 proteinuric type II patients for 10 years revealed that almost all patients with the DD genotype progressed to end-stage renal disease (ESRD) within 10 years.[28] ACE gene polymorphism is associated with increased progression even during ACE inhibitor therapy[29]; however, a recent report showed protection from progression of diabetic nephropathy in type I patients with ACE II and DD genotypes treated with losartan.[30]

Although there are suggestive studies for a genetic association, no definitive answer is forthcoming. For example, a report from the Pittsburgh epidemiology of diabetes complications study[31] evaluated the relationship of genetic associations with apolipoprotein E, ACE I/D, and lipoprotein lipase *Hind*III

polymorphisms with overt diabetic nephropathy (defined as >200 µg/min, which is equivalent to >300 mg/24 hours of albumin excretion in the urine). Only in specific subgroups were there positive predictive values for these genes. In fact, insulin resistance, hypertension, and lipid abnormalities were much stronger predictors. However, there is strong evidence that specific genes are involved in the development and progression of diabetic nephropathy.

A national effort to address the genetics of kidney disease in diabetes has been launched as a joint endeavor of the Juvenile Diabetes Research Foundation, the Centers for Disease Control and Prevention, the George Washington University, and the Joslin Diabetes Center. The Genetics of Kidneys in Diabetes (GoKinD) Study was initiated in order to develop a repository of DNA and clinical information on patients with type I diabetes and diabetic nephropathy (see http://www.gokind.org). "The fundamental aim of GoKinD is to provide a resource to facilitate investigator-initiated research into the genetic basis of diabetic nephropathy. Decisions regarding the genes and chromosomal regions to be studied will be made by individual investigators and subject to a competitive review process." The goal is to recruit 2200 patients with type I diabetes in order to identify genes that may play a role in the development of the diabetic nephropathy. The specific aims of the study are to evaluate genes from: (1) Case trios: 600 type I diabetic patients with diabetes duration at least 10 years and clinically diagnosed diabetic nephropathy together with their parents; (2) Cases: 500 type I diabetic patients with diabetes duration at least 10 years and clinically diagnosed diabetic nephropathy for whom parents are not available; (3) Control trios: 500 type I diabetic patients with normoalbuminuria and diabetes duration at least 15 years together with their parents; and (4) Controls: 500 type I diabetic patients with normoalbuminuria and diabetes duration at least 15 years for whom parents are not available. Recruitment ended on June 30, 2004. This database will hopefully provide researchers with the necessary information in order to identify genes involved in the pathogenesis of diabetic nephropathy.

NATURAL HISTORY

The earliest known manifestation of diabetic nephropathy is the presence of microalbuminuria. Protein excretion in the urine is normally less than 100 to 200 mg/24 hours, and urinary albumin excretion is normally less than 30 mg/24 hours. Excretion of more than 30 mg/24 hours (microalbuminuria) is abnormal but may be transient due to such circumstances as exercise, pregnancy, and medications. If persistent, it may reflect the presence of kidney damage. Many studies have shown that the presence of microalbuminuria is a very significant risk factor for progression of kidney disease and for the development and progression of cardiovascular disease.[32–35] Indeed, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII) hypertension treatment guidelines from the National Institutes of Health (NIH) lists the presence of microalbuminuria (the range is >30 mg/24 hr) as a major risk factor for cardiovascular disease.[36] Persistent microalbuminuria in a diabetic patient generally signifies the presence of diabetic nephropathy; as noted earlier, between 30% to 40% and up to 80% of patients

with microalbuminuria will progress to overt proteinuria.[14] Although albumin excretion rate is currently considered the principal predictor for progression of diabetic nephropathy, this is not applicable to individuals presenting with increased creatinine and normoalbuminuria and may not be applicable even to patients with microalbuminuria in the era of tighter glycemic and blood pressure control and wide spread use of angiotensin converting enzyme inhibition. A recent study by Perkins and colleagues[37] showed that in type I diabetic patients, there was as much as a 50% chance for regression of microalbuminuria to normal levels, which was correlated with blood pressure and lipid control but not the use of angiotensin converting enzyme inhibitors.

Both type I and II diabetic patients with microalbuminuria are at risk for progression to overt nephropathy. Without specific treatment, up to 80% of patients with type I DM and 25% to 40% of patients with type II DM with sustained MA will eventually develop overt nephropathy.[34] A recent prospective study in Italy indicated that 4% of type II diabetic patients with MA progressed to overt nephropathy every year.[39]

First observed in diabetic patients over a century ago, clinical proteinuria was described in a pathologic report of diabetic glomerulosclerosis by Kimmelstiel and Wilson[40] in 1936. The natural sequence of proteinuria followed by loss of kidney function was not described until decades later. The natural history of diabetic nephropathy, including changes in glomerular filtration and proteinuria and stages of preventive treatment, is shown in Figure 3–3. The average time to proteinuria from the diagnosis of diabetes in type I patients is 19 years; the interval is shorter but variable in type II patients. Several definitions of persistent proteinuria in diabetes are now in use (Table 3–1), and they refer to albuminuria as well as to increased total urinary protein excretion.[41] Yearly increases in protein excretion average about 20% but with wide standard deviations. Untreated, up to 75% of proteinuric type I and type II patients may become nephritic.[42] Progressive loss of kidney function occurs over several years without intervention in type I patients. The overall sequence is similar in type II patients[4,43] (Figure 3–4), but the exact onset of diabetes may be uncertain, pathology not related to or atypical for diabetic nephropathy may exist, and the decline in function may be more variable. In its most advanced stages, diabetic glomerular proteinuria becomes less selective, with a significant leak of large proteins, such as albumin and IgG, and with tubular proteinuria.

Although all ESRD patients have significantly greater morbidity and mortality compared to the general population, patients who also have diabetes have an even greater likelihood of concurrent conditions, such as peripheral vascular disease, neuropathy, and progressive cardiovascular disease. These conditions may greatly affect lifestyle and shorten life spans.

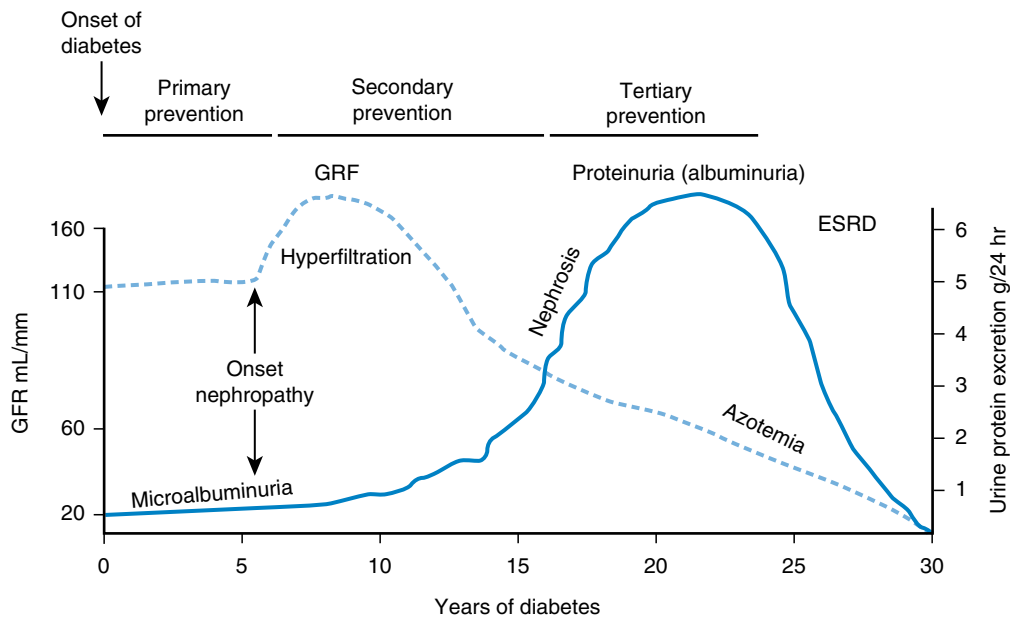
Cardiovascular disease frequently confounds the natural history of diabetic kidney disease, and, as recently reviewed, the renin-angiotensin system (RAS) appears to have an important role in the pathophysiology of both diabetic renal and cardiovascular disease. It is, thus, not surprising that kidney disease is an independent risk factor for cardiovascular disease.[45] Microalbuminuria, even without elevated serum creatinine, has been shown to be associated with an increased risk of cardiovascular events, including stroke, myocardial infarction, and mortality[46,47] in both diabetic and nondiabetic individuals.


Figure 3–3 The natural history of diabetic kidney disease. Changes in glomerular filtration rate (GFR) and microalbuminuria/proteinuria are shown. Progressive loss of kidney function occurs over years, without successful intervention. Following the onset of diabetes in susceptible individuals, treatment of diabetic nephropathy may be primary (reduce the development of microalbuminuria), secondary (prevent the transition to overt nephropathy), or tertiary (slow the progression of established nephropathy to ESRD).

Table 3–1 Definitions of Abnormalities in Urinary Albumin and Protein Excretion

|	Laboratory Test	MA	Albuminuria or Proteinuria
Urine albumin	Spot albumin/ creatinine ratio	17–250 mcg albumin/mg creatinine (males) 25–355 mcg albumin/mg creatinine (females)	> 250 mcg albumin/mg creatinine (males) > 355 mcg albumin/mg creatinine (females)
	24-hour collection	30–300 mg/24 hr	> 300 mg/24 hr
Urine total protein	Spot protein/creatinine ratio	?	> 0.20 mg protein/mg creatinine
	24-hour collection	?	> 300 mg/24 hr

Given the similarities between the renal and systemic vasculature, elevated urinary albumin excretion is felt to reflect damage to both the glomerulus and blood vessels. Clinically, MA is associated with a variety of cardiovascular risk factors, including hypertension, insulin resistance, atherogenic dyslipidemia, and obesity. The Framingham Heart Study first demonstrated that relevance of proteinuria to cardiovascular prognosis.[48] A recent study of type II diabetes confirmed the higher mortality associated with proteinuria.[49] Over a 5-year period, there was a fivefold excess risk for cardiovascular mortality for nephropathic patients (37%) compared to patients without nephropathy (8%), which was independent of other risk factors, including creatinine, age, and glycemic control. The risk of cardiovascular disease associated with diabetic kidney disease was also demonstrated in a recent observational study of 3608 patients enrolled in a multivessel coronary artery disease registry.[50] Among patients without diabetes, mortality at 7 years was 12% among patients without chronic kidney disease and 39% among patients with chronic kidney disease (serum creatinine >1.5 mg/dL) (Figure 3–5). Among diabetic patients without chronic kidney disease, mortality was only slightly higher than for nondiabetic patients

with kidney disease. However, when both diabetes and chronic kidney disease were present, the mortality risk was additive (70%) during the 7-year observation period.[50]

Given this information, efforts to reduce cardiovascular risk are as equally, if not more, imperative as efforts to reduce progression of kidney disease?fortunately, there is a large overlap in the recommended interventions. For diabetic nephropathy, treatment may be primary (reduce the development of MA), secondary (prevent the transition to overt nephropathy), or tertiary (slow the progression of established nephropathy to ESRD)[51] (Figure 3–3).

MECHANISM

Diabetic proteinuria reflects glomerular damage and increased glomerular permeability to macromolecules, although the exact molecular mechanisms are still being defined. In general, protein permeability across the filtration barrier is affected by the hemodynamic pressure gradient across the glomerular basement membrane and separate factors involving the filtration barrier itself, including the pore size and extent of anion
Figure 3–4 Proteinuria and progression to end-stage renal disease in diabetic nephropathy in type I and type II diabetic patients. Similar rates of proteinuria and time of progression from onset of proteinuria to kidney failure may occur in both types of diabetes. (From Ritz E, Orth SO: Nephropathy in patients with type 2 diabetes mellitus. N Engl J Med 1999; 341:1127-1133.)

charges. In diabetic nephropathy, both hemodynamic and intrinsic basement membrane factors contribute to proteinuria.[2] For example, angiotensin II combines hemodynamic actions such as induction of systemic vasoconstriction, increased glomerular arteriolar resistance, and increase in glomerular capillary pressure, with nonhemodynamic actions such as increased glomerular capillary permeability, reduction in filtration surface area, enhancement of extracellular matrix proteins, and stimulation of renal proliferation and fibrogenic chemokines, including monocyte chemoattractant protein-1 and transforming growth factor-B. The role of these factors in chronic kidney disease progression was recently reviewed.[52]

Although some pathologic changes characteristic of diabetic glomerulosclerosis, such as increased basement membrane width and mesangial expansion (Figures 3–6*A* and *B*), are known to precede the development of diabetic proteinuria, other changes such as mesangial and interstitial expansion correlate with the degree of albuminuria. The structural basis for the protein passage resides either in the glomerular basement membrane or in the nearby epithelial cell layer. Two adjacent molecular filters are felt to control glomerular permselectivity: the basement membrane itself and the slit diaphragm (Figure 3–6*C*). The glomerular basement membrane in humans is a complex tripartite structure of endothelial cells with fenestrations, dense basement membrane fibrils, and the outer visceral podocyte cells. The slit diaphragm arises between the interdigitating foot processes of the podocytes.

Glomerular hypertension, favorable in the short term, creates detrimental long-term nonhemodynamic consequences. According to a dominant theory of diabetic nephropathy based on animal models, glomerular hemodynamic forces lead to upregulation of fibrotic and inflammatory processes, resulting in structural damage.[53] The progression from normoalbuminuria to overt proteinuria in diabetes correlated in one study with a reduction in size and charge selectivity of the filtration barrier[54] and in other studies with a reduction in slit-pore density. More recent investigation has emphasized the role of extracellular matrix proteins[55] and glomerular podocyte injury and loss, and increased foot process width, which are prominent ultrastructural abnormalities in nephropathy in type I and type II diabetes.[56–58] Several mechanisms of podocyte loss have been speculated, including modulation of nephrin expression,[59] a transmembrane protein

gene product localized to the area of and integral to the formation of the zipper-like slit diaphragm filtration structure between foot processes. There appear to be decreased protein levels of nephrin and podocin, despite an increase in their glomerular mRNA levels in several acquired human diseases, including diabetic nephropathy.[60] Some human data suggest a downregulation of nephrin expression in both type I and type II diabetic nephropathy,[61,62] which may be inversely related to the amount of proteinuria.[63] Podocin mutations have also been described in a variety of proteinuric conditions.[64] Other postulated factors in the pathogenesis of diabetic nephropathy

factors include inflammation[65] and defective tubular albumin retrieval.[66]

A variety of experimental models and human kidney diseases have now indicated that proteinuria should be accepted as an independent and modifiable risk factor for renal disease,[67] and other studies have linked proteinuria to risk of ESRD,[68] in both diabetic and nondiabetic kidney disease. Although there is inherent intra-individual variability in urinary excretion of total protein or albumin, with a a standard deviation of up to 50%,[69] heavy proteinuria doubled the risk of progression in the Collaborative Study Group trial of

Captopril in type I diabetes[70] and may contribute to mortality risk.[71] Of two more recent well-known studies in type II patients, the IDNT (Irbesartan Diabetic Nephropathy Trial)[72] and RENAAL (Reducton of Endpoints in Non-insulin-dependent Diabetes Mellitus with the Angiotensin II Antagonist Losartan),[73] proteinuria was a prospective outcome measure only in the latter. Although no relationship of baseline proteinuria to renal outcomes was included in the original report, subsequent analysis reported proteinuria to be the most important predictor of ESRD.[74,75] For the IDNT, unpublished data revealed an increased risk of progression when baseline proteinuria equaled 3 to 4 g/24 hr.[76]

Although there is no proof of concept from clinical interventional trials that specific titration against the level of proteinuria improves the efficacy of renoprotective therapy, many consider the ultimate goal of proteinuria remission (<1 g/day) to be valid.[8] Targeting proteinuria reduction in patients with established diabetic nephropathy in order to accomplish slowing of renal progression is generally accomplished with agents that reduce both blood pressure and proteinuria. Data are very limited on therapies that might reduce proteinuria through other primary mechanisms, without correcting hypertension.

Diabetic nephropathy is an ideal disease model for testing the use of proteinuria as a surrogate end point.[77] Because early intervention is critical in diabetic nephropathy, a surrogate marker would be valuable.[78] However, disadvantages include the intraindividual variability in proteinuria, uncertainty regarding meaningful reduction in proteinuria, and the dearth of drugs with specific antiproteinuric effects. The relationship of proteinuria to the course of diabetic nephropathy is complex, and strict interpretation of available data does not readily lead to a specific goal for proteinuria reduction.

TREATMENT

Detection of Nephropathy

The presence of microalbuminuria in diabetic patients is considered indicative of nephropathy. Since it cannot be predicted who is going to develop nephropathy, widespread screening is recommended:

1. All diabetic patients should be tested yearly by examining urine for albumin starting immediately for patients with type II diabetes and after 3 to 5 years for patients with type I diabetes. Although 24-hour urine collections are ideal, the albumin/creatinine (a/c) ratio in a spot urine sample has been shown to accurately reflect the 24-hour urine collection,[38] thus is currently the recommended test for both screening and monitoring.
2. Considering the importance of early, aggressive treatment, tight control of blood sugar and blood pressure, and use of either ACE inhibitors or angiotensin receptor blockers should be undertaken in all patients with persistent microalbuminuria.

BLOOD SUGAR CONTROL

Many studies have demonstrated the critical importance in tight control of blood sugar in order to prevent the development or slow the progression of diabetic nephropathy.[79–82] The importance of tight control was definitively shown for patients with type I diabetes in the Diabetes Complications and Control Trial (DCCT).[79] In the initial study, 1441 patients with type I diabetes mellitus were studied for a mean of 6.5 years. One group received conventional treatment (mean glycosylated hemoglobin [Hgb A1c] 9.1), and another was treated intensively (Hgb A1c 7.2). With intensive therapy, there was a 39% reduction in microalbuminuria and 54% reduction in progression from microalbuminuria to overt proteinuria (defined as >300 mg/24 hours), compared to conventional therapy. Critical follow-up studies have continued to show the benefit of tight control of blood glucose in patients with type I diabetes. At the end of the DCCT, the patients in the conventional-therapy group were offered intensive therapy, and the care of all patients was transferred to their own physicians. Nephropathy was evaluated on the basis of urine specimens obtained from 1302 patients during the 3rd or 4th year after the end of the original DCCT study, approximately half from each treatment group. The median Hgb A1c values of the conventional-therapy group were 8.2%, and the intensive-therapy group's were 7.9%. Nevertheless, new cases of microalbuminuria were detected in 11% of 573 patients in the former conventional-therapy group, compared with 5% of 601 patients in the former intensive-therapy group, representing a 53% odds reduction. This longer follow-up demonstrates the importance of early aggressive management of blood sugar. It is quite common for blood glucose control to worsen over years of diabetes mellitus therapy, likely related to a combination of decreasing effectiveness of insulin due to multiple factors (e.g., changing metabolic requirements, resistance to effects of injected insulin), difficulty in maintaining the strict intensive regimen, age of the patient, genetic factors, and other as yet unanticipated factors. But even with worsening in the Hgb A1c, there were still benefits from keeping the blood sugar as tightly controlled as possible. The DCCT study organization recently reported on an 8-year follow-up study[83] (EDIC). As in the 4-year follow-up study, there was a narrowing of the difference between the Hgb A1c values of the original intensive therapy group (Hgb A1c 8.0%) and the conventional therapy group (Hgb A1c 8.2%), yet there was still a 57% risk reduction for the development of microalbuminuria in the original intensive therapy group as compared to the conventional therapy group. The risk reduction for progression to overt proteinuria from microalbuminuria was a remarkable 84% for intensive therapy compared to conventional therapy.

Patients with type II diabetes also benefit from tight control of blood sugar, as demonstrated in the United Kingdom Prospective Diabetes Study (UKPDS).[82] In this very large study of 3867 individuals with type II diabetes, the conventional therapy group averaged a Hgb A1c of 7.9%, whereas the intensively treated group had a Hgb A1c 7.0%. Intensive treatment was associated with a 33% risk reduction for developing microalbuminuria, and a 42% risk reduction for progression of microalbuminuria to proteinuria over 15 years. In addition, the risk reduction for doubling of serum creatinine was 67%. These results from both the DCCT and the UKPDS strongly support early and aggressive management of blood sugar as a highly effective approach for slowing the development and progression of diabetic kidney disease. The American Diabetes Association's official position is that

the blood sugar treatment goal for all patients with diabetes should be a Hgb A1c of less than 7% in order to reduce the risk of diabetic nephropathy.[84]

HYPERTENSION

In the United States alone, at least 11 million diabetic patients (or 60% of all diabetics) are afflicted with hypertension. It has been emphasized that the risks of elevated blood pressures are greater for the diabetic than for the nondiabetic population.[85] Both systolic and diastolic hypertension accelerate the progression of microvascular complications such as nephropathy[10,86] as well as cardiovascular complications of diabetes, and even high normal blood pressure levels place patients in a high-risk category.[87] However, the majority of diagnosed hypertensives are inadequately controlled.[88] Overall, the prevalence of hypertension in the diabetic population is at least double that in the nondiabetic population (Table 3–2). The causes are complex and likely multifactorial (Figure 3–7).

Although hypertension is a typical manifestation of kidney disease, for 2 decades it has also been recognized as an early abnormality of nephropathy,[89] and hypertension may also be associated with the insulin resistance syndrome. In addition to genetics, several other factors contribute to hypertension in diabetic patients.[90] Intensive insulin treatment with near normal glycemia reduces the incidence of hypertension, an effect shown by the DCCT to be sustained for years after intensive treatment has stopped.[83] In general, hypertension in both type I and type II diabetes is characterized by expanded plasma volume, increased peripheral vascular resistance, and suppressed plasma renin activity. Systolic hypertension has been

Table 3–2   Prevalence of Hypertension in Diabetes Mellitus

Diabetes Type	Stage	Prevalence
1	No proteinuria	44%
	Proteinuria	67%
	Elevated serum creatinine	92%
2	No proteinuria	70%
	Proteinuria	83%
	Elevated serum creatinine	100%

(From Ritz E, et al: Hypertension and vascular disease as complications of diabetes. *In* Laragh JH, Brenner BM [eds]: Hypertension: Pathophysiology, Diagnosis, and Management. New York, Raven Press, 1990.)

attributed to loss of elastic compliance in atherosclerotic large vessels.[10] In patients with type I diabetes, a rise in systemic blood pressure may precede the presence of kidney impairment, becoming manifest about the time the patient develops MA or even prior to a rise in urinary albumin excretion.[91] Microalbuminuria and its progression to overt nephropathy are associated with further increases in blood pressure.[92] In type II diabetes, overt hypertension or more subtle circadian blood pressure abnormalities are frequently present prior to proteinuria, so many patients with microalbuminuria are hypertensive.[93] In fact, hypertension is present at the time of diagnosis of type II diabetes in about one-third of patients.[10]

An association between the level of blood pressure and the clinical hallmarks of diabetic nephropathy, that is, degree of albuminuria[94] and chronic kidney disease progression, has been known for many years. In the last 2 decades, both observational and interventional studies have revealed that hypertension

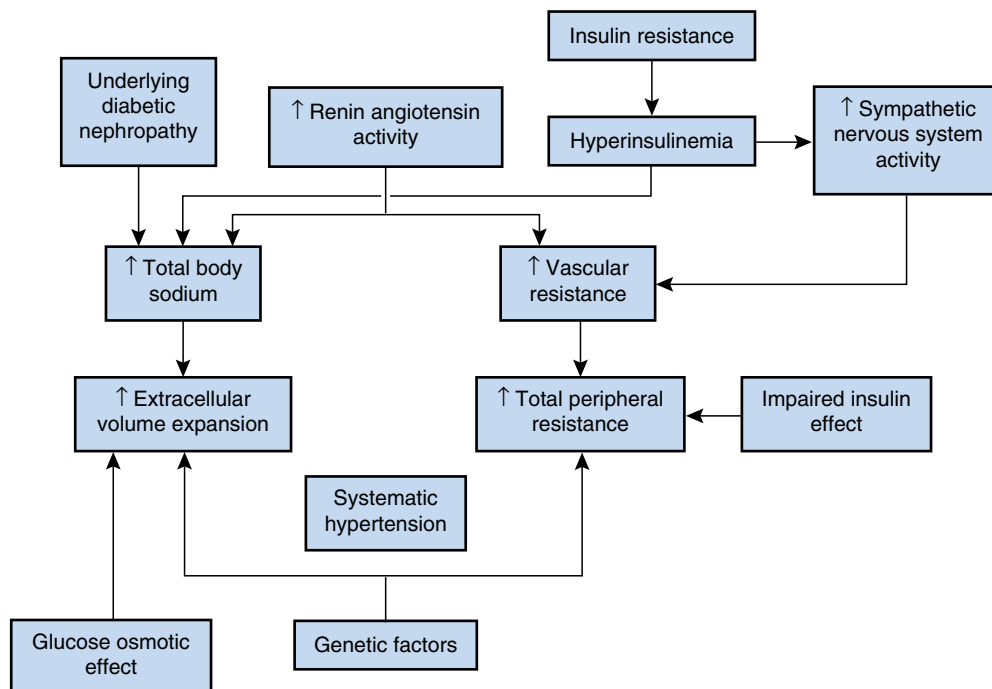

Figure 3–7 Mechanism of hypertension in diabetic kidney disease.

accelerates loss of renal function in both type I and type II patients.[95] In a recent study, each 10 mmHg increase in blood pressure was associated with about 1 cc/minute greater loss in glomerular filtration rate per year.[96] Although both systolic and diastolic blood pressures are associated with albuminuria in diabetes,[97] baseline systolic blood pressure was recently shown to be a stronger predictor of nephropathy than diastolic pressure in the RENAAL study of type II diabetics.[98]

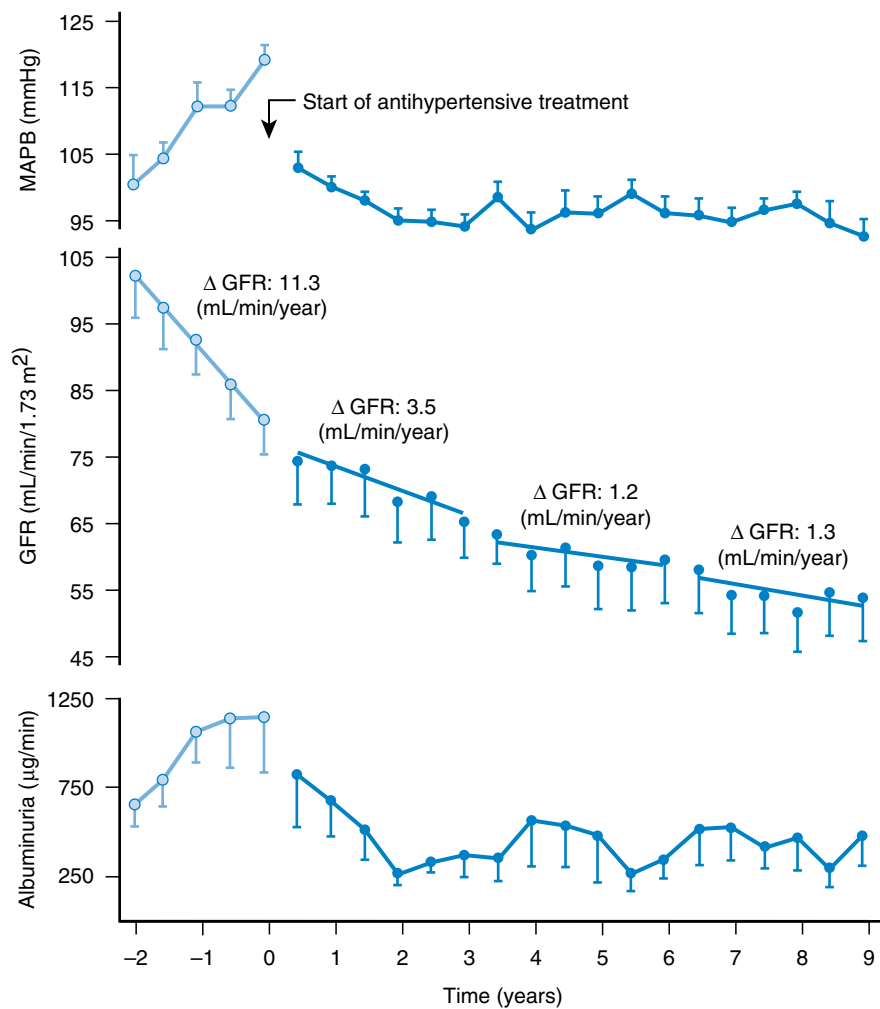
Reports initially establishing the benefit of aggressive blood pressure control on slowing the decline in glomerular filtration rate did not emphasize that rising proteinuria was reversed and then reduced to less than 50% of the pretreatment value[99] (Figure 3–8). This and similarly important early studies showing that effective blood pressure control reduces proteinuria and slows renal progression have been corroborated.[53,100] For both primary and secondary prevention of chronic kidney disease progression in diabetic patients, clinical trials and meta-analyses have now demonstrated the beneficial effects of normalizing blood pressure.[101] More recently, the effect of intensive blood pressure control on the course of type I diabetic nephropathy was evaluated in patients who had participated in the Collaborative Study Group Captopril Study.[102] In this study using ramipril in combination with other agents, with an average 6 mmHg difference in mean arterial pressure over 24 months, proteinuria decreased by 50% in the intensive blood pressure group (MAP ≤92 mmHg) and increased by about 50% in the less intensive group (MAP 100–197 mmHg). Rates of decline in renal function during the intervention did not differ. Aggressive blood pressure treatment also induced remission of proteinuria and slowed decline of renal function in a prospective trial of 300 type I diabetics, with a mean arterial pressure of 100 mmHg achieved predominantly with ACEI.[103] The relevance of intensive blood pressure control (mean BP 128/75 mmHg) versus conventional control (mean BP 137/81 mmHg) to nephropathy progression in type II diabetic patients was evaluated by Schrier and colleagues.[104] Fewer intensively treated patients developed microalbuminuria or progressed to overt albuminuria. Growing evidence suggests that significant proteinuria is associated with cardiovascular disease in patients with diabetes, so proteinuria reduction may add to the cardiovascular risk reduction associated with hypertension control. Effective antihypertensive management is considered one of the most important interventions for delaying progression of diabetic nephropathy, almost regardless of the class of agent used. When antihypertensive therapy is initiated, an initial drop in kidney function may typically occur.[105] Reductions in pressure are associated with lowering of glomerular capillary pressure and diminished proteinuria.[106]


Figure 3–8 Early report by Parving and colleagues on the benefit of antihypertensive treatment on kidney function in diabetic nephropathy. With a fall in average blood pressures in nine patients from 143/96 mmHg to 129/84 mmHg, albuminuria was reduced by 50%. (From Parving H-H, et al: Effective an antihypertensive treatment postpones renal insufficiency in diabetic nephropathy. Br Med J 1987; 294:1443-1447.)

Based on available evidence that blood pressure readings above 125/75 mmHg increased the risk of ESRD in diabetic patients, a consensus statement from the National Kidney Foundation (NKF) published in 2000 advised treatment goals of less than that.[107] Since then, several expert panels, including the NKF and the American Diabetes Association (ADA), have adopted blood pressure targets of less than 130/80 mmHg as optimal for renal and cardiovascular protection in the diabetic patient with nephropathy[88,108–110] (Table 3–3). The National Kidney Foundation is currently working on new Blood Pressure Guidelines, which should be released in 2004 or 2005. A combination regimen of three or more drugs may be required. Clinical trial data suggest that mean arterial pressures of 92 mmHg or lower (corresponding to a blood pressure of about 130/70 mmHg) achieve greater preservation of renal function. Targets for high levels of isolated systolic hypertension (<180 mmHg) are less certain; systolic pressure should be lowered gradually, as tolerated.[109]

The optimal level of blood pressure decrease to achieve cardiovascular risk reduction is unclear[111] but may be answered in 2008 by the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial. Although data to evaluate the risks associated with low ranges of systolic blood pressure in diabetic kidney disease are not sufficient, pressures less than 100 to 110 mmHg should be avoided. Paradoxically, the fear of reducing systemic pressures too far may have contributed to failure to achieve lower blood pressure goals. Nonetheless, three large studies, the systolic hypertension in the Elderly Program (SHEP),[112] the Hypertension Optimal Treatment trial (HOT),[113] and the United Kingdom Prospective Diabetes Study (UKPDS)[114] have supported the notion that aggressive blood pressure lowering may not be harmful.

Several studies have underlined the challenge of achieving blood targets even in the clinical trial setting.[115] In the RENAAL study, for example, while systolic blood pressure was a stronger predictor of renal outcomes than diastolic pressure, less than half of patients achieved blood pressure goals during the treatment phase.[98] Hypertension may require selections from several different classes of drugs, and there are special considerations in the choice of antihypertensive treatment for the hypertensive diabetic (Table 3–4). Recent clinical trials have confirmed the poor response of diabetic nephropathy to

Table 3–3 Recent Blood Pressure Management Guidelines Issued by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC), the World Health Organization-International Society of Hypertension (WHO-ISH), the National Kidney Foundation (NKF), and the American Diabetes Association (ADA)

Year	Source	Patient Population	Target BP	Notes

treatment. An analysis of the NHANES III database indicated that only 11% of diabetic nephropathy patients being treated for hypertension achieved blood pressure goals of less than 130/85.[116] Furthermore, over a third of patients in ARB clinical trials with type II diabetic nephropathy progressed to primary renal end points.[72,73] In a recent trial implementing a stepped-care approach treatment algorithm, centered on maximal doses of ACEI or ARBs, only one third of patients reached target blood pressures of less than 130/80.[90] Target systolic blood pressure levels were even more difficult to control. A recent report of hypertensive military veterans indicated that, for patients with diabetes and renal disease, blood pressure control continues to fall short of guideline-recommended levels.[117] Combination therapy with agents that are tolerated and do not exacerbate existing metabolic problems are desirable.[118] Diuretics should be included in the antihypertensive regimen.

RENIN-ANGIOTENSIN BLOCKADE

By the late 1980s, basic research studies identifying the importance of elevations of glomerular plasma flow, glomerular capillary pressures, and single-nephron glomerular hyperfiltration in experimental diabetes had led to the recognition that angiotensin converting enzyme inhibition could modify the glomerular hyperfiltration and prevent the glomerular damage characteristic of the diabetic rat model.[119] The fact that other antihypertensive agents lacked these beneficial effects supported the key notion that intraglomerular hypertension was itself deleterious, and that ACEI had intrarenal effects independent of their antihypertensive properties. Several subsequent clinical trials in a spectrum of progressive renal diseases have demonstrated the benefit of ACEI in delaying progression of disease.[120] These observations were most significantly validated in type I diabetic kidney disease in the Collaborative Study Group trial with captopril, published in 1993,[121] comparing the ACEI with placebo in patients with creatinine of less than 2.5 mg/dL and urinary protein excretion of 500 mg/day or greater. Captopril slowed the progression of kidney disease by 50% and proved to reduce urinary protein excretion, despite comparable median blood pressures in the two groups. Median 24-hour urinary protein excretion was decreased by the 3-month visit in the captopril-treated group, and the reduction of almost 30% persisted throughout the study.[122] In large, randomized, controlled trials of type I diabetics, ACEI diminish proteinuria and slow the progression of diabetic nephropathy[11,101] in patients with microalbuminuria and overt proteinuria. Other randomized, controlled trials have suggested that reduction in proteinuria is associated with slowing of renal progression in patients with overt nephropathy. ACEI reduce the level of proteinuria more than equivalent antihypertensive doses of other classes of agents (Figure 3–9),[123] although the proteinuria advantage is lost as the systemic blood pressure declines.[43,106] A small subset of patients treated in a clinical trial setting appear to achieve proteinuria remission, and renal decline becomes nonprogressive.[124]

Analogous studies in patients with type II diabetic nephropathy have been less demonstrative of benefit. In contrast to type I patients, renal protection in type II diabetic

Table 3–4 Special Considerations in the Selection of Antihypertensive Medications for the Diabetic Patient

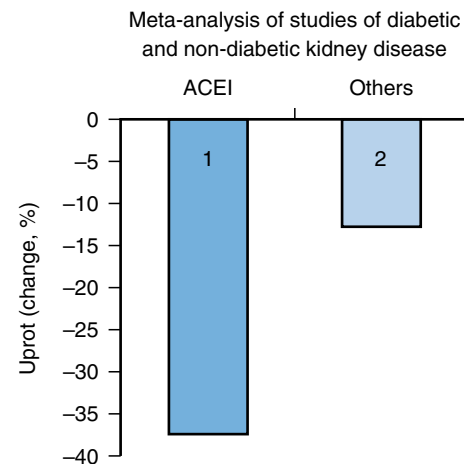
Drug Class	Special Considerations
Diuretic	Edema common in diabetic nephropathy; thiazides not effective in renal insufficiency.
Angiotensin-converting enzyme (ACE) inhibitor	Treatment of choice; Reduce proteinuria and protect from progression; Risk of hyperkalemia; Risk of worsening renal function; No adverse effects on glucose or lipid levels; Avoid in renal failure.
Angiotensin receptor blocker	Alternative to ACE inhibitor; May use in combination with ACE inhibitor;
Calcium-channel blocker	Variable effects on diabetic nephropathy.
β-Blocker	No long-term data on diabetic nephropathy; Increased risk of hypoglycemia; May mask warning signs of hypoglycemia; Use if history of myocardial infarction or tachycardia.
α-Blockers	Never shown to reduce disease progression; Neutral effect on proteinuria; Orthostatic hypotension; Neutral on lipids and glucose intolerance; Recent concern about congestive heart failure.


Figure 3–9 Effects of blood pressure-lowering agents in diabetic kidney disease. Shown are mean results for proteinuria obtained in studies that compared the effects of an ACEI with another antihypertensive agent. (From Gansevoort, Sluiter WJ, Bemmelder MH, et al: Nephrol Dial Transplant 1995; 10: 1963-1974.)

nephropathy compared against other antihypertensive agents has been less consistently demonstrated,[101] and results remain inconclusive,[125–127] possibly because of small sample sizes and use of surrogate outcomes. The clinical benefit to reduce proteinuria appears to be less significant in type II nephropathy.[128] Long-term protection was best shown in a 7-year study comparing the effects of enalapril and placebo in 94 type II normotensive patients with microalbuminuria.[125] A 5-year study period comparing the ACEI with placebo was followed by 2 additional years, during which all patients could choose enalapril or placebo. Initial ACEI therapy resulted in stable kidney function and albuminuria and reduced the risk of nephropathy by 42%; albuminuria worsened in the placebo group. Enalapril-treated patients who subsequently declined treatment noted a rise in albuminuria, whereas the placebo-treated patients who chose ACEI therapy had a reduction in albuminuria. A recent meta-analysis of ACEI in type II diabetic nephropathy indicated that ACEI produce significant reductions in proteinuria, although the effect is heterogeneous.[129] Overall, ACEI may provide similar results in type II as in type I diabetic nephropathy.

Relevant ACEI drug actions (Table 3–5) may include systemic and intrarenal hemodynamic effects, improvements in the filtration barrier, blockade of increased intrarenally-generated angiotension II,[130,131] reduced interstitial expansion,[132] tissue fibrosis[133] and extracellular expansion, attenuation of diabetes-associated reduction in nephrin expression,[59,61] and restoration of tubular albumin reabsorption.[134] Systemically, increasing attention is being given to the role of tissue-based RAS and the utility of blockade on other end-organ damage due to diabetes, primarily cardiovascular. ACEI slow the rise in creatinine and reduce the level of proteinuria more than equivalent doses of other classes of antihypertensive agents do, although event rates in clinical trial comparisons are similar when mean systemic pressure is less than 95 mmHg.[92] Extrarenal advantages of ACEI include lack of effects on lipid or glucoses levels and more effective regression of cardiac ventricular hypertrophy.

Angiotensin II receptor blockers have effects in experimental models of diabetic kidney disease to reduce proteinuria, glomerular hypertrophy, and glomerulosclerosis, similar to ACEI. ARBs share these effects with ACEI (Table 3–5) and provide a superior safety profile, including less risk of cough, angioedema, and significant hyperkalemia. Over recent years, data from clinical trials have demonstrated the beneficial effects of controlling blood pressure in secondary prevention of progression of chronic kidney disease in type II patients.[101] Published studies have included the RENAAL (Reduction of Endpoints in Non-insulin dependent diabetes mellitus with the Angiotensin II Antagonist Losartan)[73] and IDNT (Irbesartan Diabetic Nephropathy Trial).[72,135–137] In the RENAAL study, losartan was compared to conventional antihypertensive therapy in 1513 type II diabetic patients with diabetic nephropathy. Fewer ARB-treated patients reached the primary composite end point of doubling of serum creatinine, end-stage renal disease, or death (Table 3–6), and more achieved reduction in proteinuria. No improvement in all-cause mortality or cardiovascular morbidity and mortality occurred, although the rate of first hospitalizations for heart failure was reduced in the losartan group. A post-hoc analysis indicated that proteinuria, which was reduced by losartan, was the single most powerful predictor of ESRD in the study patients.[74] In the IDNT trial, the ARB irbesartan was compared with the calcium channel blocker amlodipine and placebo in 1715 type II diabetic patients with hypertension and nephropathy. Risk reduction for the primary composite end point was reduced by irbesartan compared with either amlodipine or placebo. Two subsequent evaluations of projected survival and health care cost-effectiveness of irbesartan in type II diabetes and nephropathy, based on treatment-specific probabilities derived from the IDNT, have indicated that the ARB improved survival, delayed onset of ESRD by over 1 year, and was the least costly treatment, compared to amlodip-

Table 3–5 Comparison of Clinical Effects of Angiotensin-Converting-Enzyme Inhibitors (ACEI) and Angiotensin II (Type I) Receptor Blockers (ARBs)

Effect	ACE Inhibitors	ARBs
Biologic effects		
Inhibit ACE and angiotensin-II synthesis	Yes	No
Blockade of angiotensin receptor	No	Yes
Increased plasma renin levels	Yes	Yes
Affects angiotensin-II formed by alternate pathways	No	Yes
Increased bradykinin levels	Yes	No
Side effects		
Cough, urticaria, angioedema	Yes	Less likely
Hyperkalemia	Yes	Milder
Deterioration of renal function	Potential	Potential
Contraindication in pregnancy	Yes	Yes
Approved indications		
Treatment of hypertension	Yes	Yes
Treatment of diabetic nephropathy	Yes (captopril)	Yes

Table 3–6 Results of Clinical Trials of Angiotensin Receptor Blockers in Type II Diabetic Kidney Disease

End Point	IDNT (Irbesartan)	RENAAL (Losartan)
Doubling of creatinine, ESRD, or death	20%	16%
Doubling of creatinine	33%	25%
ESRD	23%	28%
Overall death rate	NS	NS
Cardiovascular end points	NS	NS
First CHF hospitalization	23%	32%
Reduction in proteinuria	33%	35%

IDNT, irbesartan diabetic nephropathy trial; *RENAAL,* reduction of endpoints in NIDDM with the angiotensin II antagonist losartan. (See text.) Shown are percent risk reductions for study end points, and the percent reduction in proteinuria in the treatment group. (Data from Lewis EJ, Hunsicker LG, Clarke WR, et al: Renoprotective effect of the angiotensin-receptor antagonist ibesartan in patients with nephropathy due to type 2 diabetes. N Engl J Med 2001; 345:845–860; and Brenner BM, Cooper ME, De Zeeuw D, et al: Effects of Losartan on renal and cardiovascular outcomes in patients with type 2 diabetes and nephropathy. N Engl J Med 2001; 345:861–869.)

ine and control.[138,139] In both the RENAAL and IDNT studies, results were achieved in the absence of strict blood pressure control. In RENAAL, the target blood pressures (taken prior to the medication dose) of 140/90 during treatment was reached in only 47% of losartan and 40% of placebo patients.[45] In addition, examination of RENAAL and IDNT data has indicated that 43.5% of patients taking losartan and 32.6% taking irbesartan still reached a primary end point in the studies. Results of the RENAAL and IDNT studies have led to regulatory drug approval for ARBs in initial therapy for hypertensive type II diabetic patients with proteinuric renal disease. Economic evaluation of the IDNT has demonstrated the cost-effectiveness of the ARB compared to amlodipine or placebo.[137,138]

The previous review indicates that both ACEI and ARBs have demonstrated favorable effects on the progression of diabetic kidney disease.[108,140] Practice guidelines developed by the American Diabetes Association, the Joint National Commission (JNC), and the National Kidney Foundation support the uses of both ACEI and ARBs in initial therapy regimens for diabetic patients. Other studies, primarily in nondiabetic patients, have indicated that the nephroprotective effects of ARBs are similar to ACEI in reducing proteinuria. The time course of reduction in blood pressure and lowering of proteinuria are concordant.[141] ACEI may be preferred in both type I and type II patients with proteinuria, but ARBs may be substituted in patients intolerant of ACEI.

ARBs and ACEI interrupt the renin-angiotensin system through different mechanisms and could be synergistic in providing a higher degree of RAS blockade and renoprotection.[142, 143] Theoretic advantages of combination therapy include blockade by the ARB of chymase-generated angiotensin II, lack of effect of the ARB on inhibition of kinin degradation and on aldosterone suppression, and improved receptor blockade by the ARB when AII production has been diminished.[144,145] More recent data suggest that combination therapy with angiotensin receptor antagonists and ACEI at standard clinical doses is superior to maximal recommended doses of ACEI with regard to lowering blood pressure levels, with ACEI/ARB combinations leading to greater reductions in blood pressure than either class used alone.[140] Limited data also suggest that combination therapy is also significantly more effective in reducing levels of proteinuria.[144] In type I patients, dual blockade with benazepril and valsartan compared to monotherapy with each in an identical dose was compared to placebo over 8-week treatment periods. Although benazepril and valsartan were equally effective in reducing blood pressure and albuminuria, dual blockade produced an additive reduction in albuminuria of 43%, and a modest further reduction in systolic and diastolic blood pressure.[96] Combination therapy was well-tolerated, consistent with previous trials, alleviating concerns that combination therapy might lead to more serious hyperkalemia.[143] The CALM study evaluated responses in type II diabetic patients with microalbuminuria. Reductions in albumin excretion were 50% with combination therapy, 39% with lisinopril, and 24% with candesartan.[146] A similar blinded short-term study in type II patients demonstrated similar reductions in albuminuria and blood pressure with dual blockade compared with maximal doses of candesartan and an ACEI.[147] An ACEI and ARB in maximal standard doses were effective as combined therapy in a recent nondiabetic trial, with a safety profile no different than the ACEI alone.[148] These recent clinical trials supporting combination therapy in the

treatment of type I diabetic patients were recently reviewed[149] However, a clinical trial using an AT1 antagonist added to a usual maximal dose of the ACEI lisinopril did not show superior benefit to the ACEI alone, including many patients with diabetic nephropathy.[150] Further trials may be needed before combination therapy can be considered standard therapy.[151]

Several studies have attempted to identify ways to maximize the antiproteinuric effects of RAS blockade by increasing dosages of agents used to maximum tolerated nonhypotensive doses. In a study of nondiabetic proteinuria patients, the ACEI ramipril titrated up to 20 mg/day reduced proteinuria by 29% compared to baseline, about three times that of comventional dosages in a comparable study.[152] However, another ACEI study showed no impact of supramaximal doses over maximal antihypertensive doses.[153]

Because cardiovascular disease is a leading cause of mortality in diabetes, particularly in type II patients, and proteinuria is a powerful predictor of cardiovascular morbidity and mortality, cardioprotection is an important challenge in the management of patients with diabetic nephropathy. Several randomized studies of ACEI in diabetic patients with hypertension have demonstrated reductions in cardiovascular events, including Heart Outcomes Prevention Evaluation (HOPE) and microHope,[154] Captopril Prevention Project (CAPP),[155] and Fosinopril versus Amlodipine Cardiovascular Events Trial (FACET).[156] However, a recent meta-analysis of the effects of ACEI in diabetics and nondiabetics with chronic kidney disease did not reveal decreased mortality in patients with overt proteinuria treated with ACEI.[120] In the Collaborative Study Group Captopril Study, the 50% reduction in risk for the combined end points of death, dialysis, and transplantation included eight deaths in the captopril group and four deaths in the control group. The benefit of angiotensin receptor antagonists in reducing cardiovascular end points has been less consistent. Both the IDNT[111] and RENAAL studies showed no significant differences in cardiovascular outcomes with ARB therapy, except for similar reductions in hospitalizations for congestive heart failure. However, each trial was designed to evaluate renal, not cardiovascular, outcomes. The recent Losartan Intervention For Endpoint Reduction in Hypertension (LIFE) study showed more promise, with the ARB losartan more effective than conventional therapy in reducing cardiovascular morbidity and mortality in mostly type II diabetic patients with hypertension and left ventricular hypertrophy. However, there are no human data that prove cardioprotection independent of blood pressure when ARBs are given for renoprotection.[157] In addition, there have been no trials directly comparing ACEI and ARBs in cardioprotection in patients with diabetic nephropathy. The recent Optimal Therapy in Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL) study comparing losartan and captopril in over 5000 patients with myocardial infarction reported a slightly higher cardiovascular death rate with the ARB.[158] Taking into account the results of these trials, some controversy remains regarding the selection of ACEI or ARB for cardiorenal protection in type II patients with diabetic nephropathy.[159]

NOVEL THERAPIES

Based on experimental models of diabetic kidney disease, advanced glycation end products (AGEs) have been postulated

to play a role in human diabetic nephropathy.[160–162] Biologically active AGEs, formed from complex nonenzymatic glycosylation reactions of proteins, lipids, and nucleotides, can result in cross-linking between proteins, post-AGE receptor tissue effects, and altered cellular functions.[163] Several different AGE compounds have been identified in diabetic glomerulopathy lesions.[164] Toxic potential of AGEs has been described for mesangial cells, where overproduction of collagen, oxidative stress, and upregulation of insulin-like growth factor, transforming growth factor, and extracellular matrix components occur, and for tubular cells, where AGE binding may lead to tubulointerstitial fibrosis.

Pharmacologic inhibitors of AGE formation, including pimagedine[165] and pyridoxamine,[166] have been in development for several years and recently reached clinical development. Pimagedine inhibits AGE formation by binding irreversibly to reactive intermediates of early glycated products.[167,168] A major phase III clinical trial of pimagedine in type I diabetic nephropathy has recently been published.[169] In a randomized, double-blind, placebo-controlled multicenter study design, patients with established diabetic nephropathy were followed for a median of 2.5 years. Almost all were also on ACEI or ARB therapy. Both doses of the AGE inhibitor produced a statistical reduction in urinary protein excretion compared to placebo. In a subset with over 2 g of proteinuria per 24 hours, doubling of serum creatinine was less likely. In addition to a transient flu-like illness and anemia, pimagedine also produced unexpected toxicity in the form of ANCA positivity and a small number of cases of glomerulonephritis. A newer AGE inhibitor, pyridoxamine, is related to the natural compound, pyridoxine (vitamin B6), and appears to act at a later stage of the AGE biosynthetic pathway by inhibiting post-Amadori activity.[170] A recent phase II study of proteinuric type I and II diabetic patients with serum creatinine levels less than 2 mg/dL demonstrated that the agent was safe and well-tolerated.[171] Preliminary efficacy analysis indicated a reduction in urinary protein excretion and blunted rise in serum creatinine over 6 months. Other AGE inhibitors are also currently being evaluated.[172]

There are other new approaches to the treatment of diabetic nephropathy. These are based on an ever-growing mechanistic understanding of the causes of diabetic nephropathy where specific pathogenic roles for protein kinase C,[173] oxidative stress,[174] and transforming growth factor β have been well-established in animal models of diabetes.

Protein kinase C (PKC) is comprised of a family of serine/threonine kinases that have been shown to play important roles in a number of physiologic and pathophysiologic intracellular processes.[175] Research by King,[174] Whiteside,[176,177] and others has established that activation of PKCβ and PKCδ likely play important pathophysiologic roles in the development of diabetic nephropathy. A highly specific inhibitor (LY333531) directed against PKCβ has been shown to be very effective in preventing the development of diabetic retinopathy and in slowing the development of diabetic nephropathy in animals.[178] In 1996, Ishii and colleagues[179] reported in Science that LY333531 prevented the typical increase in glomerular filtration rate seen in diabetic rats and reduced albuminuria by 60%. In 1996, Koya and colleagues[179] studied the effect of oral PKCβ inhibition on mesangial cells from diabetic rats. They found that glucose-induced increases in arachidonic acid release, prostaglandin E 2 production, and

inhibition of Na-K ATPase activities in the cultured mesangial cells were completely prevented by the addition of LY333531. They also found that PKCβ inhibition prevented the increased mRNA expression of transforming growth factor β1 and reduced expression of extracellular matrix components such as fibronectin and type IV collagen in the glomeruli of diabetic rats in parallel with inhibition of glomerular PKC activity. A detailed review of LY333531 and its potential may be found in a recent review by Tuttle and Anderson.[180] Similar but even more promising results for PKCβ inhibition have been found for the prevention of diabetic retinopathy. A worldwide trial of the PKCβ inhibitor is currently underway for retinopathy. Nephropathy trials are to be started in the near future.

Much research has shown that increased oxidative stress is likely a critical factor in the development of diabetic nephropathy.[173] Because of this a variety of trials of antioxidants in people and animals have been done. The animal studies strongly suggest that the addition of antioxidants can significantly slow development of diabetic nephropathy.[173] For example, work by Koya and colleagues[181] has shown that heme oxygenase 1 mRNA expression, which was increased 16-fold in glomeruli of diabetic rats, had virtually no increase in animals treated with the antioxidants vitmamin E or probucol. Other studies in animals have shown beneficial effects for other antioxidants such as alpha lipoic acid and taurine. Some studies in small numbers of patients suggest that antioxidants may be of benefit.[182, 183] Currently, there are a number of studies aimed at determining whether antioxidants such as vitamin E have a therapeutic role in the treatment of diabetic nephropathy. But to date the human studies have been disappointing. It is possible that the currently available antioxidants are not effective as used. There are likely many reasons for this. For example, it is possible that the antioxidant tissue levels are increased adequately with current approaches. It is also possible that a better understanding of the mechanisms responsible for the increased oxidative stress will lead to the development of more targeted approaches to controlling levels of reactive oxygen species. For example, recent work suggests that mitochondria are a major source of reactive oxygen species[184] and that deficiencies in intracellular antioxidants both may play major roles in the development of increased oxidative stress.[185,186] Thus, therapies specifically targeted at mitigating the effects of mitochondrial oxidant production[187] and increasing specific intracellular antioxidants might provide powerful new treatments for diabetic nephropathy.

Another potential mechanism that holds much promise for therapy is inhibition of transforming growth factor β (TGFβ). Diabetic nephropathy is associated with glomerulosclerosis and tubulointerstitial fibrosis. TGFβ is a protein that is prosclerotic and has been strongly implicated in the pathogenesis of diabetic nephropathy. Ziyadeh and colleagues[188,189] have done many studies showing that high glucose upregulates TGFβ and that specific monoclonal neutralizing antibodies and antisense oligonucleotides prevent the accumulation of mesangial matrix proteins in diabetic animals. Furthermore, long-term TGFβ inhibition in *db/db* mice prevented mesangial matrix expansion and preserved creatinine clearance.[190] Interestingly, there was no change in albuminuria. Because of this promising results, studies are being done to determine whether inhibition of

TGFβ will help to treat progression of diabetic nephropathy in humans. Pirfenidone inhibits the actions of TGFβ and has been used to treat pulmonary fibrosis.[191] Shumar and colleagues[192] are now using pirfenidone in an NIH sponsored clinical trial to determine whether it can prevent worsening of diabetic nephropathy.

At this time there is no clear approach to complete prevention or cure for diabetic nephropathy. An intriguing, although drastic, possible approach to treating diabetic kidney disease is pancreas transplantation. Fioretto and colleagues[193] studied patients up to 10 years post-pancreas transplants and showed by renal biopsy that there was a clear regression of disease that was not evident 5 years post-transplant. Clearly, this approach cannot be widely used because the risks of immunosuppression and the relative lack of pancreases make this approach useful only in a select number of patients. Of interest are islet cell transplants that should work as effectively as pancreas transplants and, hopefully, be safer to do.

Nondiabetic Kidney Disease

James P. Lash, M.D. • Holly Kramer, M.D., M.P.H.

The term *nondiabetic kidney disease* encompasses a wide array of diseases, including glomerular diseases other than diabetes, vascular diseases other than renal artery disease, tubulointerstitial diseases, and cystic disease.[1] Grouping together such a diverse group of disorders has obvious limitations, and the use of the term "nondiabetic" is somewhat counterintuitive. However, the study of specific causes of kidney disease is limited by the relative rarity of individual diseases and makes it necessary to group together multiple etiologies of kidney disease. The term "nondiabetic kidney disease" is useful from the perspective of epidemiologic and clinical trials and in the clinical approach to patients with kidney disease. This chapter will review the epidemiology of nondiabetic kidney disease, screening strategies, risk factors for development and progression, clinical interventional trials, and treatment recommendations. This chapter will not focus on assessment of kidney function or treatment of cardiovascular disease (CVD), which are the topics of Chapters 3 and 5, respectively.

EPIDEMIOLOGY

In the United States we are facing an epidemic of kidney disease with the number of prevalent end-stage renal disease (ESRD) patients expected to double over the next decade.[2] This increase in the number of ESRD patients will have a substantial impact on health care systems, with costs projected to exceed 28 billion dollars annually.[2] The majority of end-stage kidney disease in the United States is attributable to nondiabetic kidney disease. From 1990 to 2000, nondiabetic kidney disease accounted for 98% of incident ESRD cases among individuals less than 20 years of age, 53% of individuals between 20 and 64 years of age, and 58% of those age 65 or older.[3] However, the percentage of kidney disease attributable to nondiabetic causes differs by race/ethnicity group (shown in Table 4–1). Among Native Americans and Hispanics, diabetic kidney disease accounts for greater than 60% of incident ESRD cases. Hypertension is the single most common cause of nondiabetic kidney disease in all race/ethnicity groups, accounting for approximately one third of all new ESRD cases among blacks in the United States and approximately one-fourth of new ESRD cases among whites and Asians.[3]

In 2002, the National Kidney Foundation (NKF) published the Kidney Disease Outcomes Quality Initiative (K/DOQI) Clinical Practice Guidelines for Chronic Kidney Disease (CKD).[4] These guidelines facilitate development of a clinical action plan to treat CKD. In these guidelines, CKD was defined as the presence of kidney damage or a glomerular filtration rate (GFR) less than 60 mL/min/1.73 m² body surface area for 3 months or greater. Kidney damage may be indicated by increased urine albumin excretion, histologic changes, or abnormalities in the urine sediment and/or imaging tests.

CKD was divided into five stages depending on the estimated GFR (Table 4–2). The clinical action plan for stages I through III includes the treatment of comorbid conditions and interventions for the slowing of CKD progression. Preparation for renal replacement therapy should be initiated during stage IV, whereas stage V indicates need for renal replacement therapy once symptoms of uremia ensue.

Information on the epidemiology of CKD in the United States is mostly based on data from the Third National Health and Nutrition Examination Survey (NHANES III). This was a multistage complex probability sample of the total civilian noninstitutionalized population, 2 months of age or older, in the United States, which oversampled young children, older persons, non-Hispanic blacks, and Mexican-Americans. Data on health and nutrition, and blood and urine samples were collected from over 33,000 men, women, and children over a 6-year period (1988–1994). GFR was estimated from the serum creatinine using the modified Modification of Diet in Renal Disease (MDRD) GFR prediction formula,[5] and urine albumin excretion was assessed by measuring the albumin/creatinine ratios in the spot urine samples.

From these data, the number of U.S. adults with CKD was estimated to be 19 million, not including 0.3 million requiring renal replacement therapy, such as hemodialysis or kidney transplantation.[6] Among nondiabetic white and black U.S. adults, 13% have an estimated GFR less than 60 mL/min/1.73 m².[4] The prevalence of increased urine albumin excretion, defined as an albumin/creatinine ratio greater than 17 in men mg/g and greater than 25 mg/g in women among nondiabetic adults, ranges from 6.6% in 20- to 39-year-olds to 27.2% in adults age 70 years or greater.[4] Overall, approximately 3.9% of nondiabetic U.S. adults have CKD stages III to V (GFR < 60 mL/min/1.73 m²), not including individuals requiring renal replacement therapy.[4] Information from NHANES III also suggests that a substantial proportion of type II diabetics with stages III to V CKD may not have diabetic nephropathy. Approximately one third of the estimated 1.1 million type II diabetics with GFR less than 60 mL/min/1.73 m² have no retinopathy, microalbuminuria, or macroalbuminuria.[7] In the absence of albuminuria and diabetic retinopathy, reduced GFR in these adults with type II diabetes is probably due to some other process such as aging, hypertension, or renal vascular disease. More studies are needed to confirm this hypothesis.

POPULATIONS AT RISK FOR NONDIABETIC CHRONIC KIDNEY DISEASE

Patients with systemic disorders associated with kidney disease, such as hypertension, autoimmune diseases, and recurrent kidney stones, are all at increased risk for CKD.[6]

Table 4–1 Percentage of Incident End-Stage Kidney Disease from 1990-2000 Due to Nondiabetic Kidney Disease by Race/Ethnicity

Nondiabetic Kidney Disease	Whites	Blacks	Asians	Native-Americans	Hispanics
Hypertension	24.0%	32.9%	23.5%	11.0%	16.5%
Glomerulonephritis/vasculitis	12.0%	10.4%	17.3%	10.4%	11.2%
Interstitial Nephritis	4.8%	2.0%	2.9%	1.8%	2.4%
Cystic disease/hereditary	3.8%	1.5%	2.2%	1.2%	2.5%
Cancers/tumors	2.4%	1.3%	0.8%	0.8%	1.0%
Miscellaneous	3.7%	4.7%	1.6%	1.7%	2.1%
Unknown	5.7%	5.1%	5.5%	3.9%	4.1%
Total	56.5%	57.95	53.8%	30.8%	39.8%

Table 4–2 Stages of Chronic Kidney Disease

Stage	Description	GFR (mL/min/1.73 m^2)
1	Kidney damage with normal or ↑ GFR*	≥ 90
2	Kidney damage with mild ↓ GFR*	60–89
3	Moderate ↓ GFR	30–59
4	Severe ↓ GFR	15–29
5	Kidney failure	< 15 or dialysis

*Kidney damage defined as by increased urine albumin excretion (spot urine albumin/creatinine ratio > 17 in men and > 25 in women), abnormal urine sediment, imaging tests or histologic abnormalities. (Adapted from the National Kidney Foundation K/DOQI Clinical Practice Guidelines for Chronic Kidney Disease.)

Autoimmune disorders, such as systemic lupus erythematosus, are not uncommonly associated with glomerular diseases, which may go undetected unless the urine is screened for an abnormal sediment and proteinuria. Chronic infections, recurrent kidney stones, and abuse of anti-inflammatory drugs may all increase the risk of developing tubulointerstitial disease. Cystic diseases are usually associated with a strong family history but may occur spontaneously. Risk factors and clinical indicators for nondiabetic kidney disease are shown in Table 4–3.

Certain race/ethnicity groups and individuals with a family history of kidney disease are also considered to be at increased risk. Currently, over 1% of African-Americans have a serum creatinine greater than 2.0 mg/dL compared to only 0.3% of Caucasians.[8] In addition, the prevalence of increased urine albumin excretion is 30% higher among African-Americans and 20% higher among Mexican-Americans compared to whites after adjustment for blood pressure and presence of diabetes.[9] Other high-risk groups include American-Indians and Asians.[6] Because socioeconomic status, access to health care, and diet are all independent determinants of ESRD risk,[10,11] physicians should also consider screening patients with low income and education levels, especially if other susceptibility factors are present, such as hypertension or older age.

GENETICS OF NONDIABETIC KIDNEY DISEASE

Kidney disorders inherited in a Mendelian pattern are due to single-gene mutations and follow specific inheritance patterns (e.g., autosomal dominant, X-linked recessive, etc.). Approximately 8% of ESRD cases are attributed to Mendelian disorders, with polycystic kidney disease accounting for approximately half of these.[3] Examples of Mendelian kidney diseases and their associated genetic defects are shown in Table 4–4.

The majority of nondiabetic kidney diseases do not exhibit Mendelian inheritance patterns, but familial aggregation strongly suggests a polygenic effect. For example, the odds of having a first-degree relative with kidney failure was threefold higher among 612 patients with ESRD due to non-Mendelian kidney disease compared to the control group (patients' spouses).[12] Freedman and colleagues[13] examined family history data from 4365 dialysis patients, and 14% of Caucasian and 23% of African-American adults reported a first- or second-degree relative with ESRD. Family history of ESRD also varied by kidney disease etiology with 22% of patients with diabetes mellitus, 19% with hypertension, and 23% with glomerulonephritis reporting a family history of end-stage kidney disease.

The basis of racial differences implicating genetic etiology is more problematic due to lifestyle and environmental differences between populations. Marked race/ethnicity differences in kidney disease prevalence are most notable for hypertensive nephrosclerosis.[3] Although hypertension is more frequent in blacks compared to whites, the 20-fold higher risk of hypertensive kidney in these populations cannot be fully accounted by the increased prevalence of hypertension in this population. Although genetics potentially play a role, race/ethnicity differences in kidney disease prevalence could also be due to shared environmental exposures, such as socioeconomic status, access to health care and diet, which are all independent determinants of ESRD risk.[10,11,14] Most likely, non-Mendelian kidney diseases are influenced by multiple environmental factors and a varying number of genetic loci, which could interact with each other and with multiple environmental factors.

The human genome project has identified and catalogued over 1 million genetic variations such as variable number tandem repeats, insertion/deletion polymorphisms, and

Table 4–3 Risk Factors and Clinical Indicators of Nondiabetic Kidney Disease

Kidney Disease	Risk Factors	Clinical Indicators of Kidney Disease
Glomerular	Autoimmune diseases, systemic infections (e.g., endocarditis, visceral abscesses), drug exposures, cancers, family history of glomerular disease	Proteinuria (protein/creatinine ratio > 0.3 g/g or albumin/creatinine ratio > 30 mg/g), dysmorphic RBCs or RBC casts in urine
Vascular	Hypertension, family history of vascular diseases	Microalbuminuria
Tubulointerstitial	Infections, kidney stones, chronic obstruction, drugs (e.g., NSAIDS)	WBCs or WBC casts in urine, hydronephrosis
Cystic	Family history	Bilateral cysts

(Adapted from the National Kidney Foundation K/DOQI Clinical Practice Guidelines for Chronic Kidney Disease.)

Table 4–4 Examples of Mendelian Kidney Diseases and Associated Genetic Defects

Gene	Gene Product	Disease	Reference
NPHS2	Podocin	Autosomal recessive steroid resistant nephrotic syndrome	123
ACTN4	α-actinin-4	Autosomal dominant focal segmental glomerulosclerosis	124
NPHS1	Nephrin	Nephrotic syndrome of Finnish type	125
COL4A5	α-5 Chain Type IV Collagen	X-linked dominant Alport's syndrome	126
COL4A3	α-3 Chain Type IV Collagen	Autosomal dominant and autosomal recessive Alport's syndrome	127–130
GAL	α-Galactosidase A	X-linked Fabry's disease	131
PKD-1	Polycystin-1	Autosomal dominant polycystic kidney disease-1	132, 133
PKD-2	Polycystin-2	Autosomal dominant polycystic kidney disease-2	134, 135

single nucleotide polymorphisms, and over 600 studies have reported positive associations between a genetic variant and a common disease.[15] However, only 4% of 166 reported associations between a particular genetic variant and a common disease have been consistently replicated.[15] Some explanations for the lack of reproducibility are type I errors (significant findings due to chance alone), publication bias (negative findings are less likely to be published than positive findings), and population stratification (one subgroup has a higher frequency of disease and a particular genetic variant unrelated to disease compared to the other group leading to a false positive association).[15]

Such inconsistencies also apply to studies of genetic factors and kidney disease. For example, many studies have investigated the angiotensin converting enzyme (ACE) gene because ACE plays such an important role in renal physiologic processes and the development of kidney disease. The presence (insertion) or absence (deletion) of a 287 base pair Alu sequence [(I/D) polymorphism] within the ACE gene has been associated with both diabetic and nondiabetic kidney diseases in several studies, but almost every positive association has been countered by subsequent studies that failed to confirm the original findings.[16] Advances in molecular genetics show great promise in unraveling diseases with strong genetic effects, but it remains unclear how genetic epidemiology will impact the diagnosis and treatment of common polygenic disorders, including kidney disease.[17] Examples of potential candidate genes for risk of non-Mendelian kidney diseases are shown in Table 4–5.

SCREENING FOR NONDIABETIC KIDNEY DISEASE

Urinary Protein Excretion

Urine protein excretion in healthy men and women ranges from 30 to 200 mg/day. Tamm-Horsfall protein accounts for the majority of this protein, while approximately 10% to 30% is albumin, depending on the amount of protein excreted in the urine.[22] A positive dipstick test for proteinuria indicates urine protein excretion greater than 300 mg/L and should subsequently be quantified.

Previously, a timed urine collection has been considered the gold standard for quantifying protein excretion. However, due to diurnal variance in urinary protein excretion and difficulty in obtaining adequate and/or accurate timed urine collections, the NKF recommends the use of the protein/creatinine ratio measured in spot urine samples to quantitate urinary protein excretion.[4] If the GFR remains stable, then the excretion of creatinine will be fairly constant. Ginsberg and colleagues[23] compared spot urine protein/creatinine ratios to timed urine collections in 46 patients with kidney disease and stable kidney function and noted a high correlation ((r = 0.97). Assuming that urinary protein excretion is constant, dividing the urine protein concentration by the urine creatinine concentration cancels out the time factor, and the calculated ratio reflects the cumulative protein excretion over a 24-hour period.[23] Because creatinine is a metabolic by-product of skeletal muscle creatine and phosphocreatine metabolism, its excretion is lower in subjects with lower muscle mass such as women or the elderly compared to individuals with higher muscle mass such as

Table 4–5 Potential Candidate Genes for Non-Mendelian Kidney Diseases

Gene	Gene Product Activities	References
Transforming growth factor-β (TGF-β1)	Modulates cellular growth, matrix degradation and production	136, 137
G Protein β-3 subunit (GBN3)	Mediate receptor-stimulated intracellular calcium mobilization	138–140
Endothelial nitric oxide synthase (NOS1)	Nitric oxide mediates vasorelaxation by activating soluble guanylate cyclase and suppresses vascular smooth muscle cell proliferation and platelet aggregation	141, 142
Aldosterone synthase (CYP11B2)	Catalyzes the production of aldosterone from its precursor	143–146
Endothelin-1 (EDN1)	Vasoconstrictor which also stimulates angiotensin II and aldosterone production	147–151
CD-2 associated protein (CD2AP)	Important for intracellular trafficking	152, 153

young men. Thus, protein/creatinine ratios may underestimate or overestimate protein excretion in individuals with high or low muscle mass, respectively.[23]

The spot urine protein/creatinine ratio is a simple test, which can be used to monitor protein excretion. As a general rule, a urine protein to creatinine ratio greater than 1000 mg/g indicates glomerular disease while nonglomerular disease such as tubulointerstitial and vascular diseases tend to have urine protein/creatinine ratios less than 1000 mg/g. Nevertheless, a protein/creatinine ratio greater than 200 mg/g warrants further evaluation.[1] However, determining level of albuminuria is a more sensitive screening tool for the presence of CKD.

Microalbuminuria

Albumin excretion rates greater than 30 mg/day (20–200 mcg/min) are considered abnormal, however, standard urine dipsticks cannot detect urinary albumin concentration less than 300 mg/L, leading to the term *microalbuminuria*. Microalbuminuria is a more sensitive marker of kidney disease than total protein excretion, thus, when "screening" adults for kidney disease, physicians should use either an albumin-specific dipstick to detect microalbuminuria or measure the albumin/creatinine ratio in a spot urine sample.[22]

According to the American Diabetes Association, the gold standard for measuring urine albumin excretion is a 24-hour urine collection.[24] However, a more convenient method to detect microalbuminuria is the albumin (mg)/creatinine (g) ratio (ACR) measured in a random urine specimen[4]; this may also actually be less prone to errors due to improper collection and variations in 24-hour protein excretion. Currently, the NKF recommends using a spot urine ACR obtained under standardized conditions (first voided, morning, mid-stream specimen) to detect microalbuminuria.[4] First void morning samples are recommended because upright posture,[25] exercise,[26,27] and smoking[28] may all increase urine albumin excretion.

The ACR threshold to define microalbuminuria remains controversial. The NKF K/DOQI Workgroup recommends an ACR cut-point greater or equal to 30 mg/g in both men and women.[6] Others advocate the use of sex-specific cut-points, which reflect sex differences in creatinine excretion to define microalbuminuria (≥17 mg/g in men and ≥25 mg/g in women).[9] The ACR values 17 to 250 mcg/mg in men and 25 to 355 mcg/mg in women corresponded to 30 to 300 mcg/min of urine albumin excretion measured in timed urine

specimens, respectively, and were the 95th percentile ACR values among 218 nondiabetic healthy men and women, respectively.[29] Using a single ACR threshold to define microalbuminuria may thus underestimate microalbuminuria in subjects with higher muscle mass (men) and possibly in certain race/ethnicity groups.[9]

Increased urine albumin excretion should be confirmed in a subsequent urine sample within 3 months. The NHANES III repeated spot urine collections in a subsample of 1241 participants, including diabetics. Among those with microalbuminuria in the first urine specimen, only 63% had increased urine albumin excretion in the second urine specimen.[30] However, all individuals with macroalbuminuria (ACR > 250 mg/g in men and > 355 mg/g in women) in the first urine sample had increased urine albumin excretion in the second urine sample.[30] A positive and persistent urine albumin dipstick or increased albumin/creatinine ratio on at least two occasions over a 3-month period indicates the presence of CKD.[1]

Microalbuminuria and the Risk of Progression of Nondiabetic Kidney Disease

The presence of increased urine albumin excretion has been hypothesized to reflect increased glomerular pressure,[31,32] which could predict a faster rate of GFR decline over time.[33,34] A cross-sectional study of 7728 nondiabetic subjects noted an independent association between increased GFR and microalbuminuria, while overt proteinuria (> 300 mg/24 hr) was associated with a higher odds of decreased GFR compared to subjects without increased urine albumin excretion (< 15 mg/24 hours).[35] However, data from cross-sectional studies cannot determine the temporal relationship between changes in urine albumin excretion and GFR. One retrospective study of 141 hypertensives without end-organ damage reported that GFR loss was significantly higher in subjects with microalbuminuria compared to those without microalbuminuria with similar baseline GFR, after 7 years of follow-up (−12.1 ± 2.77 versus −7.1 ± 0.88 mL/min, $P < .05$).[36] However, the small number of subjects, and the different antihypertensive regimens in the subjects, with and without microalbuminuria, limits the interpretability of these results.

Among men and women with a history of cardiovascular disease enrolled in the Heart Outcomes and Prevention Evaluation (HOPE) study, nondiabetic subjects with baseline

microalbuminuria were 19-fold more likely to develop overt proteinuria compared to nondiabetics without baseline microalbuminuria, after a median follow-up of 4.5 years (6.6% vs. 0.34%; $P < .001$),[37] an association which persisted after adjustment for age, sex, smoking, hypertension, increased cholesterol, obesity, and increased serum creatinine levels. Whether these findings would apply to nondiabetic populations without established vascular disease is not certain.

Microalbuminuria and the Risk of Cardiovascular Disease

Microalbuminuria is not only a marker of CKD, but it also serves to identify individuals who are at high risk for cardiovascular events. Increased urine albumin is associated with an increased risk for development of both macrovascular (coronary and peripheral arteries)[38–40] and microvascular (retina and glomeruli) disease.[41–44] Multiple cross-sectional studies have demonstrated an independent relationship between microalbuminuria and several cardiovascular risk factors, including cholesterol,[45] insulin resistance,[46] C-reactive protein,[47] and hypertension.[48,49] Individuals with microalbuminuria are also more likely to have subclinical cardiovascular disease such as increased thickness of the intima and media layers of the carotid artery[50] and increased left ventricular mass.[51,52] Aside from reflecting the presence of cardiovascular risk factors, microalbuminuria may be a more important independent predictor of future cardiovascular events than cholesterol or hypertension.[53–55] Among the nondiabetic HOPE study participants, the adjusted relative risk of a major cardiovascular event (myocardial infarction, stroke, or cardiovascular death) was 61% higher in subjects with microalbuminuria compared to those without microalbuminuria (95% Confidence Interval [CI] 1.36-1.90).[54] All-cause mortality was also increased in nondiabetic individuals with microalbuminuria (Relative Risk 2.00; 95% CI 1.65-2.41).[54] The association between microalbuminuria and increased risk of cardiovascular mortality has also been demonstrated in the general U.S. population[53] and in healthy adults living in Norway.[56]

Pathophysiologic Implications of Microalbuminuria

It has been hypothesized that increased urine albumin excretion reflects the presence of widespread vascular disease and endothelial dysfunction,[57] but data supporting this theory are somewhat limited. Endothelial damage leads to the release of von Willebrand factor (vWF), which is synthesized and stored in endothelial cells.[58] A few studies have noted an association between serum vWF levels and increased urine albumin excretion, but the results have been mixed.[59–61] In a small study of 64 healthy nondiabetics between the ages of 40 to 65 without microalbuminuria, increased levels of vWF at baseline ($\geq$ 1.12 units/mL) were associated with significantly higher increases in urine albumin excretion after 4 years.[59] These findings, however, were not confirmed in subsequent larger cohort studies.[60,61]

Other indicators of endothelial function include cellular adhesion molecules such as intercellular adhesion molecule 1 (ICAM-1) and endothelial selectin (E-selectin). These proteins are synthesized and expressed by activated endothelial cells and mediate the adhesion and transendothelial migration of leukocytes.[62] Information with respect to the association between ICAM-1 and E-selectin and urine albumin excretion is currently limited. Among 191 type II diabetics followed for a mean of 9 years, baseline values of E-selectin greater than 79 mcg/L were associated with a twofold higher risk of developing microalbuminuria compared to levels less than 58 mcg/L (95% CI 1.24-3.32) after adjustment for demographic values and prior cardiovascular disease.[63] This study also noted that baseline C-reactive protein levels independently predicted the development of microalbuminuria. These results were similar to a study by Jager and colleagues,[60] where a 50% increase in baseline C-reactive protein levels increased the risk of developing microalbuminuria by 16% (95% CI 1.03-1.30) in both diabetic and nondiabetic subjects.[60]

Importance of Microalbuminuria Screening in Nondiabetics

The Seventh Report of the Joint National Committee (JNC 7) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends checking a urinalysis and estimating GFR in all hypertensive patients prior to the initiation of therapy, but measurement of urine albumin excretion is considered optional.[64] However, without routine surveillance of urine albumin excretion, some hypertensive patients may not be adequately treated according to JNC VII guidelines, which recommend a BP goal less than 130/80 mmHg in the presence of CKD.

Several large trials have suggested that interventions in nondiabetic patients with microalbuminuria may improve clinical outcomes. Among the nondiabetic HOPE Study participants, treatment with ramipril decreased risk of cardiovascular events (myocardial infarction, stroke, or cardiovascular death) associated with presence of microalbuminuria by 50%.[54] Ramipril also decreased the risk for all-cause mortality in patients with microalbuminuria. The Losartan Intervention for Endpoint reduction (LIFE) Study, a randomized trial of losartan versus atenolol in nondiabetic patients with essential hypertension, measured the urine albumin/creatinine ratio and left ventricular hypertrophy by echocardiography at baseline and after 1 year of antihypertensive treatment. Left ventricular hypertrophy regressed with antihypertensive treatment, and echocardiographic changes were significantly associated with decreases of the urine albumin/creatinine ratio after controlling for changes in systolic blood pressure.[52]

Neither of these studies showed that the identification of microalbuminuria would change the overall clinical management of these patients, and some physicians doubt that routine testing of microalbuminuria will improve clinical outcomes in a general population.[65] However, the presence of microalbuminuria may indicate the presence of risk factors not routinely measured in primary care settings such as insulin resistance or left ventricular hypertrophy. Due to the important implications of persistent microalbuminuria, physicians may be more aggressive in treating patients with microalbuminuria. Finally, testing for microalbuminuria is not time-consuming, costly, or difficult for patients or physicians, and may provide valuable information on both kidney disease and cardiovascular risk.

OTHER STUDIES FOR ASSESSMENT OF NONDIABETIC KIDNEY DISEASE

Glomerular Filtration Rate (GFR)

The clearance of markers such as inulin and ^{125}I-iothalamate have been considered the gold standard for measuring GFR because they are not secreted or reabsorbed after being filtered by the kidney. However, administering these exogenous markers is very time-consuming and expensive and not practical for most clinical settings. In 1976 Cockroft and Gault developed a formula to estimate creatinine clearance, which incorporates age and body weight in order to account for age and sex differences in muscle mass.[18]

$$\frac{(140\text{-age in years}) \times (\text{body weight in kilograms}) \times (0.85 \text{ if female})}{\text{serum creatinine (mg/dL)} \times 72}$$

The Cockroft-Gault equation predicts creatinine clearance, which includes tubular excretion and intestinal catabolism in addition to GFR. Thus, creatinine clearance may overestimate GFR by as much as 16% to 25%.[19] Levey and colleagues[5] developed a newer prediction equation using demographic and laboratory data collected from subjects enrolled in the Modification of Diet in Renal Disease (MDRD) Study. The variables that jointly predicted GFR measured by the clearance of ^{125}I-iothalamate in a training sample (1070 randomly selected subjects) were determined using stepwise regression. These equations were then validated in the remaining 558 subjects.

$$GFR = 186 \times [\text{Plasma Creatinine}]^{-1.154} \times [\text{Age}]^{-0.203} \times [0.742 \text{ if female}] \times [1.210 \text{ if black}]$$

This prediction equation is easily implemented and does not require a timed urine collection, but the validity of this equation has yet to be tested in a group of patients with normal kidney function. A more detailed discussion of kidney function testing is provided in Chapter 2.

Urine Sediment

Urine sediments should be examined in all patients with CKD and in patients who are at high risk of developing kidney disease.[6] Ideally, the urine should be a first void morning specimen, because formed elements will more likely be seen in highly concentrated urine with a low urine pH. When examining the urine sediment, clinicians should carefully look for cellular elements such as red blood cells (RBCs), white blood cells (WBCs), or casts. Casts, formed in the renal tubules, are comprised of Tamm-Horsfall protein[20] and may also contain cells (RBCs, WBCs, renal tubule cells), cellular debris, crystals, and fat. These cellular elements may not be diagnostic of a specific disease process but may help narrow the diagnosis and determine the need for further work-up such as a kidney biopsy. Microscopic hematuria should be verified in subsequent urine samples in order to rule out transient hematuria due to exercise, menstruation, or trauma to the urethra from sexual activity.[21] If the RBCs appear dysmorphic, especially in the presence of decreased GFR and/or spot urine protein/creatinine ratio greater than 0.3, further evaluation, such as kidney biopsy may be warranted. Dysmorphic RBCs may originate from the glomeruli while RBCs of normal morphology, especially in the absence of proteinuria, may be shed from the lower urinary tract. The presence of RBC casts indicates a glomerular disease process such as IgA nephropathy, vasculitis, or anti-GBM disease. In contrast, the presence of dysmorphic RBCs by itself does not definitively rule in a glomerular lesion. For more information on urine sediment findings and associated kidney diseases, see Table 4–6.

Imaging Studies

Imaging studies are frequently used in the work-up of kidney disease, and these tests can provide valuable information for the physician evaluating a patient with CKD (Table 4–7). Ultrasound of the kidneys is inexpensive and easily performed with little discomfort to the patient and may reveal obstruction, asymmetry in size, increased echogenicity, or abnormalities in kidney size. Ultrasound may also provide a definitive diagnosis, such as multiple bilateral cysts in a patient with a family history of polycystic kidney disease, or bilateral hydronephrosis in a patient with known prostatic hypertrophy. In addition, the kidney ultrasound may determine whether further work-up is necessary. For example, if a patient presents with severely decreased GFR and is found to have small, scarred kidneys bilaterally, the physician may opt to not pursue further work-up because the disease is chronic and irreversible.

HYPERTENSION IN NONDIABETIC KIDNEY DISEASE

Hypertension Prevalence and Role as Risk Factor for Progression

The prevalence of hypertension (HTN) in nondiabetic kidney disease has been found to be high in clinical trials. The prevalence was 92% in the Angiotensin-Converting Enzyme-Inhibition in Progressive Renal Insufficiency (AIPRI) Study and 84%[66] in the Ramipril Efficacy in Nephropathy (REIN) Study.[67,68] Table 4–8 details the prevalence of HTN in the MDRD Study for types of nondiabetic kidney disease.[69] Observational studies and clinical trials have established that there is a strong relationship between uncontrolled HTN and risk for progressive kidney failure.[70–72] Furthermore, systolic blood pressure has been found to have a larger impact on the progression of kidney disease than diastolic blood pressure.[73–76] Despite the well established importance of HTN, there is ample evidence that HTN remains poorly controlled in this population.[4]

Clinical Interventional Studies

Table 4–9 provides an overview of the major trials conducted in patients with nondiabetic kidney disease. We will review in detail three of the largest studies and two important meta-analyses.

Angiotensin-Converting Enzyme-Inhibition in Progressive Renal Insufficiency (AIPRI)

The Angiotensin-Converting Enzyme-Inhibition in Progressive Renal Insufficiency (AIPRI) Study included 583 participants

Table 4–6　Urine Sediment

Finding	Normal	Pathologic	References
Cells			
RBCs	Up to 2-3/HPF; Transient microscopic hematuria may be noted with vigorous exercise	Dysmorphic RBCs may indicate glomerular disease, whereas RBCs with normal morphology may indicate a lower urinary tract lesion	21, 154, 155
WBCs	Up to 2-3/HPF	Infection or inflammation, pyelonephritis, interstitial nephritis	156, 157
Renal tubule		Large numbers indicate tubular damage	158–162
Transitional		Large numbers may indicate inflammation of bladder or ureters or be seen after bladder instrumentation	163, 164
Epithelial	Indicates contamination of urine		
Casts			
RBC	*	Indicates glomerular disease but may also be seen with renal infarction or pyelonephritis	21, 164, 165
WBC	*	Interstitial nephritis, pyelonephritis, renal infarction, glomerulonephritis	165
Waxy		Broad waxy casts may indicate advanced disease[†]	165
Granular casts	Small numbers may be seen with strenuous exercise	Large numbers, especially coarse brown (muddy) casts, suggestive of acute tubular necrosis	166–168
Hyaline	Exercise, dehydration, diuretic use, fever	Large wide hyaline casts may indicate advanced kidney disease[†]	166–169

*Always pathologic.
†Does not indicate a specific kidney disease.

Table 4–7　Abnormal Findings on Imaging Studies in Nondiabetic Kidney Disease

Imaging Study	Possible Diseases
Ultrasound	
Hydronephrosis	Obstruction
Asymmetry in size	Renal artery stenosis, unilateral obstruction
Scarring	Tubulointerstitial disease due to stones or infection
Small kidneys	Chronic kidney disease*
Large kidneys	Infiltrative disorders, tumors, HIV nephropathy, amyloidosis, growth hormone tumor
Increased echogenicity	Glomerular disease, tubulointerstitial diseases, cystic disease
CT scan without contrast	
Collecting system dilation	Ureteral or bladder outlet obstruction
Calculi	Kidney stone disease
CT scan with contrast	Kidney tumors, cysts
Helical CT scan with contrast	Renal artery stenosis
Magnetic resonance imaging	Tumors, renal vein thrombosis, cysts
Magnetic resonance angiography	Renal artery stenosis

*Does not indicate a specific kidney disease.

with a variety of nondiabetic kidney diseases (glomerular disease, 33%; tubulointerstitial, 18%; hypertensive nephrosclerosis, 16%; diabetic nephropathy, 3%).[66] Participants were randomized to benazepril or placebo. The primary outcome was doubling of the serum creatinine or ESRD. After 3 years, the risk in the benazepril group for reaching the primary end point was 53%. The risk reduction was greatest for those with a glomerular disease and for those with a baseline protein excretion greater than 1 g/day.

Ramipril Efficacy in Nephropathy (REIN) Study

The Ramipril Efficacy in Nephropathy (REIN) Study included 352 patients with chronic nondiabetic nephropathies who

Table 4–8 Prevalence of HTN by Type of Nondiabetic Kidney Disease in MDRD Study

Type of Kidney Disease	Prevalence (%)
Glomerular diseases	85%
Vascular diseases	100%
Tubulointerstitial diseases	62%
PKD	87%

(Modified with permission from National Kidney Foundation. K/DOQI Clinical Practice Guidelines for Chronic Kidney Disease: Blood pressure management and use of antihypertensive agents in chronic kidney disease. Am J Kidney Dis 2004; 43:S1–S290.)

were randomized to receive ramipril or placebo. Prior to randomization, patients were stratified by level of proteinuria (stratum 1: proteinuria > 1 g/day and < 3 g/day; stratum 2: ≥ 3 g/day).[67,77] The primary end points were changed in iohexol measured GFR and time to ESRD. In stratum 2, the trial was terminated early because the ramipril group had a slower decline in GFR, a greater decrement in proteinuria, and improved renal survival as measured by the composite outcome of doubling of serum creatinine or ESRD (Figure 4–1). In stratum 1, the decline in GFR did not differ significantly between the ramipril and placebo groups. The relative risk for ESRD was 2.72 for the placebo group compared to the ramipril group. Baseline urinary protein excretion of greater than 1.5 gm was associated with a faster rate of GFR decline and for this subgroup, ramipril was associated with a slower decline in GFR (0.31 mL/min/month versus 0.40 mL/min/month) and decreased development of ESRD (18% vs. 52%).

African-American Study of Kidney Disease and Hypertension (AASK)

The African-American Study of Kidney Disease and Hypertension (AASK) was a randomized trial in patients with hypertensive nephrosclerosis.[78] In this trial, 1094 African-American participants were randomly assigned to a usual blood pressure goal or to a lower pressure goal and to initial treatment with one of three drugs (an ACE inhibitor,

ramipril; a β-blocker, metoprolol; or a nondihydropyridine calcium channel blocker, amlodipine). The usual blood pressure goal was a mean arterial pressure (MAP) of 102 to 107 mmHg (corresponding to a BP of less than 140/90 mmHg) and the low blood pressure goal was a MAP of less than 92 mmHg (corresponding to a BP of less than 125/75 mmHg). The main outcome measures were rate of change in GFR slope and a composite outcome of reduction in GFR of 50% or more, ESRD, or death. The amlodipine arm was terminated early because an interim analysis found ramipril to be more beneficial than amlodipine.[79] There was no benefit in terms of slowing progression with lower BP (Figure 4–2A). However, a trend was seen favoring the lower blood pressure target in individuals with higher baseline proteinuria levels and an opposite trend in participants with little or no proteinuria. In the final analysis, there was no difference in GFR slope between the drug groups (Figure 4–2B). However, the ramipril group had a risk reduction in the clinical composite outcome of 22% compared to metoprolol and 38% compared to amlodipine (Table 4–10).

Meta-Analyses

The ACE Inhibition in Progressive Renal Disease (AIPRD) Study Group performed a patient-level meta-analysis of 1860 subjects with nondiabetic kidney disease enrolled in 11 randomized trials of ACE inhibitors to slow progression of kidney disease.[80] In these pooled studies, the mean duration of follow-up was 2.2 years. Individuals treated with ACE inhibitors had a greater decrease in systolic and diastolic blood pressure (Figure 4–3A). After adjusting for baseline characteristics and longitudinal changes in systolic blood pressure, ACE inhibitors were more effective in reducing proteinuria, reducing the risk for end-stage renal disease (relative risk, RR of 0.69) and in reducing the risk for the composite outcome of doubling of serum creatinine or ESRD (RR 0.70) (Figures 4–3B, C, and D).

In another analysis of the same database, this group of investigators also examined the relationship of levels of blood pressure and urine protein excretion with the progression of kidney disease.[76] These analyses demonstrated a strong, graded relationship between higher levels of systolic BP and urine protein excretion and the risk for kidney disease

Table 4–9 Summary of Clinical Interventional Trials of Nondiabetic Kidney Disease

| Study or Author	N	Baseline GFR (mL/min/1.73 m²) or Serum Creatinine	Baseline Proteinuria (mg/24 hr)	Intervention	Kidney Disease Progression	Methodologic Quality
ACE-versus placebo						
AIPRI	583	2.1 mg/dL	1800 mg	Benazepril	*	A
REIN	186	49 mL/min	1700 mg	Ramipril	*	B
REIN	166	40 mL/min	5600 mg	Ramipril	*	B
ACE versus other agents						
Hannedouche	100	2.9 mg/dL	No data	Enalapril	*	B
Chinotti	131	36 mL/min	506 mg	Lisinopril	*	A
AASK	1094	45 mL/min	600 mg	Ramipril	*	A
van Essen	103	51 mL/min	2500 mg	Enalapril	NS	A

progression. After adjusting for the level systolic blood pressure, diastolic blood pressure level was not found to be a risk factor for the progression of kidney disease. The lowest risk for kidney disease progression was seen in patients with a systolic BP of 110 to 129 and urine protein excretion of less than 2.0 g/day. Moreover, the relationship between the systolic BP and the risk for kidney disease progression was influenced by the level of proteinuria (Figure 4–4). In patients with more than 1.0 g/day of proteinuria, the risk for kidney disease progression increased significantly when systolic blood pressure was greater than 120 to 130 mmHg. However, in patients with less than 1.0 g/day of proteinuria, the risk for kidney disease progression was relatively constant over a range of systolic blood pressures between 110 to 159 mmHg. The study group

also found that a systolic blood pressure of less than 110 was associated with a nearly fivefold increased risk of kidney disease progression among individuals with more than 1.0 g/day of proteinuria. In interpreting these results, it is important to recognize that the analyzed clinical trials were not primarily designed to evaluate the effect of lowering blood pressure and urinary protein excretion. In addition, the confidence intervals for the risk of kidney disease progression were wide. Nonetheless, the authors argue that the findings are strongly statistically significant and corroborate the results of other studies. As discussed in the accompanying editorial, the findings regarding the increased risk of lower levels of blood pressure need to be viewed with caution.[81] It is unclear whether this was the result of renal hypoperfusion or related to

Table 4–10 Analysis of Clinical Event Composite Outcomes in the AASK Trial

	Drug Intervention							
	Lower vs. Usual Blood Pressure Goal Intervention		Ramipril vs. Metoprolol		Metoprolol vs. Amlodipine		Ramipril vs. Amlodipine	
Outcomes	% Risk Reduction (95% Confidence Interval)	*P* Value	% Risk Reduction (95% Confidence Interval)	*P* Value	% Risk Reduction (95% Confidence Interval)	*P* Value	% Risk Reduction (95% Confidence Interval)	*P* Value
GFR event, ESRD, or death	2 (–22 to 21)	.85	22 (1 to 38)	.04	20 (–10 to 41)	.17	38 (14 to 56)	.004
GFR event or ESRD	–2 (–31 to 20)	.87	22 (–2 to 41)	.07	24 (–9 to 47)	.13	40 (14 to 59)	.006
ESRD or death	12 (–13 to 32)	.31	21 (–5 to 40)	.11	42 (17 to 60)	.003	49 (26 to 65)	<.001

independent factors, such as poor underlying health in the individuals with lower blood pressure.

Blood Pressure Goal

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends a target blood pressure goal of less than 140/90 mmHg or less than 130/80 mmHg for patients with chronic kidney disease.[82] This blood pressure goal corresponds to the achieved systolic blood pressure in many of the clinical studies reviewed in Table 4–9, which provide strong evidence that this goal is beneficial for both CVD risk reduction and for slowing the progression of kidney disease. This blood pressure goal has been recommended by the K/DOQI Work

Group on Blood Pressure Management and other published guidelines.[83] Two large clinical trials have examined the impact of a lower blood pressure goal on the progression of nondiabetic kidney disease. In the Modification of Diet in Renal Disease (MDRD) Study and the AASK trial, patients were randomized to a mean arterial pressure (MAP) goal of less than 92 mmHg (equivalent to a blood pressure less than 125/75 mmHg) or to a MAP goal of less than 107 mmHg (equivalent to a blood pressure less than 140/90 mmHg). The MDRD Study included predominantly nondiabetic kidney disease of various causes, and participants had a mean baseline proteinuria of 2.2 g/day.[84] By post hoc analysis, a beneficial effect of the lower BP goal was observed in patients with higher rates of urinary protein excretion (Figure 4–5). In the AASK Study, participants had a mean baseline proteinuria of about 0.6 g/day. As dis-
Figure 4–4 Meta-analysis: Relative risk for kidney disease progression based on current level of systolic blood pressure and current urine protein excretion. (Used with permission from Jafar T, Stark P, Schmid CH, et al: Progression of chronic kidney disease: The role of blood pressure control, proteinuria, and angiotensin-converting enzyme inhibition. A patient-level meta-analysis. Ann Intern Med 2003; 139[4]:244-252.)

cussed earlier, there was no significant beneficial effect of the lower BP goal (Figure 4–2).[78] Nonetheless, a trend was detected favoring the lower BP goal in participants with higher baseline proteinuria. These findings are all consistent with the results of the meta-analysis by Jafar and colleagues.[76]

Choice of Antihypertensive Agent

ACE Inhibitors

As summarized earlier, a number of large scale studies have demonstrated that ACE inhibitors reduce kidney end points in nondiabetic kidney disease. In the first meta-analysis by Jafar and colleagues,[80] the relative risk for kidney disease progression associated with ACE inhibitors was 0.67. Moreover, the beneficial effect was greater in patients with higher levels of proteinuria. Conversely, the strength of evidence favoring the use of ACE inhibitors was weaker for subclasses of nondiabetic kidney disease characterized by low levels of proteinuria (polycystic kidney disease and tubulointerstitial disease).

Number of Agents Required and Diuretics

Most patients with nondiabetic CKD will require multiple antihypertensive agents to achieve blood pressure control. In several large trials, at least two to three antihypertensive agents were required to achieve blood pressure control (Table 4–11).
Figure 4–5 MDRD study: Effect of strict blood pressure control by baseline proteinuria. For Study A (baseline GFR 25-55 ml/min/1.73 m^2), estimated mean (±SE) rates of decline in GFR from baseline to 3 years, based on a 2-slope model are shown. For Study B (baseline GFR 13-24 ml/min/1.73 m^2), mean (±SE) rates of decline in GFR are estimated from the 1-slope informative censoring model. Closed circles designate the usual blood pressure group; open circles designate the low blood pressure group. The number in parentheses in each column is the total number of patients in both blood pressure groups who had a least one follow-up measurement. Greater baseline proteinuria is associated with a steeper mean GFR decline and with a greater benefit form the low blood pressure goal (P=.02 in Study A; P=.01 in Study B). (Used with permission from Klahr S, Levey AS, Beck GJ, et al: The effects of dietary protein restriction and blood-pressure control on the progression of chronic renal disease. Modification of Diet in Renal Disease Study Group. N Engl J Med 1994; 330[13]:877-884.)

Table 4–11   Summary of Number of Antihypertensive Agents to Reach Target Blood Pressure

Study, Year, Reference	Target BP	Achieved BP	Mean Number of Agens
AASK, 2002	<125/75	125/76	3.5
	<140/90	140/84	2.7
MDRD, 1997 (study A only)	<125/75	125/78	1.9
	<140/90	138/78	1.5
AIPRI, 1996	Diastolic = 90	135/84 (ACE inhibitor)	1.7
		144/89 (placebo)	2.1

(Modified with permission from National Kidney Foundation. K/DOQI Clinical Practice Guidelines for Chronic Kidney Disease: Blood pressure management and use of antihypertensive agents in chronic kidney disease. Am J Kidney Dis 2004; 43:S1–S290.)

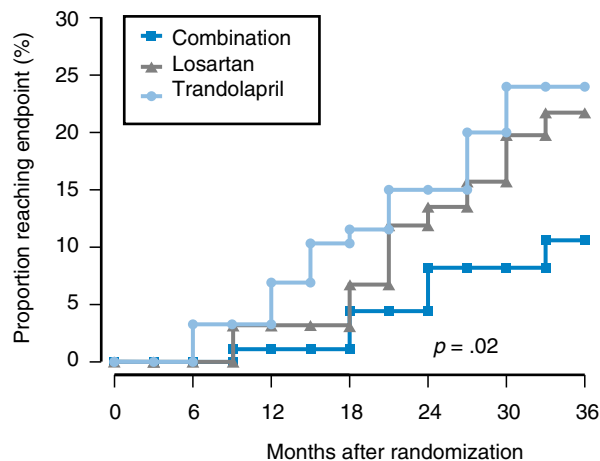
Moreover, in most of the clinical studies, diuretics were prescribed in addition to ACE inhibitors.[78]

The ALLHAT study raised questions regarding the relative benefits of ACE inhibitors versus diuretics in CKD. A recent post-hoc analysis of the large subgroup of nondiabetics with estimated GFR less than 60 mL/min/1.73 m^2 demonstrated no beneficial effects of an ACE inhibitor (lisinopril) compared to a diuretic (chlorthalidone) on decline in GFR or onset of kidney failure over a 4-year interval.[85] However, evidence suggests that diuretics potentiate the effects of ACE inhibitors, which may partially explain the lack of beneficial effect seen in ACE inhibitors compared to diuretics.

Angiotensin Receptor Blockers (ARB) and Combined ACE Inhibitor/ARB Therapy

Though extensively studied in diabetic kidney disease, the impact of angiotensin receptor blockers (ARB) has not been well studied in nondiabetic kidney disease. Although it might be reasonable to assume that ARBs would also be of benefit in nondiabetic kidney disease, only limited evidence is available at this point. Combined ACE inhibitor and ARB therapy was studied in the COOPERATE study.[86] In this trial, 263 participants with nondiabetic kidney disease (65% had glomerular disease, 24% with IgA) were randomized to either ACE inhibitor (trandolapril), ARB (losartan), or ACE inhibitor and ARB combination (trandolapril and losartan). As demonstrated in Figure 4–6, combination therapy was more effective in reducing the progression of kidney disease than therapy with each agent alone. Though combination therapy may be a consideration for an individual proteinuric patient who is refractory to either agent alone, it is premature to recommend this approach for all patients with nondiabetic kidney disease until it is confirmed in other large trials.

Calcium Channel Blockers

In diabetic nephropathy, there is significant evidence demonstrating a greater antiproteinuric effect of ACE inhibitors as compared to dihydropyridine calcium channel blockers (CCB). The AASK Study was the first large study to examine the impact of a dihydropyridine CCB on nondiabetic kidney disease. As described earlier, when compared with amlodipine, both ramipril and metoprolol reduced the risk of kidney failure and of kidney failure and death combined.[78,79] In addition, the rise in proteinuria was significantly higher in the amlodipine group than in the other two drug groups. For these reasons, the K/DOQI Work Group recommended that


Number at risk

Losartan	89	88	84	79	65	59	47
Trandolapril	86	85	83	75	72	63	58
Combination	88	87	86	83	76	73	67

Figure 4–6 Proportion of patients reaching a kidney end point in the COOPERATE study. (Used with permission from Nakao N, Yoshimura A, Morita H, Kayono T, Ideura T et al: Combination treatment of angiotensin-II receptor blocker and angiotensin-converting-enzyme inhibitor in non-diabetic renal disease COOPERATE: A randomised controlled trial. Lancet 2003; 361[9352]:117-124.)

dihydropyridine CCBs should not be used in nondiabetic kidney disease in the absence of therapy with an ACE inhibitor or an ARB.

Summary of Blood Pressure Management Recommendations

The NKF-/DOQI Work Group recommended initial therapy with an ACE inhibitor if the individual has proteinuria, and a diuretic is preferred as the first line additional agent if one is required to achieve target blood pressure. A blood pressure goal of less than 130/80 is recommended by both K/DOQI and JNC 7.[4,64] As discussed earlier, for patients with higher levels of proteinuria, current evidence suggests that an even lower blood pressure goal may be beneficial.[76] Table 4–12 outlines the treatment approach recommended by the K/DOQI Work Group and emphasizes the importance of stratifying patients by level of proteinuria. As discussed later

Table 4–12 Target Blood Pressure and Antihypertensive Agents in Nondiabetic Kidney Disease

Clinical Assessment	Target Blood Pressure	Recommended Agents for CKD	Additional Agents to Reduce CVD Risk and Reach Target Blood Pressure
Blood pressure ≥130/80 mmHg and spot urine total protein-to-creatinine ratio ≥200 mg/g	<130/80 mmHg	ACE inhibitor	Diuretic preferred, then β-blocker or calcium channel blocker
Blood pressure <130/80 mmHg and spot urine total protein-to-creatinine ratio ≥200 mg/g	<130/80 mmHg	ACE inhibitor	Diuretic preferred, then β-blocker or calcium channel blocker
Blood pressure ≥130/80 mmHg and spot urine total protein-to-creatinine ratio <200 mg/g	<130/80 mmHg	None preferred	Diuretic preferred, then ACE inhibitor, ARB, β-blocker or calcium channel blocker

(Used with permission from National Kidney Foundation. K/DOQI Clinical Practice Guidelines for Chronic Kidney Disease: Blood pressure management and use of antihypertensive agents in chronic kidney disease. Am J Kidney Dis 2004; 43:S1–S290.)

in this chapter, other interventions of potential benefit include smoking cessation, low protein diet, and treatment of hyperlipidemia.

ROLE OF OTHER FACTORS IN THE PROGRESSION OF DIABETIC NEPHROPATHY

Dietary Protein Restriction

Although several large trials of dietary protein restriction for the slowing of CKD progression have been completed, the National Kidney Foundation K/DOQI guidelines state that currently available data are too inconclusive to support or not support dietary protein restriction to reduce GFR loss.[4] The Modification of Diet in Renal Disease (MDRD) Study, the largest randomized trial of dietary protein restriction in patients with CKD to date, did not determine definitively whether protein restriction retards CKD progression.[84] Diabetic patients requiring insulin were excluded from the study. Participants with moderately reduced GFR (25–55 mL/min/1.73 m^2) were randomized to either a low protein intake (0.58 gm/kg/day) or usual protein intake (1.3 gm/kg/day) and to a usual blood pressure control group (mean arterial pressure, 107 mmHg) or a low blood pressure control group (mean arterial pressure 92 mmHg). Patients with severely reduced GFR were randomized to low protein intake (0.58 gm/kg/day) and very low protein intake (0.28 gm/kg/day) supplemented with keto acid-amino supplements and a usual or low blood pressure control group. Mean follow-up was 2.2 years. After study completion, GFR decline was found to be 3.8 mL/min/year in patients with moderately decreased GFR and 4.0 mL/min/year among adults with severely decreased GFR. The total number of subjects needed for adequate power was based on a predicted GFR decline of 6 mL/min/year. Due to the slower GFR decline, fewer patients reached the end point (need for renal replacement therapy), and the study had less power overall

than expected to determine whether protein restriction ameliorates GFR loss.[87] The risk of ESRD requiring renal replacement therapy or death was reduced by 35% in the low protein group compared to usual protein intake, but the 95% confidence intervals included 1. Risk of ESRD and/or death was similar between the low protein and the very low protein groups among patients with severely reduced GFR (Relative Risk 0.93; 95% CI 0.65, 1.3), but these patients had no usual protein intake arm.[88]

The possibility that GFR loss would not be constant was not incorporated into the original MDRD Study design.[88] GFR decline was actually 1.6 mL/min faster with protein restriction during the first 4 months compared to those assigned to the usual protein diet among patients with moderately reduced GFR. After the first 4 months, GFR decline was then noted to be 1.1 mL/min/year (28%) slower than the usual protein group, but the large increase in GFR decline during the first 4 months led to no overall significant difference between the two groups over the entire study period. However, the MDRD investigators contend that a 28% reduction in GFR decline may translate into clinically meaningful differences in the length of time a particular patient progresses to end-stage renal disease, even preventing older patients from ever reaching this end point. Patients with severely decreased GFR assigned to the very low protein intake group had a 19% slower rate of GFR decline but the difference was not statistically significant. Secondary analyses of the MDRD data have found that every 0.2 g/kg/day decrease in protein intake significantly reduces GFR decline by 30% among patients with severely reduced GFR.[88] No significant association was noted between protein intake and GFR decline among patients with moderately reduced GFR. It must be noted that this degree of protein restriction is difficult to maintain without close supervision by a dietitian and supplementation with essential amino acids, thus, it may be difficult to incorporate into usual clinical practice.

A meta-analysis of five studies (including the MDRD Study) pooled information from a total of 1413 patients with nondiabetic kidney disease to assess the efficacy of dietary

protein restriction on CKD progression.[89] Low protein diets decreased the risk of ESRD or mortality by 33% (95% CI 0.50, 0.89). These results did not appear to be confounded by blood pressure because there were no significant differences in pooled mean arterial blood pressure between the low protein and usual protein diet groups. This decrease in risk of ESRD was similar to the risk reduction with low protein intake observed in the MDRD patients with moderately reduced GFR. Changes in GFR with protein restriction could not be determined with meta-analysis due to heterogeneity in assessing GFR among the different studies.

Although dietary protein restriction does appear to ameliorate the progression of kidney disease, the evidence is certainly not overwhelming. The decision to restrict dietary protein intake should incorporate the patient's ability to comply with the diet and maintain close follow-up with the physician and dietitian in order to avoid malnutrition. Moreover, patients should be advised on the current evidence and be involved in the decision-making process.

Smoking

Multiple studies have documented the strong association between smoking and mortality due to cardiovascular disease and cancers, including renal cell carcinoma.[90] Although all physicians are strongly encouraged to prescribe smoking cessation to their patients who continue to smoke, the importance of smoking cessation for the prevention of kidney disease has been poorly emphasized in the nephrology community despite increasing evidence of the adverse effects of smoking on kidney function.[91]

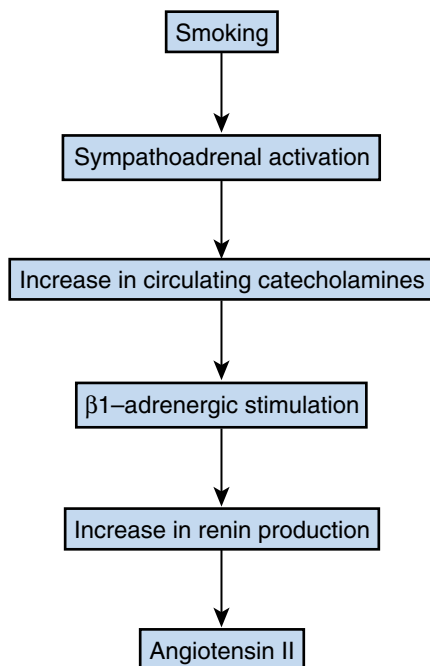
In nonsmokers, nicotine acutely increases renal vascular resistance and decreases GFR.[28] After a 48-hour abstinence from cigarettes, healthy volunteers were requested to smoke two cigarettes. During this 10-minute smoking period, GFR and renal plasma flow were assessed by measuring ^{111}In-diethylene-triamine penta-acetic acid (DTPA) and ^{131}I-hippurate clearances, respectively. GFR decreased by 15% from baseline values (115 ± 15.2 mL/min/1.73 m^2 to 97.3 ± 16.9 mL/min/1.73 m^2) while mean arterial pressure and renal vascular resistance increased. The investigators then repeated the study in seven occasional smokers with IgA nephropathy (serum creatinine ranged from 0.79 to 1.68 mg/dL). Although the increase in mean arterial pressure among the subjects with IgA nephropathy paralleled the mean arterial pressure increase in the healthy controls, no consistent decrease in GFR or increase in renal vascular resistance was noted. However, the urine albumin/creatinine ratio significantly increased in six to seven subjects with IgA nephropathy. No increase in urine albumin excretion was noted in the healthy volunteers with undetectable urine albumin concentrations at baseline, whereas the median urine albumin creatinine ratio among the subjects with IgA nephropathy was 55.5 mg/g.[28] A dose of nicotine gum revealed identical findings; thus, the renal hemodynamic changes with tobacco use were confirmed to be mediated by nicotine.

Halimi and colleagues[92] performed a similar study in 9 chronic smokers and 10 nonsmokers, but the chronic smokers refrained from smoking only 2 hours prior to the study. After chewing 4 mg of nicotine gum, both GFR and effective renal plasma flow decreased by 15% compared to baseline levels among the nonsmokers while no changes in GFR or effective renal plasma flow were noted in the smokers. The short tobacco abstinence period in the smoking group may explain the lack of changes in GFR and effective renal plasma flow.[92] Gambaro and colleagues[93] measured GFR and renal plasma flow in 30 healthy smokers and 24 age and sex matched healthy nonsmokers. There was no significant difference in GFR between the two groups, but renal plasma flow was significantly lower in the smokers compared to nonsmokers (199.2 mL/min/1.73 m^2 vs. 256.6; $P < .005$). In addition, endothelin-1 levels were measured in the two groups and were noted to be significantly higher in the smokers compared to nonsmokers (25.0 pmol/L vs. 21.6; $P < .001$).[93]

Smoking and CKD: Cross-Sectional Studies

Among 1567 nondiabetic men and women who participated in the Gubbio Population Study, smokers were almost twofold more likely to have microalbuminuria (urine albumin excretion 20 to 199 μg/min) compared to nonsmokers.[94] Similar results were noted in a study of 28,000 nondiabetic French adults recruited during routine medical checkups from nine social medical centers.[95] The AusDiab Kidney Study examined the association between smoking and markers of kidney function (estimated creatinine clearance and spot urine/protein ratios) in a nationally representative sample of over 11,000 Australian normotensive, nondiabetic adults.[96] Each 10-pack year smoking increase among current tobacco users was associated with a 3.2 mL/min/1.73 m^2 lower creatinine clearance compared to individuals who never smoked. The association between smoking and decreased creatinine clearance was stronger in men than in women, but this was probably due to the fact that men smoked substantially more cigarettes per day than women in this population. The number of cigarettes smoked per day was also associated with proteinuria as assessed by spot urine protein/creatinine ratios, but the results were not statistically significant.[96] A population based survey of 7476 nondiabetic residents of Groningen, the Netherlands, also observed a twofold higher prevalence of microalbuminuria among current smokers compared to never-smokers.[97]

Smoking and CKD: Prospective Studies

The consistent and strong link between smoking and markers of kidney disease observed in cross-sectional studies has, for the most part, been supported by several investigations using large cohorts. For example, the PREVEND (Prevention of Renal and Vascular End Stage Disease) Study, a population-based survey of residents of Groningen, the Netherlands, noted an independent association between current smoking status and risk of developing microalbuminuria or a decreased GFR (2 standard deviations less than the mean GFR among healthy nondiabetic subjects without microalbuminuria).[97] Current smokers were almost twofold more likely to develop microalbuminuria and 58% more likely to develop decreased GFR compared to nonsmokers. In addition, a dose response was noted: The higher the number of cigarettes smoked per day, the higher the risk of microalbuminuria or decreased GFR. The HOPE study noted a 20% higher risk of the development of new proteinuria (microalbuminuria or dipstick positive proteinuria) among current smokers compared to never-smokers.[37] However, approximately half of the


HOPE study participants were diabetic and all were considered high risk for cardiovascular events. When the investigators stratified the HOPE study participants by presence of diabetes mellitus, the association between smoking and development of new proteinuria in nondiabetics was no longer statistically significant.[37] Several smaller studies have also reported that smoking accelerates the progression of kidney disease associated with primary glomerulopathies such as lupus nephritis[98] and polycystic kidney disease.[99]

Why Does Smoking Increase the Risk for Chronic Kidney Disease in Nondiabetics?

It is well established that chronic smoking increases blood pressure levels by stimulation of the sympathetic system leading to increased levels of circulating catecholamines, endothelin-1 and subsequent activation of the renin-angiotensin system. The hypertension induced by chronic exposure to nicotine may lead to arteriole damage in multiple organs, including the kidney.[100–102] Orth[103] proposed a mechanistic pathway whereby nicotine exposure leads to activation of the renin-angiotensin system and subsequent kidney damage (Figure 4–7). Cigarette smoke also contains carbon monoxide, which may by itself activate the renin angiotensin system or lead to kidney damage due to chronic hypoxia in the tubulointerstitium.[104] Kidney damage may also be mediated by increased thrombogenesis from cigarette smoke[105,106] leading to glomerular intracapillary thrombosis and subsequent endothelial damage.

Cardiovascular mortality is over 10-fold higher in dialysis patients compared to the general population,[107] and CKD is an independent predictor of cardiovascular events and mortality.[53,54,108,109] Therefore, all individuals with kidney disease or those who are at high risk for the development of kidney disease should strongly be advised on the advantages of smoking cessation and encouraged to quit.

Lipid Abnormalities

Lipid abnormalities are more common in patients with CKD compared to the general population,[109] and lipid laden (foamy) macrophages and lipid deposits may be noted histologically in a variety of glomerulopathies.[110] In light of these findings, many investigators have hypothesized that lipid abnormalities participate in the development and progression of kidney disease. Oxygen radicals formed by mesangial and tubular cells in the presence of angiotensin II oxidize lipoproteins. These oxidized lipoproteins stimulate cytokine production and inflammatory cell migration leading to subsequent cell death and glomerulosclerosis.[111,112] Research supporting this theory include the acceleration of glomerulosclerosis in animal models with lipid rich diets,[113–115] and the decrease in albuminuria and glomerulosclerosis with lipid lowering treatment after 5/6 nephrectomy in rats.[116]

Clinical studies, however, have not demonstrated a consistent association between lipid abnormalities and the development of nondiabetic kidney disease. Using data from the Atherosclerotic Risk in Communities Study, a cohort of middle-aged adults recruited from four U.S. communities, investigators examined the association between baseline lipid levels and changes in serum creatinine after 3 years of follow-up.[117] Several types of lipid abnormalities were included, such as total cholesterol, triglycerides, HDL, LDL, Lp(a), apolipoprotein A, and apolipoprotein B. Patients taking lipid-lowering agents at baseline and those with an elevated baseline creatinine ($\geq$ 2.0 mg/dL in men and $\geq$ 1.8 mg/dL in women) were excluded from the analyses. After adjustment for blood pressure, age, sex, and race, only baseline serum levels of HDL and triglycerides remained significant predictors of a $\geq$ 0.4 mg/dL creatinine increase from baseline. However, insulin resistance confounded this association because no significant association between HDL and triglycerides and serum creatinine changes was noted after adjustment for serum insulin levels.

Similar results were also observed in the Helsinki Heart Study, a 5-year randomized trial of gemfibrozil versus placebo in middle-aged healthy men with hyperlipidemia.[118] Enrollment criteria included absence of cardiovascular disease and normal serum creatinine, and patients with dipstick positive proteinuria were excluded from the analyses. Baseline serum triglycerides and HDL levels did not predict changes in serum creatinine over the 5-year period. However, the ratio of LDL/HDL was associated with a significantly higher change in serum creatinine among hypertensives and was noted in both treatment groups. In normotensive patients, changes in serum creatinine did not differ by level of the LDL/HDL ratio, regardless of the treatment group.[118] The null findings in these studies may have been due to the relatively short follow-up period.

Cohort studies with adequate follow-up to examine changes in kidney function include the Physicians Health Study. This study examined whether baseline lipid levels predicted an increased serum creatinine ($\geq$ 1.5 mg/dL) after a 14-year follow-up period in over 4000 initially healthy men.[119]

Figure 4–7 Sequence of smoking-induced activation of the renin-angiotensin system: A proposed mechanism of smoking-induced renal damage. (Reproduced with permission from Orth SR: Smoking and the kidney. J Am Soc Nephrol 2002; 13[6]:1663-1672.)

After adjustment for multiple covariates, a baseline total cholesterol level greater than or equal to 240 mg/dL increased the risk of an elevated serum creatinine by 77%, while HDL levels less than 40 mg/dL increased the risk by over twofold. Hsu and colleagues[120] reported similar results in nondiabetic ambulatory patients followed at a university teaching hospital. Baseline serum cholesterol greater than 350 mg/dL increased the risk of developing CKD (GFR < 60 mL/min/1.73 m^2) by fourfold after a mean of 5 years compared to adults with baseline serum cholesterol less than 250 mg/dL.

Few studies have examined whether lipid abnormalities accelerate the progression of GFR loss in patients with established nondiabetic kidney disease. In 44 adult nondiabetic patients with CKD (mean GFR 40 mL/min/1.73 m^2), plasma concentrations of triglyceride rich apolipoprotein Bc particles were reported to be highly and significantly correlated with rate of GFR loss (r=0.43).[121] However, this study did not determine whether apolipoprotein Bc concentrations independently predicted progression of kidney disease. The Modification of Diet in Renal Disease Study, which included 840 patients with chronic kidney disease of different causes, noted an independent association between GFR decline and baseline HDL levels, but the association was limited to patients with baseline GFR levels greater than 25 mL/min/1.73 m^2.[122] Overall, the cumulative evidence suggests that lipid abnormalities influence the progression of GFR loss in patients with established kidney disease and may also increase the risk of developing CKD in healthy men.

AREAS FOR FUTURE RESEARCH

There are numerous areas for future research in nondiabetic kidney disease. Some important potential areas include: studying the potential protective effects of ARBs and other classes of antihypertensive agents, either alone or in combination with ACE inhibitors. In addition, more work is needed to better determine the optimal levels of blood pressure control for different levels of proteinuria of nondiabetic CKD. The impact of smoking cessation and treatment of hyperlipidemia also remains to be explored. Although this chapter has not focused on CVD in nondiabetics, interventional studies are needed to investigate interventions to reduce the toll of CVD in nondiabetic CKD. Finally, there is a need for the development of more precise diagnostic techniques for differentiating between types of nondiabetic CKD, as well as larger studies focusing on individual types of nondiabetic CKD. As discussed, the term "nondiabetic kidney disease" has obvious limitations because it encompasses such a broad array of disease. It is our hope that this term will one day be an anachronism, once we have reached a better understanding of the pathophysiology and treatment of individual causes of kidney disease.

The Role of the Chronic Kidney Disease Clinic

Bryan M. Curtis, M.D., F.R.C.P.C. • Adeera Levin, M.D., F.R.C.P.C.

The purpose of this chapter is to outline the structure and function of a clinic-based approach for the comprehensive care of patients with chronic kidney disease (CKD Care) and describe some of the potential utilities of such a clinic. The described structure and function may serve as a template for the future development of such clinics. To ensure a context for such a clinic we also review the evidence and rationale supporting this concept. Unlike the paradigm for diabetes, or more recently for heart failure, the role of a clinic facilitating the care of patients with CKD has not been as clearly defined. Thus, data to support the concept and implementation are relatively scant, much being drawn from logical arguments as well as from experience with other chronic diseases.

This chapter will describe CKD as an important health problem, key goals of care, and the evidence on which these are founded. It will also describe the principles of chronic disease management and a model of integrated multidisciplinary team-based care structured on these goals. To complete the chapter, we will review ongoing and future clinical trials to ensure that the reader is prepared for upcoming publications.

Kidney Disease Is an Important Health Care Concern

The burden of disease and the growing population of patients with end-stage renal disease (ESRD) remain exceedingly high. In the United States a diagnosis of ESRD may impart more lost life years than prostate or colorectal cancer.[1] As of 2001 in the United States, there were over 290,000 patients on dialysis and over 15,000 patients with kidney transplants.[2] Population studies such as the NHANES III cross-sectional survey of 29,000 persons revealed that 3% of people over age 17 had elevated creatinine.[3] It is estimated that by 2030, the number of patients with ESRD may reach 2.24 million.[2] Furthermore, the direct cost of caring for a patient on dialysis can cost over $50,000 (U.S.) annually.[4,5]

Kidney Disease Is Largely Due to Chronic Diseases

In North America CKD is largely due to diabetes and hypertension,[2] both relatively easy to identify and treat with evidence-based interventions. The NHANES III survey, for example, showed that an elevated creatinine was more common in people with hypertension.[3] Furthermore, clinical trials and prospective cohort studies have identified risk factors associated with accelerated loss of kidney function. In patients with CKD secondary to diabetic, glomerular and hypertensive/vascular diseases, the strongest predictors of more rapid progression are hypertension, especially systolic,[6–14] and the degree and/or persistence of proteinuria.[15–18]

Historically, the focus of CKD care was to coordinate placement of vascular access, to attend to uremic symptoms and complications, and to provide dialysis. However, the focus has changed; not only is it increasingly recognized that the majority of patients with CKD do not progress to ESRD due to varying rates of progression[11,17] and competing risks for death,[19] but also conditions associated with CKD itself, such as anemia and malnutrition, impart significant morbidity. Moreover, there is now a greater appreciation of the epidemiology of the disease, which has led clinicians to understand that the major competing risk for dialysis therapy was death from cardiovascular disease (CVD). Evidence has accumulated regarding the need for more proactive care and institution of strategies to delay progression. Thus, the focus of CKD care has broadened to include CVD risk reduction, in addition to or concomitant with, reducing the progression of kidney decline.[20] As our understanding has grown of the pathophysiology of kidney disease, and CVD within the CKD population, it has become clearer that the treatment and care options are increasingly complex. In addition, it was logical that identification and intervention in the population with earlier stages of CKD would provide the greatest opportunity to reduce morbidity and mortality.

Goals of Therapy

The goals of therapy (Figure 5–1) are to (1) delay progression of CKD, (2) delay/treat known CVD comorbidities, (3) manage uremic complications (such as anemia, mineral metabolism, nutrition, blood pressure), (4) ensure modality choice and timely placement of access or transplant workup, and (5) initiate timely kidney replacement therapy, including preemptive transplantation where feasible. Each of these goals requires education of patients and caregivers, as well as communication between them, and comanagement by different caregivers within medicine, including allied health professionals. With the one aim to maintain health, it is essential that the structure of the clinic reflect all goals and the demand for communication and investigation, to ensure success.

Staging and Terminology for CKD and Impact on Need for Coordinated Care

In 2002 the National Kidney Foundation sponsored Kidney Disease Outcomes Quality Initiative (K/DOQI) published guidelines targeting earlier evaluation and intervention in patients with CKD.[21] Using evidence-based review, the cornerstone of the working group was the establishment of five

Figure 5–1 Care Goals and Elements of CKD Programs. *EOL,* End of life. *KRT,* Kidney replacement therapy.

CARE GOALS AND
ELEMENTS OF CKD PROGRAMS

1º Prevention			2º Prevention

Delay progression	Treat co-morbidities	Manage complications	Prepare for KRT or EOL

Education	Patient independence	Communication	Tools

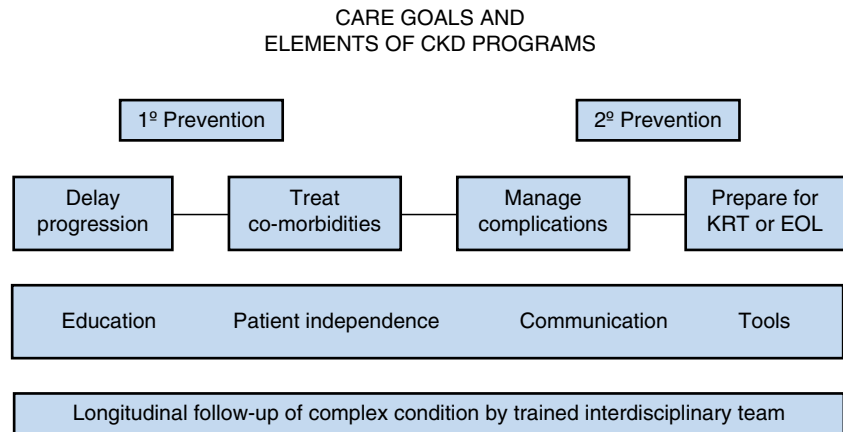
Longitudinal follow-up of complex condition by trained interdisciplinary team


Table 5–1 Five Stages of Chronic Kidney Disease

Stage	GFR (ml/min/1.73 m²)	Description
1	>90	Kidney Damage With Normal or ↑ GFR
2	60-89	Kidney Damage With Mild ↓ GFR
3	30-59	Moderate ↓ GFR
4	15-29	Severe ↓ GFR
5	< 15 or (or dialysis)	Kidney Failure

Adapted from Am J Kidney Dis. 2002 Feb;39(2 Suppl 2):S1-246.

stages of kidney disease (Table 5–1). Importantly, the classification system focused on estimated glomerular filtration rate (GFR) rather then serum creatinine levels alone, because use of serum creatinine alone may lead to overestimation or underestimation of kidney function in those with low (i.e., elderly, women) or high (i.e., muscular males, blacks) muscle mass, respectively. The new system based the classification not only on severity of kidney function decline, but also on the presence of conditions associated with the kidney disease, such as proteinuria and hypertension. In attempting to clarify the historic terms, which are confusing and sometimes misleading (pre-dialysis, progressive renal disease, progressive renal insufficiency), this new definition and classification system is an important tool, which aids in the understanding of CKD and will help standardize its definition. A universal language or terminology will facilitate knowledge acquisition by the medical community, patients, and public bodies and improve research clarity and applicability.

The estimates of populations with CKD that were generated from the new classification system, and the NHANES population database, have helped identify the large burden of CKD that potentially exists in the community. The focus on earlier identification will result in increased referrals for diagnosis, care, and follow-up that will overwhelm current nephrology resources, thus the need to create the appropriately structured care delivery systems described herein and to educate other health care providers in CKD care.

Referral

Late referral to nephrology has been recognized as a problem for many years, because it is associated with increased cost.[22–25] Published recommendations emphasize timely referral to maximize potential gains from involvement of specialized nephrology teams.[26] The appropriate time of referral to a nephrologist is debatable for many reasons, including: (1) other physicians should be capable to manage earlier stages of CKD, (2) estimated high numbers of patients overwhelm current nephrology resources, and (3) many patients with early stages of CKD may not progress. Nonetheless, a minimum recommendation would be for referral at GFR levels of less than 60 mL/min/1.73m² if the primary caregiver cannot identify the cause of the disease or requires help in the management of disease. All patients with GFR less than 30 mL/min/1.73m² should be seen by a nephrology team in order to ensure adequate psychologic and clinical preparation for kidney replacement therapy,[26,27] unless the patient is of an age or has a condition that leads them to not consider chronic dialysis. The new CKD staging system focused on GFR estimation should reduce some of the problems of late referral due to misinterpretation of serum creatinine values.

OVERVIEW OF CKD CLINIC

Philosophic Basis

Clinics for the care of CKD should be based on the fundamental principle of ensuring the delivery of longitudinal, complex care to a large diverse group of individuals. This requires that the structure of the clinic and services offered optimize communication within and between individuals, including the patient and other physicians and medical teams.

Role of Multidisciplinary Clinics

The importance of early referral to nephrologists is not disputed,[26] because identification of the myriad of abnormalities and plans for their treatment is best achieved in consultation with a specialist. However, the ability of nephrologists "alone" to attend to the multiple and complex aspects of care in this patient group is debated.[28] A multicenter cohort of patients

starting dialysis demonstrated that even those patients known to nephrologists for greater than 3 months have suboptimal care. In this study, one third did not have permanent access ready for dialysis initiation, mean hemoglobin was 94 g/L, and mean albumin was below 34 g/L.[29] In another multicenter study of patients with CKD followed by nephrologists, the majority of patients had blood pressure over recommended targets, and only 50% were taking angiotensin converting enzyme (ACE) inhibitors. Furthermore, despite a history of significant heart disease and 66% prevalence of dyslipidemia, only 22% of at-risk patients were on lipid lowering medications. Abnormalities of calcium, phosphate, and parathyroid hormone levels were also demonstrated with only 15% of patients receiving therapy.[30] While there are undoubtedly patient and compliance factors that explain why patients with CKD under the care of nephrologists do not have optimal care, it is also probable that patients were not provided the appropriate elements of care. It is important to note, however, that it was these studies and others that contributed to the recognition of the importance of CKD care and lack of attention to it.

Given the multiplicity of goals of CKD care, the complexity of treatment options, and educational needs, it is clear that a team of individuals will be required. Treatment targets, such as blood pressure, may be reached by involving expert nurses, pharmacists, or other members of the team in conjunction with the physician.[31] Thus, a team approach with well-defined roles, responsibilities, and objectives appears to be both logical and practical. Improved patient care and outcomes due to a multidisciplinary team clinic have been demonstrated in disciplines such as diabetology,[32,33] cardiology,[34–36] rheumatology,[37–39] and oncology.[40] Similarly, compared to standard care by a nephrologist alone, there is evidence of benefit of a multidisciplinary care (MDC) team approach in the care of patients with CKD.[41–43] It appears that outcomes can be improved with protocol-based blood work, clinic visits, and education. This requires involvement of a patient educator, dietitian, social worker, and physician.

There has been only one randomized, controlled trial of case management in CKD, published by Harris and associates,[44] and it did not show a benefit to case management in CKD. However, the intervention in that study was limited to written suggestions made to primary care physicians and the assigned clinic patients did not receive any specific treatment for anemia, mineral metabolism, or for preparation for dialysis/transplant. Failure to show a benefit in the Harris study may well have been due to the failure of individual primary care physicians (PCP) to implement the recommendations from the clinic. Given that PCPs are inundated with protocols and guidelines for the management of numerous chronic conditions, it is unrealistic to expect them to be able to fully attend to the many complex issues of advancing CKD.

Structure and Definition of Multidisciplinary Clinics

These definitions help to clarify the definition of a multidisciplinary team as intended by the authors. It allows the readers to determine what type of resources they currently have available and may help in the interpretation of clinical studies so that similar types of clinics can be compared. Clinic structures can be categorized as follows with respect to multidisciplinary teams:

Formal Multidisciplinary Team

Nurses, nurse educators, dietitians, social workers, and physicians allied in a formal relationship, who interact with the patient and each other defines a multidisciplinary team. Although it is recognized that there are a number of different configurations due to funding and local health care system issues, for the purpose of definition, this team is readily identifiable as dedicated (part time or full time) to CKD care, and may or may not have team rounds or meetings to discuss patient care.

Informal Multidisciplinary Resources

Nurses, social workers, dietitians, and physicians associated with the kidney team to whom patients are referred may constitute informal resources. In such a schema, patient access is dependent of individual patient needs, and the group of individuals may or may not interact as a team or be necessarily dedicated to the longitudinal follow-up of patients. Each team member is able to interact with the patient on a regular basis as necessary, but no coordination with other team members is inherent to its structure.

No Multidisciplinary Team

Nurses, social workers, and dietitians may or may not be available to the patient. There is no team structure or function.

KEY GOALS OF CKD CARE

The following section describes the key goals of comprehensive CKD care, citing evidentiary basis as appropriate for the described strategies, including diagnosis, education, delay of progression, identification and treatment of comorbidities associated with CKD, and of complications of CKD. As well, the institution of primary prevention strategies, including vaccination programs and the preparation of patients for renal replacement therapy as appropriate, will be discussed. The goals described are comprehensive and complex, thus the need for a protocolized structured delivery system, such as a formal clinic.

Diagnosis

The first goal of the nephrology clinic medical staff should be to attempt to establish or confirm a diagnosis and to determine the rate of progression of kidney disease.

The nephrologist should ensure that appropriate tests have been undertaken to establish a diagnosis. Kidney biopsy or imaging may be helpful,[26] especially to rule out any potentially treatable or reversible etiologies such as rapidly progressive glomerulonephritis or obstruction. In early visits, reversible causes of kidney disease should be sought, even if a chronic etiology is suspected, especially if there has been a rapid decline in kidney function. In addition to diagnostic tests, review of current medications to ensure the absence of nephrotoxic medications is prudent. Further workup includes a review of family history and medications, and a search for systemic disease, including diabetes, vascular disease, connective tissue disorders, infections, and malignancy. Several

contributory factors may coexist. The extent of comorbidities, especially the commonly associated vascular diseases[45] should be continually assessed. Although established kidney disease may progress even if the original cause is removed,[46] similar interventions that can slow loss of kidney function may prevent cardiovascular complications. Potentially harmful interventions, such as iodinated intravenous contrast dye, must be reviewed with the patient so that educated decisions may be made regarding their use.

Education

Patient education and awareness are an integral component of the clinic. Education is important from a decision-making perspective as well as to alleviate fear and psychologic suffering. Educated patients are more likely to take an active part in their care, with better outcomes noted in other chronic diseases.[47–49] Ideally, involvement of family members or other support network individuals should be encouraged. The clinic environment can provide a set of resources as well as sessions related to patient education. Minimal education should include the following, presented at the appropriate stages of CKD:

- Explanation of normal kidney function, blood pressure, and laboratory test results and their significance.
- Explanation of specific disease conditions, symptoms, and complications of CKD.
- Dietary teaching and diabetes education, if appropriate.
- Ensuring that patient understanding of medications is adequate.
- Discussions about vein preservation (blood taking and blood pressure).
- Erythropoietin hormone therapy teaching, including: importance of anemia and its treatment; ensure patient understanding of dose changes; warning of the side effects of iron therapy; self-administration or local administration by PCP or community nurse; and provision of educational materials to PCP.
- Discussion of choices for treating ESRD, including conservative therapy, hemodialysis, peritoneal dialysis, and transplant.
- The education effort can be augmented with pamphlets or video materials. Using the principles of adult learning, regular reinforcement of the key messages should be incorporated into the education program.

Delay of Progression

The cornerstone of CKD care is to delay progression of kidney disease and, thereby, reduce complications related to kidney failure. The evidence is relatively consistent in citing that interruption of the renin-angiotensin system (RAS) is a key component to delaying progression. Control of hypertension and reduction of proteinuria are important consequences of RAS interruption and are described more fully later.

Hypertension Treatment

Blood pressure goals should be based on the average of two or more seated readings on each of two or more office visits.[50] There is substantial evidence to support the optimal and target blood pressure of less than 130/80 mmHg in patients with established kidney disease, as suggested in the guidelines of the Seventh Joint National Committee for Prevention, Detection, Evaluation and Treatment of High Blood Pressure.[11,50–53] The goals are to reduce the rate of decline of kidney function[56] and decrease cardiovascular events and mortality. The recommended target blood pressure for patients with proteinuria greater than 1 g/day is less than 125/75.[53] This is based on evidence of slower progression of kidney failure at this level of blood pressure in a large randomized trial, which showed the greatest gain in those with the most proteinuria.[11–12] Patients with kidney disease often need between three and four different medications in addition to lifestyle modification in order to achieve this goal.[55] ACE inhibitors, angiotensin receptor blockers, β-blockers, calcium channel blockers, and diuretics are key drug classes for achieving blood pressure control.[11, 57–59]

Proteinuria Reduction

Patients with CKD and persistent proteinuria of greater than 3 g/day may progress to requiring dialysis or transplant within 2 years.[6, 60, 61] A number of large, randomized, controlled trials demonstrated the efficacy of ACE inhibitors in slowing progression of kidney disease, reducing proteinuria, and also in regressing left ventricular hypertrophy.[62–68] As some of these trials were placebo-controlled, it is difficult to be sure that the benefit was drug specific and not just due to blood pressure lowering. Nevertheless, follow-up studies suggest that long-term ACE inhibition, as a component of a blood pressure therapy, can be associated with stabilization and even improvement of kidney function.[68] Prophylactic use can also be justified in type II diabetics, because ACE inhibition preserved kidney function for over 6 years in normotensive type II diabetics without microalbuminuria.[69] More recently, the use of angiotensin receptor blockers (ARB) have been shown to reduce the time to doubling of serum creatinine, reduction of proteinuria, and time to dialysis.[57,58,70] All of these recent studies have been performed in diabetics. Mann and associates[71] have demonstrated the utility of ace inhibitor use in patients with established CVD, diabetes plus one risk factor, and kidney disease, in a subanalysis of HOPE. More recently, a trial demonstrated that dual blockade of the renin-angiotensin system with both an angiotensin-converting enzyme inhibitor and an angiotensin-II receptor blocker (vs. monotherapy and placebo) may offer additional renal and cardiovascular protection in type I diabetic patients with diabetic nephropathy.[70]

Management of Comorbidity: Secondary Prevention

Cardiovascular Disease

CKD is a risk factor for vascular events and death.[72,73] Creatinine values as low as 130 to 150 μmol/L confer a threefold risk of death within 8 years.[72] Cardiovascular death is 25 times as common as death due to kidney failure in type II diabetics with microalbuminuria.[74] The prevalence of cardiomyopathy, symptomatic heart failure, and symptomatic ischemic heart disease is very high at dialysis initiation.[75] This suggests that the later stages of CKD are a state of high cardiac risk.

Reversible cardiac risk factors, identified in these earlier stages, persist following entry to dialysis. Left ventricular hypertrophy (LVH) occurs in the CKD population, and its prevalence is inversely related to the level of declining kidney function.[76] Anemia and hypertension are also risk factors for progressive LV growth.[76] In kidney transplant recipients, a model of CKD, hypertension is a risk factor for LV growth, de novo heart failure, and de novo ischemic heart disease.[77,78] Anemia predisposes to de novo heart failure, as does hypoalbuminemia.[78] In addition, dyslipidemia and smoking are risk factors for ischemic heart disease.[79,80]

The National Kidney Foundation convened a task force in 1997 to specifically examine the epidemic of CVD in chronic kidney disease.[81] With a focus on decreasing death rates via strategies for prevention of disease, the task force considered whether strategies learned from the general population are applicable to patients with CKD. Recognized traditional risk factors identified in the general population include diabetes, hypertension, smoking, family history of coronary disease, male gender, older age, high low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, physical inactivity, menopause, and psychologic stress (Table 5–2).

As CKD progresses, additional risk factors related to chronic uremia also emerge. Excess cardiac risk may also be due to hemodynamic and metabolic perturbations, including fluid overload, anemia, malnutrition, hypoalbuminemia, inflammation, dyslipidemia, prothrombotic factors, hyperhomocysteinemia, increased oxidative stress, divalent ion abnormalities, vascular calcification, and hyperparathyroidism.[82,83]

Patients with kidney failure therefore require assessment and therapy for vascular disease and associated risk factors. It should be noted that many risk factors for CVD are also associated with the risk of progression of chronic kidney failure.[84] Thus, risk factor reduction strategies used to prevent CVD in the general population can be applied to patients with CKD and may slow the progression of kidney disease as well.[84] It remains unclear whether a raised serum creatinine is a marker for more severe hypertension, diabetes mellitus, and vascular disease, which causes death, or a marker for some intrinsic property of kidney disease, which accelerates CVD. However, some factors more peculiar to kidney disease (anemia, hypoalbuminemia, dyslipidemia) induce cardiac risk and may be amenable to intervention.

Anemia

It has become increasingly evident that anemia is an important predictor of morbidity and mortality in the dialysis population.[85–87] It is associated with ischemic heart disease, left ventricular hypertrophy, and impaired quality of life.[85,87,88] Correction of anemia in CKD improves physical function, energy, cognitive function, and sexual function.[85,89–92]

Treatment of anemia with erythropoietin is effective. Studies are currently underway to determine whether early initiation of therapy among individuals with earlier stages of CKD is effective in preventing CVD, decreasing progression of kidney disease, or improving QOL.[87, 93, 94] There is evidence to suggest that iron supplementation in early kidney disease is important to maintain erythropoiesis, and that erythropoietin therapy is needed to maintain hemoglobin levels. Specific targets for hemoglobin levels have not yet been determined, though levels between 110 and 125 g/L are the current recommended guidelines.[85,95,96]

Mineral Metabolism

There is evidence to support the efficacy of calcium and/or vitamin D supplementation for treatment of hyperparathyroidism.[97–100] At the current time, recommendations regarding target values for patients with earlier stages of CKD have been extrapolated from those for patients with ESRD. We propose an approach that attempts to prevent hyperparathyroidism and its associated long-term complications. Phosphate reduction using dietary restriction, and inexpensive phosphate binders/calcium supplementation in those who have evidence of elevated intact parathyroid hormone (iPTH), and low normal calcium levels is reasonable. Vitamin D analogues are useful for those in whom PTH remains elevated despite calcium supplementation and phosphate restriction. Physiologic release of hormones is pulsatile and, thus, intermittent oral vitamin D therapy is recommended. Unfortunately, evidence for the effectiveness of therapeutic strategies and for specific target levels of each of the variables mentioned above is not available for earlier stages of CKD. Adherence to the principle of prevention, combined with early identification of calcium, phosphate, and PTH abnormalities at early stages of CKD, should lead to minimizing hyperplasia of the parathyroid glands and the attendant metabolic derangements. Future studies will need to address long-term targets and therapeutic strategies.

Nutrition

Malnutrition is common in patients with later stages of CKD. There is a strong association between decreased albumin and worse nutritional status, and adverse outcomes.[89,101–103] Even small decreases in albumin are associated with increased mortality. Unfortunately, albumin is a late index of malnutrition and is a negative acute phase reactant. Acidosis is also a contributor to protein breakdown and mineral metabolism aberrations. Thus, assessment of nutritional status generally requires the expertise of a dietitian.

Table 5–2 Risk Factors for Cardiovascular Disease*

Traditional	Uremic
Diabetes	Hemodynamic overload
Hypertension	Anemia
History of smoking	Malnutrition
Family history of coronary disease	Hypoalbuminemia
Male gender	Inflammation
Older age	Prothrombotic factors
Dyslipidemia	Hyperhomocysteinemia
Proteinuria	Increased oxidative stress
Physical inactivity	Divalent ion abnormalities
Menopause	Vascular calcification
Psychological stress	Hyperparathyroidism

Progression of CKD →

*As CKD progresses there is a parallel evolution of risk factors from taonal to those characteristic of chronic uremia.

Low protein diets have been extensively studied as a means to slow the progression of kidney disease, with mixed results. Meta-analyses and a large, randomized trial suggest that the impact may be slight.[11,104–106] Optimal dietary protein intake is not clear,[104] and there is a potential for protein malnutrition. Appropriate nutritional counseling to avoid malnutrition, acidosis, and phosphate excess is important. There are extensive guidelines for assessment of nutritional status and dietary management proposed by the National Kidney Foundation.[107] Ensuring adherence to a prescribed diet is difficult and requires frequent, continuous input from dietitians. This becomes especially important as the patient approaches ESRD, since worsening malnutrition may become the principal indication to initiate dialysis.

Management of Comorbidity: Primary Prevention

Primary prevention strategies are also important in the management of patients with CKD and may sometimes be overlooked due to the time-intensive management of conditions associated with uremia. Vaccinations, use of aspirin and lipid lowering agents and other CVD primary prevention strategies, as well as diabetes control, smoking cessation, and lifestyle modification are important. This section briefly touches on these strategies in CKD patients.

Vaccinations

Hepatitis B infection remains a concern in dialysis populations, and current recommendations are to vaccinate if eligible. In addition, there are recommendations to vaccinate patients with CKD against pneumococcal infections and influenza, which are common sources of morbidity in patients with chronic illnesses. Vaccination programs have been less successful among CKD patients compared to the general population, both in terms of implementation and response to vaccine. Reasons for poor response include malnutrition, uremia, and generalized immunosuppressive state of patients with CKD. However, variations in vaccination dose and dosing schedule to increase response rates in dialysis patients have been tried with reasonable success, which could be implemented among patients at all stages of CKD. In general, patients with higher GFR levels are more likely to respond with seroconversion to hepatitis B[108] and other vaccines. This reinforces the need to identify CKD early and provide comprehensive care.

Aspirin

The use of low dose aspirin should be considered to reduce the risk of subsequent CVD in patients with coronary artery disease or in those who are at high risk of developing coronary disease,[81] which included most patients with CKD. Recommendations to use aspirin should take into consideration the individual patient's risks of bleeding or other complications of aspirin. If there are contraindications to aspirin use, the use of other antiplatelet agents could be considered.

Dyslipidemia

There are no trials showing that treating dyslipidemia slows the progression of kidney disease. Based on randomized trial evidence of cardiovascular protection, current guidelines recommend an aggressive approach to lipid abnormalities in diabetics and other high-risk patients, which would include those with CKD.[52,109] Thus, best practice would suggest following the guidelines of the National Cholesterol Education Program Adult Treatment Panel II for initial classification, treatment initiation, and target cholesterol levels for diet or drug therapy.[110] Finally, the Heart Protection Study suggested benefit in treating patients with coronary disease, other occlusive arterial disease, or diabetes largely irrespective of initial cholesterol concentrations.[111]

Diabetes Control

Optimal glycemic control in those patients with diabetes mellitus should be encouraged and facilitated with referral to a diabetes clinic if possible. Tight glucose control in both types I and II diabetes may prevent or stabilize the early stages of microvascular complications, including nephropathy.[112,113] The impact seems to be sustainable for years.[114] However, diabetic control has not been shown to slow progression of advanced diabetic nephropathy. Furthermore, as kidney function deteriorates, diabetes management will require modification.

Lifestyle Modification

Smoking cessation is recommended for many reasons, including the possibility that it may slow loss of kidney function.[115,116] Obesity, poor diet, and sedentary lifestyle contribute to diabetes, hypertension, and vascular disease. Current recommendations are thus to achieve and maintain an ideal body mass index and moderate level of physical activity for 30 minutes per day for most days of the week.[81]

Rehabilitation

Cost of kidney disease from loss of work and associated loss of QOL is substantial. Strategies to enable patients to remain working or return to work should be in place and may involve referral to work retraining programs or occupational therapists, if available.[43,117]

PREPARATION FOR KIDNEY REPLACEMENT THERAPY

Preparation for kidney replacement therapy should be based on a good basic knowledge of kidney function, ideally a long process that begins well before the imminent need for initiation exists. Modality selection is done collaboratively with the team and the patients, with an attempt to ensure that patients maintain independent care status and choose modalities that foster such independence. The appropriate timing of initiation of dialysis remains unclear, but it is certain that it must be individualized and must be based generally on a combination of low GFR, patient symptoms, and other factors. Close follow-up of patients at the later stages of CKD, with objective assessment of global functioning, permits appropriate timing of dialysis initiation.

Modality Selection and Access Placement

Modality selection is a decision for the informed patient. It is unknown whether peritoneal dialysis or hemodialysis imparts a survival advantage over the other, as neither randomized trials have been done nor is one feasible in the future. Transplantation is a medically and economically superior treatment[128] for kidney replacement therapy and is associated with higher quality of life. At any given time approximately 50% to 60% of patients receiving dialysis are eligible for transplantation, but estimates are not available for those with earlier stages of CKD. Not all patients are eligible for transplantation, such as those with severe underlying illness. Preemptive transplantation, that is, before the need for dialysis, is generally possible for only those with an available live donor. In the United States, approximately 30% of transplants are from living donors, and a fifth of these are unrelated to the recipient.

It is clear that for some people, contraindications to one of the modalities may exist; for example, extensive prior abdominal surgery may negate the possibility of peritoneal dialysis. Importantly, the patient's desire to undertake chronic dialysis must be closely explored, because there may be some with serious underlying illnesses who choose to not undertake renal replacement therapy.

The options for kidney replacement therapy need to be reviewed with the patient, and access should be planned appropriately, if needed. The reality of how long it takes to decide on modality, get access placed, and let access mature should be stressed to patients, as should the possibility that the first access may not work. A perspective on the relative amount of time required to prepare for each of the options, including transplantation, should be provided. It should also be stressed that the presence of a working access (such as a functioning fistula) does not mean the patient has to start dialysis any earlier. A functioning, albeit unused, access only ensures that additional procedures such as placement of a temporary catheter, might be avoided.

Lack of preparation for dialysis increases morbidity and cost.[118–120] Cost and morbidity implications of temporary catheter access are extensive. They include the cost of catheters, insertion fees, radiology tests, and costs associated with complications such as infection and thrombosis, as well as the pain, discomfort, and time of the patient.

Planning for kidney replacement therapy should begin at least 6 months in advance of anticipated start. According to most published guidelines,[95] access should be created at GFR at approximately 20 to 25 mL/min in those who are anticipated to progress and who do not have a reasonable chance for a preemptive transplant. Reasons for lack of access at dialysis start may include patient factors such as denial of inevitable dialysis, being too sick to undergo permanent access procedures, or late decision to undertake chronic dialysis. However, this may also reflect the CKD team's inability to predict dialysis start, lack of resources, or poor planning. Late recognition of CKD and late referral to nephrology contribute to the problem.

In consultation with the patients and the clinic team, optimal timing around education, decision making, and access creation should be undertaken.

Timely Initiation

When to initiate dialysis is a complex decision that involves the consideration of many variables. There are some easily identi-

fied absolute indications for initiation,[121] however, debate exists with respect to "timely" dialysis when these indicators are not so apparent. Indeed, since the 1970s Bonomini[102, 122–125] has argued for initiation of dialysis before clinically significant markers of uremia appear. His studies suggested a positive association between residual kidney function at dialysis initiation and clinical outcomes. Unfortunately, lead-time bias, patient selection, or referral bias may favor outcomes in the population of patients starting "timely" dialysis. Further complicating the issue is the lack of a tool to define where a patient is on the time line of CKD, for both planning and comparison of study results. To date, there is no solid evidence regarding how "early" dialysis should be started for optimizing patient outcomes.

Presently, two main indices for initiating dialysis for the treatment of kidney failure following progression of CKD are: (1) low GFR and (2) symptoms or signs of uremia, or evidence of malnutrition.[95] Despite the lack of firm evidence, the National Kidney Foundation guidelines, first published in 1997 and updated in 2000, recommend that patients should begin dialysis when the GFR falls below 10.5 mL/min/1.73m^2 (approximates a Kt/V$_{urea}$ of 2.0), unless edema-free body weight is stable or increased, the normalized protein nitrogen appearance nPNArate is greater than or equal to 0.8 gm/kg/day, and there are no clinical signs or symptoms of uremia.[126] More recently, the Canadian Society of Nephrology has recommended that dialysis should be initiated when the GFR is less than 12 mL/min if evidence of uremia or malnutrition (nPNA < 0.8 g/kg/day, or clinical evidence of malnutrition) exists. Despite these and other guidelines, when to initiate dialysis remains debatable. Overall, the key factor is to avoid commencing dialysis when the patient is so ill that education opportunities and the chances for maintaining independence are impaired.

Hemodialysis

The goal is a nontraumatic start to hemodialysis care, and the CKD clinic staff should ensure the appropriate commencement of dialysis, including ensuring that patients have appropriate vascular access and are oriented to the hemodialysis unit. Schedules should be coordinated with appropriate team members in the hemodialysis unit, family members, and other medical professionals. The CKD clinic should send initial dialysis orders and transfer summaries to the hemodialysis unit.

Peritoneal Dialysis

Patients should be oriented to the peritoneal dialysis unit and staff. The role of the CKD clinic in organizing peritoneal dialysis catheter placement will vary from center to center. However, the timing, placement, and preliminary education should be done in concert with the peritoneal dialysis team. As in hemodialysis, specific orders and transfer summaries should be sent to the peritoneal dialysis unit and the training/initiating schedule coordinated with appropriate team members, family members, and other health professionals.

Transplant

As part of the educational process early in the course of CKD, the concepts of transplantation and living donation should be

explored with patients and families. The CKD clinic working closely with the transplant assessment team can help determine eligibility for a transplant. Furthermore, a CKD clinic can facilitate preemptive transplantation, which is generally only possible if the patient with CKD has an available live donor.

Conservative Care

Not all patients will desire or benefit from kidney replacement therapy; longer-term education, longer follow-up time, and an established relationship with CKD team members will facilitate making this choice. In these cases, the CKD clinic staff may be the first to be aware of the wishes of the patients and families, and other caregivers should be informed of these decisions. Once such a decision is made, end-of-life wishes should be formalized, in particular extent of resuscitation attempts, with appropriate consent and documentation. Resources to ensure appropriate supportive care short of dialysis should be mobilized, because much can be done to maintain a patient who chooses to not undertake chronic dialysis. The patient should have referral for home care and for palliative care when appropriate. Patients may benefit from remaining in the care of the CKD team as plans of care may require revision or the patient may change his mind.

CLINIC LOGISTICS

Services

The CKD clinic would presumably exist within a health care system and society where the common goal is the health of the patients. Comprehensive care delivered in only one location is presumed to be beneficial. The frequency with which any individual patient accesses care is determined by the specific circumstances of the medical system, the other physicians involved in patient care, additional comorbid conditions, as well as the specific stage of disease. The clinic should provide a wide range of services for patients with kidney disease, and their physicians, with the overall goals of:

1. Ensuring patient and family understanding of kidney disease.
2. Ensuring understanding of health care system/hospital and outpatient systems and services available to kidney patients.
3. Identifying potential issues related to long-term patient management.
4. Facilitating longitudinal and parallel care of patients with CKD.

Key Components of the Clinic

The clinic should ideally be an outpatient facility providing easy access to all facilities and personnel in one location. This permits familiarity with team members and access to ancillary services as needed. If also located in proximity to the hospital or dialysis center, it provides familiarity with the respective hospital services and locations. Non-English patients should have interpreters provided and booked for entire duration of the clinic visit. It helps if interpreters are able to return with specific patients to facilitate continuity. An information package should be available and given out at the first visit, including an introduction to how the clinic works and various educational mate-

rials, including goals and expectations. Patients and families should also have an introduction to team members and explanation of roles and responsibilities. Finally, the clinic should facilitate peer support for patients with CKD.

In addition to ongoing assessment of patient by the team through regular clinic visits, weekly multidisciplinary rounds should be organized to facilitate communication and develop or adjust plan of care. This will allow for comprehensive follow-up by nurses, clerical staff, and others and facilitate:

- Bookings for tests (US, CT, etc.) and referrals to other specialists
- Medication changes/tolerance, etc.
- Reminders for appointments/blood work.
- Follow-up of test results.
- Liaison with laboratories and pharmacies.
- Liaison with GP and other consultants, including palliative care team (in hospital or community).
- Patients should receive education about kidney or kidney/pancreas transplant and screening for potential donors and referrals as appropriate.

Individual Roles

In order for any team to function, definition and clarification of roles of the individuals involved are important. Below are listed key roles and responsibilities for each of the key staff deemed important in the delivery of CKD care. The specifics may vary depending on local issues, but the principal roles need to be clearly defined.

Nurse

The CKD nurses function as case managers and facilitate care of patients, directly and through physician and team member liaison. Nursing support should be available 5 days a week by telephone or in person to triage medical concerns, answer questions, provide education or emotional support and referral to other team members or community resources. This should allow for ongoing collaboration and reevaluation with the patient, and facilitate changes in care plan with input from team members. A regular review of symptoms, medications, and monitoring of lab work results should occur, again responding to critical values by notifying physician, patient, and dietitian as necessary. The nurse should be able to liaise with family physicians, consultants, and other chronic disease clinics (e.g., diabetes, health heart, heart function clinic).

Nurses should be able to implement protocols such as hepatitis screening and vaccination program or peri-angiogram protocols. Similarly, they should be able to arrange treatment and procedures such as I.V. iron and transfusions or arrange referral for dialysis access and follow-up care. If patients progress to kidney failure, then the nurse should ensure coordination of initiation of dialysis or referral for transplantation and transfer of relevant data to dialysis or transplant facility. Finally, they should coordinate services in remote settings for the convenience of patients.

Dietitian

Patients should receive individualized diet education and counseling regarding CKD, diabetes, and heart disease, from a

dietitian knowledgeable about the nutritional abnormalities of CKD. The dietitian should review diet history, habits and nutritional health, and advise patient about food choices and meal ideas. There should be a periodic dietary review, including blood work, to help reach goals and to avoid malnutrition.

Social Worker

Social workers may provide assistance with emotional and practical concerns of patients and their families, and assess emotional needs or potential issues that may arise, such as acceptance of kidney failure and end-of-life issues. The social worker should have a mechanism to liaise with psychiatry as needed. They also advocate on patient's behalf to ensure maximum allowable benefit from available resources such as home support, financial assistance, employment/retraining, and housing, and may need to assist the patient with insurance issues, including referral to institutional financial counselors.

Pharmacist

If possible, pharmacy services should be available for initial medication review and follow-up. They may advise about medication costs, pill burden, and possible interactions. They may also provide education and support as needed.

Clerical or Administrative Support

Clinics should have a dedicated unit coordinator/clerical support worker. Their main role is to ensure that data and patient charts are maintained accurately. A paper/electronic chart should be established with complete information available and maintained with ongoing follow-up data. This will include data such as labs, medications, and comorbidities. The coordinator is an essential component of the team as the organization of booking and coordinating appointments with other clinics, consultants, diagnostics, and community resources and follow-up is essential. Additionally, they are integral for information and chart transfer to programs within the kidney programs such as dialysis or transplant clinic. They may also triage patient concerns with the team and have appointment reminders for patients. Finally, they should identify interpreter requests and book interpreters as needed.

CKD Clinic Role in Longitudinal Care: Different Stages of CKD

Given the current estimates of the CKD population (between 10 and 20 million in the United States), it is unlikely that the optimal resources described in this chapter are available to all patients with CKD. It is still debated whether a nephrologist must see all patients with early CKD, as it is not clear who will and will not progress. Although there is consensus that nephrologists and teams need to see the patients at least 6 months, and ideally 12 months, prior to dialysis start for access, there remains skepticism regarding the utility of nephrology input prior to that time.

Although much has been learned about care of patients close to initiating dialysis, it is not known how to optimally care for patients in early CKD (frequency of visits, frequency of blood work, when to initiate "early" drug therapy, etc.). It seems reasonable that a "phased" approach is applicable. As outlined, the focus of the clinic must be adjustable from early disease detection and risk factor modification to preparing for kidney replacement therapy. Key at all phases would be communication and education between patients, medical caregivers, and allied health teams (Figure 5–2).

One end of the spectrum is an early referral (stage I or II) and a broad plan outlined to another caregiver about goals of treatment for that caregiver to follow. Patients could be familiarized with the clinic and kidney disease at this initial period and then referred back to the clinic if the kidney function deteriorates, for further education and refinement of management plan. Both the patient and the other caregiver are informed that the clinic is available when needed for either informal consultation or formal evaluation. The other end of the spectrum is for the clinic to assume most of the care, if not all, surrounding issues pertaining to kidney disease and other issues such as diabetes management. In between, the clinic could do a formal initial evaluation and then arrange follow-up once every year or so. To date there are no studies that have systematically evaluated the impact of different methods of care at earlier stages of CKD, though a number of trials are being planned.

CKD Clinic Role in Parallel Care: Integrating with Other Caregivers

An important issue in dealing with individual patients who are obtaining care in parallel locations (i.e., family physicians, diabetic services, and CKD clinic) is communication. The clinic should be viewed as a resource to both patients and parallel caregivers such as family and other physicians, and as such, could integrate care with other caregivers. For example, other caregivers could call to seek advice regarding safety of medications, and the clinic can serve as a facility to follow the patients during acute events (e.g., increased creatinine around diarrhea and temporarily holding the ace inhibitor). It is vital for such a clinic to communicate information about patient status, medications, plans, and so forth, not only to the patient but to all other caregivers involved (family physicians, diabetes clinics, hospital charts).

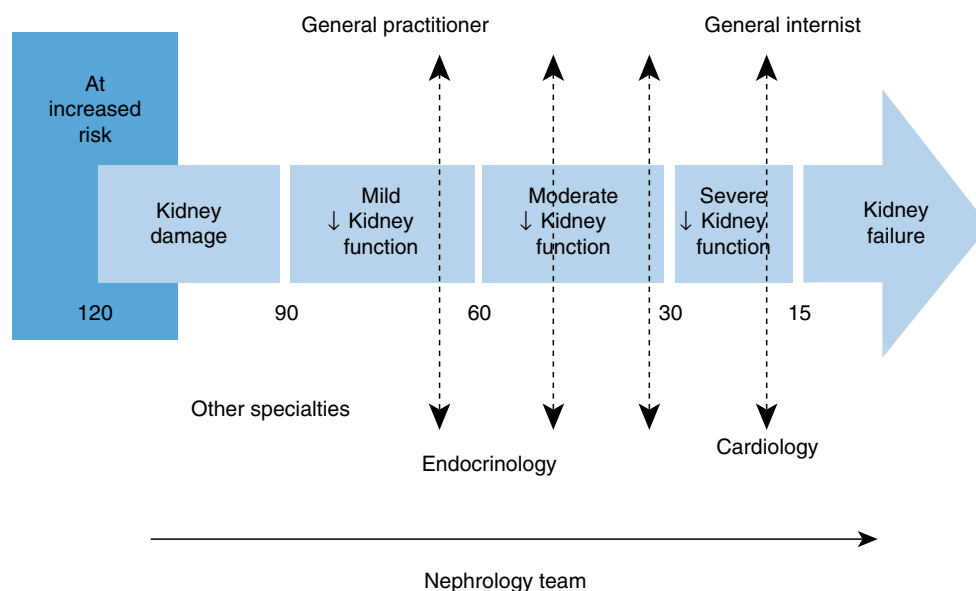
When inpatients are accessing different care systems due to the complex nature of their disease or due to practical issues such as locale, it is not so clear how to determine the responsibility of each of the individual medical practitioners. Should the CKD clinic assume the ace inhibitor is being managed by the heart failure clinic? Or does the CKD clinic assume the diabetes clinic is managing the blood sugar control or counseling about smoking cessation? At what point in the stage of CKD does the CKD clinic take a more active role? These are not questions that will be answered in clinical trials, so practical solutions to the issue of responsibility for care implementation will need to be developed. Again the key issue here is the communication between different physician group and medical teams and customization to individual patient and health care system particulars. There is an accumulating body of literature[47–49] that suggests involvement of the patient in all implementation plans, and knowledge of and active involvement in therapy targets and test results improve the ability of physicians to implement care strategies.


Figure 5–2   Integration of care over the progression of CKD (Longitudinal Care) and between other caregivers (Parallel Care).

Other Benefits of the CKD Clinic and Organized Protocolized Care

The key to the care of patients with chronic diseases is acknowledgment of the complexity of the condition(s) and the need for longitudinal follow-up by a well-trained team. As in oncology, rheumatology, and other areas of medicine, the care of CKD patients requires some adoption of protocols for investigation, therapy, and follow-up (Figure 5–3 and Table 5–3). In so doing, we will be able to develop sensible strategies based on data, and management of selected conditions will be uniformly undertaken. The systematic evaluation and management of patients with chronic diseases has been demonstrated to reduce resource utilization and to enhance patient compliance.

Table 5–3   Example of a Protocol for Follow-up/Blood Work Intervals*

Minimum follow-up/bloodwork intervals as a function of kidney function		
Creatinine Clearance (mL/min)	Interval between visits/bloodwork	
	Diabetics	Non-diabetics
31-60	3 months	3 months
15-30	2 months	3 months
10-14	1 month	2 months
<10	1 month	1 month

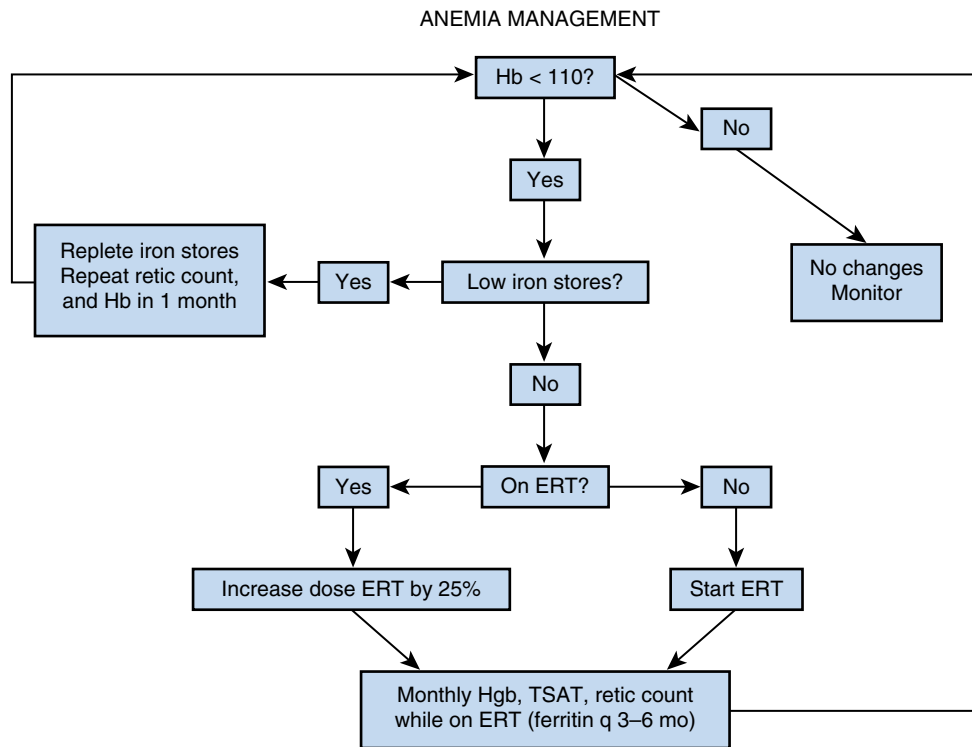
*Maximum intervals (or minimum frequency) between visits are given for stable patients. Shorter intervals may be necessary at discretion of physician or specialized nurse in less stable patients, or be specified in therapy titration algorithms (e.g., initiation of erythropoietin replacement therapy).

The additional advantages to the clinic models for the care of CKD include the ability to optimize all aspects of care by using individual team member's expertise more appropriately and to optimize follow-up and monitoring of large groups of patients in one area. Furthermore, a clinic-based approach would allow database development and evaluation of outcomes in large cohorts of patients, the ability to enroll patients in clinical trials, and importantly, the adoption of newer proven therapies may be easier in a clinic setting than in individual physician offices.

The clinic structure may also ensure that patients have access to appropriate current information and materials that may not be available in individual physician offices. Also, it will permit coordination of care plans and execution of those plans within any health system structure.

Barriers to care or implementation of strategies can be identified in a clinic setting. The costs and the number of medications required for CKD is becoming progressively daunting and leads to problems with compliance. These problems are more likely to be identified within a clinic setting, where social workers, pharmacists, and others may identify issues not identified by physicians. The importance of an asymptomatic condition can be reinforced in clinic settings where the patient–team interaction is far longer than the usual patient–doctor interaction.[41] Although there may be multiple problems and barriers that interfere with achieving the care goals in any one individual, the presence of an organized team approach is more likely to ensure the identification of those barriers in a timely manner.

FUTURE STUDIES

The CAN-CARE (Canadian Care Prior to Dialysis) Study is a prospective multicenter cohort study of incident patients with estimated GFR less than 50 mL/min referred to nephrol-


ANEMIA MANAGEMENT

Figure 5–3 An example of a protocol for anemia management that may guide therapy by physician or specialized nurse. It assumes all secondary causes of anemia have been ruled out. *ERT,* erythropoietin replacement therapy (erythropoietin or darbopoieten); *Hb,* hemoglobin.

ogists across Canada. Enrollment began November 2000 with a planned follow-up of up to 4 years. The objectives are to describe: (1) the specific care ("elements") these patients receive over time, (2) the prevalence of cardio-renal risk factors at referral and at 12 and 24 months, and (3) the link between specific elements of care and outcomes/quality of life. The Study of Treatment for Renal Insufficiency: Data and Evaluation (STRIDE) registry will study data on prevalent CKD patients in nephrology practices in the United States.[128] The Chronic Renal Insufficiency Cohort (CRIC) Study will examine risk factors for progression of CKD and CVD among those patients. The main goal is to develop models identifying high-risk subgroups and, subsequently, increase application of preventive therapies.[129] The Kidney Early Evaluation Program (KEEP) was implemented to increase awareness of kidney disease among those at highest risk and, subsequently, to improve outcomes through early detection and referral for care. The KEEP 2.0 screening program identified persons with reduced kidney function and suboptimal care. The KEEP 3.0 will continue to identify individuals at high risk for kidney disease and will address educational needs by randomly assigning participants to one of several educational programs.[130]

The Can-Prevent trial is a proposed Canada-wide multi-center clinical trial to address the hypothesis that compared to usual care, a nurse supported by a nephrologist, running a multiple risk factor intervention and disease management clinic for people with moderate chronic kidney disease identified by laboratory based case-finding, will reduce or delay the onset of advanced kidney disease, cardiovascular events,

and death. The study will also assess the effect on health care resource use, costs, and quality of life. Measurements of quality of life (QOL) in kidney patients have demonstrated worsening QOL as a function of anemia and need for dialysis. A systematic study of QOL prior to dialysis has not been undertaken, because there is a lack of organized access to this group of patients. Well designed studies are needed to better understand the impact of various therapeutic regimens on patient perceptions of health and wellness. Furthermore, the study will measure aspects of the professional care delivered (e.g., time spent, education provided) and assess the association of these with outcome. Interventions applied will include lowering blood pressure to target, maximal use of renin-angiotensin system interruption, treatment of dyslipidemia, prophylactic aspirin when indicated, treatment of renal anemia, disordered calcium/phosphate and parathyroid metabolism, use of β-blockers in heart failure and post myocardial infarction, control of diabetes, and smoking cessation.

CONCLUSION

Kidney disease involves the complex physical, mental, and social aspects of health mandating an understanding and rational utilization of available resources. Opportunities exist to improve early identification and follow-up of patients with CKD and to ensure better outcomes overall, regardless of whether patients ultimately require dialysis.

In order to focus on these complex aspects of care, the inclusion of medical, nursing, dietary, social work, and pharmacy staff in a coordinated system, with protocolized goals and systematic approaches to longitudinal follow-up is required. It is hoped that the information supplied herein will help develop templates and deliveries of care models for further evaluation, so that, ultimately, the outcomes of patients with CKD at all stages of disease are improved.

SECTION B

Complications of Chronic Kidney Disease

Chapter 6

Uremic Toxicity

Raymond Camille Vanholder, M.D., Ph.D. • Griet Glorieux, M.Sc., Ph.D. • Rita De Smet, M.Sc., Ing. • Norbert Hendrik Lameire, M.D., Ph.D.

The uremic syndrome is a complex of biologic and biochemical alterations that result in a host of failing organs and disturbing symptoms. It originates from the retention of solutes, that under normal conditions are cleared by the kidneys into the normal urine, although derangements of hormonal, metabolic, and enzymatic axes also play a role. The impact of retention is underscored by the clinical improvement resulting from dialysis and kidney transplantation.

The uremic syndrome is characterized by a deterioration of biochemical and physiologic functions (Table 6–1), in parallel with the progression of renal failure. This results in a variable number of symptoms, which mimic the picture of exogenous poisoning. Although the link between clinical deterioration and uremia has already been recognized decades ago, and although the number of new pathophysiologic elements provided in this area has risen exponentially over the last few years, our knowledge about the responsible factors remains incomplete.

In this chapter, the current knowledge about the uremic syndrome, its clinical and biochemical characteristics, and the factors playing a role in its development will be reviewed.

CLINICAL CHARACTERISTICS

Cardiovascular System

Cardiovascular anomalies occur almost invariably when renal function deteriorates[1]: hypertension, congestive heart failure, valvular stenosis or insufficiency and accelerated atheromatosis are among the most frequent epiphenomena.[2–4] Cardiovascular death is the most frequent cause of mortality in patients with end-stage renal disease.[5] A major point of concern in the uremic population is the accelerated development of atheromatosis, which starts already in the pre-dialytic phase.[6] Recently, atheromatosis has been classified as an inflammatory, rather than a degenerative disease.[7] Also in renal failure, inflammation and cardiovascular disease have been linked to each other.[8–10] Recently, a failure of the arterial

vessel wall to relax,[11] resulting in systolic hypertension and diastolic hypotension, as well as an accelerated deposition of calcium in the vessel wall, even in young patients, has been described.[12] These events result in an inadequate coronary perfusion, since blood stream through the coronaries normally takes place during diastole.

Pericarditis has become rare with the advent of adequate dialysis strategies, except in patients who are referred too late and/or in patients with major access problems.

Cardiac hypertrophy and dilated cardiomyopathy are common findings in end-stage renal failure.[13] Myocardial dysfunction is related to an increase in myocardial cell calcium content.[14] Increased cytosolic Ca^{++} is also related to increased peripheral vascular resistance and hypertension.[15] Endothelium-dependent vasodilation is impaired in uremia.[16, 17]

In spite of elevated circulating catecholamines, a diminished response of the cardiac α- and β-receptors has been reported,[18] which may be related to uremic autonomic neuropathy. Vasoconstrictive response during postural stress is lacking.[19] Moreover, the binding properties of catecholamines to vascular and myocardial adrenergic receptors may be altered.[20]

Apart from changes in systolic cardiac contractility, a decrease in diastolic compliance also plays a major pathophysiologic role.[21] This alteration is not necessarily related to previous hypertension. The basic mechanism is associated with an activation of interstitial cells and increased volume of interstitial cell nuclei and cytoplasm, whereby uremia increases myocardial interstitial ground substance.[21]

Although the importance of cardiovascular changes has been emphasized in end-stage renal failure,[22] uremia-induced atherogenic alterations probably start to take place much earlier, especially in patients with additional risk factors.[23]

Although many factors and retention solutes seem to be involved in cardiovascular disturbances of uremia, at present pro-inflammatory agents such as the cytokines,[8] oxidation products[24] and glycation products[25] are considered the main culprits. In view of its role in the general population,[26] also the role of homocysteine has been considered,[27] but its

Table 6–1   The Uremic Syndrome — Main Clinical Alterations

1) *Cardiovascular system* – atheromatosis – arteriosclerosis – cardiomyopathy – decreased diastolic compliance – hyper/hypotension – pericarditis 2) *Nervous system* – concentration disturbances – cramps – dementia – depression – fatigue – headache – motor weakness – polyneuritis – reduced sociability – restless legs – sleep disorders – stupor, coma 3) *Hematological system / coagulation* – anemia – bleeding – hypercoagulability 4) *Immunological system* – inadequate antibody formation – stimulation of inflammation (baseline) – susceptibility to cancer – susceptibility to infection 5) *Endocrinology* – dyslipidemia – glucose intolerance	– growth retardation – hyperparathyroidism – hypogonadism – impotence, diminished libido 6) *Bone disease* – adynamic bone disease – amyloidosis (β_2-microglobulin) – defective calcitriol metabolism – osteitis fibrosa – osteomalacia – oseoporosis 7) *Skin* – melanosis – pruritus – uremic frost 8) *Gastro-intestinal system* – anorexia – dyspepsia – gastro-intestinal ulcers – hiccup – nausea, vomiting – pancreatitis 9) *Pulmonary system* – pleuritis – pulmonary edema – sleep apnoea syndrome 10) *Miscellaneous* – hypothermia – thirst – uremic foetor – weight loss

relevance remains difficult to prove in the uremic population.[28] Phosphate and an increased calcium-phosphate product are also considered to play a germane role[29] by provoking calcium deposition in the vessel wall. Also, hyperparathyroidism induces vascular calcification, essentially of the small and medium-sized vessels.[30] The guanidine asymmetric dimethyl arginine (ADMA) which is known to inhibit nitric oxide (NO) generation, has been related to vascular damage.[31]

Nervous System

During the progress of renal failure, uremic encephalopathy may develop alone or in combination with peripheral neuropathy.[32] The spectrum of central neuropathy is variable and ranges from minor mental disturbances to coma, but in the case of adequate dialysis, encephalopathy is exceptional today. Sleep disorders, on the other hand, are frequent, often in the context of the obstructive sleep apnea syndrome.[33] Brain stem-evoked potentials are disturbed, both in the pre-dialysis stage and after dialysis has been started.[34]

Also clinically overt peripheral polyneuropathy is exceptional today, although less pronounced variants that are only detectable by electromyography still persist, even in patients treated by acceptable dialysis, according to the current standards. Data regarding the responsible toxins are scarce; a substantial part of the presently available evidence points in the direction of the guanidines.[35] A recent comprehensive study disclosed an additional number of potential culprits, essentially small protein-bound compounds, such as spermine, spermidine and *p*-cresol.[36] Peripheral polyneuropathy might be improved by the application of large pore/high-flux membranes, which points to a role for larger "middle" molecules,[37] although this effect might as well be the result of the biocompatibility of these membranes. Vitamin and trace element deficiencies might additionally contribute to this problem.[38, 39]

HEMATOLOGY

Until the therapeutic applicability of recombinant erythropoietin, uremic anemia was one of the main components of the unsatisfactory quality of life of many renal failure patients. Anemia is mainly attributable to inappropriate erythropoietin production by the failing kidneys, but also defective body iron stores, resistance to iron, vitamin deficiencies, and increased blood losses might be at play, as well as erythrocyte fragility, in part related to hyperparathyroidism.[40]

The role of uremic retention solutes in the inhibition of erythropoiesis remains a matter of debate. The polyamines spermine and spermidine were suspected to inhibit hematopoiesis *in vitro*.[41,42] Segal and associates[46] suggested, however, that their inhibitory effect was aspecific,[43] and the above impact of polyamines on hematopoiesis was, to our knowledge, never confirmed. Other uremic retention solutes that have been incriminated are furancarboxylic acid (3-carboxy-4-methyl-5-propyl-2-furanpropionic acid [CMPF]),[44] parathyroid hormone,[45] and the inflammatory cytokines.

Insulin-like growth factor I (IGF-I) may modulate erythropoiesis by enhancing the effect of erythropoietin. A highly significant correlation was found in hemodialysis patients between IGF-I and hematocrit values.[47]

COAGULATION

Coagulation disturbances in uremia are reflected by an enhanced bleeding tendency, as well as by hypercoagulability. Other, nontoxic factors, such as the bioincompatibility of dialyzer membranes and circuits, are equally involved.

Uremic bleeding tendency is multifactorial. Platelet alterations (adherence, aggregation), anemia, hyperparathyroidism, and disturbances of prostaglandin production play a role.[48,49] The number of circulating thrombocytes remains unaltered in uremia, pointing to the role of functional changes in the induction of coagulation disturbances. Thrombocyte retention by glass beads,[50] aggregation response to adenosine diphosphate and collagen,[51] exposure of fibrinogen receptor,[51] cyclo-oxygenase activity,[52] and carbohydrate metabolism[53] are disturbed in renal failure.

Until a few years ago, no specific inhibitor of coagulation had been identified. More recently, nitric oxide (NO) was incriminated as a potential inducer of defective coagulation in at least a part of the uremic population.[54] In many uremic patients, however, NO-activity is inhibited,[55] which at least in theory should result in hypercoagulability.

In spite of the fact that a tendency for bleeding is found in most patients, isolated defects such as elevated amplitudes at thromboelastography[56] and increased von Willebrand factor activity,[57] point to hypercoagulability. Retention of altered fibrinogen fragments might modify coagulatory function and platelet response.[58]

IMMUNE STATUS

The susceptibility to infections, increased incidence of cancer, the burnout of immunologic disorders, and the presence of an inadequate antibody response, illustrate immune dysfunction in uremia. It is apparent at different levels: abnormalities of polymorphonuclear cell function (disturbances of locomotion and phagocytosis), changes in levels and quality of immunoglobulins, reticuloendothelial dysfunction, and disturbed cell-mediated immunity.[59,60] The number of circulating leukocytes remains unaltered, pointing to functional changes.

Bacterial infection remains one of the most prevalent clinical complications. A crucial role in the host-defense against bacterial infection is occupied by phagocytes.[61] Failure of phagocytes to ingest microparticles and to kill bacteria, points

to a depression of their functional capacity.[59,60,62] The start of hemodialysis induces a further depression in polymorphonuclear functional response,[62,63] but an improvement is observed when patients remain on dialysis for longer periods.[64]

Cellular immunity primarily involves T-lymphocytes and their production of lymphokines. Granulocytes and macrophages interfere with each other as effector cells of this system. Many cellular functions such as T-cell growth factor activity, T-cell subset identification, metabolic responsiveness, lymphatic immune response and/or proliferation, and E-rosette forming capacity are disturbed. Raskova and associates[65] demonstrated that B-cell activation and immunoregulation, as well as helper T-cell functions, are quantitatively deficient. Lymphocyte response to stimulation is disturbed in cultured cells from dialyzed patients.[66] T-cell adhesion to extracellular matrix proteins is depressed in the presence of uremic sera.[67] Impaired proliferation of peripheral blood leukocytes and T-cell activation have been attributed to an accessory cell defect in the B7/CD28 pathway.[68] *In vitro* restoration of this B7/CD28 pathway reconstitutes leukocytic cellular function.

Many toxins have been claimed to suppress immune function: endorphins, phenols, indoles, parathyroid hormone, several peptidic structures, *p*-cresol, guanidino compounds, and advanced glycation end products, inhibit activated immune cell functional capacity.[25,59,69–74]

Other toxic factors might be involved, such as the disruption of protective skin barriers by vascular access, the bioincompatibility of dialyzers,[62] vitamin D deficiency or resistance,[75] infection-prone anatomic anomalies (e.g., polycystic kidney disease, vesicoureteral reflux, and cardiac valvular damage),[59] dysfunction of opsonins,[76] iron overload,[77] and anemia.[78]

In contrast to the ineffective response towards stimuli and infectious agents, the baseline uremic immune status is activated.[79, 80] This results in a hyperoxidative condition and in an oxidative modification of molecules and structures.[24] This mechanism is most likely involved in atherogenesis and cardiovascular damage.[80]

ENDOCRINOLOGY

Carbohydrate Metabolism

Alterations of glucose-induced insulin secretion,[81] and target organ insensitivity to insulin,[82] are reflected by glucose intolerance,[83] which is not related to a decrease of insulin receptor binding or receptor kinase activity,[84] but to a decrease of glucose transport sites.[85,86] Remarkably, 1,25-dihydroxycholecalciferol corrects glucose-intolerance in hemodialysis patients.[87]

MacCaleb and associates[88] characterized and partially purified a peptide from uremic serum, which induces insulin resistance, although without exact identification. Dzúrik and associates[89–91] suggested hippuric acid, 5-hydroxyindoleacetic acid, and pseudouridine as potential inhibitors.

Glucagon levels are elevated because of inadequate renal metabolism.[92]

Thyroid Hormone

Levels of T3 and T4 may be depressed, in spite of a euthyroid appearance.[93] Both 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid (CMPF) and indoxyl sulfate inhibit the deiodination

of thyroxine by cultured hepatocytes.[94] The release of thyroid stimulating hormone (TSH) is suppressed, possibly by a dopamine-dependent mechanism.[95]

Growth Hormones

Baseline levels of growth hormone (GH) progressively increase during the progression of renal failure. Nevertheless, growth retardation is one of the onerous facets of pediatric nephrology. Contributing factors are the resistance to growth hormone,[96] malnutrition, acidosis, renal osteodystrophy, hyperparathyroidism, and inadequate gonadotropic hormone secretion.[97] Hepatic insulin-like growth factor-1 (IGF-1) expression is reduced in uremia, whereas the production of IGF-binding proteins is enhanced.[98] The administration of recombinant human GH and of IGF corrects the growth disturbances of uremic children[97,99] and improves protein utilization in stable hemodialyzed adults.[100,101] Use of this compound should, however, be avoided in critically ill patients, where protein turnover is accelerated.[102] Children with GH deficiency have higher plasma levels of soluble CD30, which is an index of Th2 lymphocyte activation.[103]

In uremic rats, the prevalence of growth hormone receptors in growth plates is decreased, and this defect is corrected by the administration of GH combined to IGF-I.[104]

Reproductive Hormones

Advanced renal failure results in reproductive abnormalities in both men and women. The cyclic peaks that are normally observed immediately before ovulation, do not occur in uremia,[105] pointing to a disregulation of the hypothalamic-pituitary-ovarian axis. Uremic men are often infertile and/or impotent. This is associated with an increase of plasma LH and FSH levels and a decrease of testosterone and results in compromised spermatogenesis. Prolactin levels are elevated, which induces galactorrhea and amenorrhea in women and impotence in men.[106] One of the epiphenomena of reduced gonadotropin pulsatility during pubertal maturation is growth retardation.[107]

BONE DISEASE

Uremic bone disease is a multifactorial problem, depending upon diverging mechanisms such as hyperparathyroidism, aluminum toxicity, vitamin D deficiency and resistance, intrinsic osteopenia, and amyloidosis.[108] Also, inflammatory elements might suppress bone formation.[109] Defective production of IGF-1 may play a role in deficient bone formation.[110] A low molecular weight inhibitor of cartilage sulfation, with negative influence on bone cell proliferation, has been detected in the plasma of dialysis patients.[111] Andress and associates[113–115] described an inhibitor of osteoblast mitogenesis with a molecular weight range between 750 and 900 dalton (D).[112] Several authors found evidence that uremic retention solutes reduce the molecular response to active vitamin D and its analogues.

Hyperparathyroidism as such is the result of relative hypocalcemia, hypovitaminosis D, and resistance to vitamin D.[116] Although it was accepted that hyperphosphatemia indirectly caused hyperparathyroidism, it was recently demonstrated that hyperphosphatemia also directly stimulated the response of the parathyroid gland.[117]

Therapeutic maneuvers to refrain parathyroid response, such as administration of oral calcium salts or vitamin D analogues, might as a counterbalance enhance calcium load and hence vascular calcification. The advent of noncalcium phosphate binders[118] and calcimimetics[119] might help to overcome this dysbalance.

Uremia-associated amyloidosis is a disease that mainly strikes the bone, tendons, and joints. ß$_2$-microglobulin is the main component of this amyloid.[120] Several modifications have been proposed to participate in amyloid formation: proteolysis of the N-terminus of ß$_2$-microglobulin,[121] deamination of Asn17,[122] and modification of ß$_2$-microglobulin by Advanced Glycation End Products (AGEs).[123] Other protein components of amyloid than ß$_2$-microglobulin, such as α$_2$-macroglobulin,[124] glycosaminoglycans,[125] and amyloid P components,[126] may also play a pathogenetic role. Furthermore, to explain the predilection of this disease for synovial and periarticular structures, a role for local predisposing factors should be postulated.[127]

Probably because of the recent adaptation in our therapeutic arsenal, the incidence of uremia-related amyloidosis has followed a pattern of decreasing frequency.[128]

PRURITUS

Several factors have been incriminated: increased serum vitamin A, hyperparathyroidism, high skin contents of divalent cations, mast cell proliferation with increased release of histamine, liver dysfunction, and/or abnormal cutaneous innervation.[129] Erythropoietin treatment may improve pruritic complaints.[130] Parathyroid hormone and phosphorus are the main responsible toxins.

PROGRESSION OF RENAL DISEASE

Motojima and associates[131] found compelling evidence that one or more ultrafiltrable uremic retention solutes were involved in the progression of glomerulosclerosis. Later studies by Niwa and associates[132,133] identified indoxyl sulfate as one of the responsible molecules. The administration of an oral sorbent alleviated the overload of indoxyl sulfate on remnant proximal tubular epithelial cells[134] and reduced the gene expression of Tissue Growth Factor-β1 (TGF-ß1) and of tissue inhibitor of metalloproteinase-1 (TIMP-1), which resulted in a delay of the progression of chronic renal failure. Sympathetic overactivity may also play a role in this progression.[135]

MALNUTRITION

A substantial number of end-stage renal disease (ESRD) and pre-ESRD patients suffer from malnutrition,[136] and a link between malnutrition, cardiovascular disease, and inflammation has been proposed.[8,9,80,136] Several pro-inflammatory compounds such as AGE, advanced oxidation end products (AOPP), and cytokines are accumulated in renal failure and might play a role in this process.[137] Leptin, a 16 kD suppressor

of appetite, is retained in renal failure[138] and does so more in patients with a loss of body mass.[139]

Apart from inflammation, central and gastrointestinal mechanisms are involved in malnutrition. Brain serotonin hyperproduction, related to disturbances of tryptophan metabolism, has been related to uremic anorexia.[140] Gastric emptying disturbances are observed in a substantial fraction of the uremic population.[141,142] Also, acidosis provokes uremic catabolism,[143,144] by induction of proteolysis and resistance to growth hormones.

END-STAGE RENAL FAILURE

Until a few years ago, it was current practice to wait with the start of renal replacement until the creatinine clearance reached a level of 5 mL/min or less. Already more than a decade ago, some authors advocated the start of dialysis at an earlier stage (Ccrea 10–15 mL/min),[145] although well controlled studies proving the benefit of this approach were, to our knowledge, never published.

More recently, it became clear that the normalized clearance of low molecular weight molecules such as urea (Kt/V), which is a current marker of dialysis adequacy, is much lower in patients awaiting dialysis, than the values pursued once dialysis has been started.[146]

Studies still need to be undertaken to define the exact values of renal function at which dialysis should be initiated, although recent guidelines forward a cutoff value of weekly Kt/V of 2.0, a native creatinine clearance of 12 mL/min, or a GFR of 15 mL/min, in the presence of symptoms.[147–149] It should be noted that symptoms that are seemingly uremic, may be induced by nonuremic mechanisms such as the concomitant presence of hepatic failure, cerebrovascular disease or diabetes mellitus, disturbances of electrolyte and water homeostasis, and drug intoxication. An incorrect interpretation of these signs will result in the inappropriate start of renal replacement therapy. On the other hand, damaging side effects, such as vascular lesions and endothelial dysfunction, might occur early during progression,[150] so that even an earlier start than advocated at present might be desirable, if such an early start is not responsible for its own specific morbidity and mortality.[151]

Recent observational evidence points to a similar outcome of early and late start,[152] but it is practically impossible to avoid selection bias in this type of study.[153]

UREMIC SOLUTE RETENTION

General Classification of the Uremic Solutes

A gradual retention of a large number of organic metabolites of proteins, fatty acids, and carbohydrates characterizes the progression of renal failure, whereby partial metabolization and elimination by other than renal pathways may compensate for the loss of renal clearance. Some of the retained compounds are proven toxins. Toxicity is not a simple monofactorial process whereby only one or a few toxins affect many different metabolic processes at a time. Other retained substances are nontoxic but can be used as markers of retention.

A recent survey of the literature revealed the retention in uremia of at least 90 compounds, of which the concentration had been reported.[154] It is very likely that this is only the tip of the iceberg.

Under normal conditions, the glomerular filter clears molecules with a molecular weight up to ± 58,000 D. All of these substances are supposed to be retained in renal failure. An additional role should be attributed to changes in tubular secretion, reabsorption, and metabolic breakdown, which are all altered when renal mass decreases. The molecules metabolized by the kidneys may have a higher molecular weight (>58,000 D) than those cleared. Renal and nonrenal metabolization of solutes and nonrenal clearance may in their turn be inhibited following uremic retention.

Uremic retention products are arbitrarily subdivided according to their molecular weight.[155,156] Low molecular weight molecules are characterized by a molecular weight (MW) up to 500 D (e.g., urea [MW: 60], creatinine [MW: 113]). They can further be subdivided in protein bound and nonprotein bound molecules. Substances with a molecular weight range above 500 D are called middle molecules (e.g., parathyroid hormone [MW: 9,424], β_2-microglobulin [MW: 11,818]). Several clinical, metabolic, and/or biochemical disturbances such as food intake, apolipoprotein (apo) A-I secretion, osteoblast mitogenesis, cell growth, lymphocyte proliferation, and interleukin production are caused by uremic compounds that conform with the middle molecular weight range.[112,157–161] Several of the recently defined uremic compounds, for example, β_2-microglobulin (β_2-M), various peptides, some of the AGE, as well as PTH, conform with the definition of the middle molecules (MM) (see following).

Dialysis membranes with the capacity to remove MM (high-flux membranes) have been related to lower mortality,[162–166] as well as a slower loss of residual renal function,[167] less preponderant dyslipidemia,[168] improvement of polyneuropathy,[169] and a lower prevalence of the carpal tunnel syndrome.[170] However, these highly efficient membranes are often at the same time less complement activating than unmodified cellulose, in many studies their counterpart. Hence, the relative importance of the removal of MM versus biocompatibility related events is not always clear. Two studies, however, point to an independent benefit of large molecule removal. Leypoldt and associates[171] demonstrated that independent from urea removal, MM clearance correlated to patient survival. In a study applying nothing but synthetic membranes, large pore size was associated with a better survival.[172]

In the prospective randomized HEMO-study, however, no significant impact on mortality was found for high-flux dialyzers upon primary analysis, although there was a trend.[173] Upon secondary analysis a benefit was found for large pore membranes regarding cardiovascular events.[173] Patients who had been treated long-term on dialysis received an extra benefit.

Removal of larger molecules is more efficient when the high-flux membranes are used in a convective mode[174]; no data is available whether this affects mortality. Convective treatment modalities have a positive impact on the development of the carpal tunnel syndrome.[170] On line hemodiafiltration with large convective volumes results in a rise of erythrocyte counts and a decrease of erythropoietin needs.[175] Even if highly efficient dialysis is clinically superior, its cost effectiveness still needs to be demonstrated.

Small protein-bound compounds such as hippuric acid or p-cresol behave like MM during dialysis, due to their high protein binding. Their removal by classical hemodialysis systems, even with large pore membranes, remains disappointingly low,[176] which may be attributed to the complex distribution and intra-dialytic kinetics of these compounds. Therefore, alternative removal strategies than the classical ones should be considered, such as adsorption, changes in timeframes, use of protein-leaking membranes, and/or stimulation of metabolic pathways.

Peritoneal dialysate is a much richer source of protein bound compounds than hemodialysate,[177] since peritoneal pore size allows the transfer of substantial quantities of albumin together with its bound moieties, which is not the case for even the most open hemodialyzer membranes. Also, the continuous timeframe might enhance the removal of these compounds.[178]

Until recently, no data had confirmed a potential clinical impact of protein bound molecules. Recently, a correlation of free p-cresol with hospitalization rate and hospitalization for infection was confirmed.[179]

MAIN UREMIC RETENTION PRODUCTS

Several uremic retention solutes influence biologic functions. Other compounds have no proven direct toxicity but may be useful markers of uremic retention. A review of the most currently known uremic retention solutes with their molecular weight is given in Table 6–2. It should be acknowledged that anorganic compounds such as water and potassium exert toxicity as well. In what follows, we will concentrate on the organic retention compounds.

Table 6–2   Major Uremic Retention Solutes and their Molecular Weight (Daltons)

Compound	MW	Compound	MW
ADMA/SDMA	202	Adrenomedullin	5729
ANF	3080	Benzylalcohol	108
ß-endorphin	3465	ß-guanidinopropionic acid	131
ß₂-microglobulin	11818	CGRP	3789
Cholecystokinin	3866	CIP	8500
Clara cell protein	15800	CML	188
CMPF	240	Complement factor D	23750
Creatine	131	Creatinine	113
Cystatin C	13300	Cytidine	234
DIP I	14400	DIP II	24000
3-Deoxyglucosone	162	Dimethylarginine	202
Endothelin	4283	γ-guanidinobutyric acid	145
Glomerulopressin	500	GIP I	28000
GIP II	25000	Guanidine	59
Guanidinoacetic acid	117	Guanidinosuccinic acid	175
Hippuric acid	179	Homoarginine	188
Homocysteine	135	Hyaluronic acid	25000
Hypoxanthine	136	Imidazolone	203
Indole-3-acetic acid	175	Indoxyl sulfate	251
Leptin	16000	Melatonin	126
Methylguanidine	73	Myoinositol	180
Neuropeptide Y	4272	Orotic acid	156
Orotidine	288	o-OH-hippuric acid	195
Oxalate	90	P-cresol	108
p-OH-hippuric acid	195	Parathyroid hormone	9225
Pentosidine	135	Phenylacetylglutamine	264
Phenol	94	Phosphate	96
Pseudouridine	244	Putrescine	88
Retinol binding protein	21200	Spermine	202
Spermidine	145	Thymine	126
Trichloromethane	119	Tryptophan	202
Urea	60	Uric acid	168
Uridine	244	Xanthine	152

The underlined compounds conform with the definition of MM (MW between 7500 and 12,000 Daltons, or above). *ADMA,* asymmetrical dimethylarginine; *SDMA,* symmetrical dimethylarginine; *ANF,* atrial natriuretic factor; *CGRP,* calcitonin gene related peptide; *CIP,* chemotaxis inhibiting protein; *CMPF,* 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid; *CML,* carboxymethyllysine; *DIP I,* degranulation inhibiting protein I; *DIP II,* degranulation inhibiting protein II; *GIP I,* granulocyte inhibiting protein I; *GIP II,* granulocyte inhibiting protein II.

Advanced Glycation End Products (AGE)

As first described by Maillard,[180] glucose and other reducing sugars react nonenzymatically with free amino groups to form reversible Schiff base adducts (in days) and stable Amadori products (in weeks), which are then converted into AGE through chemical rearrangements and degradation reactions. Several AGE-compounds are peptide-linked degradation products[181] (MW 2000–6000 D), although the baseline AGE-products such as pentosidine, 2-(2-fuoryl)-4(5)-(2-furanyl)-1H-imidazole (FFI), imidazolone, 3-deoxyglucosone, pyrrole aldehyde, and N^ε–(carboxymethyl)lysine have a substantially lower MW (Table 6–2).

AGE are retained not only in renal failure but also in diabetes mellitus and aging,[182] where they are held responsible for tissular damage and functional disturbances. In the uremic population, the level of glucose-modified proteins is higher than in diabetics without renal failure,[183] and AGE-concentration does not depend on the glycemic status.[184,185] The production of AGE in ESRD has been related to oxidative and carbonyl stress, rather than to reactions with glucose.[186] Not all AGE-generation is oxidative, however. Imidazolone, a nonoxidative AGE, is found as well in serum and urine of uremic patients.[187]

Schiff base formation affects the interaction of the vitamin D receptor with responsive DNA-elements, such as osteocalcin, vitamin D-responsive elements (VDRE), or constructed VDRE in transfected cells.[188] AGE provoke monocyte activation,[189] as well as the induction of interleukin-6, tumor necrosis factor-α, and interferon-γ generation.[190] AGE-modified β_2-M may play a role in the generation of dialysis-associated amyloidosis [123] (see later text). Serum pentosidine levels are higher in patients with dialysis-related amyloidosis, compared to their amyloid-free counterpart.[191] AGE can react with and chemically inactivate nitric oxide (NO),[192] a potent endothelium-derived vasodilator, anti-aggregant, and antiproliferative factor. Inversely, NO inhibits the formation of AGE.[193] AGE are also related to oxidative protein modification.[24] 3-Deoxyglucosone inactivates glutathione peroxidase, a key enzyme in the neutralization of hydrogen peroxide.[194] Transferrin and lysozyme, after contact with AGE-modified albumin, lose their immune-enhancing properties.[195] AGE accumulate in atheromatous plaque of the aortic wall of subjects with ESRD, where they may contribute to a more rapid progression of atherosclerosis.[191] There is, however, no observational study in uremia, linking AGE directly to atherogenesis.

Early glycation of proteins induces an increase of glucose uptake and accelerated apoptotic cell death of polymorphonuclears (PMNL).[25] Late glycation products increase PMNL chemotaxis.[25] Other recent data suggest that whereas AGE increase baseline leukocyte response, activated response to infectious stimuli is blunted.[74] This suggests a dual response, related at the clinical level to both atherogenesis and susceptibility to infection.[75]

Most of the biologic actions of AGE that have been registered up to now, have not, however, been obtained with AGE recovered from uremic or diabetic serum, but with AGE artificially prepared in the laboratorium.[75] In vivo collected uremic human serum albumin appeared to be only minimally AGE-modified.[196] It remains unclear which AGE exert toxicity in vivo, and what their real toxicity is.

Concentrations in ESRD patients might be attributed to increased uptake, production, and/or retention. During industrial food processing, cooking procedures and storage of foods, food proteins are modified by carbohydrates,[197–199] and those are absorbed via the gastrointestinal tract.[184] The healthy kidneys are responsible for not only glomerular filtration but also for tubular reabsorption and degradation of AGE.[200,201] Specific receptors for AGE have been identified (RAGE) and their expression is enhanced during uremia.[202] AGE binding to RAGE has been shown to stimulate mesothelial cell activity and results in overexpression of vascular cell adhesion molecule (VCAM-1), which activates human peritoneal cells and promotes local inflammation, implicating the development of tubular injury.[203]

In spite of continuous contact with glucose via the dialysate, CAPD patients do not have higher serum AGE levels than hemodialysis patients.[181] Nevertheless, protein glycation has been demonstrated in the peritoneal membrane.[204] The heat sterilization of glucose-containing peritoneal dialysate induces the formation of glucose degradation products (GDP), which are precursors of AGE.[205] GDP inhibit leukocyte response, and this effect is attenuated when heat sterilization is replaced by other procedures (e.g., filter sterilization).[206]

Removal of AGE is significantly more important with high-flux hemodialysis than with conventional dialysis with low-flux membranes.[207] Even then steady state serum levels still remain substantially above normal. Concentrations of AGE are subjected to a post-dialytic rebound[207] but are normalized by kidney transplantation. Nevertheless, albumin-bound pentosidine remains longer elevated after transplantation than free pentosidine,[208] whereas intratissular levels of AGE also remain elevated for a longer period than plasma levels.[209] In hemodialyzed ESRD patients, a decrease in AGE-apolipoprotein B is observed after 8 weeks of treatment with high-flux AN69 dialyzers, compared to low-flux polysulfone.[210] This effect could be attributed mainly to adsorption to the dialysis membrane and is paralleled by a decrease in total apolipoprotein B, pointing to a possible positive effect of AGE-removal on overall dyslipidemia. AGE show a marked heterogeneity in removal pattern, even during high-flux dialysis.[198,211] It is unclear which compounds could be representative by their removal pattern in a way that they could serve as a marker for the overall group of AGE.

Recently, Miyata and associates[212] demonstrated that two widely used families of antihypertensive agents, the angiotensin converting enzyme inhibitors, as well as the angiotensin II type I receptor antagonists, attenuated *in vitro* the production of AGE.

β_2-Microglobulin (β_2-M)

β_2-M (MW approximately 12,000 D) is a component of the major histocompatibility antigen. Uremia-related amyloid is to a large extent composed of β_2-M and is essentially found in the osteo-articular system and in the carpal tunnel, although deposition can be systemic as well.[213,214] Uremia-related amyloidosis becomes most often clinically apparent after several years of chronic renal failure and/or in the aged.[215] Recent data, however, show that amyloidosis develops earlier than previously suspected,[216,217] even in patients not yet submitted to dialysis.[218] According to the most recent studies, its prevalence tends to decrease.[219]

The exact pathophysiology of this disease remains largely unknown. In several studies, it was impossible to relate ß₂-M serum concentrations to the development of ß₂-M amyloidosis.[220–222]

AGE (see earlier text) and ß₂-M amyloidosis are closely connected. AGE-modified ß₂-M has been identified in amyloid of hemodialyzed patients.[223] At least three major AGE-modifications of ß₂-M have been recovered: pentosidine-ß₂-M,[184] carboxymethyllysine-ß₂-M,[186,223] and imidazolone-ß₂-M.[224] AGE-modified ß₂-M enhances monocytic migration and cytokine secretion,[225] suggesting that foci containing AGE-ß₂-M may initiate inflammatory response, leading to bone and joint destruction. AGE-ß₂-M was shown to delay monocyte apoptosis and to alter their phenotype.[226] Recent studies, however, suggest that macrophage infiltrates might be a secondary phenomenon.[227,228] Next to macrophages, fibroblasts seem to also play a key role in the pathogenesis of amyloidosis.[229]

Other modifications that have been proposed to participate in amyloid generation are proteolysis of the N-terminus of ß₂-M[121,230] and deamination of the Asn-17.[122,231] Some arguments, such as the lack of a higher clinical incidence of ß₂-M-amyloidosis in diabetic dialysis patients,[232] who generate large quantities of AGE in the presence of hyperglycemia, cast a doubt on the patho-physiologic role of AGE in amyloid formation. Possibly, the AGE-transformation plays a more important role in the inflammation surrounding ß₂-M-amyloid than in its generation.

Long-term hemodialysis with large pore membranes results in a progressive decrease of pre-dialysis ß₂-M concentrations; the levels remain, however, far above normal, even after intensive removal therapy.[233,234] Long-term dialysis with large-pore dialyzers results in a lower prevalence of dialysis-related amyloidosis and/or carpal tunnel syndrome.[162,170,235,236] Whether this benefit is attributable to a better removal of ß₂-M, to lower complement and leukocyte activating capacity, or to protection against the transfer of dialysate impurities into the bloodstream (e.g., lipopolysaccharides)[219] is not evident, because most of the dialyzers associated with a lower incidence of amyloidosis have all three abovementioned properties.

Because ß₂-M is only removed by dialyzers with a large pore size, its kinetic behavior might be representative for other large molecules. Behavior of ß₂-M during dialysis is, however, not necessarily representative for that of other MM. Discrepancies in behavior in the long run have been demonstrated in relation to other MM, such as complement factor D.[237]

Recently, several devices with strong adsorptive capacity for ß₂-M have been developed.[238,239]

The clinical expression of dialysis-related amyloidosis disappears after kidney transplantation, but the underlying pathologic processes such as bone cysts and tissular ß₂-M remain preserved.[240] Possibly, immunosuppressive therapy plays a role in the regression of the symptomatology.

ß₂-M-related compounds might also be involved in other aspects of the uremic syndrome. One of the peptides with granulocyte inhibitory effect described by Haag-Weber and associates[70] has partial homology with ß₂-M.

3-Carboxy-4-Methyl-5-Propyl-2-Furanpropionic Acid (CMPF)

One of the urofuranic acids, 3-Carboxy-4-methyl-5-propyl-2-furanpropionic acid (CMPF) is a lipophilic and strongly protein-bound uremic solute and one of the major inhibitors of the protein binding of drugs[241,242] and of bilirubin.[243] CMPF and bilirubin share the binding site for dicarboxylate molecules on human serum albumin.[244] CMPF is also a potent binding inhibitor for salicylic acid and phenole red (site I).[245] The renal clearance of CMPF is strongly reduced in renal failure,[246] which results in a marked rise of its serum concentration.[247] CMPF inhibits the renal uptake of para-amino hippuric acid (PAH) in rat kidney cortical slices[248] and causes a decrease in renal excretion of several drugs, of their metabolites, and of endogenously produced organic acids that are removed via the PAH pathway. *In vivo* CMPF clearance in the rat is inhibited by PAH and probenecid.[249] CMPF inhibits hepatic glutathione-S-transferase,[250] deiodination of T4 and T3 by cultured hepatocytes,[94] ADP-stimulated oxidation of NADH-linked substrates in isolated mitochondria,[251] and erythropoiesis.[252]

Costigan and associates[252–255] demonstrated a correlation between plasma concentration of CMPF and neurologic abnormalities and a negative correlation with blood hemoglobin.

CMPF levels are lower in CAPD than in hemodialysis. This might be attributed to the slower removal pattern and/or to the more important losses of the proteins that bind CMPF. Differences in residual renal function may also be involved in this effect, but this aspect has not yet been evaluated. The strong protein binding of CMPF[176] hampers its removal during hemodialysis, which is virtually nil.[176] Alternative removal strategies, such as adsorption or strategies that modify generation, should be considered.[256] Protein leaking hemodialysis induces a reduction of CMPF and is at the same time related to a rise in pre-dialysis hematocrit.[44]

Complement Factor D

Plasmatic concentrations of complement factor D increase in uremia, essentially because of alterations in renal removal.[257–259] Complement factor D exerts specific protease activity on its natural substrate, complement factor B, which results in an activation of the alternative complement pathway. This effect could in part be responsible for the baseline inflammatory status observed in chronic renal disease.[260] Furthermore, complement factor D was shown to adversely affect stimulated PMNL functions.[261] Some dialysis membranes remove complement factor D,[262] and this is at least in part attributed to adsorption.[257]

Creatinine

Creatinine belongs to the large group of guanidines (see later text). Because of the specific value of creatinine as a marker of renal function, this compound will be discussed separately.

The rise in serum creatinine during renal failure is not linearly related to the decrease in glomerular filtration rate (GFR), which may decrease by more than 50% without marked changes in serum creatinine. Changes become more prominent in the lower range of filtration. The determination of creatinine clearances as a parameter of renal function leads to an overestimation of true GFR, due to the secretion of creatinine in the renal tubular system. Unfortunately, the evolution of this tubular secretion does not parallel that of GFR. Some authors try to obtain a more accurate estimation of GFR

by blocking the tubular secretion of creatinine, for example, by cimetidine.[263] Others calculate the mean of urea and creatinine clearance, although this approach remains a matter of debate.[264]

In spite of the extensive use of creatinine as a marker of uremic toxin retention, it has been held responsible for only a few uremic side effects, such as chloride channel blocking[265,266] and the reduction of the contractility of cultured myocardial cells,[267] however, at concentrations exceeding those encountered in ESRD. Injection of creatinine in uremic rats shortens their life span.[268] Creatinine is also a precursor of the toxic compound methylguanidine.[269,270] It interferes with some of the central neurologic functions.[266,271]

Serum creatinine concentration is not only the resultant of uremic retention but also of muscular breakdown; therefore, a high serum creatinine may be the consequence of high muscular mass, and hence an indicator of metabolic well-being. Morbidity and mortality in hemodialyzed patients are positively correlated with serum creatinine.[269]

Cytokines

In view of the strong associations between atherosclerosis, malnutrition, and inflammation,[272] it may be speculated that factors associated with malnutrition and inflammation may contribute to the excess prevalence of cardiovascular disease. The causes of inflammation in ESRD patients are probably multifactorial. All available evidence suggests that the pro-inflammatory cytokine system activity is elevated in ESRD patients.[273] It has been hypothesized that epoetin resistance is due to enhanced levels of immune activation because chronic inflammation can modify the process of erythropoiesis, which is probably mediated via pro-inflammatory cytokines.[274] The accumulation of TNF-α may contribute to the development of neurologic and hematologic complications in uremia; it has been suggested that TNF-α may, indeed, be considered a uremic toxin.[275] Several lines of evidence suggest that decreased renal clearance might play an important role.[276] However, as the half-life of various cytokines is short and local tissue cytokine inactivation may be the most important pathway of cytokine degradation, more research is needed to determine the relative importance of the kidney in cytokine clearance. Recently, the importance of the IL-10 genotype, which determines the production of the anti-inflammatory cytokine IL-10 on uremia- and dialysis-induced chronic inflammation, has been demonstrated.[277]

Glomerulopressin

Glomerulopressin is a low molecular weight (<500 D) hepatic hormone, which increases glomerular capillary pressure and enhances glomerular filtration rate.[278] Circulating levels are elevated in chronic renal failure.[279] Removal by dialysis is 75% of that of urea. Production is stimulated by dietary protein ingestion.[280] This hormone is possibly related to the progression of renal failure subsequent to high protein intake.

Guanidines

The group of the guanidines is composed by several structural metabolites of arginine. Among them are well known uremic retention solutes, such as creatinine and guanidine and

newly detected moieties, such as asymmetric and symmetric dimethylarginine (ADMA and SDMA). Creatinine has been discussed separately.

Guanidine compound levels have been determined in serum, urine, cerebrospinal fluid, and brains of uremic patients.[281,282] Four compounds, creatinine, guanidine, guanidinosuccinic acid (GSA), and methylguanidine (MG) are highly increased.

Several of the guanidine compounds modify key biologic functions. GSA inhibits the production by 1α-hydroxylase of the active vitamin D metabolite, $1,25\text{-}(OH)_2VitD_3$ (calcitriol)[283] and interferes with activation of ADP-induced platelet factor 3,[284] at concentrations currently found in hemodialyzed uremics.[285,286] A mixture of guanidine compounds suppresses the natural killer cell response to interleukin-2[73] and free radical production by neutrophils.[287] GSA, γ-guanidinobutyric acid, methylguanidine, homoarginine, and creatine induce seizures after systemic and/or cerebroventricular administration to animals.[265,266] GSA plays an important role in the hyperexcitability of the uremic brain.[35] Recent studies using the patch clamp technique suggest that GSA and MG might act as competitive antagonists at the transmission site of the γ-aminobutyric $acid_A$ ($GABA_A$) receptor.[271] GSA probably also acts as a selective agonist at the N-methyl-D-aspartate (NMDA) receptor.[288,289] GSA displays *in vivo* and *in vitro* neuroexcitatory effects that are mediated by ligand- and voltage-gated Ca^{2+} channels, suggesting an involvement of the guanidines in the central nervous complications of uremia.[36]

Arginine enhances NO-production. Some of the other guanidines, such as arginine-analogues, are strong inhibitors of NO-synthase. The inhibition of NO-synthesis results in saphenous[290] and mesenteric vasoconstriction,[291] hypertension,[292] ischemic glomerular injury,[293] immune dysfunction,[294] and neurologic changes.[295] NO-synthase is inhibited in chronic renal failure,[296] and the capacity of the NO-system to regulate hemodynamics is disturbed.[297] The strongest NO-synthase inhibitors are synthetic. ADMA is the most specific endogenous compound that inhibits NO-synthase. ADMA accumulates in the body during the development of renal failure,[298,299] related to decreased renal excretion but possibly also to suppressed enzymatic degradation by dimethylarginine dimethylaminohydrolase.[300] In addition, ADMA is produced in human endothelial cells.[301] The increase in SDMA is more pronounced, but this compound is biologically less active. In the brain, ADMA causes vasoconstriction and inhibition of acetylcholine-induced vasorelaxation.[302] Also in thoracic and radial vessels, ADMA induces contractions.[303] Recently, estrogen has been shown to alter the metabolism of ADMA, reducing the circulating concentration *in vivo*.[304] Methylguanidine, another endogenous guanidine, also shows a certain inhibitory activity on cytokine- and endotoxin-inducible NO-synthase, be it to a limited extent.[187]

In contradiction to the hypothesis of inhibition of NO-synthase in uremia, Noris and associates[54,305] described an enhanced NO-production in patients susceptible to uremic bleeding tendency. Possibly, this effect is limited to a subgroup of the uremic population. GSA might induce NO-production.

In the renal proximal convoluted tubule of rats with renal failure, the generation out of arginine of guanidinoacetic acid and creatine is depressed,[306] whereas the synthesis of GSA, guanidine, and methylguanidine is markedly increased, due to urea recycling.

Dialytic removal of guanidine compounds is subjected to a substantial variability.[286] Possibly, tissular distribution or protein binding play a role. In spite of a low MW, removal by hemodialysis of ADMA is only in the range of 20% to 30%.[299]

Hippuric Acid

Hippuric acid interferes with the transport of a variety of organic acids at the cortical tubular level,[307] the chorioid plexus of the brain, the ciliary body of the eye, the thyroid, the liver, and the erythrocytes.[308] Hippuric acid causes net fluid secretion in isolated proximal straight tubules of the rabbit.[309] Indirect data reported by MacNamara and associates[310] and by Gulyassy and associates,[311] and more direct studies on ultrafiltrate collected from dialyzed patients,[241,312] demonstrate an interference of hippuric acid with the protein binding of drugs. According to Dzúrik and associates,[313] hippurate interferes with glucose tolerance.

Hippuric acid is largely originated from the transformation of the quinic acid moiety of chlorogenic acid—the ester of caffeic acid—with quinic acid.[314] The intestinal flora may contribute to the generation of hippuric acid and hydroxyphenylpropionic acid.[315] The protein binding of hippuric acid tends to increase during dialysis.[316] Procentual dialytic removal is, however, close to that of urea,[176] possibly because protein binding is only moderate.

Homocysteine

Homocysteine (Hcy), a sulphur-containing amino acid, is produced by the demethylation of dietary methionine. Retention results in the cellular accumulation of S-adenosyl homocysteine (AdoHcy), an extremely toxic compound, which competes with S-adenosyl-methionine (AdoMet) and inhibits methyltransferase.[317] Moderate hyperhomocysteinemia, caused by a heterozygous deficiency of Hcy breakdown or by vitamin B_6, B_{12} or folate deficiency, is an independent risk factor for cardiovascular disease in the general population.[26,318] Reduced and oxidized forms of Hcy are present in the plasma, and total fasting levels are a reflection of intracellular metabolism and cellular excretion of Hcy.[27]

Hcy increases the proliferation of vascular smooth muscle cells, one of the most prominent hallmarks of atherosclerosis.[319] Moderate hyperhomocysteinemia may involve endothelial dysfunction and generate reactive oxygen species.[320] The administration of excess quantities of the Hcy precursor methionine to rats induces atherosclerosis-like alterations in the aorta.[321] Hcy also disrupts several anticoagulant functions in the vessel wall, which results in enhanced thrombogenicity.[322]

Patients with chronic renal failure have total serum Hcy levels twofold to fourfold above normal. The serum concentration depends not only on the degree of kidney failure, but also on nutritional intake (e.g., of methionine),[323] vitamin status (e.g., of folate),[324,325] genetic factors,[326–328] and decreased renal metabolization.[317] Almost all filtered Hcy is reabsorbed in the tubular system so that urinary excretion is minimal.[329] Detoxification by remethylation of homocysteine to methionine is inhibited in hemodialysis patients,[330,331] possibly due to folate resistance.[27]

Hyperhomocysteinemia is the most prevalent cardiovascular risk factor in ESRD[328,332] and is also present in kidney transplant recipients with cardiovascular disease.[333] In dialysis patients, there is a direct correlation between plasma homocysteine levels and the odds ratio for vascular complications.[332] Plasma homocysteine and cardiac mass correlate to each other.[334] In a study by Suliman and associates,[323] however, total plasma Hcy was lower in hemodialysis patients with cardiovascular disease than in those without. In this study, a correlation was found between total Hcy and serum albumin, pointing to a negative impact of malnutrition on Hcy concentrations. According to Shemin and associates,[335–337] hyperhomocysteinemia is also an independent risk factor for vascular access thrombosis. Such a relation was, however, not confirmed.

Hcy is partly bound to albumin, which hampers removal by hemodialysis. Hyperhomocysteinemia is more pronounced in hemodialysis patients than in PD.[325] In hemodialyzed patients, homocysteine levels correlate with plasma folate[324,325] and with the activity of enzymes that are at play in Hcy metabolism. Even with peritoneal dialysis, it is impossible to reduce total Hcy plasma levels to normal.[338] The application of amino acid containing PD fluids tends to increase the plasma homocysteine level.[339]

Dialysis with extremely leaky hemodialyzer membranes with large pore size (so-called super-flux membranes) results in a progressive decline of pre-dialysis plasma homocysteine concentrations.[340,341] This effect has at least in part been attributed to changes in homocysteine metabolism, induced by enhanced middle molecule removal through these highly efficient membranes.

Hcy levels can be reduced by folic acid, vitamin B_6, and vitamin B_{12}.[342,343] The population with ESRD might require high quantities of vitamins.[344] In pre-dialysis outpatients, folic acid (5 mg/day) causes a consistent decrease in Hcy levels.[345] Oral supplementation with high doses of folic acid (15 mg/day) and pyridoxine (200 mg/day) for 4 weeks in hemodialysis patients reduces Hcy but does not restore levels to normal.[346] Extremely high doses of 30 to 60 mg folic acid per day have no additional impact.[347] In ESRD patients, vitamin B_{12} alone reduces plasma Hcy levels, if it is administered to patients with low vitamin B_{12} plasma levels.[348] Patients on a high dose of vitamin B_{12} show a lower total Hcy than those on a high dose of folic acid.[349]

Possibly, the disappointing efficiency of folic acid might be related to an impairment of the metabolization of folic acid to 5-methyltetrahydrofolate (MTHF), which is the active compound in the remethylation pathway.[350] In an attempt to obviate such a deficiency, Bostom and associates[351] directly administered oral MTHF (17 mg/day) to hemodialyzed patients. No benefit was found, however. Touam and associates,[350] on the other hand, could reduce total Hcy to normal in approximately 80% of the studied population, by the administration of folinic acid, a precursor of MTHF. The folinic acid was administered IV (50 mg/week) and combined with pyridoxine (250 mg, three times weekly).[350] Therefore, it is not clear which element in this therapeutic strategy is responsible.[351] Since the supplementation with folate is inexpensive and relatively harmless, there is no formal objection against its therapeutic use.

Direct clinical proof of the benefit of a lower Hcy concentration in uremia is not available. Even when it was possible to decrease Hcy levels therapeutically, carotid artery stiffness was not altered,[28] but this finding might have been the consequence

of too-late therapeutic intervention. Also, endothelial function was not improved, however.[352]

Hyaluronic acid

Hyaluronic acid concentration increases above normal in the large majority of patients with chronic renal failure.[353] The basic entity is a nonpolymerized molecule of 25 kD, but the compound may be present in a polymerized form as well. Concentrations correlate with β_2-microglobulin but not with creatinine. High values are found especially in patients with a bad clinical condition. In hemodialysis patients, hyaluronic acid correlates negatively with serum albumin[354] and is a strong independent predictor of long-term survival.[355–357]

Hyaluronic acid enhances the expression of the adhesion molecule VCAM-1[358,359] and of monocyte chemoattractant protein-1.[360] Hyaluronan stimulates cyclooxigenase type 2 (COX-2) and subsequent thromboxane A2 (TXA2) production in renal tubular cells and macrophages and therefore could play a role in inflammatory renal lesions.[361] Increased hyaluronan also promotes proliferation of rat interstitial fibroblasts, which could play a role in the pathogenesis of interstitial fibrosis.[362] These elements might be of relevance to the loss of residual renal function.

Indoles

Indoles are found in various plants and herbs and are produced by the intestinal flora. Several indolic metabolites are retained in uremia.[363] Indole itself is oxidized to indoxyl sulfate and various indigoid pigments by cytochrome P450.[364] CYP2E1, the major isoform of the isoenzyme P450, is responsible for the microsomal oxidation of indole to indoxyl.[365] Indoxyl sulfate, tryptophan, melatonin, and indole-3-acetic acid all are indoles. Indoxyl sulfate and melatonin are discussed under separate headings (see later text).

As a protein-bound compound, indole-3-acetic acid enhances drug toxicity by competition for protein binding and inhibition of tubular secretion.[241,366] Indole-3-acetic acid has been related to encephalopathy as well.[367] After oxidation, it becomes cytotoxic.[368]

Not all indoles show a similar kinetic behavior. Some of them do not even conform with the strict definition of uremic retention solutes, because their global concentration in ESRD is low rather than high (e.g., tryptophan),[369] but this decrease in concentration affects mainly the protein bound fraction, which is probably functionally inactive.[369] A relative increase of free plasma tryptophan has been described in uremia.[140] The decrease in plasma tryptophan is related to shifts in metabolic pathways that, at the same time, result in an increase of concentration of other related metabolites, such as quinolinic acid and kynurenine.[370] These compounds may exert neurotoxicity.[371] Central increases of free tryptophan have been related to anorexia.[140] This effect might be attributed to the generation of serotonin,[140] which also plays a role in thrombogenesis.[372]

The administration of AST-120, an oral adsorbent of uremic toxins, significantly reduced plasma indoxyl sulfate levels, increased tryptophan levels and improved the tryptophan plasma protein-binding ratio.[373] AST-120 improved partly the nutritional state, possibly by correcting the impaired metabolism of tryptophan.[373] Quinolinic acid is an endogenous excitotoxic agonist of NMDA-receptors[374] and an inhibitor of hepatic phosphoenolpyruvate carboxykinase and gluconeogenesis.[375] Quinolinic acid may also inhibit cardiac contractility[376] and may initiate lipid peroxidation in the brain.[377]

Indoxyl Sulfate

Indoxyl sulfate is metabolized by the liver from indole, which is produced by the intestinal flora as a metabolite of tryptophan. It enhances drug toxicity by competition with acidic drugs at the protein binding sites,[312,378] inhibits the active tubular secretion of these compounds,[366] and inhibits deiodination of thyroxin 4 by cultured hepatocytes.[94]

It is known that uremic retention solutes induce glomerular sclerosis.[131] The oral administration of indole or indoxyl sulfate to uremic rats causes a faster progression of glomerular sclerosis and of renal failure.[133] This effect is possibly mediated by the renal gene expression of transforming growth factor ß (TGFß), tissue inhibitor of metalloproteinase-1 (TIMP-1) and pro-α1 (type I) collagen.[134,379] Indoxyl sulfate as well as other protein bound solutes were shown to induce direct proximal tubular injury via organic anion transporter 1-mediated uptake.[380] In animals, progression of renal failure is refrained by adsorbent administration, together with a diminished expression of the abovementioned factors.[134] A similar attenuating effect is observed on the progression of diabetic nephropathy, based on the same mechanisms.[381,382]

Reduction of serum indoxyl sulfate concentration, by intraintestinal absorption of the precursor indole, reduces uremic itching.[383] AST-120 retards the development of acquired renal cystic disease and aortic calcification[384] and ameliorates tubulointerstitial injury by reducing the expression in the kidneys of ICAM-1, concopontin, TGF-β1 and clusterin in uninephrectomized rats.[382]

The oral administration of bifidobacterium longum, in gatro-resistant seamless capsules (Bifina) reduces serum levels of indoxyl sulfate in hemodialysis patients.[385]

Because of protein binding (approximately 100% in normal subjects and 90% in uremics), the intra-dialytic behavior of indoxyl sulfate diverges from that of other small compounds such as creatinine. If the percentage removal of creatinine during one hemodialysis session is approximately 50%, removal of indoxyl sulfate is only 0% to 20%.[252,386,387] Removal by CAPD is more effective.[252] High-flux hemodialysis does not enhance removal.[176] Alternative extracorporeal removal procedures such as hemoperfusion might be considered. Dialysis against albumin-containing dialysate removes albumin-bound uremic toxins such as indoxyl sulfate more efficiently than conventional dialysis and may be useful for reducing these compounds.[388]

Melatonin

The pineal hormone melatonin plays a role in the regulation of the hypothalamic-pituitary axis, sleep pattern, mood changes, cellular immunity, antibody response, and skin pigmentation, all of which are altered in end-stage renal disease. Melatonin inhibits the expression of lipopolysaccharide induced NO-synthase,[389] and acts as a free radical scavenger and an antioxidant,[390-393] although some authors attribute pro-oxidant activity to this compound.[394] Vaziri and associates[395] found no differences in early morning serum melatonin

between healthy subjects and dialyzed uremic patients. In contrast, Viljoen and associates[396] demonstrated elevated melatonin levels in patients with CRF. Hemodialysis has no effect on the concentration of these compounds. The fluctuating concentration pattern, that normally occurs in healthy subjects, is absent in dialyzed uremics.[395]

Methylamines

Methylamine, dimethylamine, and trimethylamine are retained in uremia,[397,398] especially intracellularly.[397] The generation of methylamine increases after intake of fish, seafood, and vegetables (tomatoes, pears, peas).[399]

Maxfield and associates[400] demonstrated *in vitro* inhibition of fibroblast cellular function in the presence of methylamines. Increased deamination of methylamines might play a role in oxidative stress and atherogenesis.[398,401] Dimethylamine and trimethylamine inhibit human erythrocyte choline uptake.[402] Methylamine might play a role in central nervous disturbances.[399] At least at supraphysiologic concentrations, such as those occurring in normal renal medulla, methylamines counteract the biologic effects of urea.[403] This protective effect might be at play in uremia as well.[404] Trimethylamine oxide (TMA-O) protects myosin structures against urea-induced effects (2–8 mol/L).[405]

The gastrointestinal degradation of l-carnitine to trimethylamine and other compounds might limit the usefulness of long-term oral l-carnitine administration to hemodialysis patients.[406]

Myoinositol

An increased concentration of myoinositol has been found in uremic nervous tissue (cauda equina nerve), compared to tissue from nonuremic patients.[407] Sciatic nerve conduction velocity is decreased in rats after administration of myoinositol,[408] suggesting a possible role of this compound in peripheral neuropathy. Myoinositol also inhibits proliferation of Schwann cells, as estimated from their [^{3}H]-thymidine uptake.[409]

Myoinositol serves as a clinically relevant osmolyte in the cerebral nervous system[410] and inhibits red blood cell membrane ATPases at concentrations above 50 μmol/L, which corresponds to the high-normal physiologic range of concentration in uremic serum.[411]

Orthohydroxyhippuric and Parahydroxyhippuric Acid

In spite of its low molecular weight, orthohydroxyhippuric acid is characterized by a middle molecular intradialytic behavior because of its protein binding.[412, 413] It interferes with the albumin binding of acidic drugs.[414] The urinary excretion of this glycine conjugate is increased in catabolic patients.[415] Possible precursors are compounds from the tyrosine-dopa-catecholamine pathway, and salicylate.[416] Use and abuse of salicylate and related compounds was a current cause of end-stage renal failure at the moment of the detection of orthohydroxyhippuric acid as a so-called uremic toxin. Therefore, the endogenous origin of orthohydroxyhippuric acid has always been a matter of debate.

Parahydroxyhippuric acid is a substance with a structural relationship to hippurate.[415] It is one of the uremic retention solutes that interfere with protein binding of organic acid drugs.[241] Recently, it was demonstrated to inhibit cellular CA^{++}-ATP-ase.[417] Parahydroxyhippuric acid and orthohydroxyhippuric acid together with other protein bound uremic solutes, were shown to cause tubular damage, albeit to a lesser extent than indoxyl sulfate or indoleacetic acid.[380]

Oxalate

In ESRD patients without primary hyperoxaluria, oxalate plasma levels are increased approximately 40-fold, compared to healthy controls.[418] Secondary oxalosis in ESRD patients without primary hyperoxaluria can be complicated by deposition of calcium oxalate in the myocardium, bone, articular surfaces, skin and blood vessels, especially if dialysis is inefficient, or in the presence of excessive intake of oxalate precursors (ascorbic acid, green leafy vegetables, rhubarb, tea, chocolate or beets[419]) or of inflammatory bowel disease.[420]

In rats with chronic renal failure, pyridoxine depletion resulted in increased urinary oxalate excretion and depressed renal function.[421] However, pyridoxine supplementation up to 300 mg/day for 1 month did not reduce plasma levels in CAPD patients.[422] Pyridoxine at 800 mg/day, on the other hand, caused a decrease in hemodialysis patients,[423] however, in combination with gastrointestinal intolerance.

Peritoneal clearance of oxalate is less than 10% of the normal renal clearance, which results in oxalate accumulation in CAPD patients.[422] Also in hemodialysis, oxalate levels are not restored to normal because removal does not match generation, and clearances are lower than those of urea.[325,424]

Oxidation Products

Oxidative capacity is increased in uremia[425-427] both before and after the start of dialysis, which points to a general uremic mechanism.[24] The Fenton reaction results in the generation of hydroxyl radicals, which react with proteins, causing structural modifications and irreparable damage.[428] Uremic patients also show an impaired antioxidant response, partly related to plasma glutathione deficiency.[429]

The concentrations of advanced oxidation protein products (AOPP) are increased in the plasma of uremic patients.[24,430] AOPP act in their turn as mediators of oxidative stress and monocyte respiratory burst.[24] Albumin seems to be one of the target proteins of these oxidative reactions.[24,431] Structural modification of albumin may alter its binding capacity for drugs and other solutes.[432] Modification of hemoglobin to glutathionylhemoglobin has been proposed as another marker of oxidative stress.[433]

Low-density lipoprotein (LDL) from uremic patients is more susceptible to oxidation than that from control subjects[434] (oxidized LDL [oxLDL]). This chemically modified LDL is more readily accumulated in macrophages, which results in the development of foam cells, an early event in atherogenesis. LDL autoantibodies against oxLDL have been demonstrated in ESRD, especially in hemodialyzed patients.[435] Oxidative modification of the protein moiety of LDL is a trigger of macrophage respiratory burst.[436,437] The LDL of chronic renal failure patients treated by hemodialysis and peritoneal dialysis is potentially more atherogenic, since it induces greater monocyte-endothelial adhesion.[438] The repeated use

of vitamin E–coated hemodialyzers improves neutrophil function, oxidant stress and LDL concentrations, compared to uncoated cellulosic membranes.[439]

Malondialdehyde levels are increased in ESRD.[440] The capacity of malondialdehyde to form DNA adducts[441] may play a pathophysiologic role in carcinogenesis. Low-dose I.V. folinic acid given to dialysis patients reduced the levels of serum malondialdehyde and thus improved the cardiovascular risk profile.[442]

Several small molecular compounds might also be modified by oxidation. Organic chloramines are generated by the chemical binding of hypochlorite, a free radical produced by activated leukocytes, to retained organic compounds.[443] Chloramines increase endothelial permeability[444] and affect liver function and perfusion pressure.[445] They have a longer life span than genuine hypochlorite. In as far as binding occurs with liposoluble compounds, such as spermine or spermidine,[446] removal by hemodialysis will be hampered, whereas the capacity to penetrate cellular membranes and to cause toxic metabolic effects will be enhanced. Preliminary data with hemolipodialysis, a strategy that incorporates liposomes and antioxidants, suggest an attenuation of oxidation with this procedure.[447]

Parathyroid Hormone (PTH)

PTH, an MM with an MW of ± 9000 daltons (D), is generally recognized as a major uremic toxin, although its increased concentration during ESRD is merely attributable to enhanced glandular secretion, rather than to decreased removal by the kidneys. Excess PTH gives rise to an increase in intracellular calcium, which results in functional disturbances of virtually every organ system, including bone mineralization, pancreatic response to glucose, erythropoiesis, cardiovascular, and immune and liver function.[30,448-452] PTH is one of the few substances that has been causally linked to uremic neuropathy.[453] It also plays a role in fibroblast activation[448] and has been related to uremic pruritus.

Paradoxically, moderate hyperparathyroidism (intact PTH 60–200 ng/mL; normal range up to 60 ng/mL) has been demonstrated to improve the osseous response of uremic patients. If PTH remains in the lower range, patients may suffer from relative hypoparathyroidism, which results in aplastic bone, inadequate calcium handling, incapacity of the bone to buffer calcium,[454] and redistribution of body calcium stores leading to metastatic tissue calcification.[455] The current test methods for the determination of PTH-levels overestimate true concentrations, because they react as well with intact PTH as with functionally inactive fragments.[456] As a consequence, it has been suggested that to have a normal bone turnover, PTH-levels measured by classical methods should be two to three times above the upper normal limit.[451] At present, new test methods have been developed that estimate only intact PTH.[456,457]

The increased PTH concentration in uremia is the result of a number of compensatory homeostatic mechanisms. Hyperparathyroidism results from phosphate retention, decreased production of calcitriol (1,25 [OH]$_2$ vitamin D$_3$) and/or hypocalcemia. Remarkably enough, metabolic acidosis in rats reduces hyperparathyroidism, probably by enhancing phosphate excretion.[458] In HD patients, however, correction of metabolic acidosis reduced intact PTH levels in the presence of secondary hyperparathyroidism.[459] PTH-related peptide (PTHrP) enhances the secretion of PTH in response to hypocalcemia.[460]

Therapy with calcitriol alone or one of its analogues lowers serum PTH levels,[461] which not only suppresses PTH release, but also restores the secretory reserve of the parathyroid gland during hypocalcemia.[461] Uremia is, however, not only characterized by a depressed production of calcitriol, but also by resistance to this hormone; this resistance is induced by uremic biologic fluids, such as ultrafiltrate and chromatographic fractions of this ultrafiltrate.[113]

Downregulation of PTH-PTHrP receptor mRNA expression is observed in liver, kidney, and heart of rats with advanced chronic renal failure[462,463] and in bone from uremic patients.[464] Parathyroidectomy does not entirely prevent PTH/PTHrP receptor downregulation,[465] suggesting that this alteration depends on more than elevated PTH alone. Also, calcium receptors might show an abnormal function.[116]

Only dialysis membranes with a large pore size remove PTH.[466] Differences in concentration at the end of the dialysis session are, however, subtle[466] and presumably without clinical relevance. Increased removal will probably be compensated by enhanced endocrine production (trade-off). A more efficient way to correct parathyroid hormone hypersecretion is the correction of the plasma calcium, calcitriol, and phosphorus.[467] If these interventions remain ineffective, parathyroidectomy is the ultimate therapeutic resource. In the future, it might become possible to suppress the by-effects of hyperparathyroidism, such as hypercalcemia, by the administration of PTH antagonists. Serum calcium was, however, not lowered by the PTH antagonist BIM-44002, in a recent study in hypercalcemic hyperparathyroid patients.[468] Another pharmacologic option for the future are the calcimimetics.[469, 470] Apart from hypocalcemia, side effects are very rare.[471] A calcium-free phosphate binder (Renagel) is now commercially available with promising results.[472] Another calcium-free phosphate binder that became recently available is lanthanum carbonate. This compound is a trace element but it seems possible to administer it safely without its deposition in the bone. New vitamin D analogues that have less calcemic and phosphatemic effects are under development.[473] All these newly developed measures should help in combating hyperparathyroidism without increasing circulating calcium levels. In contrast, the traditional therapeutic options such as classical vitamin D analogues and calcium salts, easily induce hypercalcemia, hence increasing the risk for calcium deposition in the tissues and vascular damage.

Peptides

Peptides constitute a heterogeneous group of molecules. In general, peptides can be considered as typical MM • ß$_2$-M and PTH have been discussed previously.

Granulocyte inhibiting protein I (GIP I–28 kD), recovered from uremic sera or ultrafiltrate, suppresses the killing of invading bacteria by polymorphonuclear cells.[474] The compound has structural analogy with the variable part of kappa light chains. Free immunoglobulin light chains (25 kD) increase the number of viable neutrophils by inhibiting spontaneous apoptotic cell death.[71] Another peptide with granulocyte inhibitory effect (GIP II–9.5 kD) is partially homologous with ß$_2$-M and inhibits granulocyte glucose

uptake and respiratory burst activity.[70] A degranulation inhibiting protein (DIP–24 kD), identical to angiogenin, was isolated from ß$_2$-M plasma ultrafiltrate of uremic patients.[475] The structure responsible for the inhibition of degranulation is different from the sites that are responsible for the angiogenic or ribonucleic activity of angiogenin. A structural variant of ubiquitin inhibits polymorphonuclear chemotaxis (chemotaxis inhibiting protein–CIP–8.5 kD).[476]

Atrial natriuretic peptide (ANP–3.1 kD) and endothelin (3.5 kD) are elevated in dialysis patients and may play a role in the regulation of blood pressure.[477] ANP levels correlate with left atrial size, fluid overload, and decreased systemic clearance.[478] ANP-fragments have been detected in uremia[479] and are removed by dialyzer membrane adsorption.[479] Endothelin causes peripheral insulin resistance, even at concentrations that induce no blood flow changes[480] and may play a role in uremic hypertension.[16,481,482] Progression of renal failure,[481] reduction of number of cardiac capillaries,[483] myocardial fibrosis,[484] as well as left ventricular dysfunction[485] are prevented by endothelin receptor blockade. Endothelin release is opposed by nitric oxide, especially in erythropoietin-treated uremic rats.[486,487]

The opioid peptides ß-endorphin (3.5 kD), methionine-enkephalin (0.6 kD) and ß-lipotropin (1.9 kD) are elevated in dialyzed patients,[488] although some studies do not confirm this rise in concentration.[489] Delta sleep-inducing peptide (0.9 kD) may modulate sleep-wakefulness.[490] Most toxic actions of this group of peptides remain speculative. ß-endorphins might downmodulate T-cell response.[491]

Neuropeptide Y (NPY–4.3 kD) is increased in uremia[492] and tends to increase further during hemodialysis.[493] It is a 36 amino acid peptide with renal vasoconstrictive activity.[494] Recently, plasma NPY was found to predict incident cardiovascular complications in end-stage renal disease.[495] NPY also acts as an orexigen.[496] Uremic patients with anorexia have lower neuropeptide Y levels.[140,496] The concentration of the anorexigen cholecystokinin (CCK) is increased in most patients with chronic renal failure.[496]

Adrenomedullin, a 52-amino acid and potent hypotensive peptide, is found at markedly increased concentrations in chronic renal failure patients[497] and activates inducible nitric oxide synthase.[498] Apart from enhancing the risk for hypotension under certain conditions, this factor may be involved in defensive mechanisms preventing or counterbalancing the damage to the cardiovascular system in chronic renal failure.

Cystatin C (13.3 kD), Clara cell protein (CC16) (15.8 kD), and retinol binding protein (RBP) (21.2 kD) are elevated in renal failure.[499] Cystatin C is an inhibitor proteinase and cathepsins.[500] CC16 is an α-microprotein, playing an immunosuppressive role in the airways.[501] Leptin, a 16 kD plasma protein that suppresses appetite[502] induces weight reduction in mice[503] and has been suggested to play a role in the decreased appetite of uremic patients.[504] Most,[138,505-507] but not all, ESRD-patients[508-510] have inappropriately high leptin levels. The rise in serum leptin is mostly attributed to decreased renal elimination[505,511-514] and is almost entirely limited to a rise in the free (non-protein-bound) concentration.[505] Increased leptin is associated with low protein intake and loss of lean tissue in chronic renal failure patients.[504] Recent data suggest an inverted correlation between leptin and indices of nutritional status, such as serum albumin or lean body mass,[515] and a direct correlation with C-reactive

protein (CRP).[506] In a recent study in CAPD-patients, serum leptin showed a progressive rise only in those patients developing body weight loss over time.[139] The ratio of serum leptin to body fat mass is higher in hemodialysis patients than in controls[516] and correlates with subsequent body weight loss.[517] Dialysis patients with the highest leptin/fat mass ratio have low protein intakes and lower lean tissue mass.[504] Erythropoietin treatment results in a decline of leptinemia and an improvement of nutritional status.[518]

However, leptin levels are also elevated in obese people and are hence not necessarily related to reduced appetite. Body fat and serum leptin also correlate in uremia.[506] Female gender and obesity are important factors that affect serum leptin also in ESRD-patients.[519] Several authors found no correlation between leptinemia and markers of protein malnutrition.[507,520,521] The administration of cytokines, such as IL-1ß and TNF-α, has been shown to increase serum leptin levels.[522,523] However, Don and associates[524] suggest that in ESRD-patients, leptin may be depressed during inflammation and may actually act as a negative acute phase reactant. Therefore, the biochemical role of leptin in renal failure remains inadequately defined.

Phenylacetylglutamine

Phenylacetylglutamine is a metabolite of phenylalanine,[525] is found at increased concentrations in uremic plasma and ultrafiltrate,[526] and is removed during dialysis in parallel to urea and creatinine.[527] No biologic effects have been demonstrated, although several structural precursors and analogues inhibit tumor growth and induce differentiation.[528]

Phenols

Phenol depresses various functional parameters of enzymatic activity in polymorphonuclear leukocytes.[529] A depressive effect was demonstrated on the 3′:5′-cyclic monophosphate response of the neostriatum to dopamine.[530] This effect was abolished after conjugation of phenol to phenylglucuronide. These findings may be relevant to hepatic and uremic coma. Phenol prevents *in vitro* the inhibition of parathyroid cell proliferation induced by calcitriol.[531]

P-cresol, a phenolic volatile compound with a MW of only 108.1 D, is retained in renal failure,[532] induces LDH-leakage from rat liver slices,[533] blocks liver mitochondrial respiration,[534] and inactivates the transformation of dopamine to norepinephrine by ß-hydroxylase.[535] Several other functions, such as drug protein binding[310] and cell growth,[536] oxygen uptake,[537] and membrane permeability[538] are affected as well. *P*-cresol inhibits various metabolic processes related to the production by activated phagocytes of free radicals, which are involved in the destruction of invading bacteria.[72] Aluminum uptake by hepatocytes and the toxic effect of aluminum on these hepatocytes are increased in the presence of *p*-cresol.[539] A similar toxic effect was also observed on neuroblastoma and erythroleukemia cells.[539] *P*-cresol and phenol inhibit platelet-activating factor (PAF) synthesis by phagocytic leukocytes,[540] and *p*-cresol inhibits detoxification of arsenic by methylation.[541] It also alters neuronal cell function.[36] *P*-cresol is produced by the intestinal flora, as a result of the metabolism of tyrosine[542] but might be generated from environmental sources as well.[543] Prevention of the intestinal absorption of

p-cresol by administration of oral sorbent decreases serum concentration in rats.[544] Changes of composition of intestinal flora might influence *p*-cresol generation.[545]

P-cresol is lipophilic and protein-bound, and its removal by hemodialysis is markedly less than that of urea and creatinine.[176,256] Daily hemodialysis results in lower pre-dialysis serum *p*-cresol levels compared to conventional alternate day dialysis.[546] In a hemodialysis setting, the removal of *p*-cresol and that of urea and creatinine are not correlated,[176] demonstrating that the latter markers are not representative for the intradialytic behavior of protein-bound *p*-cresol. *P*-cresol levels are markedly lower in PD, compared to hemodialysis.[547] Rises in free *p*-cresol during hemodialysis with heparin as an anticoagulant, appeared to be artifactual.[178] Hypoalbuminemia and a rise in total *p*-cresol are correlated to an increase of the free active fraction of *p*-cresol.[179] A correlation between free *p*-cresol and hospitalization rate was demonstrated.[179] Patients hospitalized for infection also had a higher free *p*-cresol.[179] In rats with normal renal function, the total clearance of *p*-cresol largely exceeded the renal clearance in contrast to creatinine, for which renal clearance equals total clearance.[548] The distribution volume of *p*-cresol is approximately four times larger than that of creatinine, and is not significantly affected by renal failure.[549] The intravenous administration of *p*-cresol results in the immediate metabolization of the compound into *p*-cresylglucuronide,[550] pointing to the role of metabolism in the removal of this compound.

Phosphate

High phosphate levels are associated with pruritus and hyperparathyroidism.[551] They affect PTH levels indirectly by decreasing Ca^{++} and calcitriol,[552] but also by direct stimulation of PTH secretion.[553,554] Phosphorus causes a decrease in the activity of spermine/spermidine N^1-acetyltransferase, the enzyme responsible for polyamine degradation,[555] and is also engaged in intestinal dysfunction and proliferation of the intestinal villi.[555] Low dietary phosphate prevents parathyroid hyperplasia in early uremia, whereas a high dietary phosphate enhances the production of tumor growth factor α (TGF-α), which functions as an autocrine signal to further stimulate growth.[556]

Hyperphosphatemia is not only a direct cause of hyperparathyroidism,[557] but also the result of the action of PTH on the bone. The administration of calcitriol in an attempt to control PTH produces hyperphosphatemia as well.[558]

The blood phosphorus concentration is the result of protein catabolism and protein intake as well as of the ingestion of other sources (e.g., Coca-Cola). Restriction of oral intake increases the risk of protein malnutrition,[551] which can be avoided by the administration of oral phosphate binders.[559] Until recently, these consisted mainly of aluminum or calcium salts. The effect of the latter, however, is often insufficient, especially in subjects with a high phosphorus intake. The presence of a high calcium-phosphate product results in tissular deposition of calcium. New phosphate binders such as lanthanum carbonate, sevelamer hydrochloride and trivalent iron-containing compounds offer the advantage that they contain no calcium, so that the risk of hypercalcemia is reduced.[560–563] Whether these compounds are more efficient phosphate binders is, however, less obvious. Sevelamer hydrochloride has a lipid lowering effect[564] and reduces cardiovascular calcification.[565] Lanthanum is a cationic trace element[563] and in this regard could impose similar problems as aluminum if absorbed into the body.

Phosphorus is a small water soluble molecule, but with a retention and removal pattern that hardly mimics that of any other molecule. Cellular clearance during hemodialysis is markedly lower than that of urea,[566] resulting in a substantial post-dialysis rebound.[567] Removal seems to be effective only during the initial phase of a hemodialysis session, after which transfer from the intracellular compartment becomes the rate-limiting step.[568] Alternative dialytic strategies such as daily dialysis,[569,570] slow prolonged dialysis sessions,[570] or hemodiafiltration[571] all might improve phosphate removal. The application of daily dialysis even results in a decreased intake of peroral phosphate binders.[569,570] The serum phosphate levels in nocturnal hemodialysis patients are better under control compared with daily hemodialysis or conventional hemodialysis patients,[572] although oral phosphate binders may still be required.[573] High-flux hemodialysis fails to produce higher phosphate removal.[574] Gotch and associates[575] describe a kinetic model of inorganic phosphorus mass balance in hemodialysis therapy to monitor the individual effects of diet, dialysis and binders, to optimize inorganic phosphorus mass balance, and to reduce phosphate accumulation in the tissues.

Currently, 60% of hemodialysis patients in the United States have serum phosphate levels higher than 5.5 mg/dL.[576] Such high phosphate levels are directly correlated to mortality,[29] which appears to be linked to a high $Ca \times P$ product and an enhanced tissular deposition of Ca-containing complexes, for example, in vessel walls.[29,577]

Phosphorus and uremic serum upregulate osteopontin expression in vascular smooth muscle cells,[578] which might explain, at least in part, the trend for vessel calcification in relation to hyperphosphatemia.

Polyamines

Spermine is a polycathionic polyamine, which inhibits erythropoiesis.[42] Other polyamines, such as spermidine, putrescine, and cadaverine, are also found at increased concentrations in renal failure and inhibit erythroid colony formation in a dose-dependent manner.[41] Polyamines have a high affinity for body proteins and cells. In uremic serum, the polyamines are conjugated to protein carriers, resulting in complexes with molecular weights from 1500 to 5000 D.[579] Polyamines might play a role in anorexia, vomiting, ataxia, seizures, hypothermia and immune deficiency.[580] The accumulation of putrescine may lead to oxidative stress causing cell death.[581] Putrescine inhibits *in vitro* cell growth and alters cytoplasmic, mitochondrial and nuclear membrane structures at high concentrations, where it causes irreversible cell degeneration at lower concentration.[160] Several polyamines interfere with the NMDA receptor,[582] and subsequently with channel conductance and Ca^{++} permeability of brain cells,[36] but spermine might induce neurotoxicity by other pathways as well.[583] Spermine reduces intracellular free calcium in permeabilized pancreatic islets[584] and inhibits NO-synthase.[585] Polyamines antagonize platelet aggregation.[586] Polyamine-related cytotoxicity is attributed to the generation of acrolein as a result of polyamine oxidation by amine oxidase.[587] Polyamine-protein conjugates have been

shown to accumulate in uremia and, in vitro, these substances inhibit erythroid proliferation.[588] Oxidation of polyamines by amine oxidase results in cytotoxic compounds, with a potential role in brain damage.[589,590] Remarkably, a potent antiglycation effect of the polyamines spermine and spermidine at physiologic concentrations has been observed, comparable to the effect of aminoguanidine and carnosine.[591]

One of the problems with the polyamines is the relative impermeability of the cell membrane for these compounds, which will result in a multicompartmental behavior during dialysis.[41]

Pseudouridine

Pseudouridine accumulates in uremia in parallel to creatinine.[592] Dzúrik and associates[91] demonstrated inhibition of glucose utilization in isolated rat soleus muscle. Other pyrimidine derivatives, such as orotic acid, orotidine, uridine, and thymine also accumulate in uremic plasma; the concentrations of orotic acid and orotidine are further increased by allopurinol administration.[593]

Purines

Uric acid, xanthine, hypoxanthine, cytidine, and guanosine are the most important purines retained in uremia. The purines disturb calcitriol production and to a lesser extent also its metabolization.[594] Administration of purines to animals results in a net decrease of serum calcitriol and of the binding of vitamin D receptor to DNA-chromatin.[594] A decrease of uric acid in response to allopurinol administration results in a rise of plasma calcitriol levels.[595] Purines are involved in the resistance to calcitriol of immune competent cells,[115] by a reduction of the expression of the lipopolysaccharide receptor CD14 on the surface of monocytes. Xanthine and hypoxanthine have been implicated as modulators of neurotransmission and may be related to poor appetite and weight loss.[596] Both xanthine and hypoxanthine induce vasoconstriction, inhibit platelet induced vasorelaxation,[597] and disturb endothelial barriers.[598] Hypoxanthine also blocks detoxification by methylation of arsenic.[541] Uric acid acts as an antioxidant and hence reduces oxidative stress,[599, 600] although this effect is mainly limited to *in vitro* conditions.[430,599] In young children with chronic renal failure, cytidine is found in cerebrospinal fluid at concentrations that are at least 10 times above normal, and that are also higher than the corresponding concentrations in blood.[601] Based on indirect arguments, this finding has been related to delayed cognitive development.

In spite of a markedly diminished urinary secretion of uric acid in renal failure, the rise in plasma uric acid levels is only moderate because of net intestinal secretion.[602] Uric acid is a small water soluble compound that is removed by hemodialysis from the plasma in a similar way as urea,[387] but removal from the intracellular compartment is by far not as efficient.[603] Possibly, other uremic toxins play a role in the inhibition of this transfer. Dialytic removal of xanthine and hypoxanthine shows no correlation with that of urea and creatinine.[387] Microencapsulated genetically engineered E. Coli cells have been developed, which have the capacity to lower uric acid both *in vitro* and *in vivo*.[604]

Trace Elements

Sources of trace element accumulation are dialysate, food intake, drugs, and prosthetic materials. Retention is the consequence of insufficient renal elimination. Although alterations in concentration of trace elements modify a host of biologic functions, it has been difficult to demonstrate a link between trace element accumulation and uremic side effects.[39]

Aluminum accumulates as a result of its presence in dialysate, or of excessive intake of aluminum hydroxide as a phosphate binder. It provokes mental changes (aluminum encephalopathy) and osteomalacia as a result of the competition of aluminum with calcium at the bone matrix.[605] Aluminum intoxication has become less prevalent, since the implementation of more adequate water treatment systems.

Iron overload results in a baseline activation of leukocyte biologic activity,[606] which is related to chronic inflammation and possibly atherogenesis, and in a depressed response of the leukocytes upon activation,[606] linked to an increased susceptibility to infection. Fortunately, iron overload has become less frequent since the introduction of erythropoietin.

The concentration of other elements, such as copper, cadmium, mercury, chromium, strontium, and molybdene is also increased.[607-610] In recent studies, retention of arsenic has been evidenced in a substantial segment of the uremic population.[609,611] For some trace elements, such as zinc, bromine, selenium, rubidium and caesium, a decreased concentration has been reported.[609,612,613] Selenium deficiency might be related to atherogenesis.[614] Selenium supplementation not only prevents oxidative stress but renal structural energy as well.[615]

Trihalomethanes

Trihalomethanes are common contaminants of chlorinated tap water, which are found in dialysate if they are incompletely eliminated by water treatment systems. They are present at increased concentrations in the blood of hemodialyzed patients,[616] are potentially mutagenic, carcinogenic,[617-619] and a possible cause of spontaneous abortion.[620]

Urea

For the extensive number of toxicity studies to which urea has been submitted, the number in which a well defined adverse biochemical or physiologic impact has been reported at concentrations currently encountered in uremia is relatively low. Interestingly, in a classical study by Johnson and associates,[621] long lasting dialysis against dialysate containing high urea concentrations had no consistent impact on uremic clinical symptoms. More recently, two large controlled clinical studies, the ADEMEX and the HEMO-study, could not demonstrate an impact of enhanced urea removal on survival outcome.[173,622]

Lim and associates[623,624] have shown that urea inhibits NaK2Cl cotransport in human erythrocytes, as well as a number of cell volume sensitive transport pathways. A heat shock response is elicited by urea in human neuroblastoma cells, which might be a factor playing a role in uremic neurotoxicity. In a recent study by Moeslinger and associates,[625] urea was shown to induce macrophage proliferation by inhibition of inducible nitric oxide synthesis (iNOS). This inhibition of iNOS occurs at the posttranscriptional level.[626] Urea inhibits *in vitro* L-arginine transport and endothelial NO-synthase activity,[627] but *in vivo*, 7

days of urea administration to rats had no impact on renal cortical I-arginine concentration or on NO-synthase activity.[628] Urea increases the expression of the oxidative stress-responsive transcription factor, Gadd153/ CHOP.[629]

It has been suggested that *in vivo*, urea toxicity is counterbalanced by the methylamines, which are retained in parallel in renal failure.[404] A direct proof of this effect has, however, not yet been delivered. Trimethylamine oxide (TMA-O) protects myosin structures against urea-induced effects (2–8 mol/L).[405] Urea, when administered alone to bilaterally nephrectomized rats, shortens their life span.[268] This could possibly be attributed to an osmotic effect.

Urea is also the precursor of some of the guanidines, especially guanidinosuccinic acid (see earlier text), which by themselves induce direct biochemical alterations. As the uremic retention solute with the highest net concentration, urea may also be involved in dialysis disequilibrium, if the decrease in plasma concentration during dialysis occurs too rapidly. Urea may also be a source of generation of cyanate and isocyanic acid, and these might be at the origin of carbamoylation, resulting in structural and functional changes of amino acids and proteins.[630-634] Serum urea is the most consistent predictor of carbomylated hemoglobin in uremia.[631] Spontaneous dissociation of urea to isocyanate has been held responsible for the decreased affinity of oxygen for hemoglobin.[635]

Urea is unequivocally recognized as a marker of solute retention and removal in dialyzed patients. It is one of the few solutes that has been correlated convincingly with clinical outcome of hemodialysis.[636] However, it is not the peak concentration per se, but the low reduction ratios during dialysis together with the high ambient level (time average) that are related to increased mortality.[637] Therefore, dynamic urea kinetic parameters, reflecting dialytic removal (total clearance normalized for distribution volume–Kt/V) are more valuable indices of dialysis adequacy than static parameters (e.g., pre-dialysis urea concentrations). Standard Kt/V (stdKt/V) enables the quantitative comparison of dose with widely varying dialysis schedules.[638] High blood concentrations of urea do not necessarily relate to poor outcome if removal is sufficient, such as in continuous ambulatory peritoneal dialysis (CAPD) patients and/or in patients receiving high protein diet.[639] The reason for this apparent paradox is that urea concentration is not only influenced by dialytic removal but also by protein intake, which is actually a factor related to a good metabolic status.

One might question the validity and representativity of urea as a marker for the retention and the removal of other solutes. Biochemical systems are, at least in part, affected by compounds with a kinetic behavior that largely differs from that of urea (e.g., MM, protein bound solutes). Even if dialytic removal from the plasma is similar, as is the case for other small, water soluble, non-protein-bound compounds such as creatinine or uric acid,[387] the shift from intracellular to the plasma might occur at a different rate,[603] again resulting in divergent kinetics.

FACTORS INFLUENCING UREMIC SOLUTE CONCENTRATION (TABLE 6–3)

Removal Pattern

Conventional hemodialysis easily removes small water-soluble compounds, such as urea and creatinine, which are the most current markers of uremic retention and removal. Urea removal is linked to dialysis-related mortality.[640] Removal pattern of urea and creatinine is markedly different from that of many other uremic solutes with proven toxicity. MM are better removed by hemodialyzers containing membranes with larger pore size, and by convection (e.g., hemodiafiltration).[234] Also CAPD results in a relatively more efficient removal of MM, compared to conventional hemodialysis.

Table 6–3 Factors Influencing Solute Concentration in Dialyzed Patients

Solute-related factors
    Compartmental distribution
    Intracellular concentration
        Resistance of cell membrane
    Protein binding
    Electrostatic charge
    Steric configuration
    Molecular weight
    Hydrophilicity/lipophilicity

Patient-related factors
    Distribution volume and body weight
    Intake and generation
        Solute
        Metabolic precursors
    Residual renal function
    Access quality
    Metabolic generation
    Metabolic degradation
    Absorption from the intestine
    Haematocrit
    Blood viscosity
    Serum albumin concentration

Dialysis-related factors
    Dialysis time
    Interdialytic intervals
    Blood flow
        Mean blood flow
        Blood flow pattern
        Shear in dialyzer
    Blood distribution
    Dialysate flow
    Dialysate distribution
    Dialysate processing (single pass/batch)
    Dialyzer surface
    Dialyzer volume
    Dialyzer membrane resistance
    Dialyzer pore size
    Dialyzer hydrophilicity/hydrophobicity
    Adsorption
        On the membrane
        On other constituents of the circuit
    Ultrafiltration rate
    Intradialytic changes in efficacy
    Changes with a direct impact on solute related factors
        Blood pH
        Heparinization
        Free fatty acid concentration
        Hemodynamic stability during dialysis

Protein bound molecules behave during dialysis like larger (middle) molecules. Nevertheless, their removal will insufficiently be influenced by an increase in pore size,[176] unless the carrier proteins (mainly albumin) are removed at the same time, but this enhances the risk of caloric malnutrition. Until recently, the current dialytic methods offer no satisfactory possibilities to remove protein-bound compounds, except for PD.[256]

In recent studies, however, super flux cellulose triacetate as well as so-called protein-leaking membranes were shown to enhance removal of protein-bound molecules,[340, 341] although it remains unclear whether this effect is the result of enhanced removal unto or through the membrane, or of improved metabolism. Likewise, super flux polysulphone dialysis could decrease pre-dialysis AGE-concentration.[641]

Adsorption

Adsorption on specifically designed devices may be a promising solution for the elimination of difficult to remove molecules, such as the protein bound compounds, and renewed interest has recently been gained for this concept.[642-644] Adsorption already occurs on most hemodialysis membranes, but surface is not sufficient to allow adequate removal. The most acceptable option is the development of chemical polymers that contain structures in which the targeted molecules perfectly fit. As most small water-soluble molecules are easily removed by diffusion, it is of greater interest to develop devices with high adsorptive surface area (> 200 m^2) for large and/or lipophilic molecules. The question arises whether the adsorptive capacity of such devices will be sufficient, especially if confronted with toxins with a multicompartmental distribution.

Sorbent techniques can be used to extract compounds from dialysate (e.g., hemadsorption,[645] hemolipodialysis,[646] from ultrafiltrate[647,648] in a regeneration procedure before the treated ultrafiltrate is returned to the blood stream, from plasma[649,650] if combined with plasma filtration, or directly from blood.[238,651-653]

Removal of protein bound compounds during hemodialysis might be increased by the addition of albumin to the dialysate,[388,654] which is efficient but expensive.

Alternative Time Frames

Even under optimal conditions, Kt/V$_{urea}$ in PD-patients is low compared to the values obtained in hemodialysis-patients, but the clinical status of patients treated with both modalities is similar. This suggests that other compounds than urea, presumably with dissimilar physical characteristics, play a role in uremic toxicity, and/or that the slow toxin removal by PD and/or its capacity to remove protein-bound moieties, may have an additional beneficial impact.[177,655] Because removal is more gradual with continuous strategies, more compounds will be cleared, especially those with low clearance rates. Continuous hemodialysis strategies, slow, low efficiency dialysis applied over prolonged time periods, or daily dialysis might therefore result in more adequate toxin removal. While shifting patients from alternate day high-flux hemodialysis to daily overnight slow online hemo-diafiltration, Raj and associates[656] were able to provoke an additional decline in pre-dialysis serum ß$_2$-microglobulin concentration.

Likewise, similar or lower phosphate plasma levels have been observed with daily hemodialysis, compared to classical alternate day hemodialysis, in spite of a lower intake of phosphate binders.[569,570] Several studies suggest an improvement of clinical status if patients are submitted to daily and/or slow prolonged hemodialysis.[569,657] This has been confirmed recently in a well-conducted controlled study.[491] AGE-levels were lower in patients treated by daily dialysis than if the same patients were submitted to an alternative day scheme, in spite of identical weekly dialysis time and similar Kt/V.[301] Similarly, the pre-dialysis concentration of several protein bound molecules was decreased significantly after 6 months of daily hemodialysis treatment.[546]

Intracellular Shifts and Removal

Uremic solutes accumulate not only in the plasma but also in the cell, where most of the biologic activity is exerted. Removal of intracellular compounds across the cell membrane may be delayed during dialysis, resulting in multicompartmental kinetics, as removal will largely be limited to the plasmatic compartment. Even small water soluble compounds, such as urea, which are not subjected to resistance during their passage through the cell membrane, may display a multicompartmental behavior,[658] due to sequestration of certain body compartments. One of the consequences is a rebound at the end of the dialysis session.[659] In rats, the protein-bound toxin p-cresol was shown to distribute over a volume that exceeded the rat's weight by a factor of two to three,[548] which might explain its difficult removal even with the most efficient dialysis strategies.[176]

NONDIALYTIC FACTORS

Nutritional and Environmental Effects

Most toxins or their precursors enter the body via the gastrointestinal route. The metabolic processes that are generated by the intestinal flora play a role in this process. Inhibition of intestinal absorption, and modifications in the composition of the intestinal flora could influence solute concentration.[544,660,661] A specific oral sorbent (AST120) decreases serum indoxyl sulfate and p-cresol in uremic rats.[133,544,662,663] A few potassium and phosphate binders are applied in the clinical setting today, but in general, the resources to decrease intestinal delivery of uremic solutes are insufficiently explored.

A number of toxins are produced from protein breakdown or from metabolization of amino acids. Therefore, protein restriction might reduce toxicity, were it not that protein malnutrition increases morbidity and mortality by itself.[637]

Several toxins or their precursors, such as AGEs, trace elements, conservation agents (e.g., benzylalcohol as a precursor of hippuric acid), or vitamin C (precursor of oxalate), are present in food; these compounds are not necessarily linked to protein intake, the classically accepted main source of uremic toxin generation. Other rarely considered sources are forensic contact with volatile precursors (e.g., toluene), that are inhaled or swallowed, the intake of herbal medicines, and psychedelic drugs, or contact with environmental noxes, leached from elements of the dialysis circuit or from the dialysate (e.g., glucose degradation products present in heat-sterilized glucose-containing PD-solutions).

Pharmacologic Interaction

One of the future aspects of the treatment of uremia will consist of influencing toxin metabolization by drugs or other compounds. Some elements are known already as of today. Allopurinol decreases uric acid.[664] Rhubarb tannins decrease the concentration of urea, creatinine, guanidino-succinic acid and methylguanidine in rats with renal failure.[665] Vitamin C increases urinary excretion of CMPF.[666] Homocysteine can be lowered in uremic patients by supplementation of folic acid, pyridoxine and/or vitamin B$_{12}$.[344,346,348,667,668] Pyridoxine also reduces oxalate levels.[423] Aminoguanidine has the presumed property to reduce AGE generation.[669] The *in vivo* effect of aminoguanidine is not entirely convincing, but other inhibitors of AGE formation, which might turn out to be more efficient, will become available in the future.[670]

In a recent study, Lesaffer and associates[549] demonstrated in uremic rats that not only renal but also nonrenal clearance was dramatically inhibited. Enhancing metabolic clearance, for example, by applying the principles as they are in vigor during artificial liver treatment, might be of help as well in the uremic population.

Most uremic patients receive several drugs, which can result in: (1) accumulation of the mother compound because of decreased renal clearance and/or decreased metabolization by the kidneys or other organs; (2) interference of drugs with protein binding and/or tubular secretion of uremic toxins; and (3) the generation of drug metabolites that are not excreted by the failing kidneys, and that exert toxic side effects on their own.

Residual Renal Function

The impact of residual renal function on uremic retention is substantial.[636] This relative contribution is even more important for larger molecules and molecules with multicompartmental behavior, which are removed less efficiently by the dialysis procedure. Therefore, the longer preservation of residual renal function with CAPD compared to conventional hemodialysis[671, 672] may have a substantial impact on toxicity. Also with high flux biocompatible membranes, residual renal function is preserved longer.[167, 673]

Uremic retention solutes have been held responsible for a faster deterioration of residual renal function.[131] At least one of these compounds, indoxyl sulfate, is removed more efficiently by CAPD.[133]

CONCLUSIONS

The uremic syndrome is the result of a complex set of biochemical and pathophysiologic disturbances, emanating in a state of generalized malaise and dysfunction. This condition is related to the retention of a host of compounds; many of them exert a negative impact on key functions of the body; those molecules have consequently been identified as uraemic toxins. Up to now, the toxic action of single solutes has repeatedly been studied, but the intermutual interference between compounds has rarely been considered. Although solute retention is one of the major pathophysiologic events, deficiencies are functionally important as well.

Removal and generation of many compounds with proven biologic or biochemical impact, especially toxins that are hydrophobic and/or not generated from protein breakdown, can hardly be predicted by the intradialytic behavior of urea, a current marker but a small water soluble compound generated from protein, with relatively little biologic impact.

Solute clearance eventually reaches a plateau as dialyzer blood flow and/or dialysate flow are increased; this plateau is reached much sooner for molecules with a higher molecular weight. As a result, clearance of MM stricto sensu is relatively blood and dialysate flow independent. Only an increase of dialysis time, dialyzer surface area, ultrafiltration rates and/or dialyzer pore size can enhance their removal.

Removal of solutes that behave like larger molecules due to their protein binding, multicompartmental distribution and/or lipophilicity, will be less affected by the use of high flux dialyzers and/or dialyzers with a larger pore size. To improve the clearances of these "new definition MM," it may be necessary to develop renal replacement systems with different characteristics, for example, specific adsorption systems and/or procedures that allow a slower exchange of solutes.

Earlier concepts of charcoal adsorption, eventually largely abandoned, should perhaps be reconsidered, especially for the removal of organic acids. More specific and/or more efficient adsorptive systems may be needed, however. As an alternative, adsorption of toxins or of their precursors may be pursued at the intestinal level. Another alternative to be considered is dialysis against recycled albumin-containing dialysate, to allow a better diffusion of protein bound toxic compounds.[388] Finally, a last alternative could be the use of protein permeable membranes, to remove larger molecules as well as protein bound substances.[340] Whether the amount of removal will be sufficient to reduce uremic toxicity, whether this removal will not enhance or induce protein malnutrition, and whether the cost of such procedures will outweigh the benefit remains a matter of debate. Even if solute removal is improved by alternative strategies, mass transfer may be limited if the compounds of interest are distributed over multiple compartments.

The next step is to pursue more specific removal. However, before this can be realized, we will need to know more about the toxic compounds responsible for these disturbances. Some progress has been made in this area during the last few years. What is still lacking is a structural approach, comparing a large panel of putative toxins, at well defined concentrations, and with well defined test methods. The subsequent step is then to launch controlled studies, whereby therapeutic strategies that remove the toxins that have been characterized, will be tested on their impact on morbidity and mortality.

We are convinced that our views on how to enhance uremic toxin removal need to be changed. Increasing pore size, alone or in combination with adaptations in dialyzer geometry, is certainly not the only solution, and might have come close to its maximal capacity.

Anemia in Chronic Kidney Disease

Steven Fishbane, M.D. • Naveed Masani, M.D.

Anemia is a frequent complication of chronic kidney disease (CKD). When cardiac output and blood oxygenation are constant, hemoglobin concentration is the variable that determines oxygen delivery to the body's tissues. The anemic patient suffers the consequences of reduced systemic oxygen delivery, with fatigue being the most pronounced symptom. The body's attempts to compensate for anemia lead to secondary pathology, such as left ventricular hypertrophy of the heart, with its attendant increase in risk for adverse outcomes. Patients with CKD are often exposed to years of anemia (if untreated) with important effects on quality of life and cardiac function.

The prevalence of anemia in CKD depends on both the severity of renal insufficiency (CKD stage) and the definition of anemia. In a study of patients seen in nephrology practices in Boston (Figure 7–1), hematocrit (Hct) less than 36% was found in 45% of patients with serum creatinine (SCr) less than 2 mg/dL; 50% with SCr 2.1 to 3 mg/dL; 58% with SCr 3.1 to 4 mg/dL; and 92% with SCr greater than 4 mg/dL.[1] In end-stage renal disease (ESRD, CKD Stage V) the prevalence, if untreated, increases to greater than 90%.[2]

Most patients with ESRD receive erythropoietin replacement treatment (rHuEPO); however, in earlier stages of CKD anemia may go unrecognized and rHuEPO treatment may be underutilized. In a recent analysis of Medicare beneficiaries who, as patients, started hemodialysis, 60% had Hct less than 30%, and only 15.6% had ever been treated with rHuEPO.[3] Similarly, Obrador and colleagues[4] found that among 155,051 patients new to dialysis between 1995 and 1997, only 23% had been treated with rHuEPO during their years with CKD. Moreover, of those patients with Hct less than 28%, only 20% had received rHuEPO treatment.[4]

PATHOGENESIS

The most common form of anemia in CKD is one of reduced erythrocyte production, with cells generally normal in size and shape.[4,5] Bone marrow studies fail to show the expected increase in erythropoiesis as compensation for anemia. In the past many believed that circulating uremic factors inhibited marrow erythropoiesis.[6–8] A preponderance of evidence now demonstrates that inadequate stimulation of erythropoiesis is the primary defect. The kidneys in CKD may continue to produce erythropoietin, but the quantity produced is insufficient to support normal oxygen delivery.[9,10] Eschbach and colleagues,[11] in seminal studies performed in sheep, clearly demonstrated the importance of erythropoietin deficiency as the primary cause of the anemia of CKD. In the years since rHuEPO replacement treatment was first used, the clinical effectiveness of rHuEPO has been the strongest confirmatory evidence for the primacy of erythropoietin deficiency.

Erythropoietin is a glycoprotein hormone, and its known receptor is a member of the cytokine receptor superfamily.[12] The hormone is produced in response to hypoxic conditions that cause reduced systemic oxygen delivery.[13,14] Hypoxia is sensed in erythropoietin-producing renal peritubular cells by the recently discovered hypoxia inducible factor-1.[15,16] This protein degrades rapidly when normal oxygen tension is present. In hypoxic conditions it is stabilized[17,18] and interacts with the oxygen-sensitive promoter of the erythropoietin gene, resulting in upregulated erythropoietin production.[19] In nonuremic subjects, plasma erythropoietin levels range from 0.01 to 0.03 U/mL. When hypoxia or anemia is present, levels may increase up to 100- to 1000-fold.[20]

Most of the body's erythropoietin production occurs in the kidney, and the primary site of action is in erythroid tissues of the bone marrow. Binding of erythropoietin to its receptor leads to a cascade of signal transduction events that work to stimulate erythrocyte production.[21–25] This occurs in intermediate-stage erythroid burst-forming units (BFU-E) and erythroid colony-forming units (CFU-E), where cell proliferation is stimulated and programmed cell death is reduced.[26] Serum hemoglobin levels increase, systemic oxygen delivery improves, and the stimulus for erythropoietin production decreases.

Although erythropoietin deficiency is the primary cause in over 90% of cases of anemia in CKD, other etiologic factors may be present. Indeed, the patient with CKD may suffer from any of the large number of causes of anemia for which people in the general population are at risk. This would include common causes of anemia, such as iron deficiency, folic acid or vitamin B12 deficiency, bleeding, hemolysis, and myelodysplastic syndromes. Of particular importance in patients with CKD is iron deficiency, a subject that will be discussed in great detail in subsequent sections.

Consequences of Anemia in Chronic Kidney Disease and the Effects of Treatment

Increased Risk of Mortality and Morbidity

It is biologically plausible that anemia could increase the risk of death in CKD. Anemia reduces oxygen delivery to tissues, which could adversely impact on organ function. For patients with chronic organ dysfunction, such as congestive heart failure or coronary artery disease, reduced oxygen supply could potentially increase the risk for ischemic adverse events. Furthermore, maladaptive compensations for anemia, such as left ventricular hypertrophy, might independently increase the risk for mortality. To date, however, no studies have rigorously proven that anemia in CKD causes an increase in mortality risk. Instead, a number of observational studies have successfully
Figure 7–1 Prevalence of anemia in chronic kidney disease.(Adapted from Kazmi et al: AM J Kidney Dis 2001; 38[4]: 803–812.1)

associated anemia in CKD with an increased risk of death. Among a large cohort of patients with ESRD, Ma and colleagues[27] found the risk of death for patients with Hct less than 30% to be increased by 12% to 33%, compared to those patients with higher Hct values. Foley and colleagues[28] prospectively followed 432 ESRD patients and found that each 1 g/dL increase in Hgb was associated with a decrease in mortality risk of 14%. Similar observational findings were reported by Lowrie and Lew.[29] In a post hoc analysis of a large congestive heart failure study, Al-Ahmad and colleagues[30] found that anemia was an independent risk factor for mortality. Every 1% decrease in Hct was associated with a 3% increase in mortality risk. Despite sophisticated multivariate analyses, these studies cannot fully exclude the possibility that low Hct was simply a marker for sicker patients, and that anemia may not be causally linked to an increased mortality risk. Besarab and colleagues[31] reported the results of an interventional study that offered some potential to examine this issue from a different perspective. Patients with preexisting cardiac disease on hemodialysis were randomized to rHuEPO treatment targeted to a low or normal level of Hct. The study did not find anemia, or a lower Hct level, to result in greater mortality risk; in fact, there was a trend to greater mortality in the normal Hct group. Further research will be needed to fully elucidate the relationship of anemia and its treatment to death risk in CKD.

Hospitalization risk in relation to anemia in CKD has also been studied by observational analyses. Collins and colleagues[32] found the risk of hospitalization to be lower in hemodialysis patients with higher Hct values. In the Hct category of 36% to 39%, the risk was 16% to 22% lower than when the Hct was 33% to 36%. Similar findings in hemodialysis patients were reported by Churchill and colleagues.[33] Xue and colleagues[3] studied the pre-ESRD period and found that lower Hct values were associated with greater hospitalization risk. As for mortality, the studies cannot demonstrate that anemia is causally linked to greater risk.

Reduced Quality of Life

Fatigue is the cardinal symptom of anemia.[34] It is often associated with dyspnea and loss of stamina and may result in diminished overall quality of life (QOL). A good-sized body of

evidence has accumulated demonstrating that partial or complete correction of anemia in CKD improves measures of QOL.[35–41] A recent systematic review analyzed 16 studies composed of 2253 patients with CKD. The baseline Hct averaged 24.4%, and the mean increase after treatment was 8.3%. Meta-analysis showed a consistent positive correlation between change in Hct and change in QOL measures ($P < .001$).[42] Moreno and colleagues[39] raised Hct from 30% to 38.4% in 156 selected hemodialysis patients. The functional status and quality of life improved significantly with increased Hct.[39] Painter and colleagues[41] found that normalization of Hct accompanied by exercise training led to a significant increase in exercise capacity, although not to normal levels.[41] In contrast, employment status does not seem to improve with anemia treatment.[43] In a recent study of 126 CKD patients with coexistent severe congestive heart failure, Silverberg and colleagues[44] treated with rHuEPO to raise mean hemoglobin levels to approximately 13.1 g/dL. Subjects' functional status, fatigue, and shortness of breath improved significantly, and hospitalization over the next year was reduced by 95% (Figure 7–2).[44]

Reduced Brain and Cognitive Function

Neurocognitive function in relation to CKD and anemia has been examined in several reported studies. Marsh and colleagues[45] studied 24 hemodialysis patients treated with rHuEPO to increase Hct from a mean of 23.7% to 36.5%. An electrophysiologic parameter was found to improve, as were most neuropsychological test results. Temple and colleagues[46] partially corrected anemia in 17 peritoneal dialysis patients and found that IQ results improved as did other measures of cognitive function. Pickett and colleagues[47] studied the effect of normalization of Hct in 20 hemodialysis patients and found improvement in various tests of brain function. These results are consistent with the finding in dogs that systemic oxygen consumption is optimized when Hct is in the normal range.[48,49] Benz and colleagues[50] normalized Hct in 10 hemodialysis patients and found that various measures of sleep function improved significantly.

	Before	After
Hemoglobin (g/dL)	10.3	13.1*
Serum creatinine (mg/dL)	2.4	2.3
NYHA class (1–4)	3.8	2.7*
Fatigue/SOB index	8.9	2.7*

Cardiac Complications

Left ventricular hypertrophy (LVH) and dilatation develop as compensation for anemia in CKD.[51–53] Levin and colleagues[53, 54] found that left ventricular mass index (LVMI) correlated with hemoglobin concentration in pre-ESRD CKD patients. For each decrease of 1 g/dL in serum hemoglobin, LVH risk increased by 6%. Furthermore, they found that worsening of LVMI over a 1-year period correlated with lower hemoglobin levels.[53, 54] Harnett and colleagues[55] found that 75% of patients who started dialysis in the United States had LVH present, and that anemia was an important risk factor for LVH.

The importance of the association between anemia and LVH cannot be understated. In nonuremic populations there is a significant and independent relationship between LVH and risk of death.[56,57] Among patients with kidney disease the same relationship holds true.[58] Given the high cardiovascular death rate of hemodialysis patients,[59] the great prevalence of LVH at the onset of hemodialysis,[55] the role of LVH in increasing death risk, and the importance of anemia in the pre-ESRD period as a predictor of LVH, a chain of logic can be constructed that links anemia in the CKD period with subsequent poor outcomes of hemodialysis patients. In fact, Levin and colleagues[53] found that the prevalence of LVH increased progressively with decreasing creatinine clearance levels (Figure 7–3). The causality relationship between anemia and LVH risk in CKD has not yet been sufficiently examined in interventional studies. In uncontrolled studies of partial anemia correction with rHuEPO, regression of LVH has been demonstrated in hemodialysis[60–62] and pre-ESRD CKD patients.[63,64] In one fair-sized randomized controlled trial, Foley and colleagues[65] randomized 146 hemodialysis patients with LVH or left ventricular dilatation to anemia correction to hemoglobin levels of 10.0 or 13.5 g/dL. No difference was found between the groups in subsequent changes in LVH. Therefore, no definitive conclusions can be reached as to whether anemia is causally linked to LVH in CKD. Further randomized controlled trials are in progress.

Ischemic heart disease is a frequent problem for patients with CKD. It is plausible that anemia could increase the risk of ischemia in patients with coronary obstructive disease by reducing coronary oxygen delivery. Conlon and colleagues,[66] in a randomized controlled study of 31 hemodialysis patients, found no reduction in silent ischemia episodes with treatment to a normal Hct level. In contrast, Wizemann and colleagues,[67] in an uncontrolled study of 81 hemodialysis patients, found that partial correction of anemia led to significant reductions in exercise-induced electrocardiograph changes. Hase et al[68] studied the effect of rHuEPO treatment in nine hemodialysis patients with coronary artery disease. Mean hemoglobin concentrations increased from 7.9 g/dL to 10.4 g/dL. Exercise duration improved by approximately 40%, and electrocardiographic ischemic changes were reduced. The effect of anemia or anemia treatment on cardiac mortality is discussed separately above.

Treatment with Recombinant Human Erythropoietin (rHuEPO)

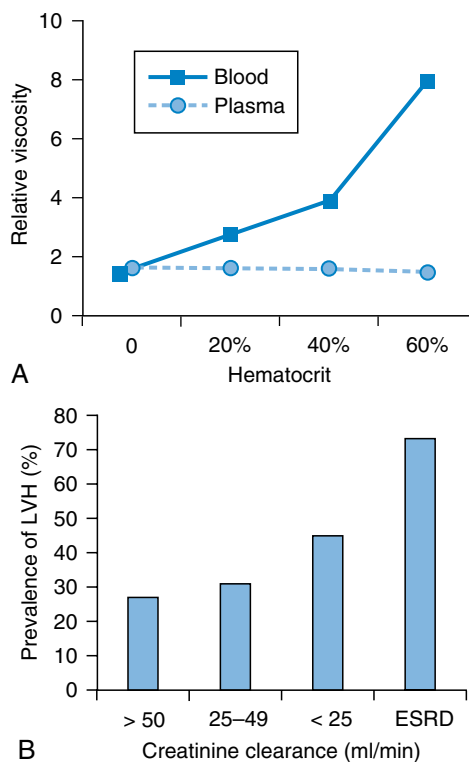
Erythropoietin is a glycoprotein hormone synthesized and released primarily by peritubular type I interstitial cells located in the renal cortex. The native compound is composed of 166 amino acids, although in the circulating


Figure 7–3 **A,** Relative viscosity as measured by viscometer. **B,** Prevalence of LVH increases as the creatinine clearance decreases. (Adapted from Levin A, Singer J, Thompson CR, et al: Prevalent left ventricular hypertrophy in the predialysis population: identifying opportunities for intervention. Am J Kidney Dis 1996; 27:347-354, and Foley RN, Parfrey PS, Morgan J, et al: Effect of hemoglobin levels in hemodialysis patients with asymptomatic cardiomyopathy. Kidney Int 2000; 58:1325-1335.

form there are only 165 amino acids. It is N-glycosylated at three amino acids and O-glycosylated at one, Ser126.[69] The gene for erythropoietin was cloned by Jacobs and colleagues[70] in 1985. Within 2 years clinical studies were published demonstrating the safety and efficacy of a recombinant form of the hormone.[71,72] The U.S. Food and Drug Administration approved rHuEPO for the treatment of anemia of kidney disease in 1989.

Recombinant human erythropoietin (rHuEPO or epoetin) is a generic term that encompasses all genetically produced forms of erythropoietin. The drugs are produced through recombination of the human erythropoietin gene with Chinese hamster ovary cells.[73,74] Four forms of the drug are currently available: epoetin-α, epoetin-β, epoetin-Ω, and darbepoetin-α. Epoetin-α, epoetin-β, and epoetin-Ω are indistinguishable from the native human hormone and are very similar in clinical characteristics. Darbepoetin-α has a modified carbohydrate content that yields a longer serum half-life.[75] The drug contains five N-linked carbohydrate chains as opposed to the three contained in standard epoetin. This results in improved serum half-life, despite decreased erythropoietin receptor affinity. Darbepoetin-α has approximately three times the half-life of standard epoetin-α, with an intravenous administration half-life of approximately 25 hours (compared to 8 hours for epoetin-α).[75,76] It is not clear whether the longer half-life allows for extended dosing intervals relative to other forms of rHuEPO.[77–81]

Dose, Route of Administration, Titration, and Monitoring

Because of easy access to the circulation and practicality, rHuEPO administration for patients on maintenance hemodialysis is typically via the intravenous route. The typical starting dose of epoetin-α is 120 to 180 U/kg, divided three times per week.[82] Darbepoetin-α may be started at a dose of 25 mcg once weekly. Since erythropoiesis takes time, and since newly made erythrocytes join a large pool of existing cells in circulation, there will usually not be an increase in serum hemoglobin for 2 to 4 weeks after the initiation of treatment. The rate of response varies between patients and is related to the dose chosen. In the initial clinical trials of epoetin-α, doses as high as 500 U/kg were used, resulting in an overly rapid increase of as much as 10 Hct points in 3 weeks.[71]

Certain factors may preclude epoetin from achieving its maximum efficacy, including reduced iron stores, presence of infection, lack of adequate dialysis, hyperparathyroidism, and chronic inflammation, which results in a reticuloendothelial blockade and impaired iron release.[83] Although controversial, it appears that angiotensin-converting enzyme inhibitors and angiotensin-II receptor blockers may also result in relative erythropoietin resistance and the need for higher doses.[84,85] When a patient's response to rHuEPO is inadequate, a careful search for factors that may lead to hyporesponsiveness should be undertaken. As discussed in subsequent sections, iron deficiency may be the most important of these factors.

During the initiation of rHuEPO treatment, hemoglobin and Hct levels should be checked every 1 to 2 weeks. The goal should be for Hct to increase by approximately 0.5 to 1.5 points per week. The target is to raise the Hct to a range of 33% to 36% (hemoglobin 11 to 12 g/dL).[82] Once the goals of therapy are reached, hemoglobin/hematocrit monitoring can be reduced to every 2 to 4 weeks. Because of the important link between iron supply and erythropoiesis, iron stores should be tested every month during the initiation of rHuEPO treatment and every 3 months thereafter.

The target hemoglobin concentration for CKD patients treated with rHuEPO has been the subject of some controversy.[86] Normal Hct values for adults are 36% to 46%, with the lower part of the range applying to women. Most interventional studies in CKD have evaluated the effect of rHuEPO treatment for raising Hct from levels below 30% to levels between 30% and 36%. The effects analyzed have generally been outcomes such as need for blood transfusion, Hct level achieved, or measures of quality of life or functional status. These studies have generally demonstrated good efficacy for rHuEPO treatment within these parameters and support the current Kidney Disease Outcomes Quality Initiative (K/DOQI™) target hemoglobin level (11 to 12 g/dL).[82] There has been only one published, well powered interventional study that has examined the effect of normalizing Hct. Besarab and colleagues[31] studied 1233 hemodialysis patients randomized to an Hct of approximately 30% or 42%. The primary finding was of no benefit and, in fact, suggested a trend toward a greater mortality risk in the higher Hct group. In a recent cost effectiveness analysis, Tonelli and colleagues[87] found no value to raising hemoglobin levels above 12 g/dL in hemodialysis patients. Similarly, a recent systematic literature review by Strippoli and colleagues[88] did not result in a benefit for higher Hct levels. Therefore, the current target hemoglobin level of 11 to 12 g/dL would seem to be quite adequate.

The route of administration for rHuEPO is usually intravenous for hemodialysis patients and subcutaneous for patients with earlier stages of CKD or for those on peritoneal dialysis. Convenience tends to be the main driver of the route selected. However, there is a difference in efficacy that has been consistently demonstrated in clinical trials.[89–91] In one study, Kaufman and colleagues[89] randomly assigned 208 hemodialysis patients to treatment with epoetin-α, either by intravenous or subcutaneous routes. The main result was a mean 32% reduction in epoetin dose requirements when the drug was administered by the subcutaneous route. McClellan and colleagues[90] studied administrative data on 7092 hemodialysis patients and found that the subcutaneous route yielded equivalent Hct outcomes with an approximate 14% reduction in dose requirement. It is likely that when rHuEPO is administered intravenously, the very high plasma levels of erythropoietin immediately after injection fully saturate erythropoietin receptors. Some drug may be metabolized before there is any interaction with receptors, essentially wasting the drug. Subcutaneous dosing results in a slower accumulation phase in plasma and less saturation of erythropoietin receptors.[82] However, despite the strong data and national guidelines supporting subcutaneous administration, most hemodialysis patients are still treated with intravenous rHuEPO. This is probably the result of patient and provider preference.

Potential Adverse Effects of Treatment

A variety of side effects may be seen with epoetin therapy, including hypertension, seizures, increased arteriovenous (AV) graft clotting, and the recently described phenomenon of pure red cell aplasia. Hypertension develops or worsens in approximately 25% to 35% of patients treated with rHuEPO.[92,93] This may be countered with additional antihypertensive therapy or with reduction of the dry weight of hemodialysis patients. Unless the extremely rare complication of hypertensive encephalopathy is encountered, rHuEPO therapy need not be discontinued.[93] Particular care must be taken with patients with progressive CKD, where hypertension is the major driver of disease progression. Worsening hypertensive control in these patients may outweigh any benefits derived from rHuEPO treatment. In a study of rats with CKD (renal ablation), Garcia and colleagues[94] found that rHuEPO treatment resulted in uncontrolled hypertension and faster disease progression. Hypertension should first be under good control before rHuEPO is initiated in patients with CKD. Blood pressure should be carefully monitored during all phases of treatment and, especially, after the rHuEPO dose is increased.

The etiology of the rHuEPO-induced hypertension is incompletely understood and is probably multifactorial. Factors implicated in the pathobiology include (1) an increase in blood viscosity, (2) improved cardiac output, (3) increased synthesis of endothelin-1 and an imbalance in vasoactive hormones and autacoids, (4) reduction in vasodilatation as compensation for anemia, and (5) improved vascular responsiveness to circulating catecholamines.[93, 95–97] Not one of these factors has yet been identified as the primary cause of hypertension. Interestingly, Caravaca and colleagues[98] found that hypertension risk was reduced by approximately 95% in patients who were taking antiplatelet drugs at the time of their

rHuEPO treatment. The authors suggested that changes in platelet aggregability induced by rHuEPO might play an important role in the pathogenesis of the hypertension.

Blood viscosity increases as Hct rises. The relationship is nonlinear, with the rate of rise of viscosity increasing at high levels of Hct (Figure 7–3). Treatment with rHuEPO increases Hct and blood viscosity, and there has been a concern that either native vessel or graft thrombosis risk may be increased. Recently, Wun and colleagues[99] found venous thrombosis risk in cervical cancer patients treated with rHuEPO to be increased 10.3-fold compared to non-rHuEPO-treated patients. A trial study of Hct normalization in hemodialysis patients resulted in a trend toward a greater risk of myocardial infarction among patients randomized to the higher Hct group.[31] Churchill and colleagues[100] studied hemodialysis vascular access thrombosis and found that rHuEPO treatment was associated with increased risk in AV grafts but not in fistulas. In contrast, Besarab and colleagues[101] did not find an increased risk of vascular access clotting during rHuEPO treatment. In general, until the magnitude of risk for thrombosis is better understood, limiting target hemoglobin to 12 g/dL is probably reasonable.

The effects on native AV fistula stenosis have also been studied with respect to rHuEPO therapy. A 3-year, placebo-controlled, prospective study in hemodialysis patients evaluated the effects of rHuEPO treatment on the progression of native AV fistula stenoses. Treatment with rHuEPO was not found to accelerate the development of stenoses. Interestingly, the treatment group was found to have a statistically significant decrease in plasma values of platelet-derived growth factor and vascular cell adhesion molecule-1, signaling molecules that tend to favor neointimal proliferation.[102]

The development of pure red cell aplasia (PRCA) during rHuEPO therapy, secondary to the formation of anti-erythropoietin antibodies, was first reported in 2002.[103–105] The antibodies have a strong neutralizing capability, blocking erythropoiesis and erythroid colony formation from normal bone marrow. Over a 3-year period, 13 patients who were receiving epoetin-α for chronic kidney disease developed transfusion-dependent anemia anywhere from 3 to 67 months after initiation of treatment. After discontinuing rHuEPO, six patients regained erythropoietic activity after being treated with immunosuppressants or a renal allograft, while three remain transfusion-dependent more than 2 years later. Many other cases have now been reported in Europe and elsewhere, while the incidence in the United States appears to be extremely rare. One possible explanation for the recent development of PRCA is a difference in stabilizing agents used in rHuEPO production. The vast majority of reported cases occurred with only one type of epoetin-α formulation, Eprex (Johnson & Johnson). In 1998 the European formulation of this drug was changed at the request of regulatory agencies, with the replacement of human serum albumin (HSA), by polysorbate 80 and glycine. There was a clear temporal relationship between this formulation change and with the suddenly increased incidence of PRCA. In contrast, the incidence of PRCA has remained low with HSA-containing epoetin-α products. It may be that this formulation change was a major cause of the rapid increase in PRCA cases. There is little reason to believe that PRCA is an important problem with other forms of rHuEPO. Another interesting finding is that in all cases in which the route of administration could be determined, the drug was administered subcutaneously. It is possible that interaction of the drug with tissue proteins, without the stabilizing effect of HSA, may occasionally render the drug immunogenic. The incidence is not completely clear, but probably less than 1 in 10,000 patients is treated with Eprex.

Pure red cell aplasia should be considered when a patient who has previously responded to rHuEPO suddenly becomes unresponsive. Usual causes of hyporesponse, as described above, should be excluded. The diagnosis of PRCA is confirmed by analysis of bone marrow biopsy samples, with the demonstration of no erythroid precursors. Anti-erythropoietin antibodies can be demonstrated in serum by immunoprecipitation. Treatment with Eprex (or other rHuEPO) should be discontinued and no other rHuEPO treatment initiated. Immunosuppressive treatment (steroids, immunoglobulin, plasmapheresis, corticosteroids) may help to restore marrow erythropoietic function.

Iron Management in Chronic Kidney Disease

Introduction

Monitoring of iron status and treatment of iron deficiency are essential components of the treatment of anemia in CKD. It has long been recognized that insufficient iron storage diminishes the effectiveness of rHuEPO therapy.[106] Iron deficiency may occur at any stage of CKD but is particularly frequent among hemodialysis patients.[82] Although the exact incidence of iron deficiency in hemodialysis patients is not known, it occurs in the majority of patients.[107]

Pathobiology of Iron Deficiency in Chronic Kidney Disease

Iron balance in man reflects a homeostatic system in which dietary iron absorption is adjusted based on iron losses and storage. Dietary intake of iron is usually far in excess of actual need, therefore it is unusual for iron deficiency to develop on the basis of inadequate intake.[108,109] Rather, excess external loss of iron causes most cases of iron deficiency. In hemodialysis patients iron losses are common for several reasons. First, a certain amount of blood and iron are left behind in the dialysis lines and filter at the end of each treatment.[110] Iron is also lost as a result of frequent venipuncture for laboratory testing, surgical blood loss, gastrointestinal bleeding, and vascular access accidents.[111,112] The second reason for iron deficiency in hemodialysis patients is insufficient absorption of dietary iron resulting from the use of phosphate binders. This effect may be less profound with sevelamer than with calcium- and aluminum-containing binders.[113,114] If phosphate binders are not used, basal absorption of dietary iron may be unimpaired in hemodialysis patients.[115] The third reason for the high incidence of iron deficiency in hemodialysis patients is the accelerated demand for storage iron caused by rHuEPO therapy. Normal total body iron stores are 3000 to 4000 mg. A much smaller quantity of iron, 3 mg, is in circulation at any given moment.[108] During the intensified erythropoietic stimulus of rHuEPO treatment, this small amount of circulating iron may be rapidly exhausted, leading to iron deficient erythropoiesis, even if there is stainable iron in storage tissues.[116] For peritoneal dialysis patients and CKD patients not yet on dialysis,

iron deficiency is probably a less frequent occurrence because there is less blood loss. However, there is little published data to critically assess the incidence of iron deficiency in these populations.

Monitoring and Diagnosis of Iron Deficiency in Chronic Kidney Disease

The K/DOQI™ anemia guidelines recommend that during the initiation of rHuEPO treatment, iron status should be tested every month in patients not receiving iron repletion.[82] Once rHuEPO dosing and iron maintenance have stabilized, the guidelines recommend monitoring every 3 months. Two tests, serum ferritin and transferrin saturation, have been widely used for the diagnosis of iron deficiency in CKD.

Serum ferritin is a marker for iron storage and believed to reflect iron deficiency in CKD patients when less than 100 ng/mL.[82] The diagnostic value of serum ferritin, however, is limited by its behavior as a potent acute phase reactant.[117] Clinical settings often arise in CKD where ferritin values may be high, even in the presence of iron deficiency, resulting in a test sensitivity of only 41% to 60% in hemodialysis patients.[118–120] Given the low sensitivity, a high or normal serum ferritin is not sufficient to exclude the possibility of iron deficiency. Serum ferritin should not be used by itself for the assessment of iron status in patients with CKD.

Transferrin saturation (TSAT) is a measure of the availability of circulating iron, calculated as TSAT = (serum iron/total iron binding capacity) × 100. K/DOQI™ guidelines recommend using a value of less than 20% as an indicator of iron deficiency in patients with CKD.[82] This test, although reasonably sensitive, has a specificity measured in hemodialysis patients of only 36% to 63%.[118–120] As a result, low values of transferrin saturation cannot reliably make the diagnosis of iron deficiency in this patient population, and results are often falsely positive. Because of transferrin saturation's poor specificity and serum ferritin's poor sensitivity, it is not surprising that concurrently measured specimens often paradoxically suggest iron deficiency by transferrin saturation and iron overload by serum ferritin (such discordant results are frequently due to the effects of inflammation).[121,122] Both tests are further limited by their great variability. Recently, the coefficient of variation for both tests was greater than 40%.[123]

The weakness in the predictive values of serum ferritin and transferrin saturation leads logically to the conclusion that the tests are most helpful when serum ferritin is less than 100 ng/mL (highly predictive of iron deficiency) or TSAT is greater than 20% (highly predictive of iron sufficiency). All other test results are too inaccurate to be used in isolation as a guide for iron management. Rather, the clinician must consider the patient's serum hemoglobin concentration and rHuEPO dose requirements as part of the overall context of iron treatment decisions.

Other tests have been used with varying success to improve the accuracy of the monitoring of iron status in CKD. The percentage of hypochromic red blood cells (PHR) appears to be a helpful test of iron status in patients on hemodialysis.[124] Tessitore and colleagues[125] found that it had the greatest utility of any test in the diagnosis of iron deficiency. When PHR was greater than 6%, the efficiency was 89.6%, indicating excellent discriminative ability.[125] The test has one important

limitation, that is, it is affected by changes in erythrocyte size. When samples are stored or shipped, the cell size may be significantly altered.[126] In the United States, the majority of laboratory samples for hemodialysis are shipped to central locations. This may help explain PHR's inconsistent results in several studies[127,128] and may limit its practicality and usefulness.

Reticulocyte hemoglobin content (CHr) is a direct measure of iron status at the level of the final precursor to mature erythrocytes, the reticulocyte. Because it is a measure of content instead of concentration, it is unaffected by changes in cell volume. In addition, since reticulocytes circulate only for approximately 24 hours,[129] test results are a "snapshot," indicating very acute changes in iron status. Studies have generally found this test to be an accurate measure of iron status in hemodialysis patients.[125,127,128,130,131] In a preliminary analysis of 32 hemodialysis patients, CHr had a sensitivity of 100% and specificity of 80%, superior to the accuracy of serum ferritin, transferrin saturation, and percent hypochromic red blood cells.[128] In a more recent three-center study, 157 hemodialysis patients were randomized to iron treatment based on (1) CHr less than 29 pg or (2) serum ferritin less than 100 ng/mL or transferrin saturation less than 20%. When treatment was based on CHr the total cost of anemia care was significantly reduced, driven by greater than 50% reduction in IV-iron dosing. Furthermore, the variability of the test was far less than that for serum ferritin or transferrin saturation.[123] Generally, a CHr value of less than 29 to 33 pg indicates a need for more intensive iron treatment in patients with CKD.

Iron Treatment in Chronic Kidney Disease

K/DOQI™ anemia treatment guidelines recommend iron treatment in CKD when the serum ferritin is less than 100 ng/mL or the TSAT is less than 20%.[82] Iron replacement may be by oral or intravenous routes. Oral supplementation of iron offers the benefits of simplicity, low cost and safety, but efficacy may be limited. K/DOQI™ guidelines recommend that when oral iron is used in adults, 200 mg of elemental iron should be administered daily in two to three divided doses.[82] A variety of different oral iron drugs are available over the counter or by prescription. All of the agents may cause gastrointestinal side effects such as dyspepsia, constipation and bloating,[132] and there is little evidence to differentiate between them based on efficacy or tolerability.

The efficacy of oral iron in CKD has been rigorously studied only in the subset of patients on hemodialysis, and the results have been disappointing. Macdougall and colleagues[133] found that during the initiation of rHuEPO treatment that oral iron was no more effective than no iron treatment.[133] Similarly, Wingard and colleagues[134] treated 46 hemodialysis patients with oral iron for 6 months and found that most patients had Hct less than 30% and declining iron stores.[134] Markowitz and colleagues[135] studied 49 hemodialysis patients in a double-blinded, randomized controlled trial and found no difference in efficacy between oral iron polysaccharide and placebo.[135] Fudin and colleagues[136] studied 39 iron deficient subjects at the initiation of hemodialysis and found no difference in subsequent hemoglobin levels between oral iron and no iron treatment.[136] Taken together, these findings indicate that oral iron does not have demonstrable efficacy for iron replacement in hemodialysis patients. In contrast, among CKD

patients not yet on dialysis and those on peritoneal dialysis, ongoing iron losses are far less than what hemodialysis patients experience. Accordingly, they have lesser needs for iron supplementation and may benefit from oral iron treatment. There are, however, few published data to support this assumption.

The reasons for the lack of efficacy of oral iron treatment in hemodialysis patients are multiple. First, compliance with oral iron therapy may be poor, although there are few published reports that cover this issue. Factors impacting on compliance with oral iron include gastrointestinal side effects,[132] the need to take the pills between meals, the obligatory intake of three pills per day with most supplements to attain adequate elemental iron intake,[137] and poor education of patients of the purpose and goals of iron therapy.

The effectiveness of oral iron in CKD patients may be enhanced through several practices: (1) The dose should provide at least 200 mg of elemental iron per day[82] (for ferrous sulfate, this would be approximately three 325 mg tablets per day), (2) the pills should be taken between meals and should be spaced at least 1 hour apart from ingestion of phosphate binders, and (3) since iron is absorbed proximally in the gastrointestinal tract, delayed-release iron supplements should probably be avoided.

Because of the poor efficacy of oral iron in hemodialysis patients, there has been a great increase in recent years in the use of intravenous iron in this and other stages of CKD. A large number of studies have consistently pointed to the excellent efficacy of intravenous iron in CKD.[133,136,138–144] Treatment results in the ability to consistently reach target hemoglobin levels and/or to achieve a significant reduction in rHuEPO dose requirements. Our group randomized hemodialysis patients to treatment with oral iron or intravenous iron dextran 200 mg per week. Despite having adequate iron test results at baseline, patients responded with higher Hct levels and a 46% reduction in mean rHuEPO dose.[138] As a result of the large body of evidence demonstrating the efficacy of intravenous iron treatment, both the European Best Practice Guidelines for the management of anemia and the K/DOQI™ place intravenous iron as a key facet of care for hemodialysis patients.[82,145] As discussed above, other CKD patients have lesser degrees of blood loss, and oral iron therapy may often suffice.

The primary goal of intravenous iron therapy is to optimally support erythropoiesis, allowing target hemoglobin levels to be reached. To achieve this goal, the amount of iron administered and the resulting levels of iron tests will vary for different patients. In general terms, the K/DOQI™ anemia guidelines recommend that serum ferritin be kept greater than 100 mg/dL and transferrin saturation be greater than 20%.[82] How high above these levels is optimal for supporting rHuEPO therapy is unclear. However, with repeated dosing of intravenous iron, iron storage may increase to potentially unsafe levels. At the present time, it is not known what levels of serum ferritin or transferrin saturation indicate such iron overload.[146] European and American practice guidelines recommend that intravenous iron not be administered if serum ferritin is greater than 800 to 1000 ng/mL.[82,145]

Intravenous iron supplementation in CKD can be delivered using different dosing strategies. For patients on hemodialysis, the ready availability of vascular access during the dialysis treatment leads to great flexibility in dosing. One of two approaches is generally used. The first anticipates ongoing iron losses by providing a regular weekly (or another interval) dose of iron. The quantity administered depends on the iron needs of the individual patient; for the most part 25 to 100 mg per week should be sufficient. Based on quarterly iron test results, the dose can be adjusted to achieve the desired level of iron storage and hemoglobin level. An alternative dosing strategy is to treat with no regular intravenous iron dose and, rather, to check iron tests every 3 months; if iron deficiency develops, the recommended strategy is to treat with a more intense, repletive course of iron. Typically, 1000 mg of iron will be dosed over the course of 10 consecutive hemodialysis treatments. Both of these treatment approaches are convenient and easy to monitor. There are few published data to establish the superiority of either approach.

Intravenous iron treatment is occasionally needed for patients treated with peritoneal dialysis or CKD not yet on dialysis. As opposed to hemodialysis, where vascular access is readily available, for these patients establishing access may be inconvenient. Therefore, the treatment approach seeks to use larger iron doses given with fewer repetitions. A typical approach is to administer 250 mg of iron over 1 to 2 hours, with repeated doses given for 1 to 3 weeks as needed.[147,148]

There are currently three forms of intravenous iron that are most frequently used in the United States and in Europe. Iron dextran is a simple complex in which a dense iron core is surrounded by a shell of glucose polymers that extend out radially from the iron center.[149] The complex binds iron tightly, releasing iron into the reticuloendothelial system, where iron is cleaved from the dextran component. Iron is released into the circulation where it associates with serum transferrin.[150] The drug has well-demonstrated efficacy, but its safety is less than desired because of the occasional occurrence of anaphylaxis.[151] This complication is believed to be a result of the dextran component, although the pathogenesis is incompletely understood. Some patients have been found to have preformed dextran antibodies,[152] and the anaphylaxis may not be associated with typical manifestations, such as IgE or immune complex mediation.[153] Indeed, there is some evidence for direct unstimulated release of mediators from mast cells.[153] The incidence of iron dextran-related anaphylaxis has been found to be from 0.6% to 0.7% of all patients treated.[154,155] A history of multiple previous drug allergies may identify patients at particular risk.[155] Because of the problem of anaphylaxis and the availability of nondextran containing a form of intravenous iron, iron dextran use should probably be limited to patients who have received the drug over a long period without problems occurring.

Sodium Ferric Gluconate Complex (SFGC) is a form of intravenous iron in which the iron core is surrounded by sucrose (20% of weight) and a gluconate function that is important for stability. The apparent molecular weight by gel chromatography is $350,000 \pm 23,000$ daltons (Da).[156] The drug has been used for several decades with excellent safety[151] and efficacy reported.[157] The risk for allergic and anaphylactic type reaction appears to be dramatically reduced compared to iron dextran. Michael and colleagues[158] reported on single dose exposure in a randomized, controlled double-blinded study of 2503 hemodialysis patients. There was only one immediate type of reaction found: a rate of 0.04%. This compares to a rate of 0.61% for iron dextran calculated from an accompanying meta-analysis.[158]

Iron sucrose is a polynuclear iron (III)-hydroxide complex composed of approximately 30% sucrose. The apparent molecular weight is 34,000 to 60,000 Da.[159] This drug, like SFGC, has been used for several decades with good reports of efficacy and safety.[160] Charytan and colleagues[160] administered iron sucrose 100 mg intravenously for 10 consecutive hemodialysis treatments and found a significant increase in Hgb and transferrin saturation and ferritin levels.[160] Van Wyck and colleagues[161] tested iron sucrose in 23 hemodialysis patients who were previously allergic to iron dextran. They found no severe reactions in 223 administered doses of iron sucrose. Silverberg and colleagues[162] treated 73 hemodialysis and peritoneal dialysis patients with intravenous iron sucrose 100 mg twice monthly and found significant increases in Hct and reductions in rHuEPO dose requirements of up to 75.7%.[162]

There is little published data directly comparing the efficacy and safety of sodium ferric gluconate to iron sucrose. One study by Kosch and colleagues[163] randomized 59 hemodialysis patients to intravenous treatment with either iron sucrose administered in a dose of 250 mg iron diluted in 100 mL normal saline given over 60 minutes once per month or ferric gluconate, 62.5 mg given once per week in a slow push injection (5 min). Serum ferritin, transferrin saturation, and hemoglobin rose significantly and similarly in both groups. There were no significant differences between the two drugs in efficacy or safety end points.[163]

Iron Treatment Safety

The main safety concern in the use of intravenous iron is risk for anaphylaxis. When iron sucrose or ferric gluconate is used instead of iron dextran, the risk, as discussed earlier, is greatly reduced. Large database reviews have suggested a slightly increased risk of death with repeated intravenous iron dosing.[164] Other safety concerns generally relate to iron's oxidizing potential or its ability to serve as a growth factor for microorganisms. The potential risk for iron overload, infection, oxidative tissue damage, and cardiovascular disease is discussed in Chapter 9.

Iron overload is best understood through familiarity with the disease state hemosiderosis and the related genetic disorder hemochromatosis. In these states, many years of excessive iron storage lead gradually to evidence of tissue damage, including restrictive cardiomyopathy, pancreatic damage, arthritis, and other pathologic changes.[165] It is unlikely that intravenous iron treatment would ever lead to such a state of iron overload unless monitoring of treatment was completely disregarded. Current recommendations of the K/DOQI™ anemia practice guidelines are that intravenous iron not be administered if serum ferritin is greater than 800 ng/mL or if transferrin saturation is greater than 50%.[82] In the era prior to the introduction of rHuEPO, Gokal and colleagues[166] and Ali and colleagues[167] found evidence of iron overload in multiple transfused hemodialysis patients, some of whom had been treated with intravenous iron as well. During the same era, various researchers associated elevated iron stores with an increased risk for adynamic bone disease,[168] hepatomegaly,[169] and cardiomyopathy.[170]

The risk of infection related to intravenous iron treatment extends from the observation that iron is a key growth factor for many microorganisms.[171] Bullen and colleagues[172,173] found that bacteria injected into animals did not cause infection unless iron was first injected. In fact, iron injection led to the development of overwhelming sepsis.[172,173] Others have found that desferrioxamine iron chelation may be associated with risk of severe infections (probably as a result of providing an iron supply to bacteria or fungi).[174] In addition, intravenous iron treatment has been associated with reduced white blood cell function.[175–177] These and other findings establish that it is at least plausible that iron treatment could promote infection.

The extent to which intravenous iron treatment actually promotes infection (if at all) is uncertain. Most attempts to evaluate the relationship between iron and potential infection risk have focused on iron storage as measured by serum ferritin. Indeed, several investigators found that higher levels of serum ferritin were associated with an increased risk of infection.[178–180] This methodology may be faulty, however, in that serum ferritin behaves as an intense acute phase reactant.[181] The relationship between serum ferritin and infection risk may not indicate causality. Rather, patients with increased infection risk or with early occult infection may have elevated serum ferritins on the basis of the acute phase response. The ability to more rigorously explore the relationship would require a greater understanding of infection risk factors and inflammatory markers to power more effective multivariate analyses. Of note, a large, prospective European multicenter study found no association between serum ferritin and risk for bacteremia.[182] The relationship of intravenous iron treatment itself to infection risk was studied by Jean and colleagues.[183] These investigators found that among patients with hemodialysis catheters in place, intravenous iron dosing was associated with a greater risk for bacteremia.[183] Similarly, Canziani and colleagues[184] studied 111 hemodialysis patients and found that higher doses of intravenous iron sucrose were associated with increased infection risk. In contrast to these studies, Hoen and colleagues[185] found no relationship between intravenous iron dosing and infection risk.

Parkkinen and colleagues[186] evaluated the relationship between intravenous iron treatment and infection risk in a novel manner. A small group of hemodialysis patients were injected with intravenous iron sucrose at a typical 100 mg dose. Half of the patients were found to have significant amounts of free iron in circulation at 3.5 hours after dosing. Plasma samples from all patients were incubated with *Staphylococcus epidermidis*. For patients with no free iron present, there was no growth of bacteria. Among patients with free iron present there was a significant linear relationship between the quantity of free iron and the degree of bacterial growth.[186] These findings suggest that free iron present after intravenous iron injection might predispose to bacterial growth. By extension, it would probably be reasonable to avoid intravenous iron treatment during episodes of bacteremia.

Iron is a powerful oxidizing substance, and the body has highly conserved mechanisms to prevent tissues from being directly exposed to iron. In storage pools, iron is tightly bound within the protective shells of ferritin and hemosiderin. In circulation, iron is protected by transferrin, and release of iron to tissues is a highly regulated receptor-mediated process.[187–188] After intravenous iron dosing, the drug should be taken up from circulation by the reticuloendothelial system with later release of iron into the circulation for carriage by transferrin.

Any direct and immediate release of iron after injection into the circulation could potentially overwhelm the ability of transferrin to bind the iron. Free, unprotected iron may then be present in circulation, with the potential to cause oxidative tissue damage and to induce the production of reactive oxygen species.

Early studies of intravenous iron and release of free iron may have used faulty methodology, including drug bound iron in the measurement of serum free iron.[189] More recent studies have used better analytic techniques to measure free iron. Parkkinen and colleagues[186] found that after injection of 100 mg of iron sucrose, transferrin saturation rose dramatically within 10 minutes, indicating immediate release of iron from the drug into the circulation. Free iron was detected in the circulation in 50% of patients at 3.5 hours after injection. Patients with lower levels of serum transferrin were much more likely to have free iron present. As discussed previously, the plasma of the patients with free iron present promoted growth of *S. epidermidis*.[186] Similarly, Kooistra and colleagues[190] and Rooyakkers and colleagues[191] found that injection of iron sucrose led to free iron in plasma of hemodialysis patients and normal volunteers, respectively. In the latter study, free iron release was associated with increased reactive oxygen species in plasma and reduced forearm blood flow.[191] Roob and colleagues[192] found that iron sucrose injection in hemodialysis patients led to free iron release and oxidation, which could be attenuated by pretreatment with vitamin E. Taken together, these and other studies indicate that intravenous iron injection does appear to be associated with some free iron appearance in plasma. The effect of the free iron on the health of patients and clinically important outcomes is not yet known. Recent studies have shown some evidence of protein oxidation and a possible association with accelerated atherosclerosis.[193,194] In another report, oxidized fibrinogen was found after intravenous ferric gluconate injection.[195] It is the opinion of the authors that all intravenous iron drugs have the potential for the release of at least small amounts of free iron after injection, with the potential for a resulting increase in oxidative stress. The ability of cellular antioxidant systems to cope with this stress has not yet been adequately studied.

The potential association of iron treatment with accelerated cardiovascular disease risk has been proposed based on iron's oxidative properties and the relationship between oxidation and atherosclerosis risk.[196] The link was first proposed by Sullivan[197] in 1981, with the suggestion that iron deficiency might protect against atherosclerotic disease. With the high prevalence of cardiac disease among patients with end-stage kidney disease[198] and frequent use of iron supplementation in this population, any relationship between the two may be clinically relevant. However, there are few reports addressing this subject specifically in patients with renal failure, so a potentially misleading approach was extrapolated from studies in other populations. In one such study, Salonen and colleagues[199] examined risk for myocardial infarction in 1931 middle-aged Finnish men. Serum ferritin greater than 200 ng/mL was found to be an independent risk factor for cardiac disease. In contrast, Magnusson and colleagues[200] studied over 2000 subjects and found no relationship between serum ferritin and cardiac risk. Similarly, other results from the literature have been mixed, with more negative than positive studies.[199-208]

Indeed, a natural model to explore the relationship exists in the form of hereditary hemochromatosis. In patients with this disease and extensive iron overload, Miller and Hutchins[209] have found a rate of severe coronary artery disease of only 12%, compared to 39% of controls with normal iron stores. Given the complexity of this subject and its possible implications for therapy with iron and rHuEPO, further research in this area is clearly needed.

Renal Osteodystrophy

Sharon M. Moe, M.D.

INTRODUCTION AND REVIEW OF MINERAL HOMEOSTASIS

In people with healthy kidneys, normal serum levels of phosphorus and calcium are maintained through the interaction of two hormones: parathyroid hormone (PTH) and $1,25(OH)_2D$ (calcitriol), the active metabolite of vitamin D3. These two hormones act on three primary target organs: bone, kidney, and intestine. The kidneys play a critical role in the regulation of normal serum calcium and phosphorus levels, and thus, derangements occur quickly in patients with chronic kidney disease (CKD). The result is abnormal serum concentrations of calcium and phosphorus and impaired bone remodeling, which together can lead to fractures and extraskeletal manifestations such as vascular calcification. These abnormalities are linked and are important causes of morbidity and mortality in patients on dialysis. There is a 2-fold to 87-fold increased risk of hip fracture in dialysis patients compared to age matched individuals in the general population at ages 80 and 40, respectively.[1–3] The mortality rate after a hip fracture in a dialysis patient is double that of the general population.[4] Similarly, dialysis patients have twofold to fivefold more coronary artery calcification than age matched non-dialysis patients with angiographically proven coronary artery disease.[5] Aorta, carotid, and peripheral artery vascular calcification is also common and is associated with increased mortality.[6] These processes may be linked, because epidemiology data in the general population[7–10] and in dialysis patients[5] have shown that as bone mineral content decreases, vascular calcification increases. In addition, recent evidence shows that vascular calcification is a cell mediated process that resembles osteogenesis[11–14] and is worsened by hyperphosphatemia.[15, 16] In turn, hyperphosphatemia is associated with increased mortality.[17, 18] Thus, abnormalities of bone strength, vascular calcification, and mineral metabolism are interrelated and associated with increased morbidity and mortality in CKD.

In the past, the term *renal osteodystrophy* was equated only with abnormalities of bone turnover, but a recent expert consensus panel convened by the National Kidney Foundation determined that renal osteodystrophy is a complex disorder of compromised bone strength in CKD patients.[19–21] Whereas *osteoporosis* is a term used to describe fragile bones prone to fracture in the general population assessed by dual x-ray absorptiometry (DEXA), *renal osteodystrophy* should be the principal term to describe fragile bones prone to fracture and other morbidities in CKD. Renal osteodystrophy is a function of bone turnover (assessed by bone biopsy), bone density (assessed by DEXA or quantitative-CT [qCT]) and bone architecture, but the principal determinant of bone fragility in CKD is abnormal bone turnover. While DEXA is useful in predicting fractures in the general population,[22] this has not been shown in CKD patients. DEXA can only detect the overall density but not how the bone is arranged, and the latter is determined principally by bone turnover. Thus, with the dramatic abnormalities in bone turnover in advanced CKD, the sensitivity and specificity of DEXA for predicting fractures is likely altered. Last, CKD patients have relative hypogonadism, or "renopause," and the impact of these abnormalities on bone fragility are unclear. Low bone mass that is common in dialysis and CKD patients[23–27] is one factor, of many, that lead to increased bone fragility. Thus, although DEXA is a diagnostic tool, and low DEXA is associated with increased mortality in a small study,[28] therapeutic decisions should not be based on these results alone and should be based on multiple factors. Furthermore, there is more data to support therapeutic interventions for abnormal bone turnover than there is for abnormal bone mass or architecture in CKD patients. Therefore, the remainder of this chapter will focus on abnormalities of bone turnover. To do so, a brief review of parathyroid hormone physiology and measurement, vitamin D metabolism, and bone histology are presented.

Parathyroid Hormone

The primary function of PTH is to maintain calcium homeostasis by (1) increasing bone mineral dissolution, thus releasing calcium and phosphorus; (2) increasing renal reabsorption of calcium and excretion of phosphorus; and (3) enhancing the gastrointestinal absorption of both calcium and phosphorus indirectly through its effects on the synthesis of $1,25(OH)_2D$. In healthy subjects, this increase in serum PTH level in response to hypocalcemia effectively restores serum calcium levels and maintains serum phosphorus levels. The kidneys are of key importance in this normal homeostatic response, and thus patients with CKD may not be able to appropriately correct abnormalities in serum ionized calcium.

PTH is cleaved to an 84 amino acid protein in the parathyroid gland, where it is stored with fragments in secretory granules for release. Once released, the circulating 1–84 amino acid protein has a half-life of 2 to 4 minutes. It is then cleaved into N-terminal, C-terminal, and mid-region fragments of PTH, which are metabolized in the liver and kidney.[29,30] PTH secretion occurs in response to hypocalcemia, hyperphosphatemia, and $1,25(OH)_2D$ deficiency. The extracellular concentration of ionized calcium is the most important determinant of minute-to-minute secretion of PTH from stored secretory granules in response to hypocalcemia. The secretion of PTH in response to low levels of ionized calcium is a sigmoidal relationship, frequently referred to as the calcium-PTH curve (Figure 8–1). The rapid response, within seconds, of changes in ionized calcium concentration has long been hypothesized to be due to a calcium sensing receptor. This calcium sensing receptor (CaR) has now been sequenced and cloned and is a member of the G-protein receptor superfamily, with a seven
Figure 8–1 **The ionized calcium-PTH curve** as calculated from data obtained from an actual hemodialysis patient. Data is obtained during successive dialysis sessions against a low calcium dialysate (hypocalcemic) curve and high calcium dialysate (hypercalcemic) curve and fitted mathematically using the four-parameter model *(solid line)*. The maximal (max) PTH and minimal (min) PTH are indicated. The four-parameter set point *(solid square)* is the ionized calcium corresponding to a PTH midway between max and min PTH. The 75% to 25% non-normalized slope *(dashed line)* is also shown. (From Ouseph R, Leiser JD, Moe SM: Calcitriol and the parathyroid hormone-ionized calcium curve: A comparison of methodologic approaches. J Am Soc Nephrol 1996; 7:497–505, with permission.)

membrane-spanning domain.[31] Inactivating mutations have been associated with neonatal severe hyperparathyroidism and benign familial hypocalcuric hypercalcemia.[32] These patients have asymptomatic elevations of serum calcium in the presence of nonsuppressed PTH, representing a true shift to the right of this curve. Activating mutations have been found in patients with autosomal dominant hypocalcemia.[33] The CaR has also been localized to the thyroid C-cells and the kidney, predominantly in the thick ascending limb, where it controls renal excretion of calcium in response to changes in serum calcium.[34,35]

PTH secretion is also regulated by vitamin D. $1,25(OH)_2D$ decreases PTH synthesis by binding to the vitamin D response element on the PTH gene. $1,25(OH)_2D$ also regulates the expression of the vitamin D receptor itself and regulates parathyroid cell proliferation.[36] In addition, elevated serum phosphorus also regulates proliferation of parathyroid cells and stimulates PTH secretion.[37] The mechanism of this appears to be mediated via post-translational binding proteins[38,39] and down regulation of the CaR.[40]

Early studies indicated that the calcium-PTH curve was shifted to the right in CKD creating an altered set point, defined as the calcium concentration that results in 50% maximal PTH secretion.[41,42] The extrapolation of this data to clinical practice was that patients with renal failure required supra-physiologic serum levels of calcium to suppress PTH. However, several studies failed to confirm these findings.[43] Others show phosphorus to be a major regulator. In rats fed a high phosphorus diet, the mRNA and protein expression of the CaR is downregulated in PTH glands.[40] In parathyroid glands removed from patients with severe secondary hyperparathyroidism, there was altered sensitivity to calcium (a shift to the right of the curve) when glands were incubated in the presence of phosphorus.[44] An in vivo study in dialysis patients demonstrated that an infusion of phosphorus shifts the calcium-PTH curve to the right.[45] These studies indicate that phosphorus may regulate the CaR. Thus, it is possible that

some of the earlier discrepancy in the literature regarding possible alterations of the set point in renal failure may have been due to differences in serum phosphorus levels in the various studies,[46] although methodologic differences can also explain some of this discrepancy.[43] This interrelationship of calcium, phosphorus, and calcitriol in regulating PTH synthesis is complex and nearly impossible to fully evaluate in humans, because changes in one leads to rapid changes in the other parameters. However, based on available literature, it appears that calcium is more important in stimulating PTH release, whereas calcitriol is more important in inhibiting PTH release. The presence of hyperphosphatemia impairs both of these homeostatic mechanisms.

PTH binds to the PTH receptor, which is a member of the G-protein linked seven membrane spanning receptor family.[47] PTH receptors are ubiquitously located in the body, although most abundantly in the kidney and bone. PTH induced signaling predominately affects mineral metabolism, however, there are many extraskeletal manifestations of PTH excess. These include encephalopathy, anemia, extraskeletal calcification, peripheral neuropathy, cardiac dysfunction, hyperlipidemia, and impotence.[48–51]

There has been a progression of increasingly sensitive assays developed to measure PTH over the past few years. The major difficulty in accurately measuring PTH is the presence of circulating fragments, particularly in the presence of CKD.[29,30] Initial measurements of PTH using C-terminal assays were inaccurate in patients with renal disease due to impaired renal excretion of fragments, and thus retention, and measurement of these inactive fragments. The development of the N-terminal assay brought hope of a more accurate reflection of end-organ effects of PTH, but it also detected inactive metabolites. The development of a two-site antibody test (commonly called INTACT assay) offered hope for improved ability to only detect entire length (active) PTH molecules. In this assay, a capture antibody binds to the N-terminus and a second antibody binds to the C-terminus.[52] This intact assay is more

discriminatory than N- or C-terminal assays in patients with renal failure,[53] however, its ability to discriminate between low and high bone turnover in dialysis patients as compared to bone histology is limited to very low levels (< 100–150 pg/mL) and very high levels (> 500 pg/mL).[54,55] Furthermore, racial differences exist. In one series, the mean intact PTH level was 460 ± 110 pg/mL in African-Americans with bone biopsy proven low turnover bone disease compared to 144 ± 43 pg/mL in Caucasians with the same degree of bone turnover.[56]

Recent data indicates that this intact assay also detects accumulation of C-terminal fragments, commonly referred to as "7–84," although the precise sequence is unknown.[57] In parathyroidectomized rats, the injection of a truly whole 1–84 amino acid PTH was able to induce bone resorption, whereas the 7–84 amino acid fragment was antagonistic.[58,59] Two new assays are now available that truly only detect the 1–84 amino acid full length molecule called whole PTH (CAP) assay (Scantabodies, Inc., San Diego, CA) or bio-active PTH (Nichols Institute, San Juan, CA). In dialysis patients, initial studies demonstrated that the measurement of the intact PTH led to results that were always greater than the whole (1–84 amino acid only) assay, regardless of whether the patients had low or high PTH levels.[58–60] While this new assay offers hope of better reproducibility across laboratories, its role in the diagnosis of underlying bone histology is controversial. An initial study demonstrated that the whole PTH was superior to the former intact assay and that a ratio of the 1–84 amino acid to 7–84 amino acid (active/antagonist) PTH levels less than one was predictive of underlying low turnover bone disease and more accurate than either assay alone.[61] However, two subsequent studies failed to confirm these findings and found no difference in the area under a receiver operating curve (ROC) with the traditional intact and 1–84 assays[62,63] (Figure 8–2). The patient characteristics, especially serum calcium levels, and vitamin D use were different in these three studies. This is important, as a recent study demonstrated that although both 1–84 and non-1–84 fragments are secreted from the PTH gland in response to serum calcium levels, the secretory responses are not proportional.[64] Thus, different serum levels of calcium will result in different ratios of fragments. The clinical use of these PTH assays for the diagnosis of renal osteodystrophy will be discussed later.

Vitamin D

Although vitamin D_3 is metabolically inactive, it is metabolized in the liver to 25(OH)D, and then converted in the kidney via the 1-α-hydroxylase enzyme to 1,25(OH)$_2$D, which has a number of important effects.[65] Its most important function is exerted on the small intestine, where it regulates the intestinal absorption of calcium, and, to a lesser degree, phosphorus.[66] Apart from its effect on calcium and phosphorus levels, 1,25(OH)$_2$D also directly suppresses PTH synthesis, as described above,[67] and may be important for normal bone turnover by enhancing formation of osteoclasts.[68] Elevated serum levels of PTH increases 1-α-hydroxylase activity in the kidney, thereby raising serum 1,25(OH)$_2$D levels. This results in a rise in serum calcium, and then 1,25(OH)$_2$D feeds back on the parathyroid gland, decreasing PTH secretion, thus completing the typical endocrine feedback loop. PTH does not directly inhibit its own synthesis, which is one reason why PTH levels increase in the presence of renal failure where
Figure 8–2 **Value of PTH assays to determine the presence of low turnover bone disease by biopsy.** This graph depicts the area under the receiver operating curves (ROC) for the intact PTH assay *(black bar)*, the 1–84 PTH assay *(light gray bar)*, and the ratio of the intact PTH assay result divided by the circulating C terminal fragments *(white bar)*. The circulating C terminal fragments are calculated as the difference of the intact PTH and the 1–84 PTH results. These ROC curves are from three separate studies with 51,[61] 35,[62] and 33[63] subjects, respectively. The data demonstrate that there are discrepancies in the diagnostic value of these assays among these three studies. (Reprinted with permission from Moe SM: Management of renal osteodystrophy in peritoneal dialysis patients. Perit Dial Int 2004; 24:209-216, with permission.)

1,25(OH)$_2$D is no longer synthesized in sufficient amounts. The 1-α-hydroxylase enzyme in the kidney is also the site of regulation of 1,25(OH)$_2$D synthesis by numerous other factors, including low calcium, low phosphorus, estrogen, prolactin, growth hormone, and 1,25(OH)$_2$D itself.[69] Thus, there is 1,25(OH)$_2$D deficiency in essentially all patients with CKD, with an inability to respond appropriately to normal physiologic stimuli.

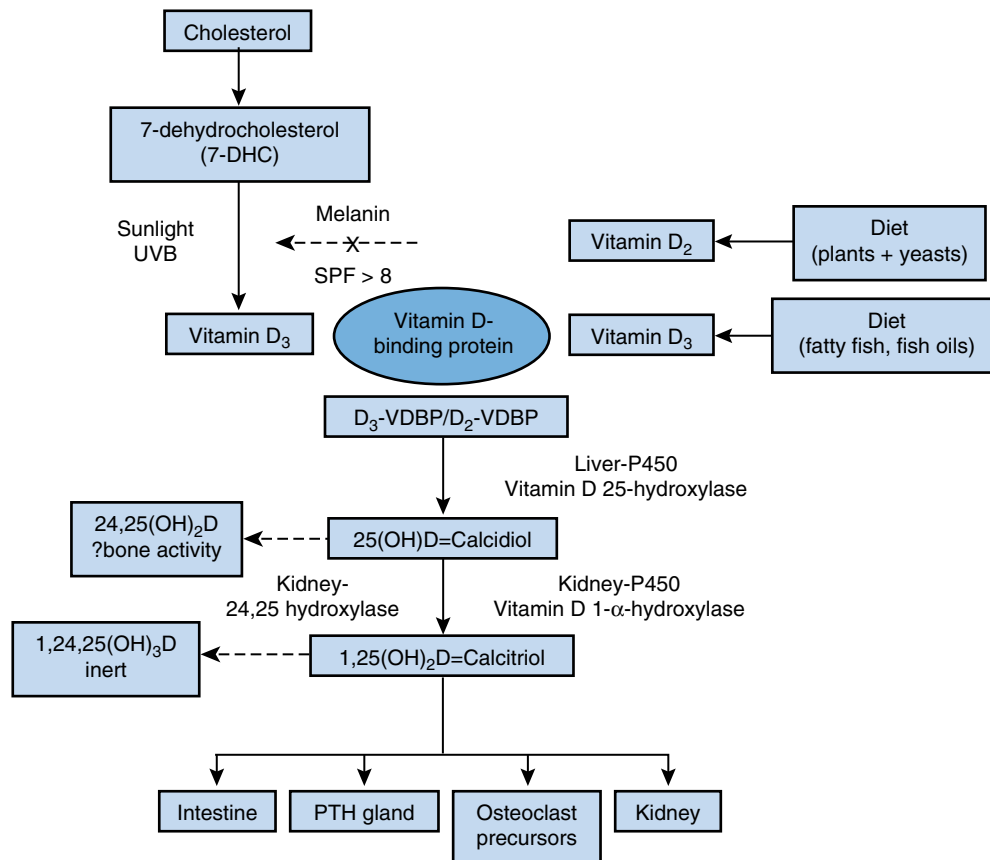
In addition, many dialysis patients are also deficient in the precursor vitamin D_3 due to inadequate dietary intake and lack of sunlight[70] (Figure 8–3). Cholesterol is synthesized to 7-dehydrocholesterol, which in turn is metabolized in the skin to vitamin D_3. This reaction is facilitated by ultraviolet light and, therefore, reduced in individuals with high skin melanin content and inhibited by sunscreen of SPF 8 or greater. In addition, there are dietary sources of vitamin D_2 and vitamin D_3. Once in the blood, vitamins D_2 and D_3 bind with vitamin D binding protein and are carried to the liver where they are hydroxylated to yield 25(OH)D, often called calcidiol. Thus, calcidiol levels in the blood are a direct assessment of nutritional (dietary) intake of vitamin D. Calcidiol is then converted in the kidney to 1,25(OH)$_2$D by the action of 1α-hydroxylase. This active metabolite is also degraded by another kidney enzyme, 24,25-hydroxylase, providing the primary metabolism of the active compound. However, this same 24,25 hydroxylase also hydroxylates 25(OH)D, yielding 24,25(OH)$_2$D, which may have an important effect in bone.[71] However, the predominate effects of vitamin D in the body are exerted through the actions of 1,25(OH)$_2$D (calcitriol).


Figure 8–3 **Overview of vitamin D metabolism.** Vitamin D is obtained from dietary sources and is metabolized via ultraviolet light from 7-DHC in the skin (which is inhibited by sunscreen > SPF 8 and decreased with increased skin melanin content). Both sources of vitamin D_2 and vitamin D_3 bind to vitamin D binding protein (VDBP) and circulate to the liver. In the liver, vitamin D is hydroxylated to 25(OH)D, commonly referred to as calcidiol. Calcidiol is then further metabolized to calcitriol by the 1-α–hydroxylase enzyme at the level of the kidney. The active metabolite 1,25(OH)$_2$D (calcitriol) acts principally on the target organs of the intestine, parathyroid (PTH) gland, bone cell precursors, and the kidney. Calcitriol is metabolized to the inert 1,24,25(OH)$_3$D through the action of the 24,25-hydroxylase enzyme. Calcidiol is similarly hydroxylated to 24,25(OH)$_2$D, which has unknown actions in humans but may be important in bone mineralization.

Hormone 1,25(OH)$_2$D mediates its cellular function via both genomic and nongenomic mechanisms. 1,25(OH)$_2$D circulates in the blood stream with vitamin D binding protein. The free form of 1,25(OH)$_2$D enters the target cell where it interacts with its nuclear vitamin D receptor (VDR). This complex then combines with the retinoic acid X receptor to form a heterodimer, which, in turn, interacts with the vitamin D response element (VDRE) on the target gene. The findings of VDRE on multiple genes and VDR in multiple organ systems point to the widespread systemic effects of vitamin D.[70,72,73] In particular, vitamin D is important in cell differentiation and proliferation, which has led to its therapeutic use in cancer and skin disorders.[70,74] In addition to these nongenomic effects, 1,25(OH)$_2$D facilitates the uptake of calcium by enhancing the production of the calcium transport protein calbindin (9kd in intestine and 28kd in kidney).[75,76] Lastly, 1,25(OH)$_2$D activates voltage dependent calcium channels, with increased intracellular calcium.[77] In order to target

1,25(OH)$_2$D to more specific cellular functions, the structure has been altered to produce several "designer" vitamin D analogues that are in clinical use today. The vitamin D analogues for use in renal failure are designed to maximize the effects on the PTH gland and minimize the effects on the intestine. Some of these vitamin D analogues may be less hypercalcemic and may be useful in patients with renal failure as described later.

Bone Biology

The majority of the total body stores of calcium and phosphorus are located in bone. Trabecular (cancellous) bone is located predominately in the epiphyses of the long bones, which is 15% to 25% calcified and serves a metabolic function with a relatively short turnover rate of 45Ca. In contrast, cortical (compact) bone is in the shafts of long bones and is 80% to 90% calcified. This bone serves primarily as a protective

and mechanical function and has a calcium turnover rate of months. Bone consists principally (90%) of highly organized cross-linked fibers of type I collagen; the remainder consists of proteoglycans, and "non-collagen" proteins such as osteopontin, osteocalcin, osteonectin, and alkaline phosphatase. Hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$) is the major bone salt.

The cellular components of bone are of utmost importance and consist of cartilage cells that are key to bone development, osteoblasts that are the bone forming cells, and osteoclasts that are the bone resorbing cells. Osteoblasts are derived from progenitor mesenchymal cells located in the bone marrow. They are then induced to become osteoprogenitor cells, then endosteol or periosteol progenitor cells, then mature osteoblasts. The control of this differentiation pathway is due to bone morphogenic proteins and the transcription factor Cbfa1 early and other hormones and cytokines later. Once bone formation is complete, osteoblasts may undergo apoptosis, or become quiescent cells trapped within the mineralized bone in the form of osteocytes.[78,79] The osteocytes are interconnected through a series of cannaliculi. Although these cells were previously thought to be of little importance, it is now clear that they serve to transmit the initial signaling involved with mechanical loading.[80]

Osteoclasts are derived from hematopoietic precursor cells that differentiate and are somehow "signaled" to arrive at a certain place in the bone. Once there, they fuse to form the multinucleated cells known as osteoclasts, which become highly polarized, reabsorbing bone through the release of degradative enzymes. They move along a resorption surface via changes in the cytoskeleton. PTH, cytokines, and $1,25(OH)_2D$ are all important in inducing the fusion of the committed osteoclast precursors. Once resorption is complete, estrogens, bisphosphonates, and cytokines can induce, and PTH can inhibit apoptosis.[78,81,82] Numerous hormones and cytokines have been evaluated, mostly in vitro, for their role in controlling osteoclast function.

The control of bone remodeling is highly complex but appears to occur in very distinct phases: (1) osteoclast resorption, (2) reversal, (3) pre-osteoblast migration and differentiation, (4) osteoblast matrix (osteoid or unmineralized bone) formation, (5) mineralization, and (6) quiescent stage. At any one time, less than 15% to 20% of the bone surface is undergoing remodeling, and this process in a single bone remodeling unit can take 3 to 6 months.[83] How a certain piece of bone is chosen to undergo a remodeling cycle and how the osteoclasts and osteoblasts signal each other are not completely clear.

Recently, the discovery of the osteoprotegerin (OPG) and RANK (receptor activator of nuclear-factor κB) system has shed new light on the control of osteoclast function and the long observed coupling of osteoblasts and osteoclasts. RANK is located on osteoclasts, and the RANK ligand (RANK-L) on osteoblasts. Osteoblasts also synthesize the protein OPG, which can bind to RANK-L on osteoblasts and inhibit the subsequent binding of RANK-L to RANK on osteoclasts, thus inhibiting bone resorption. Alternatively, if OPG production is decreased, the RANK-L can bind with RANK on osteoclasts and induce osteoclastic bone resorption. This fascinating control system is regulated by nearly every cytokine and hormone thought important in bone remodeling, including PTH, $1,25(OH)_2D$, estrogen, glucocorticoids, interleukins, prostaglandins, and members of the TGF-β superfamily of cytokines.[84–86] OPG has been successful in preventing bone resorption in animal models of osteoporosis and tumor induced bone resorption.[87,88] Not surprisingly, this system is being tested as a therapeutic agent for osteoporosis, and initial studies appear promising.[89] Interestingly, abnormalities in the OPG/RANK have been found in renal failure,[90] although the effect on bone remodeling is not yet clear.

The clinical assessment of bone remodeling is best done with a bone biopsy of the trabecular bone, usually at the iliac crest. The patient is given a tetracycline derivative approximately 1 month prior to the bone biopsy and a different tetracycline derivative 3 to 5 days prior to the biopsy. Tetracycline binds to hydroxyapatite and emits fluorescence, thereby serving as a label of the bone. A core of predominately trabecular bone is taken and embedded in a plastic material and sectioned. The use of this plastic material is why only some laboratories are equipped to process bone biopsies. Typical pathology labs normally decalcify tissue and paraffin embed, which will destroy the very architecture that is necessary to differentiate metabolic bone disorders. The sections can then be visualized with special stains and under fluorescent microscopy to determine the amount of bone between the two tetracycline labels, or that formed in the time interval between the two labels. This dynamic parameter assessed on bone biopsy is the basis for assessing bone turnover, which is key in discerning types of renal osteodystrophy. In addition to dynamic indices, bone biopsies can be analyzed by histomorphometry for many static parameters as well. The nomenclature for these assessments has been standardized.[91]

Clinically, bone biopsies are most useful for differentiating types of renal osteodystrophy, as well as other undiagnosed metabolic disorders. However, with the advent of several new markers of bone turnover, the use of bone biopsy has recently been reserved primarily for the diagnosis of renal osteodystrophy and for research purposes.[92,93] For renal osteodystrophy the most important parameters are osteoid (unmineralized bone) area as a percent of total bone area, and fibrosis. These two static parameters, together with the dynamic bone turnover assessed by bone formation rate or activation frequency can distinguish the various forms of renal osteodystrophy (Table 8–1).

THE SPECTRUM OF ABNORMAL BONE TURNOVER IN CKD

Bone turnover is tightly regulated by numerous hormones and cytokines, of which PTH is of key importance. In situations where PTH is elevated, bone turns over with excessive rapidity, replacing lamellar bone with structurally inferior woven bone. In addition, both osteoblastic bone formation and osteoclastic bone resorption are accelerated, and fibrosis eventually develops, a pathology referred to as osteitis fibrosa cystica. In contrast, low-turnover bone disease is usually observed in the presence of normal to low levels of PTH. In osteomalacia, aluminum is deposited at the mineralization front, blocking mineralization. This leads to an accumulation of osteoid, or unmineralized bone, and is the hallmark of osteomalacia. In adynamic, or aplastic, bone disease is characterized by normal amounts of osteoid, an absence of tissue fibrosis, decreased numbers of osteoblasts and osteoclasts, and low rates of bone formation.[92]

Table 8–1 Histologic Classification of Renal Osteodystrophy

Lesion	Area of Fibrosis (% of tissue area)	Area of Osteoid (% of total bone area)	Bone Formation Rate ($\mu m^2/mm^2$ tissue area/day)
Mild	<0.5	<15	>108
Osteitis fibrosa	>0.5	<15	X
Mixed	>0.5	>15	X
Osteomalacia	<0.5	>15	X
Adynamic	<0.5	<15	<108
Normal range	0	1–7	108–500

X is not a diagnostic criterion. (Adapted from Sherrard DJ, Hercz G, Pei Y, et al: The spectrum of bone disease in end-stage renal failure: An evolving disorder. Kidney Int 1993; 43:436–442.)

The prevalence of different forms of renal osteodystrophy has changed over the past decade. Whereas osteitis fibrosa cystica had previously been the predominant lesion, the prevalence of mixed uremic osteodystrophy and adynamic bone disease has recently increased. However, the overall percentage of patients with high bone formation compared to low bone formation has not changed dramatically over the last 20 to 30 years, but osteomalacia has been essentially replaced with adynamic bone disease[92,94–98] (Figure 8–4). In patients not yet on dialysis, the series of bone biopsies yield widely different results, depending on the level of GFR and the country in which the study was done[99–105] (Figure 8–5). However, it is clear from these data that histologic abnormalities of bone begin very early in the course of chronic kidney disease.

Diagnosis of Abnormal Bone Turnover

Studies evaluating the ability of the serum concentration of intact PTH to predict both low and high turnover bone disease have been disappointing. In general, the risk of high-turnover bone disease increases with the concentration of intact PTH.[54,55] However, the ability to reliably predict the presence of high-turnover bone disease is poor until intact PTH levels of 450 to 500 pg/mL are reached. Levels of intact PTH under 100 pg/mL are fairly reliable for the prediction of low-turnover bone disease,[54] but again, not perfect. Based primarily on these studies, the K/DOQI guidelines recommend a target intact PTH level of 150 to 300 pg/mL.[106] Unfortunately, these studies that correlate intact PTH with bone histology were done prior to the widespread use of vitamin D derivatives and may not be applicable in the current treatment environment. Thus, in general, levels of intact PTH below 100 to 150 pg/mL are indicative of low turnover bone, whereas levels of intact PTH greater than 450 to 500 pg/mL are indicative of high turnover bone on biopsy. Levels in between those two cutoff levels are not predictive of underlying bone histology, creating a clinical challenge for nephrologists. As described previously, the new whole or bioactive 1–84 amino acid PTH assay may offer improved diagnostic capabilities, but this remains to be proven.

Obviously, it is not practical to have all patients undergo a bone biopsy. Thus, we must use clinical judgment, PTH hormone levels, and various other bone markers. Initially, there was great hope for the new bone markers such as osteocalcin and bone specific alkaline phosphatase to be predictive of underlying bone histology. Unfortunately, these specialized tests offer little additive value to our usual measurement of calcium, phosphorus, PTH, and total alkaline phosphatase.[107] This is also true for patients not yet on dialysis, where a recent study in 84 subjects determined that measurement of intact PTH, bone alkaline phosphatase, total alkaline phosphatase, or osteocalcin had sensitivities of 72% to 83%, but specificity of 53% to 67% to discriminate adynamic bone from other types of renal osteodystrophy.[108] A new assay that measures circulating tartrate-resistant acid phosphatase 5b (TRACP) as
Figure 8–4 The spectrum of histologic types of renal osteodystrophy in patients with chronic kidney stage V. This graph represents the distribution of various pathologic forms of renal osteodystrophy in studies over the past 30 years. There is considerable variability on the number of patients with each histologic subtype in the studies, likely dependent on the geographic location and the criteria of inclusion into the research study. Data are from bone biopsy series done on patients undergoing dialysis in the United States,[94,95] Canada,[92] Thailand,[96] Israel[97] and Europe,[98] with the number of subjects in each study listed. *HPT*, hyperparathyroidism; *Mixed*, mixed uremic osteodystrophy; *Adynamic*, adynamic bone disease; *OM*, osteomalacia.
Figure 8–5 The spectrum of histologic types of renal osteodystrophy in patients with chronic kidney disease stages III and IV. This graph represents the distribution of various pathologic forms of renal osteodystrophy in studies over the past 30 years. There is considerable variability on the number of patients with each histologic subtype in the studies, likely dependent on the geographic location and the magnitude and cause of chronic kidney disease of the subjects. Data are from bone biopsy series done on patients with chronic kidney disease in the United Kingdom in 1973,[99] 1982,[100] Norway,[101] Spain in 1994[102] and 1995,[103] Italy in 1996,[104] and Macedonia in 2003,[105] with the number of subjects in each study listed. *HPT*, hyperparathyroidism; *Mixed*, mixed uremic osteodystrophy; *Adynamic*, adynamic bone disease; *OM*, osteomalacia; *NL*, normal.

a marker of osteoclast activity may be promising,[109] but more evaluation is necessary. Thus, in the absence of a perfect marker, we must look at multiple variables (Table 8–2).

In contrast to the hypophosphatemia and hypercalcemia observed in primary hyperparathyroidism, patients with secondary hyperparathyroidism tend to be hyperphosphatemic (which leads to increased PTH). The serum level of calcium is variable and depends on the overall calcium balance, type of phosphate binder, vitamin D therapy, and calcium dialysate concentration. However, in advanced cases of secondary hyperparathyroidism, patients are both hypercalcemic and

hyperphosphatemic, in part because of the efflux from bone. It is also important to look at the trend of PTH values with time. Clearly, if the PTH concentration is above 300 pg/mL by intact assay *and* consistently rising, then the patient almost certainly has high-turnover bone. In contrast, patients with low-turnover bone are often hypercalcemic, in part because of the inability of low-turnover bone to buffer an acute calcium load.[110] Bone biopsy is the only way to definitively differentiate if low-turnover bone is due to adynamic bone or aluminum induced osteomalacia, although most patients with adynamic bone disease are asymptomatic in contrast to

Table 8–2   Features of High-Turnover and Low-Turnover Renal Osteodystrophy

	High Turnover	Low Turnover
PTH	Increased	Decreased
Alkaline phosphatase	Increased	Normal
Bone alkaline phosphatase	Increased	Normal or decreased
Osteocalcin	Increased	Normal
Calcium	Variable	Can be increased
Phosphorus	Increased	Normal or increased
DFO stimulation test	Normal	Normal (adynamic)
		Elevated delta (aluminum OM)
Skeletal radiographs	Resorption, sclerosis	Normal
Symptoms	Usually asymptomatic, unless very severe disease	Asymptomatic (adynamic) Symptomatic (aluminum OM)

DFO, deferoxamine; *OM*, osteomalacia (From Moe SM. Calcium, phosphorus, and vitamin D metabolism in renal disease and chronic renal failure. *In* Kopple JD, Massry SG [eds]: Nutritional Management of Renal Disease. Philadelphia, Lippincott Williams & Wilkins, 2004, pp 261–285.)

patients with aluminum induced osteomalacia. In addition, deferoxamine stimulation tests and random serum aluminum levels can occasionally be helpful, as discussed later.[111, 112]

HIGH-TURNOVER BONE DISEASE

Pathogenesis of Secondary Hyperparathyroidism

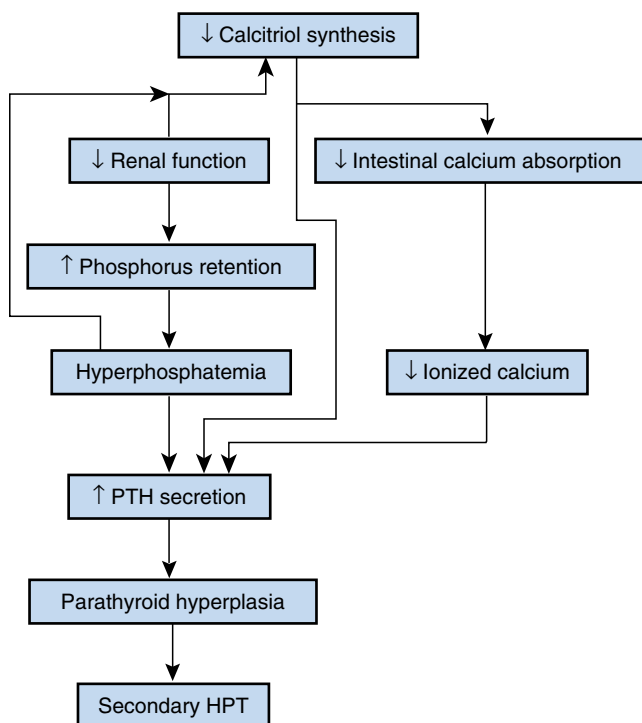
As detailed previously, the kidney plays an integral role in the maintenance of normal calcium and phosphorus homeostasis and bone health. As a result, severe abnormalities can occur in the presence of CKD (Figure 8–6). As CKD disease advances, the reduced mass of functioning renal tissue is unable to excrete the normal dietary intake of phosphorus. Early on, the serum level of phosphorus is maintained via stimulation of parathyroid hormone release, leading to the development of secondary hyperparathyroidism, the "trade-off" hypothesis.[113] Phosphorus retention further limits calcitriol production by inhibiting the activity of 1-α-hydroxylase, which converts 25(OH)-vitamin D into active 1,25(OH)$_2$D (calcitriol). The decreased 1,25(OH)$_2$D directly increases PTH release further and leads to decreased calcium and phosphorus absorption


Figure 8–6 The pathogenesis of secondary hyperparathyroidism in chronic kidney disease. Excess parathyroid hormone secretion occurs in response to hypocalcemia, hyperphosphatemia, and decreased conversion of vitamin D to the active form, calcitriol. (Reprinted from Moe SM, Drueke TB: Management of secondary hyperparathyroidism: The importance and the challenge of controlling parathyroid hormone levels without elevating calcium, phosphorus, and calcium-phosphorus product. Am J Nephrol 2003; 23:369–379, with permission.)

from the gastrointestinal tract. The impaired intestinal calcium absorption leads to relative decreases in serum ionized calcium, further augmenting secondary hyperparathyroidism. Over time, the parathyroid glands become less sensitive to the feedback suppression of calcium and calcitriol, causing continual secretion of PTH and secondary hyperparathyroidism.[114] Continual stimulation of PTH secretion has been shown to induce irreversible hyperplasia of the parathyroid glands in uremic rats[115] through a number of abnormalities of gene and growth factor expression.[36] The continued elevated levels of PTH lead to increased bone remodeling or high-turnover bone.

As indicated in Figure 8–6, hyperphosphatemia has been shown to be one of the most important factors in the pathogenesis of secondary hyperparathyroidism. Although early studies suggested hyperphosphatemia induced decline in serum calcitriol (leading to low serum calcium), was the initial stimulus for enhanced PTH secretion,[116] more recent evidence suggests that elevated serum phosphorus levels promote PTH secretion directly, independent of changes in serum calcium or calcitriol. Phosphorus restriction in dogs with renal failure[117] and in patients with chronic renal failure[118] have been shown to decrease PTH secretion directly, independently of changes in serum calcium or calcitriol. In uremic rats, phosphorus directly stimulates parathyroid gland hyperplasia.[115] Moreover, high phosphorus levels have been shown to directly stimulate PTH secretion in intact rat parathyroid glands in vitro.[117,119] In addition, in the presence of increased phosphorus load, the PTH-calcium curve is probably shifted to the right, creating resistance at the level of the PTH gland.[46] Thus, there is now substantial evidence to support that phosphorus, calcium, and 1,25(OH)$_2$D all act directly, and independently, to regulate PTH secretion. Therefore, all three factors are targeted for the prevention and treatment of secondary hyperparathyroidism.

GENERAL TREATMENT STRATEGIES FOR SECONDARY HYPERPARATHYROIDISM

The National Kidney Foundation has recently published clinical practice guidelines (Kidney Disease Outcomes Quality Initiative (K/DOQI)[106] on the management of renal osteodystrophy in all stages of chronic kidney disease. A summarized version of these guidelines are in Tables 8–3 and 8–4 and will be subsequently discussed.

Chronic Kidney Disease (CKD) Stage III (GFR 30–60 mL/min) and Stage IV (GFR 15–30 mL/min)

The treatment of secondary hyperparathyroidism should begin early in the course of CKD. Serum phosphorus levels are normally maintained within a narrow range, typically 2.5 to 4.5 mg/dL (0.8–1.5 mmol/L). Approximately 1000 to 1800 mg of phosphorus is ingested daily in the average Western diet.[120,121] Of this amount, about 30% is excreted through the gastrointestinal tract, and 70% is excreted by the kidneys.[113] The dietary sources of phosphorus include all meats, dairy products, and many cereals and grains, thus making dietary restriction nearly impossible. The amount of phosphorus excreted by the kidneys is determined by the balance between

Table 8–3 Summary of K/DOQI Guidelines for Chronic Kidney Disease Stages III and IV

- Normalize serum phosphorus by diet and phosphorus binder therapy, 2.7–4.6 mg/dL; begin when *either* elevated serum phosphorus *or* elevated serum PTH.
- Treat nutritional vitamin D deficiency if serum 25-hydroxyvitamin D is <30 ng/mL.
- Treat elevated PTH with calcitriol or other "less hypercalcemic" vitamin D analogues to target of 35–70 (CKD III) or 70–110 (CKD IV) pg/mL by intact assay.
- Normalize serum calcium.

(From K/DOQI NKF: Clinical practice guidelines for bone metabolism and disease in chronic kidney disease. Am J Kidney Dis 2003; 42:S1–S201.)

Table 8–4 Summary of K/DOQI Guidelines for Chronic Kidney Disease Stage V

- Normalize serum phosphorus by diet and phosphorus binder therapy, 3.5–5.5 mg/dL; limit elemental calcium intake from binders to 1500 mg/day.
- Treat elevated PTH with calcitriol or other "less hypercalcemic" vitamin D analogues to target of 150–300 pg/mL by intact assay.
- Normalize serum calcium, ideally < 9.5 mg/dL, and always < 10.2 mg/dL; Ca X P < 55 mg^2/dL^2.

(From K/DOQI NKF: Clinical practice guidelines for bone metabolism and disease in chronic kidney disease. Am J Kidney Dis 2003; 42:S1–S201.)

ultrafiltration and reabsorption. As renal function declines, serum phosphorus levels are maintained through a compensatory decrease in the rate of renal tubular reabsorption of phosphorus, mediated in part by elevation in the serum PTH.[113] This adaptation allows for maintenance of normal serum phosphorus levels until the glomerular filtration rate (GFR) falls below 20 to 25 mL/min, at which point elevation in the serum PTH level cannot further increase phosphorus excretion, and hyperphosphatemia develops.[113,122,123] Thus, normal serum phosphorus levels are maintained well into advanced stages of renal failure but at the cost of worsening secondary hyperparathyroidism.

Based on animal data, the key to the successful treatment of secondary hyperparathyroidism is to prevent the development of hyperplasia, because once that stage is reached, regression is unlikely.[124] Thus, more aggressive and frequent monitoring of serum PTH is recommended by the K/DOQI guidelines, including assessment every 12 months in CKD stage III, and every 3 months in CKD stage IV.[106] Treatment should probably begin at levels of intact PTH of 70 to 110 pg/mL in order to prevent hyperparathyroidism.[106]

Thus, the mainstay of therapy at this level of GFR should be to control hyperparathyroidism by (1) dietary phosphate restriction and phosphate binders and (2) increase calcitriol by either giving calcidiol or active vitamin D sterols, such as calcitriol. In CKD stages III and IV, the K/DOQI guidelines recommend measuring 25(OH)D (calcidiol) levels if the PTH is elevated. If low, this vitamin D of nutritional origin can be replaced with ergocalciferol. This substrate should then be converted by the remaining renal mass to active calcitriol that will suppress PTH. Data in non-CKD patients who are calcidiol-deficient demonstrates that hyperparathyroidism can be corrected by repleting these levels with oral ergocalciferol.[125] However, this remains to be proven in CKD patients, and it is not clear just how much renal mass is required for conversion of 25(OH)D to 1,25(OH)$_2$D. Nonetheless, studies have demonstrated that CKD patients commonly have low levels of 25(OH)D,[126,127] and in the general population deficiency is associated with hip fractures, low bone mineral density, immunologic defects, and possibly cancer.[70] If calcidiol levels are normal and PTH increased, treatment with active vitamin D sterols should be initiated. Although an early study demonstrated worsening renal failure with active vitamin D therapy,[128] other studies have failed to demonstrate this.[129,130] If vitamin D analogues are begun, close monitoring of serum calcium, phosphorus, and creatinine are indicated. However, there are no long-term studies of patients treated with this regimen.

Chronic Kidney Disease Stage V (GFR < 15 mL/min, or on dialysis)

For patients on dialysis, the treatment strategies for secondary hyperparathyroidism are threefold: (1) phosphate restriction and use of phosphate binders, (2) normalizing, but not elevating, serum calcium, and (3) use of vitamin D analogues. The current strategy is to monitor serum PTH levels quarterly, although more frequent monitoring is indicated, and reimbursed, in cases of more severe hyperparathyroidism or when therapy is adjusted. As detailed above, the target PTH is 150 to 300 pg/mL by the intact assay, which is roughly equivalent to 75 to 150 by the whole or bioactive "1–84" assays.

Control of Phosphorus

Successful clinical management of phosphorus consists of several core components: a low phosphorus diet, adequate dialysis, and safe and effective phosphate-binding therapy. The efficacy of each of these components depends on patient compliance, the key for improving phosphorus control.

Phosphorus is contained in almost all foods. Unfortunately, foods high in phosphorus are generally also high in protein.

National Kidney Foundation Dialysis Outcomes Quality Initiative (NKF/DOQI) dietary guidelines for patients on maintenance hemodialysis include a daily intake of 1.2 g of protein per kg body weight.[131] Protein requirements are even higher in patients receiving CAPD than in hemodialysis patients.[66,132] As a result, it is challenging to balance dietary phosphate restriction against the need for adequate protein intake, especially with malnutrition present in up to 50% of dialysis patients.[133] Indeed, most well nourished dialysis patients are in positive phosphorus balance. Roughly 60% to 70% of consumed phosphate is absorbed, so about 4000 to 5000 mg of phosphorus per week enters the extracellular fluid. Therefore, dietary phosphorus restriction alone, although an important component of effective phosphorus management, is not sufficient to control serum phosphorus levels in most dialysis patients.

With the limitations of dietary phosphorus restriction, dialysis plays an important role in removing excess phosphorus from the patient's blood, eliminating about 2700 to 3000 mg phosphorus per week.[134] However, a significant amount of the total body phosphorus is found in the intracellular compartment. Thus, the amount of phosphorus that can be removed during a single dialysis session is limited. Kinetic studies indicate that phosphorus is cleared more efficiently in the first half of a hemodialysis treatment, when serum levels are highest.[135] This correlation partly accounts for the rapid fall in serum phosphorus during the first 1 to 2 hours of treatment, followed by a plateau during which serum phosphorus levels remain between 1.9 and 3.4 mg/dL. The rate of phosphorus removal significantly decreases in the second half of treatment and is generally followed by a rebound in serum phosphorus levels in the first 3 to 4 hours following dialysis treatment.[136,137] Nocturnal hemodialysis and other slow continuous methods offer a hope for the future, as patients using these methods have normal or low phosphorus levels.[138]

Phosphate Binders

Because of the limitations associated with dietary phosphorus restriction and the phosphorus removal with dialysis, dietary phosphate binders are required in nearly all dialysis patients. Unfortunately, no binder is perfect and the best binder is one the patient will take consistently. Thus, a trial of multiple binder regimens is often required. The dose of phosphate binder should be titrated to dietary intake of phosphorus for both the initial starting dose and subsequent dose adjustments.

Aluminum hydroxide is extremely efficient as a phosphate binder and, consequently, was the primary phosphate binder used from the time of its introduction in 1941 until the mid-1980s. Subsequently, it has been recognized that aluminum is absorbed from the gastrointestinal tract and accumulation of even small amounts of aluminum in the body can cause toxic side effects, such as aluminum bone disease (osteomalacia), dementia, myopathy, and anemia.[66,139,140] It is now recognized that all dialysis patients receiving aluminum-containing binders are at risk for development of aluminum bone disease and other symptoms of aluminum intoxication, although diabetic patients[141] and children[142] are at particularly high risk. Thus, aluminum-containing binders should be administered only when all other resources to control phosphorus have been exhausted, and only for intervals of up to 4 weeks.[106]

Of the available calcium-containing binders, both calcium carbonate and calcium acetate have proven efficacy compared to placebo.[143,144] In addition, calcium containing phosphate binders have been shown to effectively lower phosphorus levels and to help prevent the development of secondary hyperparathyroidism.[66] Sensitive balance studies have demonstrated less calcium absorption from calcium acetate compared to calcium carbonate on a gram per gram basis.[145,146] However, studies have not consistently demonstrated that calcium acetate can lead to less hypercalcemic episodes.[147] Over the last 10 years, these two calcium containing phosphate binders have become the mainstay of therapy, with choice depending primarily on patient preference. Other calcium supplements that have been used as phosphate binders include calcium ketoamino acids,[148] calcium ketovaline,[149] and calcium citrate. However, calcium citrate should be avoided as citrate can increase intestinal absorption of aluminum.[150] The main side effects of calcium containing phosphate binders are constipation, inability to swallow the tablets due to their size, altered taste, and increased calcium load leading to positive calcium balance.

Serum calcium levels are normally tightly controlled within a narrow range, usually 8.5 to 10.5 mg/dL (2.1 to 2.6 mmol/L). However, the serum calcium level is a poor reflection of overall total body calcium, because serum levels are only 0.1% to 0.2% of extracellular calcium, which in turn is only 1% of total body calcium. The remainder is stored in bone. However, ionized calcium, generally 40% of total serum calcium levels is physiologically active and is maintained in the normal range by inducing increases in the secretion of parathyroid hormone (PTH). PTH acts to increase bone resorption, increase renal calcium reabsorption, and to increase the conversion of $25(OH)D$ to $1,25(OH)_2D$ in the kidney. The latter increases gastrointestinal calcium absorption. In individuals with normal homeostatic mechanisms, these interactions of PTH and vitamin D metabolites at target organs, including the kidney, maintain the serum ionized calcium level within the normal range to ensure proper cellular function and to ensure normal bone growth. In normal individuals, the net calcium balance (intake–output) varies with age. Children and young adults are usually in a slightly positive net calcium balance to enhance linear growth; beyond ages 25 to 35, when bones stop growing, the calcium balance tends to be neutral.[151] Normal individuals have protection against calcium overload by virtue of their ability to reduce intestinal absorption of calcium and to increase renal excretion of calcium in response to excessive calcium intake by actions of PTH and calcitriol. However, in CKD the ability to maintain normal homeostasis, including a normal serum ionized calcium level and appropriate calcium balance for age, is lost.

The K/DOQI guidelines recommend a limit on the daily ingestion of calcium in the form of calcium containing phosphate binders to be 1500 mg elemental calcium per day. This is assuming a 500 mg intake per day from diet, yielding 2000 mg per day.[106] This level is slightly below the Institute of Medicine's recommended maximum intake of calcium of 2500 mg per day for healthy adults.[152] In patients with CKD stage V, the primary intake of calcium is from calcium containing phosphate binders. Early metabolic studies demonstrated that approximately 18% to 20% of calcium is absorbed from the intestine.[153,154] Figure 8–7 shows net calcium intake per day for hemodialysis and peritoneal dialysis

NET CALCIUM INTAKE (MG/DAY)
Figure 8–7 Calcium balance in hemodialysis and peritoneal dialysis in the presence and absence of calcium containing phosphate binders. Estimated net calcium intake per day in a prototype dialysis patient comes from three sources: dialysate (2.5 meq/L calcium concentration; *dark gray bars*), diet of 500 mg elemental calcium per day (*black bars*), and phosphate binder (*light gray bars*). The left two bars are from a patient undergoing hemodialysis on calcium containing phosphate binder containing 1500 mg elemental calcium (*first bar*) and on a noncalcium containing binder (*second bar*). The third and fourth bars are similar data in a prototype patient undergoing continuous ambulatory peritoneal dialysis of four exchanges per day. These data assume an absorption of 20% of ingested calcium from diet[132,154] and binder,[145] which would be 100 mg from a 500 mg calcium diet, and 300 mg from an intake of phosphate binders containing 1500 mg of elemental calcium. As depicted graphically, the main contribution to daily calcium intake is from calcium containing phosphate binders, whereas a relatively small amount of calcium is taken in from hemodialysis,[134] and a small efflux is observed in peritoneal dialysis, depending on the ultrafiltration.[155] These data represent calcium intake, and the calcium excretion will primarily be in the form of stool, sweat, and residual renal function and will vary from 150 to 300 mg/day.[154]

patients. If patients are taking 2000 mg per day in total calcium intake (1500 mg from binder and 500 mg from diet), and 20% is absorbed, then the net intake is 400 mg/day. On hemodialysis days, this figure is slightly greater because approximately 50 mg of calcium is infused with a 4-hour dialysis treatment, using 2.5 meq/L dialysate calcium concentration.[134] In peritoneal dialysis patients there is a slight efflux of calcium, using a 2.5 meq/L dialysate in four daily exchanges.[155] The excretion of calcium in stool and sweat ranges from 150 to 250 mg/day,[152] and if patients have residual urine output, the excretion rate may increase slightly. Thus, the patients will still be in positive calcium balance at this K/DOQI maximum when taking 1500 mg of calcium containing phosphate binders. In an anuric patient, this positive calcium load has only two "compartments" to go to: bone and extraskeletal locations. If the bone is normally remodeling the calcium should be deposited there, however,

normal bone is not common in dialysis patients. If no calcium containing phosphate binder is taken, the patients will be in neutral, to slightly negative balance depending on stool and sweat output. It is important to emphasize three points: First, this 1500 mg maximum intake of elemental calcium from phosphate binders in the K/DOQI guidelines is based on opinion, because there are no recent formal metabolic balance studies. Second, in patients taking vitamin D, the intestinal absorption of calcium will be increased, and thus the amount of calcium in the form of binder should be decreased. Third, in patients with low-turnover bone disease, the bone cannot take up calcium,[110] and that is the rationale for the K/DQOI recommendation that calcium containing phosphate binders not be used in patients with intact PTH levels of less than 150 pg/mL.[106]

The noncalcemic, nonaluminum/metal phosphate binder, sevelamer, received FDA approval in 1998 in the United States. This binder is effective in controlling serum phosphorus[156,157] and leads to equivalent phosphate control but less hypercalcemia than does calcium acetate.[158,159] In addition, this phosphate binder can be used together with calcium containing phosphate binders and may allow the use of more vitamin D.[160] This phosphate binder is also unique in that it lowers total cholesterol levels, principally by lowering LDL levels.[158,160,161] Recently, this phosphate binder was compared to calcium containing phosphate binders (both calcium acetate and calcium carbonate) in a randomized, controlled year-long study. Subjects treated with both binders showed excellent and similar serum phosphorus and calcium × phosphorus products. However, sevelamer led to less hypercalcemia and less over-suppression of PTH. In addition, calcium containing phosphate binders (both calcium acetate and calcium carbonate), but not sevelamer, lead to progressive coronary artery and aorta calcification by electron beam CT.[159,162] Of note, the average elemental calcium content of subjects taking calcium acetate was 1.1 g/day, below the K/DOQI maximum, and yet calcification progressed. The reason for the attenuation of vascular calcification in subjects receiving sevelamer is not clear but may be reduced calcium load, fewer episodes of hypercalcemia, lower LDL cholesterol, or less over-suppression of PTH. The main side effects of sevelamer are gastrointestinal distress, such as bloating, flatulence, and occasional diarrhea. Unfortunately, sevelamer is much more expensive than the other phosphate binders and generally not affordable for patients in the United States without prescription drug coverage.

Lanthanum carbonate, a heavy metal, has been effective in animal studies[163] and in dialysis patients in a preliminary report[164] and a large clinical trial.[165] It is pending FDA approval. Much concern has been raised for the potential toxicity of lanthanum because a very small amount is absorbed from the gastrointestinal tract. However, 80% of lanthanum excretion is via biliary tract, and 20% is via urinary excretion, in contrast to 100% urinary excretion of another metal, aluminum. Thus, the intestinal absorption of lanthanum is less than that of aluminum, and the predominant route of excretion is biliary not urinary.[98,165] A study evaluating bone biopsies in dialysis patients at baseline and 1 year after lanthanum use did not demonstrate the development of osteomalacia in any patient, and, of interest, a considerable number of patients taking calcium containing phosphate binder developed

adynamic bone disease.[98] The eventual approval of lanthanum will offer another noncalcemic binder to the list of options for our patients. The drug is also chewable and, thus, may be helpful in individuals who have difficulty swallowing pills.[165]

Other phosphate binders that are available include magnesium carbonate, usually in combination with calcium acetate. Magnesium carbonate is an effective phosphate binder. However, the dialysate magnesium concentration should be lowered in patients taking oral magnesium,[166] which is not practical given that most dialysis units utilize central delivery systems of standardized dialysis baths. Furthermore, no long-term studies have been done. This is of particular concern given that serum magnesium levels are a poor reflection of total body magnesium. Most recent on the horizon are ferric compounds,[167–169] which appear effective in limited studies. Finally, a mixed magnesium and iron compound also has preliminary efficacy *in vitro*.[170]

The breadth of choices of phosphate binders and the number of agents in development indicate that these medications continue to be the Achilles heel of dialysis patients with large numbers of pills required to control serum phosphorus and gastrointestinal side effects, leading to patient noncompliance. However, the physician and dietitian should be aggressive in finding a regimen agreeable to the patient. Frequent snacking without phosphate binders, and taking calcium based binders with oral iron supplements, which limit effectiveness, can also lead to hyperphosphatemia and can be easily adjusted. Last, some of the serum phosphorus derives from bone, such that patients with high bone turnover due to severe hyperparathyroidism may have hyperphosphatemia despite compliance with phosphate binders.

Therapy with Vitamin D Analogues

Berl and associates[171] first demonstrated that orally administered $1,25(OH)_2D$, but not vitamin D_3, suppressed PTH in patients with renal failure, confirming that hydroxylation of the sterol at the level of the kidney is required for its actions on PTH. The intravenous formulation was introduced in 1984 by Slatopolsky and associates,[41] who found excellent suppression of PTH in patients given high dose (4 mcg) intravenous calcitriol thrice weekly on hemodialysis. Andress[172] subsequently demonstrated improvement in bone histology with intravenous therapy. Unfortunately, this therapy, although quite effective, led to uniform elevations in serum calcium. We subsequently demonstrated that in patients with mild to moderate hyperparathyroidism, low doses (0.5 to 1 mcg) given intravenously thrice weekly was effective in suppressing PTH with time and led to only minimal rise in serum calcium levels.[173]

Based on these and many other studies, intravenous pulse calcitriol was felt to be the optimal therapy to allow greater bioavailability to the parathyroid gland and bypass some of the intestinal absorption of calcium and phosphorus. However, in Japan, where intravenous medications are not paid for as they are in the United States, oral pulse calcitriol proved equally efficacious to intravenous calcitriol.[174] Subsequent studies have also demonstrated that oral and intravenous calcitriol are equally efficacious with a similar incidence of hypercalcemia and hyperphosphatemia, at least in patients with mild to moderate secondary hyperparathyroidism.[175,176] This was followed

by our study in peritoneal dialysis patients[177] and that of Hermann[178] in hemodialysis patients, demonstrating that daily and pulse therapy of calcitriol, when given in equivalent weekly doses, were also equally efficacious in suppressing PTH. Thus, these studies demonstrate that calcitriol is effective for the treatment of secondary hyperparathyroidism regardless of its route and frequency of administration. However, most of these studies treated only mild to moderate hyperparathyroidism. The vitamin D receptor (VDR) is down-regulated in the PTH glands in advanced hyperparathyroid disease, based on examination of tissue removed during parathyroidectomy.[179] In these patients, very high doses may indeed be required. In addition, none of these regimens completely remove the problematic side effect of increased intestinal calcium and phosphorus absorption, leading to the aggressive development of analogues with increased potency at the PTH gland compared to the intestine.

Two "less calcemic" analogues are commercially available in the United States: $19\text{-nor-}1,25(OH)_2D_2$ (paricalcitol) and $1\text{-}\alpha(OH)D_2$ (doxercalciferol) and others are available outside the United States.[180] All of these analogues appear effective in suppressing hyperparathyroidism in patients on dialysis.[129,181–186] Paricalcitol appears superior to calcitriol in terms of its hypercalcemic and hyperphosphatemic effects in comparison studies in rats[187] and possibly humans.[188] A recent secondary analysis of a trial comparing paricalcitol and calcitriol has recently been published. This study found that although there was no difference between these vitamin D preparations in the number of subjects who had a single episode of hypercalcemia, paricalcitol led to less sustained hypercalcemia.[189] There are no direct comparative trials of doxercalciferol to calcitriol. The lack of comparative trials makes blanket endorsement of preferential use of any of these analogues over calcitriol premature, and the K/DQOI guidelines found no evidence for superiority but did recommend that a trial of less calcemic analogues be utilized in patients prone to hypercalcemia because of the large base of anecdotal experience. Unfortunately, demonstrating this in a randomized, comparative trial is difficult, given that the concomitant use of different phosphate binders may alter serum calcium and phosphorus levels independent of the effects of the vitamin D analogues. Doxercalciferol is also available orally, and a direct comparison study of the oral and intravenous formulations indicate that the oral agent may lead to more hypercalcemia than the intravenous formulation.[129]

Interestingly, a recent study evaluating a large provider database found that patients treated exclusively with paricalcitol had a 16% reduction in mortality compared to patients treated exclusively with calcitriol.[190] This effect prevailed across many independent analyses of potential confounders, and there was no difference in serum calcium, phosphorus, and PTH in the two groups. However, it should be emphasized that these results need prospective confirmation. The two groups were slightly different at baseline, no phosphate binder data were available, and the rationale of the prescribing physician in choosing one vitamin D form over another cannot be assessed in such a retrospective review.[191] This also raises the possibility that nonskeletal effects of vitamin D on immune function and cell proliferation may be important and differ among analogues. It also raises the question: Do all dialysis patients need some vitamin D? Unfortunately, in the

absence of functioning kidneys, the adverse effects of hyper-calcemia may outweigh any improvement in immune function.[192]

Despite aggressive use of calcitriol and other vitamin D analogues, a significant number of patients remain refractory to therapy, either because of hyperphosphatemia and/or hypercalcemia leading to an elevated calcium × phosphorus product, or advanced hyperplasia of the parathyroid glands, rendering the secretion of PTH unsuppressible. In these patients surgical parathyroidectomy offers the only current solution to the ill effects of hyperparathyroidism. Katoh and associates[193] have suggested using PTH gland imaging to determine who will and will not respond to calcitriol therapy by detecting enlarged parathyroid glands, but this has not become widely accepted and requires a skilled ultrasonographer. The surgical technique utilized for parathyroidectomy is not as important as the skills of the surgeon. The patient who undergoes a parathyroidectomy gets immediate relief of musculoskeletal discomfort and a rapid fall in both serum calcium and phosphorus due to the "hungry bone" syndrome. The potential adverse effects of the surgery are primarily recurrent laryngeal nerve damage, in addition to the risk of anesthesia. There has been a tendency to avoid this procedure, but in my opinion, we probably underutilize it. Prior to the parathyroidectomy, a bone biopsy should be done to rule out coexistent aluminum bone disease in anyone with significant aluminum exposure. The problem is that the amount of "significant" exposure is unique for each patient leading some experts to argue that a biopsy should be done in all cases preoperatively.[194] However, patients given infrequent "rescue" therapy with aluminum for hyperphosphatemia do not require a bone biopsy.

Calcimimetics

New to the horizon are the calcimimetics, pharmaceutical agents that increase the sensitivity of the calcium sensing receptor in the parathyroid gland, leading to suppression of PTH release. The first generation agents were shown to be very effective in suppressing PTH in animal models of renal failure and improving bone histology.[195,196] The initial trial in humans was encouraging,[197] however, the agent had poor bioavailability and potential drug interactions. This led to the second generation agent, AMG073, or Cinacalcet (Amgen, Inc, Thousand Oaks, CA). In the initial studies, this agent proved quite effective in suppressing PTH but with some hypocalcemia.[198] The phase II trials had dramatic results: effective suppression of PTH and lowering of both calcium and phosphorus, leading to a reduction in the calcium × phosphorus product.[199] Phase III data confirm these results.[200] Preliminary composite data from all phase III studies in over 1100 patients around the world demonstrate that use of this agent can lead to suppression of PTH with a lowering of the calcium × phosphorus product,[201] allowing achievement of the current K/DOQI guidelines in many more patients than current regimens. The ability of calcimimetics to lower the calcium × phosphorus product clearly differentiates this agent from vitamin D compounds that uniformly raise the calcium × phosphorus product. Thus, calcimimetics will become an important therapeutic option for secondary hyperparathyroidism.

LOW-TURNOVER BONE DISEASE

Aluminum Induced Osteomalacia

As detailed earlier, low-turnover bone disease in dialysis patients is generally due to aluminum induced osteomalacia or adynamic bone. In aluminum induced osteomalacia, aluminum deposits at the mineralization front, leading to impaired mineralization and subsequent accumulation of unmineralized bone, or osteoid. The potential toxicity of aluminum was initially recognized by Alfrey and associates,[202, 203] who identified a fatal neurologic syndrome in dialysis patients consisting of dyspraxia, seizures, and EEG abnormalities in association with high brain aluminum levels on autopsy. The source of aluminum in these severe cases was felt to be elevated concentrations in dialysate water. Subsequently, aluminum containing phosphate binders were also identified as a source.[204–206] The additional symptoms of fractures, myopathy, and microcytic anemia were described several years after the initial reports of the neurologic syndrome.[206,207] In the more recent (late 1980s) Toronto bone biopsy study, where unselected patients at three dialysis units underwent bone biopsies and noninvasive tests ($n = 259$), 69 patients had aluminum bone disease defined as greater than 25% surface aluminum staining. In this series, aluminum bone disease was the most common bone histologic disorder associated with proximal myopathy, pathologic fractures, unexplained bone pain, microcytic anemia, and hypercalcemia.[112] The ingestion of aluminum containing phosphate binders, sucralfate, and some over the counter antacids can also lead to aluminum accumulation.[208] Children, diabetics, and individuals taking citrate are at increased risk of developing the disease.[142,150,209]

The diagnosis of aluminum induced bone disease can be difficult, because aluminum toxicity is due to tissue burden not serum levels. Milliner and associates[111] first described the deferoxamine stimulation test where serum aluminum levels are induced to rise by administering the chelator deferoxamine. An increment in plasma aluminum concentration of 200 µg/L was the threshold for best specificity (93%) but poor sensitivity (43%). Pei and associates[112] later found that the specificity of the deferoxamine stimulation test improved in patients with low levels of intact PTH (< 200 pg/mL). However, the sensitivity of the test remains poor at 48% to 66%. Also, serum aluminum levels are not predictive with poor sensitivity and specificity in asymptomatic patients.[210] Thus, bone biopsy remains the gold standard. Treatment of aluminum bone disease is with deferoxamine, 1 g/week post hemodialysis or intraperitoneally. The duration of therapy must be individualized but is usually 6 months to 1 year. The treatment is quite beneficial, with a dramatic improvement in musculoskeletal symptoms[140] and bone histology[211] in nearly all patients. Unfortunately, the treatment is not without adverse effects, including hearing loss, retinal damage, and infection with mucormycosis. The latter is nearly always fatal.[212] However, these adverse effects were much more common when patients were treated with deferoxamine at each dialysis treatment, as opposed to the current standard therapy of once weekly administration. Fortunately, this disease is now uncommon, at least in the United States, where aluminum containing phosphate binders are rarely utilized.

Adynamic Bone Disease

In adynamic bone disease, there is a paucity of cells with resultant low bone turnover. In addition, in contrast to osteomalacia, in adynamic bone there is no increase in osteoid or unmineralized bone. The lack of bone cell activity led to the initial description of the disease as "aplastic" bone disease. Early studies felt the disease was still due to aluminum, but it was later identified in the absence of positive staining for aluminun.[153,213] The disease is increasing in prevalence, and is particularly common in peritoneal dialysis patients.[92,214] The etiology of adynamic bone disease is unknown but risk factors include age, over-suppression of PTH with vitamin D and calcium containing phosphate binders, diabetes, peritoneal dialysis, and possibly calcium overload.[92,110,215,216] In addition, there is evidence for altered osteoblast response to PTH due to downregulation of the PTH receptor in renal failure,[217] which further contributes to the paucity of cells observed in adynamic bone disease. Circulating fragments of PTH (so called 7–84 amino acid fragments) may also be antagonists to PTH,[58,59] resulting in an effective resistance to 1–84 amino acid at the level of bone. There is also abnormal regulation of cell differentiation in the presence of renal failure, which may explain, in part, the relative paucity of cells in adynamic bone, although this remains to be proven.

Various risk factors have been identified: diabetes, peritoneal dialysis, older age, high calcium dialysate, and Caucasian race.[102,215,216,218,219] In addition, some of the low PTH is secondary to over-suppression with calcitriol[220] or with calcium load, as changing to a low calcium dialysate[221] or sevelamer, a non-calcium containing phosphate binder,[222] can increase the PTH. Patients with adynamic bone disease are often asymptomatic, however, they are at increased risk of hypercalcemia due to the inability of bone to buffer an acute calcium load.[110] Symptoms can usually help differentiate aluminum induced bone disease, which is often symptomatic, from adynamic bone disease, which is nearly always asymptomatic. The lack of cells in adynamic bone disease may impair the ability of bone to repair microfractures and predispose to clinical fractures. Indeed, low levels of PTH have been identified as risk factors for fracture,[4,223] which are particularly common in patients with end-stage renal disease.[3,4] However, these studies did not examine bone histology. Clearly, longitudinal studies of patients with biopsy proven adynamic bone disease are needed.

EXTRASKELETAL CALCIFICATION OR: WHAT IS THE OPTIMAL SERUM PHOSPHORUS, CALCIUM, AND CALCIUM × PHOSPHORUS PRODUCT?

In the past, a calcium × phosphorus product of 70 mg^2/dL^2 was considered the threshold above which calcitriol should not be given. This was felt to be the level above which metastatic calcification occurred. Unfortunately, this level of 70 was based on theoretical, in vitro data and extrapolations from case reports.[224–226] In addition, this number originated when the process of extraskeletal calcification was felt to be purely due to physiochemical interactions and supersaturation of sera with calcium and phosphorus. However, there is now clear evidence that vascular calcification is not purely a physiochemical process. In arteries from patients with atherosclerotic and medial calcification, ex vivo and in vitro data support that vascular smooth muscle cells can produce bone matrix proteins and mineralize similar to osteoblasts.[227–231] We have also demonstrated the presence of these "bone" matrix proteins in calcification of the arterioles of skin (calciphylaxis/calcific uremic arteriolopathy) and in medial and intimal calcification in the inferior epigastric artery of dialysis patients.[16,232,233] Thus, vascular calcification is clearly a cell mediated process. In vitro work has demonstrated that vascular smooth muscle cells can mineralize in the presence of elevated phosphorus concentrations,[15] similar to the mechanisms for phosphorus induced bone mineralization. The in vitro concentrations required to induce mineralization in vascular smooth muscle cells are well within the range of serum phosphorus observed in the majority of dialysis patients. In addition, uremic sera, even without elevated phosphorus concentrations, can induce vascular calcification in vitro to a greater extent and faster than normal sera.[234] Thus, uremia and altered mineral metabolism may lead to, or accelerate, vascular calcification.

Epidemiologic studies have demonstrated that the serum phosphorus and the calcium × phosphorus product are associated with poor outcomes. Lowrie and associates[17] found that serum phosphorus levels greater than 7.0 mg/dL were associated with increased mortality, and Block[18] found that serum phosphorus levels greater than 6.5 mg/dL were associated with increased mortality. The latter study also demonstrated that a calcium × phosphorus product greater than 73 mg^2/dL^2 was associated with increased mortality, principally due to the effects of phosphorus.[18] These studies were from data sets from over 10 years ago, during the widespread use of aluminum containing phosphate binders, and prior to aggressive use of vitamin D metabolites for the treatment of secondary hyperparathyroidism. However, the association of elevated serum phosphorus and mortality was recently confirmed by Block and associates,[235] who found an 88% higher relative risk of death for hemodialysis patients with serum phosphorus levels greater than 9 mg/dL, compared to patients with phosphorus levels in the reference range of 5 to 6 mg/dL. He also found that the relative risk of death correlated directly to serum calcium levels, rising 47% as the calcium level rises from 9 to 9.5 mg/dL to greater than 11 mg/dL.[235] Elevated serum phosphorus is also associated with poor outcomes in European studies.[236] A recent cohort study also demonstrated that management of calcium-phosphorus metabolism (defined as measuring PTH, or prescribing vitamin D or phosphate binders) prior to beginning dialysis was independently associated with a 35% decrease likelihood of death in the first year of dialysis.[237] These studies provide the rationale for the K/DOQI targets (Tables 8–3 and 8–4).[106] Furthermore, a preliminary report demonstrated that achievement of these K/DOQI target values for PTH and the calcium × phosphorus led to reduced mortality.[238]

The leading cause of mortality in dialysis patients is cardiovascular disease, and there is growing evidence for an adverse effect of mineral metabolism on the vascular system. Vascular calcification has become easier to document with the advances in imaging in the recent decade, including electron beam CT,[5] spiral CT,[11] and duplex ultrasonography.[239] These techniques are thought to be more reproducible than the older method of observing progression of vascular

calcification on plain radiographs. Electron beam CT and spiral CT allows rapid imaging of the heart in diastole, such that calcification in the coronary arteries can be easily distinguished and quantified. Braun and associates[5] found in 1996 that hemodialysis patients had markedly increased coronary artery calcification compared to age and sex matched nonrenal failure individuals with angiographically proven coronary artery disease. Furthermore, valvular calcification was present in 50% of patients, and the coronary artery calcification increased in all 57 patients over the course of 1 to 2 years. Goodman and associates[240] found that this calcification also affected children and young adults on dialysis. They demonstrated that the patients with increased coronary artery calcification were on dialysis for a longer period of time, had an elevated calcium $\times$ phosphorus product, increased intake of calcium containing phosphate binder, a trend toward higher phosphorus levels, and no difference in the serum calcium levels. Kimura and associates[241] found an elevated calcium $\times$ phosphorus product greater than or equal to 60 mg^2/dL^2 on more than 25% of measurements correlated with severity of aortic calcification by abdominal CT. Marchais and associates[242] found that patients with hyperphosphatemia greater than 6.2 mg/dL had higher diastolic and mean blood pressure and increased cardiac index caused by increased stroke index and heart rate. They also found increased carotid artery tensile stress in the patients who were hyperphosphatemic.[242] This same group subsequently found that increased arterial calcification was associated with increased intake of calcium containing phosphate binders[243] and mortality.[6] In vascular calcification of the small arterioles of the skin (calciphylaxis or calcific uremic arteriolopathy), we found elevated phosphorus and calcium $\times$ phosphorus product to be a risk factor in a case control study.[16] This was confirmed by Mazhar and associates,[244] who found that the risk of calcific uremic arteriolopathy increased 3.51-fold for each mg/dL increase in serum phosphorus levels. Last, elevated serum phosphorus, calcium, calcium $\times$ phosphorus product, and PTH were all greater in peritoneal dialysis patients with valvular calcification,[245,246] and the presence of valvular calcification was predictive of all cause and cardiovascular mortality.[246] These data are supported by that of Rubel and associates,[247] demonstrating a serum phosphorus level of greater than or equal to 5.0 mg/dL (1.62 mmol/L) was independently associated with having undergone a cardiac valve replacement procedure. Thus, elevated serum phosphorus, and calcium $\times$ phosphorus product, is associated with accelerated vascular and valvular calcification, and in vitro data support a direct role of phosphorus and other uremic toxins in this process.[15,232,248,249] In summary, there is mounting evidence that disturbances of mineral metabolism in renal failure contributes to the excessive cardiovascular disease observed in dialysis patients. Thus, we need to strive for lower values in our patients,[250] which are reflected in the target goals for the new bone and mineral KDOQI: serum phosphorus levels at 3.5 to 5.5 mg/dL. Calcium $\times$ phosphorus produce below 55 mg^2/dL^2 and serum PTH levels near 150 to 200 pg/mL.[106]

Post Renal Transplant Bone Disease

Ideally, all of these complications of calcium and phosphorus imbalance and renal osteodystrophy would be improved with renal transplantation. Unfortunately, in many cases, renal transplantation returns individuals to chronic kidney disease (as opposed to normal renal function), and thus transplant patients still suffer from renal osteodystrophy. There are limited studies evaluating bone histology in recipients of renal transplants. There appears to be a persistent mineralization defect.[251] In some studies bone turnover normalized,[251] but in others, there is low turnover with histology consistent with adynamic bone disease.[252] Aluminum staining resolves in the majority of patients. However, longitudinal studies are lacking. There does appear to be a consistent decrease in bone mineral content by densitometry, although more recent studies[253–255] have not found the dramatic decrease initially described,[251] perhaps due to the current practice of reducing steroid dose more rapidly. There is an increased risk of fracture, although this risk is less than that observed with other solid organ transplants.[256–260] The combination of a kidney-pancreas transplant increases fracture risk above that associated with renal transplant alone.[261]

The use of corticosteroids is the major determinant of low bone mineral content, as these agents impair calcium absorption from the gastrointestinal tract and inhibit bone cell recruitment and function.[255,262] The diagnosis of corticosteroid induced osteoporosis is best done with dual x-ray absorptiometry (DEXA) of the hips and spine for assessment of changes in trabecular bone. Osteoporosis, regardless of its etiology, is defined by the World Health Organization as a t-score less than 2.5 standard deviations from the norm, which is a young adult mean. The rationale for use of this comparison group is that it is measuring current bone mass to peak bone mass, which is obtained near ages 30 to 35. Furthermore, this value is the threshold below which there is increased fracture risk in postmenopausal women.[22] This threshold value was recently confirmed for nonrenal transplant corticosteroid induced osteoporosis.[263] However, as indicated earlier in this chapter, abnormal bone turnover may alter the predictive value of DEXA in patients with CKD and, thus, preexisting bone turnover likely affects the assessment and outcomes of bone disease in transplant recipients.

The treatment for corticosteroid induced osteoporosis is similar to that for other forms of osteoporosis: antiresorptive agents (osteoclast inhibitors), such as bisphosphonates, calcitonin, and estrogen in deficient women. There is substantial evidence from controlled trials in nontransplant corticosteroid induced osteoporosis that these agents, particularly bisphosphonates, are effective in preventing steroid induced osteoporosis.[264–266] However, there are limited data on treatments with bisphosphonates in renal transplantation recipients, and early uncontrolled data supported the use of bisphosphonates.[254,267] Recently, there have been several studies supporting the use of bisphosphonates postrenal transplant. In randomized, controlled trials, intravenous pamidronate[268,269] and zoledronic acid[270] were associated with improved bone mineral density in renal transplant recipients. In a few patients, bone biopsies demonstrated reduced activation frequency but increased trabecular thickness.[269, 270] Thus, although there is concern about potential long-term consequences, the data to date support the use of antiresorptive therapies to prevent corticosteroid induced osteoporosis. This last point deserves further emphasis: They are only effective in *preventing* bone loss and must be administered during the large dose of steroids given in the first 6 months

posttransplant. Furthermore, in a long-term (4 years) follow-up study of 17 male renal transplant recipients, two doses of intravenous pamidronate, given at the time of transplant and 1 month later, continued to show protective effects of bone mineral density 4 years later.[268] This conservative approach of short-term, limited administration of bisphosphonates is recommended given the current practice to quickly decrease steroid dose and limited data on potential long-term adverse effects of bisphosphonates on bone histology.

CONCLUSION

Multiple abnormalities of bone and mineral metabolism are observed in patients with chronic kidney disease. Our understanding of the cellular biology of parathyroid hormone and vitamin D in the last decade have led to new therapies that allow more aggressive treatment of renal osteodystrophy with less toxicity. This latter point is particularly important with the strong data associating abnormal mineral metabolism with cardiovascular disease, the leading cause of death in dialysis patients. Although significant progress has been made in our understanding of these disease states, there is much more knowledge to be gained.

Cardiovascular Disease in Patients with Chronic Kidney Disease

Daniel E. Weiner, M.D., M.S. • Mark J. Sarnak, M.D.

Cardiovascular disease is the leading cause of morbidity and mortality in patients with chronic kidney disease (CKD). This increased risk of cardiovascular disease may begin during the earlier stages of CKD before the onset of kidney failure. Notably, patients with CKD have a very high prevalence of cardiovascular disease risk factors such as diabetes and hypertension, but they are also exposed to other nontraditional, uremia-related cardiovascular disease risk factors. Much of the burden of cardiovascular disease in CKD may be due to atherosclerosis, but it is apparent that patients with cardiovascular disease also have a high prevalence of arteriosclerosis and disorders of left ventricular (LV) structure and function.

In this chapter, we discuss the epidemiology and pathophysiology of cardiovascular disease in patients with CKD, with a focus on dialysis patients and nontransplant recipients with stages 1 through 4 CKD. We also discuss the different manifestations of cardiovascular disease in kidney disease and review diagnostic and therapeutic options.

EPIDEMIOLOGY

Dialysis

Among dialysis patients, cardiovascular disease (CVD) is the leading cause of mortality, accounting for nearly 45% of deaths; approximately 20% of cardiac deaths are attributed directly to acute myocardial infarction (AMI).[1] This high burden of CVD mortality is well illustrated by comparing CVD mortality in the dialysis population to the general population; at all ages in both men and women, mortality due to CVD is 10 to 30 times higher in dialysis patients (Figure 9–1).[2]

In theory, the high CVD mortality rate in dialysis patients may be due to both a high prevalence of CVD and a high case fatality rate. In fact, both are true. Based on data obtained from medical evidence forms, at the time of initiation of kidney replacement therapy nearly 40% of patients have known coronary disease, over 40% have congestive heart failure, approximately 20% have peripheral vascular disease, and over 10% have had strokes or transient ischemic attacks.[3] The prevalence of CVD at initiation of dialysis is even higher if claims data are used instead of the Medical Evidence Form.

Dialysis patients with CVD also have a very high case fatality rate. Herzog and associates,[4] retrospectively studied outcomes of 34,189 dialysis patients and noted a 60% 1-year mortality and 90% 5-year mortality rate following AMI.

Stages 1 to 4 CKD

CVD Morbidity and Mortality

The high prevalence of CVD in incident dialysis patients suggests that CVD develops prior to the onset of kidney failure. Several studies have shown that manifestations of CVD may be seen relatively early in CKD. For example, in a cross-sectional study of 175 patients, 27% of patients with creatinine clearance above 50 mL/min had LVH, while 31% of patients with creatinine clearance between 25 and 49 mL/min and 45% of patients with creatinine clearance below 25 mL/min had LVH.[5] This contrasts with a prevalence of LVH of less than 20% in patients of similar age in the general population.[6]

Similarly, patients with CKD have a higher prevalence of coronary artery disease, heart failure, and CVD risk factors than those without CVD and suffer from CVD events at higher rates.[7–10] For example, among patients with reduced kidney function in the Cardiovascular Health Study (CHS), comprised entirely of subjects aged 65 years and older, 26% had coronary artery disease, 8% had heart failure, and 55% had hypertension at baseline. This is compared with subjects in the same study without CKD, where 13%, 3%, and 36% had coronary artery disease, heart failure, and hypertension at baseline, respectively. Notably, subjects with CKD had a rate of CVD events of 102 per 1000 patient years, while those without CKD had an event rate of 44 per 1000 patient years.[11] Similar findings were noted in the Atherosclerosis Risk in Communities (ARIC) Study, a community-based cohort of individuals aged 45 to 64 years. In ARIC, subjects with CKD had a baseline prevalence of coronary artery disease, cerebrovascular disease, and diabetes of 11%, 10%, and 24%, respectively, and the rate of CVD events was 26 per 1000 patient years. In comparison, subjects without CKD had a baseline prevalence of coronary artery disease, cerebrovascular disease and diabetes of 4.1%, 4.4%, and 13% respectively, and the rate of CVD events was 9 per 1000 patient years.[12]

CKD as an Independent Risk Factor for CVD

Several studies have demonstrated that in patients with CVD or at high risk for CVD, the presence of CKD is an independent risk factor for future CVD outcomes. For example, in the Studies of Left Ventricular Dysfunction (SOLVD) trial examining subjects with left ventricular ejection fraction below 40%, subjects with CKD had a 40% increased risk of mortality and a 50% to 70% increased risk of death due to heart failure.[13] Similarly, in the Heart Outcomes and Prevention Evaluation (HOPE) Trial, patients with CKD had a 40% increased risk of the composite outcome of myocardial infarction, CVD death,

CARDIOVASCULAR MORTALITY IN THE GENERAL POPULATION (NCHS) AND
IN KIDNEY FAILURE TREATED BY DIALYSIS OR TRANSPLANT (USRDS)
Figure 9–1 Cardiovascular mortality in the general population and dialysis population stratified by sex and race. (Data from Foley RN, Parfrey PS, Sarnak MJ: Clinical epidemiology of cardiovascular disease in chronic renal disease. Am J Kidney Dis 1998; 32[5 suppl 3]:S112–S119.)

and stroke.[14] These results have also been seen in subjects following myocardial infarction.[8–12]

In community studies, the independent effect of kidney function has been less conclusive. For example, analyses of the Framingham Heart Study cohort and the National Health and Nutrition Examination Survey I (NHANES I) did not demonstrate that CKD was an independent risk factor for CVD outcomes.[15,16] In contrast, in ARIC and CHS, CKD was an independent risk factor for CVD outcomes; however, the impact of CKD was diminished after adjusting for traditional CVD risk factors (Figure 9–2).

There are several reasons why CKD may be an independent risk factor for CVD outcomes. These include, but are not limited to, residual confounding from traditional risk factors and insufficient adjustment for nontraditional risk factors. Additionally, CKD may be a marker of the severity of either diagnosed or undiagnosed vascular disease. Furthermore, patients with CKD may not receive sufficient therapy for their

disease, including medications such as aspirin, β-blockers and angiotensin converting enzyme inhibitors, as well as diagnostic and therapeutic procedures.

Proteinuria as an Independent Risk Factor for CVD

Proteinuria, manifest as either microalbuminuria or macroalbuminuria, is associated with a higher prevalence of surrogates of CVD, including left ventricular hypertrophy in patients with hypertension[17] and arterial intima-media thickening in patients with diabetes.[18] Proteinuria detected by a urine dipstick examination was an independent risk factor for CVD outcomes in the Framingham cohort.[19,20] Other studies have confirmed this finding in diabetic and hypertensive patients.[21,22]

Several recent studies have expanded on the importance of microalbuminuria as a CVD risk factor. Secondary evaluation of the HOPE Trial data as well as evaluations of population-based cohorts in Norway and the Netherlands expanded on prior evaluations of proteinuria to show that microalbuminuria, even in very low quantities, may independently predict CVD outcomes (Figure 9–3).[23–25]

There are several reasons why microalbuminuria may be an independent risk factor for CVD outcomes. Microalbuminuria may represent kidney disease itself, with an associated risk of subsequent CKD progression and development of macroalbuminuria. Microalbuminuria may also represent the kidney manifestation of systemic endothelial disease burden, or may be associated with systemic inflammatory markers and abnormalities in the coagulation and fibrinolytic systems.[26]
Figure 9–2 Smoothed 5-year predicted probability of developing atherosclerotic cardiovascular disease (ASCVD) by level of GFR in the ARIC Study. The linear model includes GFR as a continuous variable in a Cox regression while the cubic spline model includes a cubic transition between linear segments with five knots. (From Manjunath G, Tighiouart H, Ibrahim H, et al: Level of kidney function as a risk factor for atherosclerotic cardiovascular outcomes in the community. J Am Coll Cardiol 2003; 41[1]:47–55.)

RISK FACTORS

Much of the increased burden of CVD in CKD is due to increased prevalence of both traditional and nontraditional risk CVD factors. Traditional risk factors are factors identified in the Framingham Heart Study as conferring increased risk of cardiovascular disease in the general population. Traditional risk factors include older age, diabetes and hypertension, all of which are highly prevalent in patients with CKD. Nontraditional risk factors are defined as those factors that increase in prevalence as kidney function declines and that have been hypothesized to be CVD risk factors in this population (Table 9–1).

Cardiovascular death

Non-cardiovascular death
Figure 9–3 Microalbuminuria. Adjusted effect of urinary albumin concentration (UAC) on the hazard of cardiovascular and noncardiovascular death. Shaded areas represent the upper and lower limit of current definition of microalbuminuria (20 to 200 mg/L). (From Hillege HL, Fidler V, Diercks GF, et al: Urinary albumin excretion predicts cardiovascular and noncardiovascular mortality in general population. Circulation 2002; 106[14]:1777–1782.)

Most CVD risk factors lead to atherosclerosis, arteriosclerosis, cardiomyopathy, or any combination of these three conditions (Table 9–2). Atherosclerosis, defined as an occlusive disease of the vasculature, and arteriosclerosis, defined as non-occlusive remodeling of the vasculature, may manifest as ischemic heart disease and heart failure (HF). Some risk factors, including dyslipidemia and hyperhomocysteinemia, primarily predispose to development and progression of atherosclerosis, while others, including volume overload and elevated calcium-phosphorus product, may predispose to arteriosclerosis. Still other risk factors, including anemia and the presence of arteriovenous fistulae, may predispose to cardiac remodeling and left ventricular hypertrophy. Essential to the understanding of CVD in CKD is an understanding of the interplay of these various risk factors in patients with kidney disease.

Traditional Cardiovascular Disease Risk Factors

Blood Pressure in Dialysis Patients

Hypertension is both a cause as well as a result of kidney disease. About 70% to 80% of patients with stages 1 through 4 CKD have hypertension, and the prevalence of hypertension increases as glomerular filtration rate (GFR) declines, such that over 80% to 90% of patients starting dialysis are hypertensive (Figure 9–4).[27, 28]

"U"-shaped relationship

The relationship between hypertension and CVD outcomes in the dialysis patient is complex, with increased adverse CVD events and mortality at both markedly elevated post-dialysis systolic blood pressures (>180 mmHg) as well as lower blood pressures (<110 mmHg) (Figure 9–5).[29,30] Reflecting perhaps increased arterial stiffness, pulse pressure, and when evaluated in conjunction with systolic blood pressure, may more accurately predict CVD outcomes than systolic blood pressure alone.[31]

Hypertension

It is important to note that high blood pressure has been associated with CVD outcomes in dialysis patients. For example, hyper-

Table 9–1 Traditional and Nontraditional Cardiovascular Risk Factors in Chronic Kidney Disease

Traditional Risk Factors	Nontraditional Factors
Older age	Albuminuria
Male gender	Homocysteine
Hypertension	Lipoprotein (a) and apo (a) isoforms
Higher LDL cholesterol	Lipoprotein remnants
Lower HDL cholesterol	Anemia
Diabetes	Abnormal calcium/phosphate metabolism
Smoking	Extracellular fluid volume overload
Physical inactivity	Electrolyte imbalance
Menopause	Oxidative stress
Family history of cardiovascular disease	Inflammation (C-reactive protein)
Left ventricular hypertrophy	Malnutrition

tension is an independent risk factor for ischemic heart disease, LVH, heart failure,[32] and cerebral hemorrhage.[33] Hypertension is likely under-treated in dialysis patients[34,35]; unfortunately, there are no large trials to date that examine blood pressure goals and medication regimens in dialysis patients.

Low blood pressure

There are two potential reasons that low blood pressure may be associated with adverse outcomes in dialysis patients. First, hypotension may be associated with other comorbid conditions, including heart failure and cardiomyopathy. Second, low blood pressure may predispose dialysis patients to experiencing intra-dialytic hypotension, which itself may lead to ischemic events.

Intradialytic hypotension is a relatively common occurrence during hemodialysis and may also be an independent

Figure 9–4 The prevalence of hypertension in chronic dialysis patients as compared to the general population. (Reprinted with permission from Agarwal R, Nissenson AR, Batlle D, et al: Prevalence, treatment, and control of hypertension in chronic hemodialysis patients in the United States. risk factor for CVD outcomes, perhaps representing either the inability of the heart or blood vessels to appropriately respond to reduced blood pressure or, alternatively, heart failure itself in the absence of overt volume overload. Hypotension, particularly in the presence of reduced preload from ultrafiltration, may represent the inability of a noncompliant left ventricle to compensate for decreased left ventricular filling pressures.

Stages 3 to 4 CKD

Blood pressure in stages 3 to 4 CKD has been investigated in more detail than in dialysis patients, although the focus of most studies has been on retarding progression of kidney disease rather than assessing CVD outcomes. In this section, we will discuss the prevalence of hypertension in CKD, its association with CVD, and therapeutic recommendations.

Prevalence
Hypertension is highly prevalent in patients with CKD. In a Canadian evaluation of patients with creatinine clearance below 75 mL/min, 80% had hypertension (defined as blood pressure greater than 140/90 mm Hg or use of anti-hypertensive medications),[36] while the prevalence of hypertension was 70% in the NHANES III population with CKD.[37] Hypertension was more commonly seen with CKD due to glomerular disease than tubulointerstitial disease.[38]

Progression of CKD
Elevated systolic blood pressure is an independent risk factor for CVD outcomes in both diabetic[39,40] and nondiabetic patients.[41] A secondary analysis of the MDRD study showed a 35% increased risk of hospitalization for CVD for each 10-point increase in systolic blood pressure, and this increased risk remained significant even after adjusting for other traditional risk factors.[42] Increased risk of progression of kidney disease is also associated with poor blood pressure control, with the lowest risk of kidney disease progression seen in treated hypertensive patients who achieved systolic blood pressure reduction to 110 and 119 mmHg, primarily in patients with proteinuria.[43]

Therapy
Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are the preferred anti-hypertensive medications in patients with CKD. Several studies have shown a reduction in progression of CKD using these medications, particularly in patients with proteinuria.[23,43–48] Notably, in a subgroup analysis of patients with CKD in the HOPE study, ACE inhibitors were beneficial for reducing CVD events in patients with either preexisting vascular disease or diabetes combined with an additional cardiovascular risk factor.[14] Based on this evidence, the National Kidney Foundation (NKF) has published practice guidelines that recommend a target blood pressure of 130/80 mmHg in all CKD patients.[48a]

Dyslipidemia

Patients with earlier stages of CKD frequently have diabetes and hypertension. In the United States, this metabolic syndrome is frequently accompanied by dyslipidemia and, in particular, elevated LDL cholesterol. Additionally, nephrotic-range proteinuria can also exacerbate hyperlipidemia and hypertriglyceridemia. In the absence of severe proteinuria, as CKD progresses levels of LDL cholesterol may normalize reflecting progressive malnutrition.[49] HDL cholesterol is often low, while triglycerides are generally moderately elevated. Other abnormalities include increased levels of lipoprotein(a), a higher proportion of atherogenic, oxidized LDL-C and abnormal concentrations of apolipoproteins that comprise the major lipoproteins (Table 9–3).

Despite these changes, approximately 50% of prevalent hemodialysis patients have LDL cholesterol over 100 mg/dL and non-HDL cholesterol levels over 130 mg/dL.[50] In peritoneal dialysis (PD) patients, the prevalence of hyperlipidemia is approximately 70%, although PD patients have a somewhat more atherogenic lipid panel than their HD counterparts, with increased LDL-C, apolipoprotein B, oxidized LDL-C, triglycerides, and Lp(a) and decreased HDL-C. Therefore, despite the fact that total cholesterol levels are often relatively normal, significant dyslipidemia is highly prevalent in the CKD population.

In hemodialysis patients, the relationship between cholesterol levels and coronary heart disease mortality is more complex than in the general population. A review of observational studies of dialysis patients found a "reverse epidemiology" between cholesterol levels and risk of death.[20] Contrary to what has been observed in the general population, low cholesterol levels were associated with a higher death rate in dialysis

Table 9–3   Lipid Abnormalities by Target Population (approximate percentage)

	Total Cholesterol > 240 mg/dL	LDL Cholesterol > 130 mg/dL	HDL Cholesterol < 35 mg/dL	Triglycerides > 200 mg/dL

†Data extracted from multiple observational studies.[168]
‡Nephrotic proteinuria was defined as > 3 g of total protein excretion in 24 hours

patients. For example, in an analysis of data from more than 12,000 hemodialysis patients, patients with low total cholesterol levels (<100 mg/dL) had a more than fourfold increase in risk of death compared with patients whose cholesterol levels were between 200 and 250 mg/dL.[51] In one study, hypocholesterolemia was associated with low serum albumin and elevated levels of C-reactive protein (CRP), possibly implicating hypocholesterolemia as a surrogate for malnutrition and inflammation. In that same study, although hypocholesterolemia was more closely associated with all-cause mortality, hyperlipidemia was also a strong predictor of cardiovascular death.[52] Similar findings were noted in a recent evaluation of the CHOICE study, an incident cohort of dialysis patients, where, after taking inflammation and malnutrition into account, higher levels of total serum cholesterol were associated with adverse CVD outcomes and mortality.[53]

Although the results of currently ongoing randomized, controlled trials are necessary to examine whether lipid-lowering treatment is beneficial in patients with CKD, the National Kidney Foundation (NKF) has recently published guidelines as part of their Kidney/Dialysis Outcomes Quality Initiative (K/DOQI) for the treatment of dyslipidemia in CKD. These recommendations stress that all patients with CKD, even in the absence of known CVD, be considered to be at the highest risk for CVD outcomes. Lipid levels should be treated to the lowest levels recommended for the general population (namely LDL-C < 100 mg/dL and non-HDL-C < 130 mg/dL) (Table 9–4).[54]

Diabetes Mellitus

Diabetes accounts for over 40% of the dialysis population in the United States and is increasingly the cause of kidney failure in other countries.[1]

Dialysis
The presence of diabetes in dialysis patients is an independent risk factor for ischemic heart disease, heart failure, and all-cause mortality.[55,56] Diabetic dialysis patients also have worse long-term outcomes following coronary interventions than nondiabetic patients with CKD.[57,58]

However, there is suggestive evidence that the management of diabetes in the dialysis unit has been suboptimal as marked by lower than expected rates of hemoglobin A1C assessment and yearly eye examinations.[59] Unlike in the general population, there have been no studies in the dialysis population of the relationship between strict glycemic control and CVD outcomes. The net benefit of rigid diabetes control may be smaller in the dialysis population because microvascular and macrovascular complications already exist and because of a potentially increased risk of hypoglycemia; however, hyperglycemia may still worsen retinopathy, hasten the loss of residual kidney function, cause or worsen peripheral neuropathy, and increase the risk of infection.

Stages 1 to 4 CKD
Diabetes mellitus is the most common cause of stages 1 to 4 CKD, with microalbuminuria as the first clinical manifestation of diabetic nephropathy. In the general population, diabetes is a powerful risk factor for cardiovascular outcomes.[60] The same holds true for patients with CKD.[61]

Left Ventricular Hypertrophy and Cardiomyopathy

LVH is highly prevalent in both stages 3 and 4 CKD and dialysis patients and represents a physiologic adaptation to a long-term increase in myocardial work requirements.

Pathogenesis
LVH may be thought of as resulting from either pressure or volume overload. Pressure overload results from increased cardiac afterload, often due to hypertension, aortic stenosis, and reduced arterial compliance from arteriosclerosis.[62,63] Some evidence suggests that increased vascular calcification in dialysis patients may also contribute to this phenomenon.[63] Volume overload may be related to anemia, developing when the heart attempts to compensate for decreased peripheral oxygen delivery.[64,65] Other causes of volume overload include increased extracellular volume seen in dialysis patients[66,67] and the presence of arteriovenous fistulae.

Most LVH is initially concentric, representing a uniform increase in wall thickness secondary to pressure overload from hypertension or aortic stenosis. The concentric thickening of the wall of the left ventricle allows for generation of greater intraventricular pressure, effectively overcoming increased afterload. Volume overload may result in eccentric hypertrophy secondary to the addition of new sarcomeres in series. Eccentric hypertrophy is defined by an increased LV diameter with a proportional increase in LV wall thickness. As this process progresses, capillary density decreases and subendocardial perfusion is reduced. Myocardial fibrosis may ensue and, with sustained maladaptive forces, myocyte death occurs. The end point of this cycle is often dilated cardiomyopathy with eventual reduction in systolic function (Figure 9–6).[68]

Although LVH was identified early on the Framingham population as a CVD risk factor, LVH in dialysis results from the confluence of at least one major traditional risk factor (hypertension)

Table 9–4 Treatment Recommendations for Dyslipidemia in Dialysis Patients

Dyslipidemia	Treatment Goal	Initial Regimen	Increased Regimen	Alternative Regimen
TG ≥ 500 mg/dL	TG < 500 mg/dL	TLC	TLC + Fibrate or Niacin	Fibrate or Niacin
LDL 100–129 mg/dL	LDL < 100 mg/dL	TLC	TLC + low dose statin	Bile acid seq or Niacin
LDL ≥ 130 mg/dL	LDL < 100 mg/dL	TLC + low dose statin	TLC + max. dose statin	Bile acid seq or Niacin
TG ≥ 200 mg/dL and non-HDL ≥ 130 mg/dL	Non-HDL < 130 mg/dL	TLC + low dose statin	TLC + max. dose statin	Fibrate or Niacin

and several nontraditional risk factors (anemia, chronic volume overload, uremia, and possibly hyperparathyroidism).

Epidemiology

Studies have shown a prevalence of LVH of 20% to 50% in the pre-dialysis population, with LVH being more common at lower levels of kidney function, decreased hemoglobin, and increased systolic blood pressure. Among incident dialysis patients, as many as 70% may have LVH present by echocardiography,[5] while, among prevalent dialysis patients, LVH is present in 50% to 75% of patients when assessed by echocardiography.[69,70]

As in the general population, LVH is an independent risk factor for adverse CVD outcomes in dialysis patients.[71,72] Notably, both concentric LVH and dilated cardiomyopathy are independently associated with increased incidence of adverse CVD outcomes and all-cause mortality.[68]

Therapy

Given the complexity of the development of LVH, it presents a challenging target for therapy. Potentially modifiable risk factors include anemia, hypertension, extracellular volume overload, abnormal calcium and phosphorus metabolism, and arteriovenous fistulae. With attention to these risk factors prior to dialysis, LVH and its eventual cardiovascular sequelae may potentially be prevented.

Some data from small studies have suggested that with modification of risk factors, including anemia and systolic blood pressure as well as strict management of volume, regression of LVH can be induced in dialysis patients.[67,73–75] However, one recent study found that only a subset of patients treated with ACE inhibitor therapy had regression of LV mass; those who did not

respond tended to have higher levels of C-reactive protein (CRP), perhaps implicating inflammation as a confounding factor in development of LVH.[76] Additionally, two randomized trials, one in dialysis patients and one in patients with stages 3 to 4 CKD, did not demonstrate any regression of LVH or decrease in LV mass with higher levels of hemoglobin.[77,78] The latter study is difficult to interpret given that diastolic blood pressure rose in the higher hemoglobin arm, follow-up was only 2 years, and the difference in achieved hemoglobin levels between the two groups was small. While future research in this field may reveal important genetic associations governing the renin-angiotensin-aldosterone system, therapy at this time is likely best directed at modifying the multiple risk factors for LVH in order to prevent its development, particularly in the pre-dialysis CKD population.

Other Traditional Risk Factors

Other traditional risk factors include advanced age, male sex, and smoking. Smoking represents an opportunity for intervention. Although there have been few studies examining specific effects of smoking in dialysis patients, a recent evaluation of U.S. Renal Data System (USRDS) data showed that smoking was a strong, independent risk factor for incident heart failure, incident peripheral vascular disease, and all-cause mortality. Importantly, dialysis patients who were former smokers were more similar to nonsmokers than current smokers in risk, demonstrating the potential benefit of smoking cessation efforts in dialysis patients.[79]

Nontraditional Risk Factors

Homocysteine

Homocysteine (Hcy), a metabolite of the essential amino acid methionine, has been implicated in the general population as a risk factor for myocardial infarction and stroke.[80,81] Hyperhomocysteinemia is much more common in dialysis patients than in the general population (Table 9–5). Normal plasma levels of Hcy range from 5 to 12 μmol/L, whereas dialysis patients have mean homocysteine levels of 24 μmol/L. Hcy levels increase proportionally as kidney function declines, with as many as 80% of dialysis patients classified as having hyperhomocysteinemia.[82] Much of this elevation is secondary to defective kidney clearance of homocysteine.[83]

Some but not all studies have demonstrated that hyperhomocysteinemia is an independent risk factor for CVD mortality in dialysis patients,[84] although the relationship is only modest.[85] However, it is important to note that Hcy levels are

Table 9–5 Comparison of Homocysteine Levels in Different Populations

Population	Mean HCY, μM (range: 10–90 percentile)
Stage 5 CKD	24 (19–39)
Kidney Transplant	15 (9–25)
CKD	15 (9–25)
General Population*	9 (6–12)

*In the age of folate supplementation.
(From Friedman et al. J Am Soc Nephrol 2001; 12:2181–2189.)

also correlated with nutritional status, and, in subjects who are nutritionally bereft, low levels of serum homocysteine are associated with adverse outcomes.[86]

Deficiencies of folate, vitamin B_{12}, and vitamin B_6 have all been linked to increased Hcy in the general population,[87] and therapy with these vitamins may both normalize Hcy levels and reduce CVD recurrence.[88,89] In the earlier stages of CKD, treatment with supraphysiologic doses of folic acid and B vitamins may also normalize Hcy levels; however, Hcy levels in dialysis patients are often somewhat resistant to folate and B vitamin administration, such that high dose supplementation may result in improvement but not normalization of homocysteine levels.[90] Extremely high flux dialyzers and daily nocturnal dialysis may also decrease lower homocysteine levels.[91,92] While trials are ongoing, to date there are no randomized, controlled trial data demonstrating the impact of Hcy-lowering therapy on CVD outcomes in dialysis patients.

Oxidant Stress and Inflammation

Oxidant stress has recently been proposed as a unifying concept linking both traditional and other nontraditional risk factors in CKD.[93] Whether or not this is the case, the hypothesis of oxidant stress is certainly illustrative of the multifactorial nature of CVD risk in CKD.

Oxidant stress may be defined as an imbalance between oxidants and antioxidants (oxidant defenses) that leads to tissue damage.[94] Most oxidation occurs in the mitochondria, although phagocytes also produce reactive oxygen (ROS) species in a "respiratory burst" designed to defend the body against infection. These ROS include hydrogen peroxide and superoxide anion, both of which function as precursors for generation of more powerful oxidants. These ROS eventually can oxidize lipids, proteins, carbohydrates, and nucleic acids, which can then be measured as markers of oxidant burden. This system is balanced by a series of antioxidant defenses, some of which work by enzymatically catalyzing reduction of oxidant species (e.g., superoxide dismutase, catalase) while others work nonenzymatically by scavenging for oxidants (e.g., glutathione, vitamin C).[95]

Numerous factors in the CKD patient population increase oxidant stress. These include inflammation, malnutrition (by reducing antioxidant defenses), uremic toxins, and potentially the dialysis procedure itself. Patients with CKD not only have higher levels of oxidant stress, but they also have decreased defenses, particularly plasma protein-associated free thiols such as glutathione.[93] This "double-hit" makes dialysis patients particularly vulnerable to sequelae of oxidant stress.

Several studies have been published that show a strong, independent association between inflammation and the risk of adverse CVD outcomes in dialysis patients.[69, 96, 97] Adverse CVD outcomes may be exacerbated by the role of oxidant stress in the development of anemia and malnutrition.[95] The dual presence of inflammation and oxidant stress may also increase the amount of atherogenic oxidized LDL, contributing to atherosclerotic disease.

At this time, specific treatment strategies for oxidant stress and inflammation in CKD have not been adopted. In the general population, therapy with statins and antioxidants has been investigated. Statins are associated with a greater beneficial effect on CVD events and mortality than would be expected by changes in the lipid profile alone. This may be due to a pleiotropic anti-inflammatory effect associated with statins,[98,99] which has also been appreciated in dialysis patients.[100]

Numerous studies have investigated the use of antioxidants for cardiovascular protection in the general population. The most notable demonstrated no benefit of vitamin E supplementation.[101] However, in dialysis patients, a study of 200 patients with prevalent CVD demonstrated a benefit associated with daily use of 800 IU of vitamin E[102] while a separate study showed a benefit with use of 600 mg of N-acetylcysteine twice daily.[103] Other investigations have used vitamin E–coated dialyzers and noted a decrease in oxidant stress.[104,105]

Other Nontraditional Risk Factors

Other nontraditional risk factors for CVD include anemia, derangements in calcium and phosphate metabolism, lipoprotein abnormalities, and sleep abnormalities. Some of these issues are discussed at length elsewhere in this text.

The contribution of anemia to increased CVD risk may be secondary to compensatory LVH as well as reflect high levels of inflammation and oxidant stress. Current research is also focusing on the effects of hyperphosphatemia and elevated calcium-phosphate product on arterial remodeling, as well as the effect of hyperparathyroidism on cardiomyopathy. Electron beam computed tomography has revealed extensive coronary artery calcification in dialysis patients and, in cross-sectional studies, this is associated with clinical CVD.[106] However, it remains to be determined whether reduction of serum phosphorus levels and calcium-phosphate product as well as treatment of hyperparathyroidism decreases CVD events. Other nontraditional risk factors include sleep abnormalities that are highly prevalent in dialysis patients and associated with coronary artery disease.[107] Nocturnal hypoxemia predicts CVD events[108] and may also represent a potentially modifiable risk factor.

ISCHEMIC HEART DISEASE

Epidemiology

Ischemic heart disease (IHD) is common in patients with stages 3 to 4 CKD and in dialysis patients. As discussed earlier, in patients aged 45 to 64 years with CKD, the rate of atherosclerotic events was approximately three times higher than the rate seen in patients with normal kidney function,[12] whereas, in the elderly, CVD event rates were approximately double those observed in the general population.[11]

In dialysis patients, rates are also high. A recent analysis of the USRDS Dialysis Morbidity and Mortality Study (DMMS) Wave 2 showed that the incidence of hospitalizations for acute coronary syndromes was 29 per 1000 person years and the incidence of AMI was 19 per 1000 person years.[109] Outcomes for patients with AMI are abysmal with 50% 1-year mortality and an 80% 3-year mortality.[109]

Pathophysiology

Atherosclerosis

Atherosclerosis is a disease of the arterial intima characterized by the presence of plaques and occlusive lesions. The development of atherosclerosis in patients with CKD is multifactorial and begins before kidney failure. Surrogates of atherosclerosis include both intima-media thickness of the carotid wall that is detectable by ultrasound[110,111] and inducible myocardial

ischemia that is detectible by coronary stress tests (Table 9–2).[112] Electron beam computed tomography has emerged as a sensitive method to detect vascular calcification that correlates with atherosclerosis and predicts development of coronary artery disease in the general population.[113] However, it may not be an ideal method to detect atherosclerosis in CKD because it is unable to distinguish between intimal calcifications of atherosclerosis and medial calcification that is common in CKD.[114]

Arteriosclerosis

Arteriosclerosis is characterized by diffuse dilatation and hypertrophy of large arteries with loss of arterial elasticity. In CKD, this occurs in response to both atherogenic factors causing direct vascular injury as well as changes in the hemodynamic burden. Classically, in response to increased blood pressure, tensile stress is maintained by compensatory increase in arterial wall thickness. This pressure overload, discussed earlier in relation to LVH, manifests similarly in the arteries with arterial wall hypertrophy and increased arterial wall to lumen ratio. Concurrently, flow/volume overload manifests with proportional lumen and wall expansion. Overall, in dialysis patients, arteries undergo remodeling characterized by lumen dilatation as well as wall hypertrophy. This is often present at the onset of dialysis, implying development during the course of CKD.[115]

The manifestations of arteriosclerosis in CKD patients include LVH and changes in the blood pressure profile. Specifically, with loss of arterial elasticity, increased systolic blood pressure with or without a decrease in diastolic blood pressure is common. This results in an increased pulse pressure, which itself is an independent risk factor for mortality in dialysis patients.[116,117] The effects of arteriosclerosis are clinically significant and include LVH-related increased myocardial oxygen demand and altered coronary perfusion with subsequent subendocardial ischemia.[115]

Clinical Manifestations

Atherosclerosis and arteriosclerosis manifest with IHD (angina pectoris, myocardial infarctions, and sudden cardiac death), heart failure, and other vascular disease manifestations, including cerebrovascular disease and peripheral vascular disease (Table 9–2). As has been presented above, arteriosclerosis with or without atherosclerosis can cause cardiac remodeling, in particular LVH. Cardiac remodeling can in turn exacerbate arteriosclerosis and atherosclerosis in a vicious circle that results in ischemia, heart failure, and other sequelae of vascular disease.

Ischemic heart disease may be present without significant atherosclerosis. In one study, up to 50% of nondiabetic dialysis patients with symptoms of myocardial ischemia did not have significant large caliber coronary artery disease.[118] The authors hypothesized that the patients may have ischemia secondary to the combined effects of volume overload and LVH causing increased myocardial oxygen demand and small vessel coronary disease, and anemia causing decreased oxygen supply. Notably, this study was conducted in the era prior to erythropoietin use when severe anemia was more prevalent.

Diagnosis

Although IHD is extremely common in CKD, routine screening is not currently recommended in CKD patients in the absence of clinical manifestations of CVD. Available diagnostic tool are similar to those used in the general population and include resting echocardiography for evaluation of cardiac structure and function; exercise and pharmacologic stress testing for detection of perfusion defects; laboratory tests for assessment of both acute ischemia and chronic cardiac risk; and cardiac catheterization for description and possible repair of coronary anatomy.

Echocardiography
Echocardiography is a safe, accurate, and readily available tool for assessment of cardiac structure and function. However, assessment of left ventricular mass may be confounded by volume status and timing of dialysis, potentially leading to inaccuracies.[119–121]

Stress testing
Evaluation of IHD in dialysis patients is dependent on exercise capacity of the patient. Because many dialysis patients are unable to achieve adequate exercise levels for valid stress tests, pharmacologic stress tests are frequently used in this population; both pharmacologic thallium and echocardiographic evaluations are acceptable.[104] One reason for the infrequent use of stress testing not accompanied by an imaging modality is the high prevalence of baseline electrocardiogram abnormalities in the CKD population, making interpretation of changes difficult without accompanying thallium or echocardiographic images.

Angiography
Coronary angiography remains the gold standard for diagnosing flow-limiting lesions that may cause ischemia. Overall, angiography is relatively safe in the CKD population. However, nephrotoxicity secondary to contrast dye remains a major concern, particularly in patients with stages 3 and 4 CKD, as well as in stage 5 CKD patients with residual kidney function. Prevention and treatment of contrast nephropathy is beyond the scope of this chapter. One major advantage to angiography is the opportunity for revascularization concurrent with diagnosis.

Cardiac markers
Some evidence exists that elevated levels of cardiac troponin I may be most specific and sensitive for AMI in CKD,[122] but conclusive evidence is lacking as most studies evaluating this issue have excluded dialysis patients. When markers are initially equivocal, diagnosis of AMI in dialysis patients may be best accomplished by following the trend of levels of troponin I and/or creatine kinase-MB, as a sequential rise and fall in levels of these markers are consistent with acute cardiac damage.[123]

Several cardiac markers may be useful for CVD risk stratification. One study has shown that even minimal elevations in troponin T predicted all-cause mortality in dialysis patients, whereas another study showed that levels of troponin T above 0.10 ng/mL predicted coronary artery disease outcomes.[69,124] Troponin T may be a marker of chronic subendocardial ischemia and may correlate with LVH and other CVD risk factors. The prognostic utility of troponin I is probably more limited in this population.[124,125]

Treatment

Treatment of IHD should not be dependent on kidney function. Numerous studies have shown that dialysis patients with coro-

nary artery disease benefit from appropriate interventions, including coronary artery bypass grafting (CABG) and angioplasty with stenting. As with most procedures, those done on an emergent basis are associated with worse outcomes. Although several studies have compared CABG with percutaneous transluminal coronary angioplasty (PTCA) with or without stent placement, none have been randomized trials. Results of observational studies are difficult to interpret given the inherent biases associated with patient selection for coronary interventions. The largest of these trials in dialysis utilized the USRDS database and noted better long-term survival for CABG and better short-term survival for PTCA.[58] Meanwhile, an investigation of admissions over an 8-year period of patients with stages 3 to 5 CKD for treatment of AMI revealed significantly improved survival in adjusted analysis for those treated with PTCA versus CABG. In this study, patients receiving either PTCA or CABG did better than those managed only medically.[126]

Chronic therapy for IHD involves management of both traditional and nontraditional risk factors described earlier. Although there are few trials of pharmacologic therapy for LVH, diabetes management and therapy of dyslipidemia in CKD, the management of hypertension has been more extensively investigated.

In studies of both diabetic and nondiabetic patients, ACE inhibitors have been shown to retard progression of kidney disease.[44,46] This has been most marked in patients with proteinuria. Additionally, in a subset of the HOPE trial examining patients with stage 3 to 4 CKD and at least one other CVD risk factor, ACE inhibitor therapy safely and effectively reduced cardiovascular outcomes.[14] ARBs have also been shown to reduce the progression of kidney disease but have not been evaluated sufficiently as CVD protective factors in CKD.[45,122,127] Therefore, whenever tolerated, ACE inhibitors remain a good option for prevention of CVD in patients with CKD.

In observational studies, β-blockers, ACE inhibitors, and also aspirin have all been shown to confer benefit in patients with stages 3 to 5 CKD and IHD.[8,9,128–130] Importantly, all of these studies demonstrated that patients with CKD were underprescribed these therapies, despite the apparent benefits.

There is a relatively small body of evidence focusing on the impact of treating nontraditional risk factors as part of a therapeutic regimen for patients with CKD and IHD. In particular, several studies have investigated treatment of anemia in CVD. In a large trial of dialysis patients with either HF or IHD, normalization of hematocrit with recombinant human erythropoietin resulted in a trend toward increased adverse events in the normal hematocrit arm.[131] Current trials are therefore evaluating whether treatment of anemia in the earlier stages of CKD may decrease CVD outcomes. With regard to other nontraditional risk factors, there are few trial data with clinical outcomes. As mentioned earlier, only with regard to oxidant stress have there been randomized trials showing a reduction in clinical events.[102,103]

HEART FAILURE

Despite the lack of a universally accepted definition, heart failure (HF) is generally characterized by volume overload, pulmonary edema, and dyspnea. Heart failure may occur as a result of left ventricular systolic dysfunction or diastolic dysfunction in which the left ventricle has a normal ejection fraction but impaired filling. Diastolic dysfunction is often associated with left ventricular hypertrophy and systemic hypertension. Systolic dysfunction often results from ischemic disease or hypertensive cardiomyopathy.

Diagnosis

Although the diagnosis of HF is clinical, echocardiography is invaluable for diagnosing both systolic and diastolic dysfunction. Several novel blood tests, including atrial natriuretic peptide and, in particular, brain natriuretic peptide, may correlate with cardiac function and predict future CVD events; these have not yet gained wide clinical use in patients with CKD.[132–134]

Treatment

Initial therapy of HF differs by stages of CKD, as loop diuretics remain a mainstay of therapy in pre-dialysis patients, whereas acute fluid overload in dialysis patients is treated with ultrafiltration. Chronic therapy for HF has not been adequately studied so most recommendations are either extrapolated from the general population or are based on smaller trials.

ACE inhibitors are of known benefit in the general population for treatment of HF with systolic dysfunction. In stages 3 and 4 CKD as well as in dialysis patients there is no reason to suspect that ACE inhibitors would not have a similar benefit. Although there are no large, randomized, controlled trials in CKD, some observational studies do suggest a benefit of ACE inhibitors independent of their blood pressure lowering effects in dialysis patients.[135] In the general population, ARBs remain a second line therapy to ACE inhibitors for HF, and this can likely be extrapolated to patients with CKD.

β-Blockers, another mainstay of HF therapy in the general population, are also beneficial in patients with CKD. A recent randomized trial in dialysis patients demonstrated that carvedilol reduced mortality in patients with left ventricular dysfunction.[129]

Cardiac glycosides are frequently used in HF in the general population where it has been shown that they improve morbidity but not mortality.[136] Although there are no specific studies of digoxin in CKD, this medication should be utilized judiciously with careful attention to dosage and drug levels, and, in dialysis patients, dialysate potassium concentration.

PERICARDIAL DISEASE

Epidemiology

Pericardial disease in CKD is generally associated with stage 5 CKD. It most commonly manifests as acute uremic or dialysis-associated pericarditis although chronic constrictive pericarditis may also be seen. Most estimates of the clinical incidence of pericardial disease in dialysis patients are less than 20%.[137]

Uremic pericarditis describes patients who develop clinical manifestations of pericarditis prior to or within 8 weeks of initiation of kidney replacement therapy. With the advent of modern dialysis, uremic pericarditis is exceedingly rare but remains an indication for and responds extremely well to initiation of dialysis.[138]

Dialysis-associated pericarditis by definition occurs after a patient is stabilized on dialysis. The precise etiology is

unknown but may be related to inadequate dialysis and volume overload, although heparin use has been implicated.

Clinical Manifestations and Diagnosis

Pericarditis may be accompanied by nonspecific symptoms including chest pain, fever, chills, malaise, dyspnea, and cough. Physical examination may reveal a pericardial friction rub. When hemodynamically significant, pericardial disease accompanied by an effusion may be characterized by hypotension, particularly during the hemodialysis procedure.[139] Although other expected signs of pericardial effusion may be present, dialysis-related pericarditis often does not manifest with the classical electrocardiogram finding of diffuse ST segment elevation because there may only be minimal inflammation of the epicardium.[140] Echocardiography is helpful to confirm pericarditis in dialysis patients; however, effusions may be absent in patients who have adhesive, noneffusive pericarditis.

Treatment

Small, asymptomatic pericardial effusions are fairly common in dialysis patients and require no acute intervention, whereas larger effusions present a risk for tamponade. Intensification of hemodialysis is the mainstay of therapy but is only effective approximately 50% of the time.[138] Traditionally, heparin has been avoided during dialysis out of concern for hemorrhagic tamponade. Adjuvant medical therapies, including oral and parenteral glucocorticoids and nonsteroidal anti-inflammatory medications, have generally not been effective. For patients with hemodynamic instability, treatment consists of emergent drainage of the pericardial effusion. This is generally accomplished by pericardiocentesis or pericardiotomy with or without pericardiostomy for the instillation of long-acting, nonabsorbable glucocorticoids.[141]

VALVULAR DISEASE

Endocarditis

Epidemiology

Although unusual in the nonhemodialysis CKD population, infective endocarditis is a relatively common complication of hemodialysis when compared to rates in the general population.[142] This likely reflects several factors, including the relatively high incidence of bacteremia, common use of dialysis catheters, and the high prevalence of preexisting valvular abnormalities. Patients using catheters for hemodialysis access, more so than patients with AV grafts and fistulae, are prone to infection with subsequent hematogenous spread of bacteria to valves.[143–145] The vast majority of endocarditis in hemodialysis patients is secondary to gram-positive organisms, with *Staphylococcus aureus* predominating.[146–148]

Clinical Manifestations and Diagnosis

Dialysis patients with endocarditis usually have fever, murmurs, leukocytosis, and septic emboli may also be common. The mitral valve is the most commonly affected, followed by the aortic valve.[146–148] Diagnosis is chiefly dependent on positive blood cultures and clinical suspicion. Transthoracic and/or transesophageal echocardiography may be critical to making the diagnosis.

Treatment

Treatment of endocarditis begins with appropriate antibiotic therapy. Surgical intervention may also be appropriate, and indications for surgery are the same as in the general population: progressive valvular destruction, progressive heart failure, recurrent systemic emboli, and failure to respond to appropriate antibiotic therapy.

Even with therapy, survival is often poor, with case series showing 30% mortality during the initial hospitalization and 1-year mortality over 50%.[146–149] Factors associated with mortality include hypoalbuminemia, involvement of multiple valves, and severe valvular insufficiency. In one study, 30-day survival among patients who had surgery was 80% while it was only 47% among those managed medically.[147] In another small study, 50% (3/6) of patients who underwent surgery were alive at 1 year.[146] Although these studies are observational and not designed to compare surgical versus medical therapy, an important inference to be made is that hemodialysis patients with endocarditis should be considered surgical candidates if they have indications.

Prevention is, however, the best treatment for endocarditis in dialysis patients. Prevention is accomplished by complete treatment of known hematogenous infections and avoidance of access infection by use of sterile techniques and early placement and use of noncatheter-based dialysis access.

Mitral Annular Calcification

Mitral annular calcification may occur in 30% to 50% of patients on dialysis and is also common in patients during the earlier stages of CKD.[150, 151] It is recognized on echocardiography as a uniform echodense rigid band located near the base of the posterior mitral leaflet and may progressively involve the posterior leaflet. The pathogenesis of mitral calcification may be linked to altered calcium and phosphate metabolism.[151,152] Serious complications can include conduction abnormalities,[153] as well as embolic phenomena, mitral valve disease, and an increased risk of endocarditis.

Aortic Calcification and Stenosis

Epidemiology

Aortic valve calcification is the most common valvular abnormality in dialysis patients, occurring in 28% to 55% of patients. This prevalence is similar to that seen in the general population; however, dialysis patients experience aortic valve calcification 10 to 20 years earlier than the general population.[154] Age is the most significant risk factor for aortic valve calcification,[153] although elevated parathyroid hormone levels, elevated calcium and/or phosphorus levels, and dialysis vintage also appear to play a role.[155] Aortic valve calcification may itself pose a CVD risk beyond the increased risk of endocarditis; one study of elderly non-dialysis patients showed an independent association between aortic valve calcification and CVD outcomes.[156]

The most significant hazard associated with aortic valve calcification is the potential for development of progressive

immobilization of the aortic leaflets, eventually restricting flow. Aortic stenosis exists when the valve leaflets thicken to the extent that commissural fusion can no longer occur and a pressure gradient develops across the aortic valve. In one study of dialysis patients, the estimated incidence of symptomatic aortic stenosis was 3.3% per year.[155] Progression of aortic valve disease to aortic stenosis in dialysis patients appears more rapid than that in the general population.[157] Very little evidence exists in the non-dialysis CKD population as to the prevalence and progression of valvular abnormalities.

Clinical Manifestations of Aortic Stenosis

Angina, heart failure, and syncope are the cardinal symptoms of critical aortic stenosis. Clinical evidence of aortic stenosis may be more readily evident in dialysis patients as they may have more frequent episodes of intradialytic hypotension, particularly as ultrafiltration can rapidly reduce preload. Frequent monitoring with echocardiography is important as dialysis patients may have very rapid progression of aortic valve disease.[154]

Treatment

Treatment of aortic stenosis is multifaceted, encompassing prevention of progression, prevention of endocarditis, and eventual repair of the valve. Management of calcium and phosphorus abnormalities are likely important in preventing worsening of aortic stenosis, although this has not been proven. Management of hypertension may also be important.

Valve replacement is the therapy of choice for critical aortic stenosis, and the timing of surgery is dependent on individual patient characteristics. Surgery should be performed before left ventricular contractility becomes diminished. There currently is no consensus for a benefit of either prosthetic versus bioprosthetic valves in dialysis patients.[158] The mortality rate for valve replacement is, however, much higher than in the general population (17% operative mortality for aortic valve replacement in dialysis patients, 23% for mitral valve replacement, 25% for aortic valve replacement and CABG, and 37% for mitral valve replacement and CABG).[159] However, in most cases the prognosis is worse if clinically indicated surgery is not performed or if emergent rather than elective surgery is performed.[150]

ARRHYTHMIAS AND SUDDEN CARDIAC DEATH IN CKD

Patients with CKD are at high risk for arrhythmia due to a high prevalence of LVH, HF, IHD, atrial enlargement, and valvular abnormalities. Hemodialysis patients are also exposed to rapid shifts in ions, including potassium, calcium, hydrogen, and magnesium.

Atrial Fibrillation

Both atrial and ventricular arrhythmias are common in dialysis patients. Mirroring the general population, atrial fibrillation is the most common of these arrhythmias, with an incidence of over 10%.[160] In the USRDS DMMS Wave 2 cohort, 123 out of 3374 patients (3.6%) were hospitalized with a primary diagnosis of atrial fibrillation (12.5 hospitalizations per 1000 person years).[161]

The major complications of atrial fibrillation include loss of the "atrial kick" and cardiac synchronicity leading to diminished cardiac function and occurrence of thromboembolic phenomena. Very little data exist as to how common thromboembolism is in dialysis patients with atrial fibrillation, although one small observational study showed a 1-year incidence of nearly 35%.[160] Optimal management involves rate control with or without restoration of sinus rhythm, although patients with symptoms may benefit from a return to sinus rhythm.[162–164] β-Blockers and calcium channel blockers are useful for rate control, whereas amiodarone is useful for both slowing the rate as well as for chemical cardioversion. Anticoagulation with warfarin has not been prospectively studied in dialysis patients, although analysis of the DMMS Wave 2 database showed a survival benefit for patients who were on warfarin at the time of hospitalization for atrial fibrillation.[161] At this time, the benefits and risks of anticoagulation in dialysis patients should be considered on an individual patient basis.

Ventricular Arrhythmias and Sudden Death

Ventricular arrhythmias and ectopy are also common in CKD. There are currently no data indicating that cardiac management of patients prone to arrhythmia should be any different than in the general population.

Identified arrhythmias and cardiac arrest of unknown cause account for 60% of cardiac deaths in dialysis patients.[165] During the first year of dialysis, the rate of cardiac arrest is 93 events per 1000 patient years; this nearly doubles by dialysis year 4 such that 43% of dialysis patients have had cardiac arrest by this time. Thirty-day survival after cardiac arrest is only 32% and 1-year survival 15%.

Potential strategies to reduce the risk of fatal cardiac arrhythmias include careful attention to fluid and electrolyte shifts. Other potential interventions may include routine use of β-blockers, although this has not been investigated. Finally, studies of the appropriate use of implantable defibrillators in dialysis patients are needed.

Chapter 10

Management of the Diabetic End-Stage Renal Disease (ESRD) Patient: Dialysis and Transplantation

Kathryn Tuohy, M.D. • Mark E. Williams, M.D., F.A.C.P.

In 2001, the prevalence of adults in the United States diagnosed with diabetes was 7.9% (16.7 million Americans) while 35% of diabetics are estimated to remain undiagnosed. This represents an increase of 61% since 1990 (prevalence 4.9%) in the number of Americans diagnosed with diabetes, which is thought to be largely due to a concurrent increase in obesity and a sedentary lifestyle. African-Americans had the highest rate of diagnosed diabetes among all races, and adults with less than a high-school education were highest among levels of education. Of Americans over age 60, 15% had a diagnosis of diabetes.[1] The prevalent number of people with insulin-dependent (type I), and non–insulin-dependent (type II) diabetes has increased for three decades as a result of both improved survival and the aging of the population, as well as the increased prevalence of obesity. Approximately one million new cases of diabetes are diagnosed each year in patients over age 20 in the United States. Recent data estimate the lifetime risk of developing diabetes for individuals born in 2000 in the United States is approximately 35%.[2] Type I diabetes accounts for 5% to 10%, and type II diabetes accounts for 90% to 95% of all diagnosed cases of diabetes.[3] About 90% of diabetic patients older than 20 years have non–insulin-dependent diabetes. A recent report states that 30% of new cases of diabetes diagnosed in North Americans in the second decade of life are also type II.[4]

Diabetic patients are three times more likely than nondiabetic patients to be hospitalized. Adult patients with complications are the most frequently hospitalized.[5] Diabetic patients may account for up to 10% of bed days for nonobstetric, nonpsychiatric admissions,[6] and their average length of stay is longer than that of nondiabetic patients.[7] Health care costs directly attributable to diabetes care were estimated to be $91.8 billion in 2002. This does not include an additional estimated $40.2 billion in indirect costs (disability, work loss, premature mortality).[3]

Risk of death in patients with diabetes is twice that of patients without diabetes, and diabetes is the sixth leading cause of death in the United States.[3] Three quarters of deaths from type I diabetes are associated with renal failure. Despite modest advances in slowing its progression[8] and ongoing research into its primary prevention, diabetic nephropathy accounts for a larger proportion than ever of cases of end-stage renal disease (ESRD) in the United States (Figure 10–1). Projections indicate that by 2006 the incident number of patients with diabetes as the primary diagnosis for ESRD will equal all other causes, and by 2017 the prevalence will also be equal.[9] Notably, however, the growth in incident rates of ESRD due to diabetes has slowed in recent years, with the

largest growth rates of diabetes as the primary cause of ESRD occurring in the Eastern, Southern, and Gulf Coast states. Also, although diabetes continues to be the most common cause of ESRD across all racial groups, it accounts for far higher rates among blacks, Hispanics, and Native Americans than in whites.[10]

Primary risk reduction was achieved with intensive insulin therapy in the Diabetes Care and Complications Trial (DCCT),[11] resulting in both a delay in onset and a decrease in complications of diabetic nephropathy. Improvements in patients at risk of developing ESRD have included the use of angiotensin-converting enzyme (ACE) inhibitors[12] and angiotensin receptor blockers (ARBs),[13] tight blood pressure control,[14] and improved glycemic control.[15,16] Between 1991 and 2001, hospital admission rates fell slightly for diabetic patients on dialysis and fell 13% for diabetic patients with a transplanted kidney. Also, diabetic patient survival has improved 17.3% on hemodialysis and 28% on peritoneal dialysis for the period of 1992 to 1996 as compared to 1987 to 1991.[9] In both diabetics and nondiabetics initiating dialysis, a higher glomerular filtration rate (GFR) predicts a higher likelihood of hospitalization, possibly reflecting a greater presence of comorbidities among patients who are pushed to start dialysis earlier.[10] The epidemic of diabetic ESRD appears to result from an increased prevalence of non–insulin-dependent diabetic patients, longer survival of all diabetic patients, and greater acceptance of ESRD treatment.[17]

Summary statistics from the 2002 U.S. Renal Data System (USRDS) report indicated that 110,041 diabetic patients were on dialysis and 21,132 had undergone transplantation by year's end of 2000, which is 34.6% of the 378,862 ESRD patients receiving Medicare benefits.[10] About 41,500 diabetic patients (44% of all new patients) initiated treatment that year. Approximately half were 65 years or older; less than 1% was younger than 20 years. Diabetic patients with ESRD now have a mean age of 64 years,[10] and about two-thirds have type II disease.[18] They make up the majority of diabetic patients on dialysis in some centers. Misclassification of the type of diabetes is common, however. For example, when clinical criteria (age, need for insulin, absence of ketoacidosis, body mass) are used, up to one-third may be misclassified as having type I disease, using C-peptide values as the gold standard. As a result, patients with type II diabetes may be underrepresented.[19]

Diabetic ESRD reflects the demographics of diabetes itself.[20] About 70% of diabetic patients with ESRD are white, and 30% are black.[21] Whereas the proportion of ESRD cases attributed to diabetes is higher in blacks,[10] type I diabetes is the predominant cause of ESRD in whites, and type II diabetes

is the predominant cause in blacks. The prevalence of diabetes in the ESRD population in 1-year survivors on dialysis regardless of the primary cause of ESRD is quite high in the United States; 80% of Native Americans, 73% of Hispanics, 61% of Asians, 59% of blacks, and 58% of whites have diabetes at 1-year survival on dialysis.[10]

In this chapter, renal replacement options for the uremic diabetic patient are compared (Table 10–1). In the United States, diabetic patients are more likely than others to be managed on chronic hemodialysis and less likely to have a functioning transplant (Figure 10–2). For all ESRD modalities, diabetic patients are considerably costlier to treat than are nondiabetic patients. Compared with an average cost in 2000 of $67,600 annually for all patients, diabetic patients cost about $3500 more per year. The annual cost in 2000 for a diabetic patient on hemodialysis

(HD) was about $72,000, which was $6500 more than that for a nondiabetic. The annual cost for a diabetic patient on peritoneal dialysis (PD) was about $61,000, which was $9200 more than that for a nondiabetic. During the last 10 years, the percentage of dialysis patients covered solely by Medicare has decreased.[10] In 2001, Medicare expenditures accounted for 63% of the total ESRD care costs, and patients with diabetes consumed the greatest amount of resources (Figure 10–3).[9]

Diabetic patients with ESRD are also at greatest risk for complications. Eighty-five percent have comorbid conditions. After 1-year of survival on dialysis, 38% of diabetics have some cardiovascular morbidity, compared with 30% of nondiabetics.[10] Whereas all uremic diabetic patients suffer from two chronic diseases, patients with type II diabetes are generally older and have more advanced coronary disease but
Figure 10–1   Point prevalence counts of patients with end-stage renal disease (ESRD) who were receiving Medicare benefits and who were alive on December 31, by treatment modality and year, 1993–2001. **A,** total ESRD population; **B,** diabetic ESRD population. (*ESRD,* all treatment modalities; *HD,* hemodialysis; *TX,* transplantation; *PD,* peritoneal dialysis.) A steady increase in total number of patients treated, and in the number treated with HD and TX, is shown, while the number of patients treated with PD has remained relatively stable. Diabetic ESRD continues to increase at a higher rate than other primary causes of renal failure. (Modified from U.S. Renal Data System: USRDS 2003 Annual Data Report. Bethesda, MD, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2003.)

Table 10–1   Renal Replacement Options for Uremic Diabetic Patients

	Hemodialysis	Peritoneal Dialysis	Transplantation
Advantages	Efficient	Better tolerated	Superior survival
	Closer medical surveillance	Easy access	Improved quality of life
	Ease of EPO administration	Cardiovascular tolerance	Improved nutrition
	Less protein loss	Intraperitoneal insulin	Better rehabilitation
	IDPN available	Heparin use not necessary	Stable retinopathy
		Potassium control	Cost savings
		Less hypoglycemia	
		Less hypertension	
		IDPN available	
Disadvantages	Vascular access necessary	Peritonitis	Immunosuppression
	Inconvenient	Must be trainable	Poor glycemic control
	Cardiac stress	Time commitment	No improvement in
	Hypotension	Technical failure	cardiovascular mortality
	Hyperkalemia	Withdrawal	Fractures
	Hypoglycemia	Orthostatic hypotension	Infections
		More gastrointestinal complaints	

EPO, erythropoietin; *IDPN,* intradialytic parenteral nutrition.

better preserved vision than patients with type I disease. Detailed recommendations are available on the standards of medical care for diabetes.[22] Only a multidisciplinary team, including a nephrologist, vascular surgeon, cardiologist, ophthalmologist, podiatrist, nutrition expert, and transplantation specialist, can provide these patients with optimal management as renal failure progresses to ESRD. New complexities then emerge in the management strategy: insulin requirements decrease, retinopathy progresses, hypertension[23] and fluid retention worsen, and gastroparesis becomes refractory to medication. When ESRD is reached, complications are severe in half of patients, one third are blind, half have gastroparesis, and one in six have had a myocardial infarction. Other

uremic problems are worsened by diabetes, such as nausea, vomiting, impotence, neuropathy, and vascular disease.

Although the optimal time to initiate dialysis has not been determined, dialysis should be initiated earlier in uremic diabetic patients to avoid life-threatening events[24] and accelerated retinopathy. Diabetic patients may have lower serum creatinine levels than nondiabetic patients but similar renal function by other parameters.[25] However, diabetics have higher GFRs at the time of initiation of dialysis than the overall population. This likely reflects a higher degree of comorbidity in diabetics necessitating earlier initiation of renal replacement therapy. A higher degree of comorbidity in patients initiating dialysis with a higher GFR is evidenced by the fact that the higher the GFR at the initiation of dialysis, the greater the probability of hospitalization and death.[10] Subsequent treatment goals include preserving vascular access, controlling hyperglycemia, preventing cardiac mortality, maintaining vision, avoiding limb amputation, and preventing malnutrition (Table 10–2).

HEMODIALYSIS

Vascular Access

Medicare spending for vascular access procedures during 2000 totaled nearly $200 million, almost doubling from $104 million in 1991. Although the number of vascular access procedures has increased fourfold between 1991 and 2000, these procedures are now being performed in the outpatient instead of the inpatient setting, resulting in a significant decrease in cost per procedure. Since 1991, arteriovenous fistula, synthetic graft, and catheter insertion costs have dropped 60%, 50%, and 50%, respectively, while the cost of vascular access complications have dropped almost 200%. The number of vascular access hospitalizations has declined 25% between 1991 and 2000, whereas the overall rates of hospitalizations for patients with ESRD has remained nearly the same, due to increased rates of hospitalization for circulatory and respiratory problems.[10] Suboptimal access has always been a problem in the total management of uremic diabetic patients and should be termed the *diabetic access syndrome*. Diabetic patients have the highest rate of access-related complications,[26–28] and access dysfunction is their most common problem. Less than half of diabetic patients have a permanent access placed or attempted before developing ESRD. Creating and preserving vascular access is one of the basic goals in management of the uremic diabetic patient.[29]

The diabetic access syndrome begins long before ESRD develops. As with nondiabetic patients, only about one-third of diabetic patients have been told to preserve their forearm vein for a permanent access.[30] The arterial inflow is usually inadequate because of atherosclerosis, and outflow veins are often scarred by phlebotomy or indwelling catheters.[31] Arteriovenous fistulas as initial permanent access have a higher primary failure rate in diabetic patients; 30% to 40% fail to develop and are never used.[32] A recent study reported an 85% greater likelihood of primary failure and a relative risk of 2.38% for ultimate failure of a native fistula in diabetics.[33] Alternative vessels may also be unsuitable for native fistulas. Distal arm vessels, the preferred site, may be fragile because of medial calcification. Because upper extremity fistulas are less

Table 10–2 Problem Evaluation in Diabetic Patients with End-Stage Renal Disease

Problem	Evaluation
Vascular access	Preservation of vasculature and early assessment for native fistula
Glycemic control	Hemoglobin A_{1c}, home glucose monitoring
Angina, myocardial infarction	Exercise treadmill test, P-thallium, echocardiography, catheterization
Visual impairment	Ophthalmic evaluation
Foot ulcers	Podiatric evaluation
Peripheral vascular disease, limb amputation	Doppler flow studies
Gastroparesis	Gastric-emptying study
Neuropathic problems	Electromyogram, neurology consultation
Malnutrition	Serum albumin level, dietary counseling, physical examination

prone to infection and vascular steal is less critical, an alternative is the brachiocephalic fistula.[34] Proximal radial artery to antebrachial vein may serve as a good alternative site even in diabetics.[35] Routine use of preoperative vein mapping is thought to enhance the efficacy of native fistulas.[36] Nonetheless, a minority of newly treated diabetic patients with ESRD has a satisfactory native vessel in place at initiation of dialysis. Other modes of hemoaccess, such as long-term catheters, upper extremity grafts, lower extremity grafts, or even conversion to peritoneal dialysis, may be needed.

Diabetic patients, especially older patients, are more likely to require temporary catheters or "permanent" tunneled venous catheters. Cuffed, dual-lumen tunneled venous catheters may provide long-term permanent access. In one center, catheter failure was a result of thrombosis or inadequate flow in about one third of patients and of infection in about one fourth of patients, most of whom had diabetes. The 6-month catheter survival rate was 53%. The major limiting factors in long-term catheter survival are infection and thrombosis.[37] Diabetes is an independent predictor of cuffed dialysis catheter failure.[38]

The risk of catheter-related infection is increased in diabetic patients, and *Staphylococcus aureus* nasal carriage may be more prevalent.[39] Infection may result from a break in sterile technique or poor exit site care, or rarely from injection of illicit drugs by the patient. Most cases of *S. aureus* bacteremia in hospitalized patients are associated with infections transmitted through venous catheters.[40] Infections are more common with temporary rather than cuffed hemodialysis catheters and are least common with arteriovenous fistulas or synthetic grafts.[41] Standard therapy of dialysis catheter-related bacteremia historically has been catheter removal and administration of systemic antibiotics, followed by placement of a new catheter at an alternate site. To avoid loss of potential future access sites, the standard of care is evolving toward guidewire catheter exchange at the same venous site, with a course of antibiotics, as long as there is no evidence of an overt subcutaneous tunnel infection,[42] or sepsis,[43] including staphylococcal, gram-negative, and yeast infections.

The risk of catheter-related thrombosis is also increased. Some data support the use of low-dose warfarin anticoagulation for permanent central venous catheters.[44] Catheter obstruction may require a venous stripping procedure or may be overcome by the intravenous administration of a thrombolytic agent, such as recombinant tissue plasminogen

activator.[45,46] The danger of iatrogenic bleeding, such as retinal hemorrhage, is increased in patients with diabetes. Alternatively, a fibrin stripping procedure in interventional radiology may be helpful in restoring function in a poorly functioning catheter.[47]

Diabetic patients have been more likely to require a synthetic graft as primary access. In a 1996 report, diabetic patients were two to three times more likely to receive a graft than a fistula and were twice as likely to require a graft as nondiabetic patients.[48] However, recent data show that there is little difference in the rates of use of fistulas in diabetics versus nondiabetics, with fistulas being used in about 28% of new patient initiating hemodialysis in 2000. Overall graft use has decreased 15%, fistula use has increased 10%, and catheter use has increased 25% in the hemodialysis population, with increasing access salvage with angioplasty, stent, and surgical revision. It is not clear whether these patterns also hold true for the diabetic dialysis population specifically.[9] Polytetrafluoroethylene has become the material most frequently chosen but remains inferior to the arteriovenous fistula even when study groups are comparable in age, diabetic status, cardiovascular status, smoking status, and degree of hypertension.[49,50] Grafts have slightly better outcomes during the first 6 months than fistulas, but fistulas subsequently perform better. Uncontrolled studies show a mean patency duration of less than 2 years, about two-thirds the duration of fistulas. Compared with nondiabetic patients, hemodialysis graft survival is decreased in diabetic patients, and complications occur earlier.[28,51]

The most common complications of grafts are thrombosis, infection, and distal ischemia. The rates of thrombosis of synthetic grafts are high in dialysis patients in general, but the risks of thrombosis in hemodialysis patients with diabetes appear greater. According to 1997 USRDS data, of patients in need of a procedure to restore permanent access, those with diabetes were more likely to have surgical declotting and less likely to have angioplasty with thrombolysis.[30] Neointimal hyperplasia, the response to vascular injury associated with spontaneous vascular thrombosis,[52] occurs earlier and more extensively in the diabetic population.[53] Synthetic grafts activate platelets, and patients whose platelets aggregate more readily (such as those with diabetes) are at risk of graft thrombosis. Other diabetic factors that might worsen the process of vascular injury are unclear. Diabetic vasculopathy is an endothelial dysfunction characterized by basement membrane thickening and endothelial cell proliferation.[54] Arterial angioplasty procedures

result in intimal hyperplasia, with smooth muscle cell proliferation and a matrix of connective tissue elements.[55] Diabetic patients are at increased risk of re-stenosis after coronary angioplasty.[56] The addition of intraluminal stent placement has decreased the risk of coronary artery re-stenosis,[57,58] however, it is not clear whether this is true in diabetics. Most cases of venous stenosis underlying graft thromboses occur at or near the venous anastomosis.[59] The hyperplastic response histologically includes collagen and proteoglycan. New techniques including drug-eluting stents are showing promise in decreasing in-stent coronary re-stenosis.[60]

Graft infection rates are increased fourfold compared with fistulas (see later).

Patients with diabetes are also more likely to develop arterial steal complications,[61] with ischemic pain or gangrene in the operated limb. Compromised vessels and microcirculation lead to necrosis and painful digital ulcerations. Tapered grafts do not appear to lower the risk of ischemia and, in fact, may reduce graft patency. Less common than overt steal, but also disabling, is ischemic monomelic neuropathy,[62] in which ischemia insufficient to produce finger ulcerations nonetheless causes severe nerve injury. In cases of arterial steal, noninvasive vascular studies, nerve conduction studies, and arteriography may be required. Lower extremity femoral artery–to–saphenous vein grafts are placed only as a last resort. Their patency rate is about 50% at 2 years.[63]

Many factors contribute to the low rate in the use of arteriovenous fistulas and to inferior access outcomes in diabetic patients. In addition to the factors described previously, they include late presentation or referral to the nephrologist[64] (as when suitability for dialysis is uncertain), indecision about the preferred dialysis modality, and rapid terminal loss of renal function. Aggressive diuresis for volume overload and contrast nephropathy commonly result in the latter.

Improving long-term access patency begins with increasing the number of native fistulas. More initial brachial fistula placements may be necessary.[65] Although diabetic patients are more likely to be viewed as poor candidates for a fistula, initial surgical evaluation should occur early enough to permit long maturation times of 4 months or more.[66] Surgical revisions, such as ligation of runoff vessels or bypass to improve arterial flow, may be required. The role of antiplatelet therapy in preventing dialysis graft thrombosis has not been proven, although it is used routinely for stroke, myocardial infarction, and maintenance of arterial graft patency.[67] Dipyridamole, whose action on platelets complements aspirin, has no added benefit in peripheral vascular disease. However, one prospective nonrandomized dialysis study showed that dipyridamole was beneficial in preventing thrombosis in newly placed grafts, whereas aspirin was not.[68] Diabetic patients were not separately analyzed in this study. A recent retrospective analysis suggested improved primary graft patency with the use of calcium channel blockers, improved secondary graft patency with aspirin, improved secondary fistula patency with angiotensin converting enzyme (ACE) inhibitors, and worse primary graft patency in patients receiving warfarin therapy.[69] Aspirin in routine doses appears to be safe in patients with diabetes, with no increased risk of vitreous or preretinal hemorrhage.[70] Because of increased platelet turnover in diabetic patients, at least 325 mg may be required.[71] Warfarin, in low doses, has been found to be ineffective in prolonging graft survival and was associated with increase in bleeding complica

tions.[72] Although thrombolysis (tissue plasminogen activator with or without mechanical thrombolysis) has been effective in salvaging both fistulas and grafts,[73,74] no separate analysis of thrombolysis in diabetic patients has been done. One study found that recombinant erythropoietin use was associated with a mean increase in hematocrit from 23% to 34% and a 10% improvement in graft patency without increased risk of venous thrombosis.[75] Prospective monitoring of access flow rates in the dialysis unit on a routine basis is considered a reasonable way to monitor for impending access failure as well as response to therapy.[76]

Glycemic Control

Maintenance of glycemic control is a priority in diabetic patients with ESRD. An analysis of the DCCT concluded that, for eligible patients, intensive diabetes therapy results in improved quality and length of life.[77] Another clinical study of type I and type II diabetes further supported the DCCT recommendations to slow the progression of nephropathy.[78] Goals for glycemic control recently published by the American Diabetes Association are: (1) preprandial plasma glucose, 90 to 130 mg/dL, (2) 1 to 2 hours postprandial plasma glucose less than 180 mg/dL, and (3) hemoglobin A_{1C} less than 7.0%. In patients who are meeting preprandial targets, but not hemoglobin A_{1C} targets, reducing postprandial plasma glucose may improve A_{1C} values.[22] Among the necessary tasks of the nephrologist as primary care provider of the uremic diabetic patient is achieving glycemic control.[79] This can retard complications of microvascular disease, prevent catabolism, minimize infection, and limit hyperkalemia.[80] It may also be associated with shorter hospitalizations, improved gastroparesis and orthostatic hypotension, decreased incidence of heart failure and myocardial infarction, and higher serum albumin levels.[81]

The signs and symptoms of hyperglycemia are modified in dialyzed patients. Consequences of hyperglycemia in hemodialyzed patients are listed in Table 10–3. Excessive thirst owing to hyperglycemia results in excessive interdialytic weight gain. Interdialytic weight gain correlated inversely with glycemic control in one study.[82] Pulmonary edema and hypertension may also occur. Severe hyperosmolality may result in hyperkalemia.[83] Ketoacidosis is less common. Shifts in serum osmolality secondary to marked variation in blood glucose levels have been implicated in the development of central pontine myelinolysis. The demyelinating disorder occurred in a diabetic hemodialysis patient without significant changes in the serum sodium concentration.[84] Anorexia, nausea, vomiting, weakness, worsened gastroparesis, and altered mental status may also occur. The risk of infection may increase as a conse

Table 10–3 Consequences of Hyperglycemia

Anorexia, nausea, vomiting, weakness
Increased risk of infection

quence of hyperglycemia. Because osmotic diuresis does not occur, volume depletion is not to be expected (unlike in patients with good renal function), and excessive volume replacement is contraindicated. Sustained severe hyperglycemia may produce only nonspecific symptoms.[85] In more modest forms of diabetes, hyperglycemia[86] may be latent but still potentially important as a contributor to complications.

Insulin dosing and glucoregulation are more complex in dialyzed diabetic patients.[87] In renal failure, reduced insulin degradation prolongs the duration of exogenous insulin, leading to decreased insulin requirements, particularly when insulin sensitivity is improved by dialysis. Hemodialysis improves glucose tolerance.[87] Smaller insulin doses suffice, and oral agents or even insulin may be discontinued in some patients. Metformin should be avoided in ESRD, but rosiglitazone and pioglitazone are hepatically cleared and can be used without dose adjustment. Glimepiride and glyburide should be used with caution in patients with ESRD. Glipizide is metabolized by the liver and is generally considered the sulfonylurea of choice in ESRD. Although repaglinide should not be used in ESRD, nateglinide can be used. Acarbose is also contraindicated in ESRD.[88] If caloric intake improves and weight increases on dialysis, insulin needs may increase.

Although dosing must be individualized, most patients do best with twice-daily dosing of intermediate (for basal requirements) and regular (for meal coverage) insulin. Long acting insulin (ultralente, glargine) should be used with caution in ESRD. Total daily doses are modest. The relative proportions of the insulin vary. Malnourished patients may do well with once-daily dosing. For simplicity, other patients may prefer a fixed 70:30 ratio of insulin. Some selected patients are willing to intensify their therapy with multiple injections. Of note, one report described proximal calciphylaxis in four cases of ESRD diabetes and suggested that sites of insulin injection led to the ischemic tissue necrosis.[89]

Home and dialysis unit glucose monitoring should be done frequently. Measurement of glycohemoglobin, which best reflects glycemic control over the previous 6- to 10-week period, has not been well standardized in uremic patients. A falsely high value of chromatographically measured glycosylated hemoglobin in uremia may result from an increase in carbamylated hemoglobin.[90] Affinity chromatography and immunoassays avoid analytic interference. Hemoglobin A_{1C} is the major component of glycohemoglobin and when measured by immunoassay accurately reflects glycemic control in a range of 6% to 7%. However, a hemoglobin A_{1C} greater than 7.5% may overestimate hyperglycemia in the diabetic uremic patient.[91] Another index of glycemic control, serum fructosamine, which is not affected by urea, has not gained acceptance.[92] A preprandial blood glucose of less than 130 mg/dL and a postprandial blood glucose of less than 180 mg/dL are suitable goals if undue risks of hypoglycemia can be avoided. The hemoglobin A_{1C} level should be checked monthly. A value of 7% or less reflects good glycemic control. A decrease of 1% results in 40% decrease in rates of subsequent microvascular complications (nephropathy, retinopathy, and neuropathy).[3]

Hyperglycemia is increasingly recognized as the major causative factor in irreversible tissue damage, leading to diabetic complications. A growing body of evidence has linked late diabetic complications to the accumulation of products of glucose-protein interactions.[93] Glucose normally reacts nonenzymatically with free amino groups of proteins to form a heterogeneous group of advanced glycation end products (AGEs) with cross-linking properties. AGEs appear to be degraded in the body and effectively cleared by the kidneys.[94] Buildup of AGEs is enhanced in ESRD,[95] and it is even more dramatic in diabetics with ESRD and may correlate with late complications.[96] Increased AGEs buildup in diabetic animal models has been documented in vascular, nerve, and kidney tissues. Multiple adverse consequences leading to tissue damage have been described.

Evidence suggests that AGE damage can be compounded in chronic renal failure because of renal retention of AGE-breakdown products and other glycated proteins. In fact, increased plasma and tissue AGEs occur in ESRD unrelated to hyperglycemia. For example, β_2-microglobulin isolated from amyloid deposits in patients with dialysis-related amyloidosis has been demonstrated to be modified by AGEs.[97] Advanced glycation in uremia has also been linked to oxidation processes and the availability of precursor molecules unrelated to hyperglycemia.[98]

AGEs are inefficiently cleared by conventional hemodialysis or peritoneal dialysis,[99] although high-flux dialysis or hemofiltration[100] may be more efficient.[101] Several different strategies for decreasing AGE levels have potential benefit including daily hemodialysis,[102] dietary AGE restriction,[103] ACE inhibitors and ARBs,[104] and compounds known to block AGE formation and AGE cross-linking activity in hemodialysis patients, such as aminoguanidine (pimagedine)[105] and a study drug, OBP-9195.[106] In fact, one study found that aminoguanidine therapy resulted not only in a decrease in AGEs, but also in a decrease in the overexpression of transforming growth factor-β and platelet derived growth factor-β (profibrotic cytokines) in renal tissue, suggesting a potential benefit in the pathogenesis of diabetic nephropathy.[107] Additional problems in managing AGE toxicity include establishing a standardized method of measurement of AGE levels and devising combination therapies.[108]

Hypoglycemia is a potentially serious complication in diabetic ESRD patients.[109] Severe episodes cause significant morbidity (including new retinal hemorrhages), or even mortality, and make tight glycemic control unfeasible. Dialyzed patients may refuse their morning insulin because blood sugar levels commonly decrease during treatment (despite the dialysate dextrose level of 200 mg/dL) as a result of glucose removal by dialysis[110] and a transient improvement in insulin sensitivity. Predisposing factors to hypoglycemia include: (1) decreased insulin clearance and gluconeogenesis by failed kidneys, (2) poor substrate for gluconeogenesis with decreased intake and absorption of food, and (3) impaired counter-regulatory responses. Hypoglycemic episodes may occur with exercise (such as seasonal walking or snow shoveling) or nocturnally. Malnourished diabetic patients with decreased glycogen stores are at highest risk. Important precipitating factors include alcohol (used uncommonly by diabetics), nonselective β-blockers (due to multiple effects), and sulfonylureas. The latter may cause hypoglycemic coma or severe brain damage. Risk is increased with chlorpropamide, tolazamide, and acetohexamide. Glipizide is the preferred oral agent because active metabolites accumulate with glyburide.

Diverse symptoms caused by hypoglycemia are predominantly neuroglycopenic and include headache, nausea, vomiting, confusion, drowsiness, lethargy, tremors, seizure, and unconsciousness; angina,[111] silent myocardial infarction, and

elevated systemic blood pressure may also occur. Patients commonly are unaware of their hypoglycemia. Postdialysis hypoglycemia may place patients who drive home from their treatments at risk of having a motor vehicle accident. When hypoglycemia occurs with increasing frequency, the accuracy of insulin given at home should be verified, glucometer accuracy tested, insulin injection sites inspected for hypertrophy or lipoatrophy, and gastroparesis evaluated. Treatment of hypoglycemia should include glucose concentrate or tablets, honey or similar foods, and intravenous dextrose. High potassium containing juices such as orange juice and grapefruit juice should be avoided. Cranberry juice is a good alternative. The blood glucose level should be retested in 30 minutes.

Ischemic Heart Disease

Ischemic heart disease complicates the management of dialyzed diabetic patients and poses a major threat to survival. Diabetes itself is an independent risk factor for coronary artery disease,[112] which is found to some degree in nearly all diabetic patients older than 45 years.[113] The risk for development of coronary artery disease is dramatically increased in patients with type I diabetes and nephropathy.[114,115] Proteinuria predicts cardiovascular events in patients with type II disease as well, even after adjusting for other cardiovascular risk factors.[116] Adults with diabetes are two to four times more likely to have ischemic heart disease than nondiabetics, and heart disease is the leading cause of diabetes-related deaths.[3] ESRD carries a high cardiovascular mortality rate in all patients. In a study of more than 400 ESRD patients followed from the start of ESRD therapy, diabetes independently predicted cardiac death over a mean follow up of 41 months.[117] Recent USRDS data show that approximately 50% of ESRD patients with diabetes (whether or not it was the primary diagnosis) have atherosclerotic heart disease, compared to only 32% of nondiabetic ESRD patients. Cardiovascular event rates, including myocardial infarction, heart failure, cardiac arrest, and coronary revascularization, were highest among ESRD patients with primary diabetic nephropathy, intermediate among patients with a secondary diagnosis of diabetes, and lowest among nondiabetics. Event rates also increased with time after diagnosis of ESRD.[10]

Management must address individual coronary risk factors.[118] Age, hypercholesterolemia, hypertension, smoking, high hemoglobin A_{1C} levels, low high-density lipoprotein (HDL) cholesterol, duration of diabetes, obesity (mostly in type II diabetes), and hereditary factors are among those identified in diabetic patients with nephropathy. In addition, nontraditional risk factors should be considered, such as hyperhomocysteinemia, inflammation, calcium phosphate product, oxidant stress, and endothelial dysfunction.[119] In patients with non–insulin-dependent diabetes, population-based studies support a linear association of glycemic control with the risk of coronary heart disease,[120] perhaps related to the effects of hyperglycemia on endothelial lesions, smooth muscle proliferation, platelets, or advanced glycation endproducts. Data also suggest that diabetes itself is an even greater risk factor in young patients, both white and black.[121] Plaque progression may also be related to vessel wall effects of AGEs[122] and cellular oxidative stress.[98,123] Diabetic patients have impaired platelet and fibrinolytic function.[124] Hyperlipidemia is an important atherogenic risk factor in dialysis patients, who are known to have elevated very-low-density lipoprotein (VLDL) and triglyceride levels and decreased HDL levels. Hypercholesterolemia and hypertriglyceridemia are common in diabetic patients before initiation of dialysis. Recent data indicate that improvement in the lipid panel in diabetics leads to a decreased risk of cardiovascular complications by up to 20% to 50%.[3] With ESRD, high cholesterol levels tend to remit, whereas triglyceride levels worsen. In addition, the apolipoprotein B/apolipoprotein A-1 ratio is an atherogenic index of uremia that is more elevated in dialyzed diabetic patients.[125] Lipoprotein A, or Lp(A), a recently emphasized risk factor, is also elevated in dialyzed patients.[126] Data suggest that hypertension increases coronary risk more in diabetic than in nondiabetic patients.[127]

Finally, limited data support an inverse relation of the dose of dialysis and coronary risk in diabetic patients.[128] A study of cause-specific ESRD mortality in the USRDS Case Mix Adequacy Study reported a relation between low dialysis dose and coronary artery disease mortality. The correlation appeared to be of even greater magnitude in diabetic patients.[129] More recently, the trend relating higher urea reduction ratios (URRs) to lower mortality (cardiac and other) showed a peak at a URR of 75% above which risk of death increased; this trend was not significantly different when comparing diabetics to nondiabetics.[10] This may reflect poor nutritional status and low initial blood urea nitrogen resulting in a high URR and is not likely to indicate that more dialysis is detrimental.

Clinical strategies to improve cardiac outcomes must improve coronary prevention and treatment (see later). The efficacy of coronary preventive measures in diabetic patients with ESRD is unclear. Dietary modification should include restricted cholesterol, saturated fats, and excess carbohydrates.[130] Caloric restriction is also necessary in obese patients. Tobacco use should be strongly discouraged.[131] All diabetic patients with ESRD are candidates for aggressive management of dyslipidemia. In cases in which cholesterol abnormalities predominate, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors can be used, with ongoing monitoring of liver function tests and muscle enzymes.[132] The new cholesterol lowering agent, ezetimibe, which inhibits cholesterol absorption, can be used in renal failure without dose adjustment. Hypertriglyceridemia can also be treated with gemfibrozil in reduced dose.

Earlier studies have shown some increase in cardiovascular death with diastolic blood pressure less than 85 mmHg in patients with ischemic cardiovascular disease,[133] however, the recent "Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure" (JNC 7) recommendations suggest that the target blood pressure in patients with hypertension and coexisting diabetes or kidney disease should be less than 130/80 mmHg, which is associated with a decreased incidence of cardiovascular events. Most patients with hypertension and diabetes or kidney disease will require two to three antihypertensive agents to reach target blood pressure.[134] Choices of antihypertensive agents will be discussed later. Control of hyperglycemia and abstention from alcohol and smoking are indicated. Exercise should be promoted. Dialysis adequacy should be maintained.

Because of risks of coronary vascular calcification, hyperphosphatemia should be corrected with phosphate binders,

and excessive calcium intake in the form of phosphate binders should be avoided. Sevelamer is a non-calcium containing phosphate binder, which may be used instead of or in conjunction with calcium containing binders and may have an added beneficial effect on lipid profiles.[135] Hyperhomocysteinemia is now a recognized risk factor in atherosclerosis and is common in dialysis patients. Folate therapy has been shown to decrease homocysteine in dialysis patients.[136] Intensified dialysis treatment regimens may also aid in normalizing homocysteine levels in dialysis patients.[137] The effect this will have on long-term cardiovascular outcomes is not yet known. With the implication of oxidative stress (which is induced by hyperglycemia[98] and more prevalent among dialysis patients[138]) in accelerated atherosclerotic disease, the role of antioxidant therapy has also been proposed in diabetics with cardiovascular disease.[98] Because the risk of developing coronary artery disease is high in these patients, aggressive diagnostic testing for coronary artery disease is appropriate.

There is insufficient literature on the outcome of percutaneous transluminal coronary angioplasty in uremic diabetic patients. Although studies to date have shown survival in dialysis patients requiring coronary revascularization to be better with coronary artery bypass surgery than with percutaneous transluminal coronary angioplasty,[139–141] most comparisons do not evaluate the influence of coronary stenting. One present report suggested success rates of less than 60%, with high acute complication rates in dialysis patients undergoing angioplasty, and identified abnormal carbohydrate metabolism as a factor contributing to poor short- and long-term outcomes in dialyzed angioplasty patients.[139] A later report did compare bypass surgery, angioplasty, and angioplasty with stenting and found that stenting offered no advantage and that stenting outcomes are worse in diabetic dialysis patients than in nondiabetics.[142] Another recent report examined stenting procedures in dialysis patients compared to patients without renal disease and found that despite comparable angiographic results, re-stenosis and need for repeat procedures were twice as likely in the dialysis patients. However, most of the dialysis patients did not develop re-stenosis during follow-up, suggesting there is some role for stenting in managing dialysis patients.[143] Diabetes is independently associated with an increased rate of coronary re-stenosis[144] and of subsequent progression of coronary disease. Outcomes are better in diabetics with coronary artery disease after bypass surgery than after angioplasty even with stenting.[145,146]

Bypass surgery is the preferred method of revascularization in diabetic dialysis patients who are surgical candidates. Reports suggest increased perioperative morbidity, such as wound complications, but little or no increase in perioperative mortality after bypass surgery in diabetic versus nondiabetic patients.[147–149] The risk of complications, such as sternal wound infections, osteomyelitis, and wound dehiscence, may be increased.[149,150] For dialysis patients in general, the perioperative mortality rate ranges from slightly higher to double that of patients with normal renal function, but is still less than 10% on average.[139–140,151–154] Symptomatic relief and improved functional status can be achieved. In an outcome study of 84 ESRD patients, including about 30% with diabetes, subsequent cardiovascular events were greater after balloon angioplasty than after bypass surgery.[139] In another study of dialysis patients undergoing revascularization, diabetics had increased risk of cardiac death after angioplasty with or without stenting as compared to bypass surgery.[142] Most series have not analyzed diabetics separately.

In diagnosing acute myocardial infarction, cardiac troponin T levels are being increasingly used because of high specificity for acute coronary syndrome and a universal measuring technique. However, cardiac troponin T levels are difficult to interpret in the setting of end-stage renal disease as it is cleared by the kidney and often elevated in dialysis patients. Elevated cardiac troponin T levels are felt, however, to be associated with cardiovascular risk factors, ischemic heart disease, and left ventricular hypertrophy[155] and to be a marker for poor short-term prognosis[156] in asymptomatic dialysis patients.

Peripheral Vascular Disease

Occlusive peripheral vascular disease is discussed in greater detail under Transplantation. In the dialyzed diabetic patient, it may lead not only to extremity amputations but also, rarely, to necrosis of penile tissue, requiring penectomy.[157]

Hypertension

In the new JNC 7 recommendations, goal blood pressure in patients with diabetes or chronic kidney disease is less than 130/80 mmHg.[134] Nearly 75% of adults with diabetes have blood pressure above the target of 130/80 mmHg or are on antihypertensive therapy.[3] Almost all patients with diabetic nephropathy are hypertensive.[125] Hypertension affects more than 90% of diabetic patients with ESRD, in whom it is associated with both microvascular and macrovascular complications. In type I diabetics, hypertension is often the result of underlying nephropathy and usually becomes apparent with the development of microalbuminuria.[17] Hypertension then accentuates the nephropathy. In type II diabetics, hypertension is often present at the time of diagnosis of diabetes as part of the metabolic syndrome.[17] The causes of hypertension in diabetes include increased total body sodium (renal hypertension), heightened vascular reactivity to angiotensin and catecholamines, and a genetic predisposition. Mechanisms of hypertension in chronic kidney disease include extracellular fluid volume expansion, stimulation of renin-angiotensin-aldosterone system, increased sympathetic activity, alteration in endothelial-derived factors such as nitric oxide, erythropoietin administration, hyperparathyroidism with hypercalcemia, calcified arterial tree, and renal vascular disease.[159] Reduction in blood pressure slows progression to diabetic renal failure.[12, 23]

In one report of hypertensive type II diabetics, a decrease in the systolic blood pressure of 10 mmHg resulted in a 12% decreased risk of macrovascular and microvascular diabetic complications, and the lowest risk was achieved with a systolic blood pressure below 120 mmHg. No threshold level below which the risk of complications was increased was observed.[160] Blood pressure control in diabetics is reported to decrease coronary artery disease and stroke by 33% to 50% and microvascular diabetic complications (nephropathy, retinopathy, and neuropathy) by 33%.[3] The management of hypertension in diabetic patients who have uremia is complicated by the presence of renal disease and renal replacement therapy. Blood pressure control is more difficult to achieve. The conventional blood pressure goal of 130/80 mmHg is frequently unrealistic in dialysis patients. In some reports,

low pre- and post-dialysis systolic blood pressures (< 110 mmHg) in diabetic and nondiabetic dialysis patients have been associated with higher cardiovascular mortality.[161,162] Target blood pressure in the diabetic dialysis patient needs to be individualized.

One report found that 62% of dialysis patients have uncontrolled hypertension, defined as blood pressure greater than 160/90 mmHg.[163] Usually two or more medications are necessary to achieve blood pressure values of less than 130/80 mmHg.[164] Factors that should be considered when hypertension is uncontrolled include high interdialytic weight gain, holding medications pre-dialysis,[164] noncompliance with dialysis regimen (skipping or shortening treatments),[165] and inadequate fluid removal during dialysis. Although different methods to accurately determine a patient's "dry weight" have been proposed, including plasma atrial natriuretic peptide levels,[166,167] a standard does not exist and the clinician must make his or her best judgment. Other important factors that may contribute to inadequate blood pressure control are poor drug absorption (in the presence of gastroparesis) and dialyzability (atenolol, methyldopa, captopril).

Correction of hypertension in dialyzed diabetic patients by ultrafiltration is likely to be hampered by paradoxical reflex systolic hypertension, orthostatic hypotension, and the ongoing need for antihypertensive medication. Some reports suggest that longer[168] or more frequent[169] hemodialysis may be more effective in achieving ideal dry weight than short (3–4 hr) hemodialysis treatments three times per week. Interdialytic fluid gains and salt intake should be moderated and physical activity increased. Excessive alcohol intake should be avoided.[22] Hypertension in obese patients may respond to weight reduction. While on dialysis, severe hypertension, related in some cases paradoxically to ultrafiltration, may force the use of short-acting nifedipine or captopril.[170]

Antihypertensives in atherosclerotic patients with ESRD should include β-blockers[171] and calcium channel blockers.[172,173] Although there has been question of increased cardiovascular morbidity such as myocardial infarction in hypertensive patients on calcium channel blockers,[174] specifically in diabetics,[175,176] this risk has been refuted in subsequent studies,[173,177,178] even in the subset of hypertensive diabetics.[177,178] ACE inhibitors have been shown to promote regression of left ventricular hypertrophy[179] and to decrease cardiovascular mortality[180] in hypertensive dialysis patients, and to decrease cardiovascular morbidity and mortality as well as progression of nephropathy in patients with diabetes.[181] ARBs are effective and well-tolerated without dose adjustment in dialysis patients.[182] They prevent progression of diabetic nephropathy in patients with type II diabetes[183,184] and appear to offer some advantage in cardiovascular morbidity and mortality when compared to atenolol in hypertensive diabetic patients.[185] Although α-blockers may improve insulin sensitivity in type II diabetics with hypertension,[186] a recent study showed an increased risk of heart failure with α-blockers as compared to diuretics, ACE inhibitors, and calcium channel blockers and so should be used as a second or third line agent.[187] They may be preferentially added to a regimen in older men with obstructive symptoms of prostatic hypertrophy. A once weekly clonidine patch may be useful in patients who are noncompliant with medications.

In choosing a blood pressure medication regimen, side effects must also be considered. Beta-blockers may worsen hyperglycemia[188] and may also mask symptoms of hypoglycemia. Hypoglycemia has also been reported with ACE inhibitors, resulting from increased insulin sensitivity.[189] Orthostatic hypotension occurring with supine hypertension in patients with type I diabetes is worsened by α-blockers and vasodilators. Hyperlipidemia may be an adverse effect of β-blockers as well as of diuretics. Erectile dysfunction may be worsened by β-blockers and methyldopa. ACE inhibitors and angiotensin receptor blockers (ARBs) may be underused because of fear of hyperkalemia, although hyperkalemia seems to be less pronounced with ARBs.[190]

Overtreatment of hypertension in uremic patients at risk of coronary ischemia may be dangerous. Diabetic patients are at particular risk because intradialytic hypotension is more common in diabetics. Depressed counter-regulatory reflexes in response to hypovolemia are the major factor.[191] During tilt testing, blood pressure decreases further in diabetic patients because of a smaller rise in total peripheral resistance and an absent catecholamine response. Previously hypertensive patients may later develop sustained hypotension as autonomic neuropathy worsens and cardiac performance deteriorates. With drops in blood pressure, the hemodialysis access itself may be threatened because of low flow and risk of thrombosis.

Dialysis hypotension may respond to increased treatment time, increased target weight, limit in interdialytic weight gain, withholding of antihypertensive medications, sodium modeling to promote vascular refilling, and erythropoietin to correct coexisting anemia.[192] Symptomatic episodes require placement in Trendelenburg's posture, infusion of normal saline, cessation of negative dialysis pressure, reduction in blood flow to the dialyzer, cooling of dialysate, and administration of ephedrine or midodrine.[193] Possible underlying causes, such as coronary ischemia, sepsis, and pericardial tamponade, should be considered.

Retinopathy

Diabetes is the leading cause of blindness in adults aged 20 to 74 years, causing 12,000 to 24,000 new cases per year,[3] and is the most common cause of blindness in uremic patients. Ophthalmologic screening programs can prevent vision loss and are cost-effective.[194] The ocular complications in type I and type II diabetes are similar.[195] Progression of retinopathy is a major problem for dialyzed diabetic patients, whose sight is necessary for functional independence and rehabilitation. Type I diabetics rarely develop signs of retinopathy within the first 3 to 5 years of diagnosis of diabetes, but nearly all have evidence of retinopathy by 20 years after diagnosis, while 20% of type II diabetics have signs of retinopathy at the time of diagnosis of diabetes.[196] Almost all patients with type I diabetes have background or proliferative retinopathy when starting dialysis. Three-fourths have visual disturbances, and half have significant visual loss.[197] Up to one-third of type I and one-fifth of type II diabetic patients are blind at the initiation of dialysis.[198] The presence of albuminuria in type I diabetics[199] and in Hispanic type II diabetics[200] predicts the presence of diabetic retinopathy independent of glycemic control and duration of diabetes.

With current technology, dialysis does not appear to exacerbate vision loss.[201] Heparin administration, abrupt changes in glycemic control, and fluctuating blood pressure

are factors that could potentially worsen retinopathy.[196] Heparin may worsen vitreous hemorrhage. Macular edema, on the other hand, may disappear with hemodialysis in the absence of proliferative retinopathy, leading to improvement in visual acuity.

The visual prognosis for uremic diabetic patients has improved because of collaboration among the nephrologist, the diabetologist, and the ophthalmologist. Therapy is primarily preventative and does not restore vision, therefore early intervention is mandatory to preserve sight. The stage of retinopathy determines the ophthalmologic treatment.[202] For macular edema, the most common cause of visual impairment in diabetes, focal photocoagulation therapy is beneficial[203] and should be combined with control of hypertension,[204] avoidance of fluid overload, and improved blood glucose control.[205, 206] Diet, exercise, and smoking cessation should also be encouraged.[207] Visual acuity may be improved by resolution of macular edema after correction of anemia by erythropoietin.[208] Raising the red blood cell mass by treatment with erythropoietin may also improve retinal hard exudates.[209]

Patients with proliferative retinopathy are treated with panretinal photocoagulation to lessen the risk of extensive vitreous hemorrhage. Even florid diabetic retinopathy, which carries a high risk of blindness, can be improved with extensive full subconfluent panretinal photocoagulation.[210] For persistent vitreous hemorrhage, vitrectomy is indicated. Lens replacement and retinal reattachment may also preserve sight. Follow-up should be at 3- to 12-month intervals, depending on the severity of the retinopathy. With aggressive eye management, dialyzed patients can achieve a visual prognosis similar to those who undergo transplantation.[211]

Foot Care

Foot complications occur in one-quarter of diabetic patients with ESRD[212] and were twice as common as in those without ESRD in one study.[213] Notably, more than 60% of nontraumatic lower extremity amputations in the United States are in diabetic patients, and there were approximately 82,000 lower extremity amputations per year in diabetic patients between 1997 and 1999.[3] Amputations of the lower extremities are a major source of morbidity for dialyzed diabetic patients, occurring 10 times more frequently than in the general diabetic population,[213] but many are preventable.[214,215] Approximately 84% of amputations are preceded by foot ulcers, which are not less likely to heal in patients with diabetic nephropathy than in diabetics with normal renal function.[214] A reduction in amputation rates requires that both the patient and the ESRD specialist be educated about the need for prophylactic foot care and lifelong surveillance. The podiatrist and vascular surgeon must also be included on the dialysis team.

Risk factors leading to lower extremity amputation include sensory neuropathy, impaired circulation, and foot deformities. Patients with diabetes for more than 10 years, poor glycemic control, cardiovascular complications, retinopathy, or nephropathy are also at increased risk. Patients at particular risk (elderly patients, immobilized patients, and those with poor vision, foot deformity, or history of foot ulcer) should be identified and educated regarding foot care, including the absence of pain as a foot ulcer symptom, wearing protective footwear at all times, and avoiding exposure of neuropathic feet to heating pads.[216]

Extremities should be examined for absent pulses, poor hair growth, atrophic skin changes, and cool temperature. The feet should be visually inspected daily for foot ulcers, ingrown nails, and calluses. Minor skin disease such as dryness and tinea pedis should be identified and treated before evolving into a more serious problem.[216] In the hospitalized bed-confined patient, the heels must be given particular attention. Toe gangrene with painful petechiae suggests cholesterol microemboli.[217] Foot inspection at home depends on adequate vision or the presence of a sighted partner. A mirror may be necessary to inspect the bottoms of the feet. Hemodialysis treatments provide an opportunity for the dialysis unit team to inspect the patient's feet.

Foot ulcers should be aggressively debrided and protected from weight bearing. Underlying vascular insufficiency may cause impaired healing. In fact, in patients who underwent toe or forefoot amputation, success of revascularization, and not diabetes or presence of ESRD, predicted healing without need for more extensive (below or above the knee) amputation.[218]

Regular exercise should be encouraged to maintain circulation, unless an active or healing ulcer is present. Because even minor sores may progress unnoticed into major infections, foot discomfort should be taken seriously. Deep cultures, prompt ulcer debridement, cessation of weight bearing, broad-spectrum antibiotics, and noninvasive Doppler studies should be ordered promptly. Foot deformities may need correction. Cellulitis should be treated before extremity revascularization. Smoking should be discouraged. Hyperbaric oxygen therapy[219] and human skin equivalent[220] may also be beneficial in aiding wound healing of ischemic or neuropathic ulcers, respectively. Diabetic patients with lower limb disability make poor psychosocial adjustments to illness and should be psychologically prepared for a long period of convalescence.[221]

Infection

Because of factors such as altered host immunity due to uremic toxins, breakdown of protective barriers, affinity of bacteria for foreign materials, carriage of infective organisms, and malnutrition, the incidence of infection in uremic patients is high, with both common and opportunistic pathogens.[222] Therefore, a high index of suspicion for infection is appropriate. Bacteremia and death from infection are more common in dialyzed patients,[223] and infection is the second leading cause of death among ESRD patients.[224] Rates of hospitalization for infection are more than five times higher in diabetic dialysis patients compared to diabetic Medicare patients without chronic kidney disease.[10] Although overall rates of hospital admission in the ESRD population have remained fairly constant, admissions for infection have increased 12% to 21% in the ESRD population and 30% specifically in the hemodialysis population between 1991 and 2001.[9] This seems largely due to increased rates of vascular access infections, which have increased 87%, and pulmonary infections, which have increased 24% between 1991 and 2001 in hemodialysis patients.[9] Hospitalization rates for sepsis have also increased 69% in hemodialysis patients between 1991 and 1999.[9] Mortality from sepsis is 50-fold higher in dialysis patients than in the general population in both diabetics and nondiabetics.[225]

Indwelling dialysis catheters are more likely to be a nidus for infection than native or synthetic arteriovenous shunts,[224]

and grafts are more likely to become infected than fistulas. Mortality due to access infections is greatest with catheters, less common with grafts, and least with fistulas.[226] The most common organism is *S. aureus*. More serious complications, such as infective endocarditis,[227] septic pulmonary emboli, osteomyelitis, meningitis, or visceral abscesses may occur in otherwise nonthreatening access infections. Catheter salvage with guidewire exchange does not appear to increase the risk of complications of catheter-related bacteremia.[228]

High nasal carriage of *S. aureus* in dialyzed patients may account for higher rates of self-infection than are seen in non-dialyzed patients.[229] Nasal mupirocin can safely eradicate carriage of *S. aureus* and may lead to a reduction in bacteremia.[230] Prophylactic topical Polysporin™ Triple antibiotic ointment applied to catheter exit sites may also reduce the rate of infection and improve survival in hemodialysis patients.[231]

Illicit drug abuse appears to be uncommon in the diabetic dialysis population, occurring in less than 5% in one study.[232] Use of cocaine, however, was associated with increased bacterial infection rates that included cellulitis, sepsis, and abscesses, often virulent. Dialysis access infections were common. Although no cocaine user tested positive for human immunodeficiency virus, more than half tested positive for hepatitis B antibody. Morbidity was evidenced by a fivefold higher hospitalization cost in the illicit drug abuse population.

Bacteremia should be suspected in febrile patients on hemodialysis, and the access promptly inspected. Blood cultures should be obtained. Empiric vancomycin and gentamicin should be administered if the access appears responsible. Antibiotic coverage should be narrowed once culture and sensitivity results are available, and treatment should be continued to complete a 3-week course. Follow-up should include careful evaluation for metastatic complications (blood cultures, chest radiograph, echocardiogram). Exploration of the graft may be required; up to half of infected grafts can be salvaged, with exploration and careful resection of the infected portion. Partly revised grafts may continue to be used with caution. Infected tunneled catheters may be changed over a wire under sterile conditions in patients without signs of sepsis. If there is evidence of associated tunnel infection, the catheter may be changed over a guidewire with the creation of a new tunnel.[233]

Hyperkalemia

Significant hyperkalemia occurs in about 10% of chronically dialyzed patients, but it is more common in diabetic patients, in part, because of insulin deficiency or resistance. Hyperkalemia is worsened by severe hyperglycemia.[234] Even severe cases may be asymptomatic. Late cardiac manifestations may occur, including a prolonged PR interval and a sine wave pattern leading to cardiac standstill.[235] The management should take into account preexisting cardiac problems and concomitant medications that might cause bradyarrhythmias. Glucose need not accompany intravenous insulin in the acute treatment of hyperkalemia in the presence of hyperglycemia. Hyperkalemia may be worsened by severe constipation in patients with diabetic enteropathy.

Gastroparesis

Gastroparesis affects more than one third of diabetic patients with chronic renal failure and is more common in type I than in type II diabetes. Symptoms include nausea, vomiting, abdominal discomfort, and bloating.[236] Symptoms of reflux esophagitis may also occur. Upper gastrointestinal bleeding is less common. Variable fluid and food intake result in hypoglycemia or hyperglycemia and in variable weight gains or losses. Gastroparesis has been associated with poor survival, protein malnutrition, poor glycemic control, orthostatic hypotension, and a high frequency of other diabetic complications.

In symptomatic patients, gastric emptying studies, or magnetic resonance imaging with radiopaque markers (combined with upper endoscopy to exclude other causes[237]), along with improvement with prokinetic agents, confirm the diagnosis. Treatment includes six small meals per day, gastric motility stimulants, and avoidance of high fiber foods and medications that may slow gastric emptying. The prokinetic agent metoclopramide[238] has a variety of extrapyramidal side effects and may cause parkinsonism. These symptoms improve promptly with discontinuation of the drug. Cisapride also reduces gastric retention,[239] but it has been taken off the market because of serious drug interactions and cardiac dysrhythmias.[240] It can now only be obtained directly from the manufacturer in cases with documented need and low risk of complications (no prolonged QTc interval on ECG and no concurrent use of medications known to have a high incidence of interaction, such as macrolides, antifungals, and phenothiazines). Erythromycin is added in refractory cases, which may respond dramatically.[241] Early studies show that gastric pacing might improve symptoms of gastroparesis.[242] Enteral nutrition via jejunostomy tube or even parenteral nutrition may be necessary when severe episodes are prolonged.

Diabetic diarrhea due to enteropathy, although less common, also contributes to malnutrition, hypoglycemia, and weight loss. Uncontrolled diarrhea may interrupt dialysis treatments and sleep. A combination of factors seem to be responsible for diarrhea, including abnormal small bowel motility, bacterial overgrowth, and anorectal dysfunction.[243] Bowel motility disorders may respond to loperamide hydrochloride or diphenoxylate with atropine. Clonidine may be helpful in refractory cases.[244] A few case reports have shown some improvement in diarrheal symptoms with octreotide.[245] Severe cases involving bacterial overgrowth require broad-spectrum or rotating courses of antibiotics. Fat malabsorption or the less common protein-losing enteropathy should be excluded.

NUTRITION

Malnutrition is common among dialysis patients, with estimated rates of severe malnutrition affecting 20% to 36% of dialysis patients in one recent study based on multiple nutritional parameters including lean body mass, normalized protein catabolic rate, albumin and pre-albumin,[246] and up to 47% of hemodialysis patients based on lean body mass.[247] Likelihood of malnutrition increases with the duration on dialysis.[248] Malnutrition is well-recognized as a predictor of increased mortality in dialysis patients, with hypoalbuminemia, although it is a late marker of protein malnutrition due to its long half-life and the large hepatic synthetic capability, being a key predictor of death in patients with ESRD.[249] Because of the high prevalence of malnutrition among dialysis patients and its association with increased mortality, frequent assessment of a patient's nutritional status with early intervention, if malnutrition is present, is important.

There is a growing consensus that nutritional status should be evaluated by a panel of measures rather than by any one single measure.[250] Recent National Kidney Foundation K/DOQI™ guidelines suggest monthly screening for albumin less than 4.0 g/dL and protein catabolic rate less than 0.8 g/kg/day to identify malnutrition.[251] Also, low blood urea nitrogen, creatinine, and cholesterol as well as declining anthropometric measurements and dry weight may suggest worsening nutritional status. Anthropometric norms in dialysis patients have been established in one study.[252] These guidelines are directed toward the general dialysis population but should be followed in the diabetic dialysis population as well.

Although protein-energy malnutrition has achieved growing recognition as an important source of mortality risk in ESRD patients,[253] its true incidence in dialyzed diabetic patients is not known. Data suggest that diabetic patients with ESRD have a poor overall nutritional status,[254] more cachexia, and slightly lower serum albumin levels.[249] Diabetic patients also have lower serum creatinine levels, probably reflecting a poor nutritional status that partly accounts for their decreased dialysis survival. One study showed that the increased mortality rates in diabetic patients with ESRD was related partly, in a logistic regression analysis, to reductions in serum creatinine and albumin levels.[255] Recent USRDS data show an 8% to 9% increased risk of hospitalization for nondiabetic and diabetic dialysis patients with a body mass index (BMI) less than 20 kg/m^2 as compared to those with a BMI of 20 to 24 kg/m^2. The risk of hospitalization continues to decline in diabetics up to a BMI of 30 kg/m^2 or more.[9]

Protein malnutrition starts before initiation of dialysis,[256] and some recommendations are evolving toward initiating maintenance dialysis for deteriorating nutritional status.[251] Multiple causes contribute to hypoalbuminemia during ESRD, including (1) reduced rate of synthesis due to inadequate protein and caloric intake due to the anorexia of uremia, (2) increased catabolism associated with infection and the dialysis treatment itself, (3) external losses in the dialysate, (4) distribution within the body,[257,258] and (5) acidosis.[259] Bioincompatible membranes can induce an inflammatory response that contributes to decreased serum albumin.[260,261] Reuse of high-flux dialysis membranes processed with bleach seems to increase protein losses with successive uses.[262] The causes more important to diabetic patients are the synergistic effects of poor protein-calorie intake due to gastroparesis[263,264] and enteropathy, catabolic stress and intercurrent illnesses, decreased albumin synthesis due to inadequate insulin anabolic effects, and psychosocial factors. Albumin homeostasis may be abnormal in diabetic patients through a specific mechanism, since insulin is necessary for basal rates of albumin synthesis. Reduced albumin synthesis may result, in hypoinsulinemic patients, from a decrease in albumin transcription. A slight increase in the prevalence of hypoalbuminemia in dialyzed diabetic patients has been reported in some studies,[249,265] although it was not confirmed in the ESRD Core Indicator Project,[266] which surveyed only about 5% of in-center adult hemodialysis patients in the United States.

Treatment of malnutrition is multifactorial. Adequate dialysis should be achieved.[267,268] Adequate insulin dosing and glycemic control may improve protein balance. Factors that cause anorexia and increased protein catabolism should be eliminated. The dietary prescription should include greater than 1.2 g/kg/day of protein, 35 kcal/kg/day,[249] 35% fat with an increase in polyunsaturated fat, and 55% carbohydrate with a special effort to limit simple sugars and concentrated sweets.

Oral dietary supplements given at hemodialysis to insure compliance resulted in increased serum albumin in a recent study.[269] Compliance with supplements is critical to the beneficial effect, and so in patients who do not like preparations specifically for kidney failure, nonspecific nutritional supplements may be preferred, if the higher intake of potassium and sodium is tolerated. Overnight enteral tube feeding may be beneficial in patients with severe anorexia unable to increase oral intake.[270] Intradialytic parenteral nutrition or total parenteral nutrition are other alternatives.[270] A retrospective analysis demonstrating an association between intradialytic parenteral nutrition and improved survival in malnourished chronic hemodialysis patients included more than one third diabetics in both the control and parenteral nutrition groups.[271] Of note, mortality in patients with nearly normal serum albumin levels (> 3.5 g/dL) who received intradialytic parenteral nutrition was increased. Another analysis examined intradialytic parenteral nutrition in chronic dialysis patients, including over 40% diabetics in both the treatment and control groups, and found a slight increased survival among treated diabetic patients over the 9-month treatment interval, with an increase in serum albumin among the survivors.[272] Newer forms of nutritional therapy being investigated include appetite stimulants like megestrol acetate,[270] growth factors like anabolic steroids (nandrolone)[273] and recombinant growth hormone,[274] oral essential amino acid supplements,[275] and carnitine supplementation.[276] None of these interventions have been specifically evaluated in dialyzed diabetic patients.

Nutritional prescriptions advocated for nondiabetic patients on dialysis also apply in general to diabetic patients. Management begins with early recognition of protein malnutrition and reversal of dietary protein restriction when dialysis commences. There should be monthly nutritional counseling by the dialysis dietician on nutritional needs, and the social worker can assist in solving reimbursement problems for those unable to afford a special diet or supplement. Serum glucose levels, hemoglobin A_{1C} values, lipid levels, and obesity management should be evaluated. Nutritional plans need to take into consideration individual, personal and cultural preferences and lifestyle.[22]

SURVIVAL

A steady improvement of survival of diabetics on hemodialysis occurred through the 1980s as a result of more effective control of hypertension and hyperglycemia. Survival has continued to improve throughout the 1990s, despite the overall aging of the diabetic population with ESRD. The survival for diabetics on hemodialysis has improved by 17.3% when the 1987 to 1991 incident cohort to the 1992 to 1996 incident cohort are compared.[9] In every study, however, morbidity and mortality remain significantly higher in diabetics than in nondiabetic patients. The inferior prognosis of diabetic patients on dialysis is due largely to ongoing progression of comorbid conditions. In addition, for elderly blacks and Hispanics with ESRD due to diabetes, inadequate medical care after the initial diagnosis of diabetes may contribute to worse outcomes.[277]

The overall mortality risk is increased about 1.2 to 1.6 times in diabetic patients with ESRD compared with nondiabetic patients with ESRD, depending on their underlying cause. The 1-, 2-, 5-, and 10-year patient survival estimates for diabetic and nondiabetic patients on dialysis in the United States are shown

in Figure 10–4. Limited data show increased, very early (< 90 days) mortality for diabetics on dialysis; short-term survival may be even lower than expected, because Medicare reporting does not begin until the fourth month after initiation of dialysis.[278] Diabetic survival is mildly reduced at 1 year but falls off more significantly with increasing vintage on hemodialysis. While hospital admission rates have fallen slightly over the past decade for dialysis patients in the United States, hospital admission rates for diabetic patients continue to exceed those for nondiabetic patients.[9] Higher mortality rates for diabetic patients on dialysis extend throughout the world.[279]

Most of the excess mortality in diabetic hemodialysis patients is due to associated cardiovascular disease, which is greater in diabetic patients than in nondiabetic patients (Figure 10–5). Deaths resulting from cerebrovascular disease and sepsis are about 1.5-fold more common among diabetic than nondiabetic hemodialysis patients.[280] All causes of death occur more commonly in diabetic than in nondiabetic dialysis patients, except for malignancy, which may affect more nondiabetics.[9]

A growing number of studies have reported predictors of survival in ESRD diabetic patients. As in nondiabetic patients, survival is affected by comorbidity. As for all ESRD patients, the number of preexisting comorbid conditions at the start of dialysis has increased,[9,281] and the number is greater than for nondiabetic patients. Diabetic patients with higher estimated glomerular filtration rates have higher mortality rates, possibly reflecting higher comorbidity, necessitating earlier initiation of hemodialysis.[10] Increasing age is associated with increasing mortality risk for all patients on dialysis.[10] While females have a higher risk of mortality among the nondiabetic population, gender does not affect mortality risk in the diabetic population.[10] Although the USRDS does not include classification of diabetes type in its survival analysis, it has reported poorer survival rates in diabetic white Americans than in diabetic black Americans, Native-Americans, or Asian-Americans, suggesting a survival disadvantage for patients with type I diabetes.[9,282]
White diabetic patients also have shorter dialysis survival times than diabetic Mexican-Americans.

Protein malnutrition, as indicated by a low serum albumin level, is a strong predictor of mortality, and similarly the BMI is associated with mortality with the highest risk at a BMI less than 20 kg/m^2 and the lowest risk at a BMI greater than 30 kg/m^2.[10] Low serum creatinine as a marker of diminished lean body mass has also been used as a marker of malnutrition and increased mortality.[283] Diabetic status itself becomes a weaker risk factor after nutritional baseline biochemical parameters are taken into account.[284]

Adequacy of dialysis also appears to influence survival. A number of studies describing a relationship between increasing dialysis delivery and lower all-cause mortality have included diabetic patients.[285] One study suggesting that diabetic patients receive lower doses of in-center dialysis than nondiabetic patients[286] is of concern because of data indicating a stronger influence of dialysis dose on diabetic patients than on nondiabetic patients.[287,288] Although an increasing URR or Kt/V as a marker for dialysis delivery has been associated with improved survival, patients with numbers in the top 10% to 20% for these parameters (URR > 75% and Kt/V > 1.6) have been found to have an increase in mortality, which is most likely reflecting protein-calorie malnutrition, which falsely elevates these parameters.[289] Recent USRDS data showed that in diabetics, increasing URRs are associated with decreasing mortality up to a URR of 70%, while the same is true up to a URR of 75% in nondiabetics.[10] The recent hemodialysis (HEMO) study prospectively examined more than 1800 dialysis patients, of whom nearly half were diabetics, and compared standard dose dialysis (Kt/V, 1.16; URR, 66%) to high dose dialysis (Kt/V, 1.53; URR, 75%). Hemodialysis patients did not experience a mortality benefit from a dose of dialysis greater than currently recommended in the United States.[290] Diabetic patients have equivalent 2-year survival on hemodialysis and peritoneal dialysis as long as adequacy is achieved.[291]

In addition to dialysis or transplantation, the other option in the management of uremic diabetic patients is withdrawal and death. Mortality by withdrawal from dialysis for diabetic patients is 1.3 times more common than in other diagnosis groups.[9] Reasons for withdrawal are similar for diabetic and nondiabetic patients.

PERITONEAL DIALYSIS

Although many advocate the use of peritoneal dialysis in uremic diabetic patients,[292, 293] it is the prevalent treatment option for less than 10% of diabetic adults in the United States.[9] The proportion of diabetic ESRD patients on peritoneal dialysis has declined over the past decade from about 11% in 1993 to 6% in 2001 (see Figure 10–1). Peritoneal dialysis is utilized more commonly among patients less than 20 years old (13.2% of ESRD patients) and less commonly among those aged 75 and over (4.3% of ESRD patients).[10] Its frequency as an ESRD treatment modality appears to be similar to that for nondiabetics. Almost half of the new patients begun on peritoneal dialysis are diabetic.[10] Increasing numbers of these patients are using *continuous cycling peritoneal dialysis* (CCPD). Of all diabetic patients initiating peritoneal dialysis in 2000, 25% began with continuous cycling and, of all prevalent diabetics on peritoneal dialysis in 2000, nearly half were using continuous cycling.[10]

Figure 10–4 First, second, fifth, and tenth year patient survival estimates for diabetics and nondiabetics receiving dialysis, adjusted for age, gender, and race. Incident cohorts from 2001, 1999, 1996, and 1991, followed through 2001. (From U.S. Renal Data System: USRDS 2003 Annual Data Report. Bethesda, MD, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2003.)

Figure 10–5 Death rates per 1000 patient years for patients on dialysis who received medicare benefits according to cause of ESRD (diabetes vs. all others), 1996–1998. *CVD,* cerebrovascular disease; *MI,* myocardial infarction. Combined cardiac causes were the most common recorded cause of death. Causes not shown include withdrawal from dialysis, acquired immunodeficiency syndrome, and hemorrhage. (From U.S. Renal Data System: USRDS 2000 Annual Data Report. Bethesda, MD, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2000.)

Peritoneal dialysis offers many advantages (see Table 10–1): (1) avoidance of vascular access problems, (2) a brief time to use after catheter placement, (3) better glycemic control through the use of intraperitoneal insulin, (4) milder fluid and electrolyte shifts, (5) avoidance of heparin, (6) lower vascular stress, (7) less antihypertensive therapy, and (8) better preservation of renal function.[294-296] Patients may also prefer it for psychosocial reasons, including lifestyle advantages, such as ease of travel and performance at home. CCPD may be preferred over *continuous ambulatory peritoneal dialysis* (CAPD) because it allows more flexibility for patients who continue to work, as the long dwell occurs during the daytime hours.[297] The disadvantages of peritoneal dialysis include risk of peritonitis, high rates of technical failure due to poor visual acuity and manual dexterity,[298] patient burnout, abdominal complaints, orthostatic hypotension, and in some cases, inadequate dialysis when residual renal function is lost (see Table 10–1).

Data to support the advantage of peritoneal dialysis in dialyzed diabetic patients are limited,[292,293] with some data suggesting that mortality for diabetics on dialysis is greater with peritoneal dialysis as compared to hemodialysis.[299] Most studies, however, once correcting for comorbidity, have not found a significant survival difference between hemodialysis and peritoneal dialysis in diabetic patients.[300,301] In the absence of hyperglycemia or advanced peritoneal microvascular disease, peritoneal transport and ultrafiltration, in most cases, are similar to those in nondiabetic patients. Hyperglycemic diabetic patients may have enhanced peritoneal transport by peritoneal equilibration tests, perhaps related to increased capillary permeability. Approximately 75% of patients remain on peritoneal dialysis after 3 years.[302]

Insulin and Glucose

An understanding of insulin and glucose physiology is essential to the care of diabetic patients on peritoneal dialysis. Glucose absorbed continuously from the dialysate may constitute one-quarter of daily caloric intake,[303] leading to poor glycemic control, hyperlipidemia, and weight gain. Adverse lipid effects include an increase in triglyceride and in plasma very low density lipoprotein levels. Glycemic control is a desirable therapeutic goal (see Box 10–1) that is associated with better outcomes and slower progression of diabetic complications, including less disabling gastroparesis and better patient and technique survival.[304] Peritoneal ultrafiltration is reduced even in the presence of moderate hyperglycemia.[305]

Intraperitoneal insulin administration may eliminate the need for injections, provides more consistent insulin absorption, lowers peripheral insulin levels, lessens the risk of hypoglycemia, and provides constant basal insulin dosing. Because it is absorbed (mainly by diffusion) into the portal venous system, detectable insulin blood levels occur within 15 minutes and peak at about 90 minutes. Fifty percent is absorbed by 8 hours of dwell time.[306] A high first-pass elimination of insulin occurs in the liver.[307] Some intraperitoneal insulin reaches the systemic circulation directly. Intraperitoneal insulin does not affect solute clearances, ultrafiltration rates, or absorption of glucose.[308]

The major benefit of intraperitoneal insulin is improved glycemic control.[309] In one report, the hemoglobin A_{1C} levels improved from 8.4% to 6.1% when diabetic peritoneal dialysis patients were switched from subcutaneous insulin to intraperitoneal insulin.[308] Initial concerns about higher peritonitis rates have waned, and the risk of peritonitis appears to be increased only minimally, if at all, with intraperitoneal insulin use.[302,306,308] In a comparison of subcutaneous and intraperitoneal administration of insulin, peritoneal insulin resulted in improved glycemic control, although it was associated with higher total cholesterol, low-density lipoprotein, and triglyceride levels, and 33% lower high-density lipoprotein levels, possibly because of a direct effect of insulin on the liver.[310] Although significant clinical benefit has not been proven in clinical trials, intraperitoneal insulin is preferred in most patients on CAPD. Use of intraperitoneal insulin in patients on automated cyclers is more complex, because it leaves less time for insulin absorption and does not provide daytime insulin, necessitating a daytime subcutaneous insulin injection.[311]

Icodextrin, a high molecular weight glucose polymer, is now available as an alternate osmotic agent to dextrose in peritoneal dialysis fluid. Its absorption from the peritoneal cavity is slow compared to dextrose, resulting in a longer and more effective

ultrafiltration,[312] with less of an absorbed glucose load.[313] Patients with impaired ultrafiltration, such as diabetics, seem to derive the most benefit, obviating exposure to high dextrose-containing solutions, which are typically relied upon to promote ultrafiltration.[314] Limited data demonstrate decreased formation of advanced glycation end-products (AGEs) with icodextrin as compared to dextrose based dialysate fluid.[315,316] Accumulation of AGEs bound to receptors in the peritoneal membrane may stimulate fibrosis and ultrafiltration failure.[317] Hypoglycemia has been reported in diabetic patients using icodextrin dialysate, resulting from falsely high glucose values with some glucose monitoring assays, prompting inappropriately high dosing of insulin.[318,319] Other adverse effects of this fluid that have limited its use include sterile peritonitis, which can result in technique failure,[320,321] and cutaneous hypersensitivity reactions.[322] However, icodextrin has been more effective than dextrose in decreasing edema weight, especially during the long dwell of the day[312,323] and is also effective in preserving ultrafiltration during episodes of peritonitis.[324] Furthermore, early data suggest an improvement in quality of life in peritoneal dialysis patients using icodextrin solution versus dextrose solution.[325] The role of this costly therapy in diabetic patients on peritoneal dialysis remains to be determined.

Uremic patients are at risk for hypoglycemia because of impaired insulin degradation, improved insulin sensitivity, and poor nutrition. In uremic diabetic patients, excessive insulin or oral hypoglycemic agents may also contribute. Severe sequelae of hypoglycemia, including convulsions and brain damage, are known to occur. However, patients on CAPD using intraperitoneal insulin experience less variability in serum glucose levels, and hypoglycemic reactions are fewer and milder than with hemodialysis[326] or with subcutaneous insulin.[308,327] When severe hypoglycemic reactions occur in a diabetic patient on hemodialysis, peritoneal dialysis with intraperitoneal insulin may be preferable.

As with subcutaneous insulin, glycemic control during intraperitoneal insulin use is assessed by self-monitoring of blood glucose levels, office fasting blood sugars, and glycated hemoglobin values. Blood glucose levels should be checked at home two to four times daily, including before meals and at bedtime. Treatment objectives include preprandial blood sugars of less than 130 mg/dL and postprandial blood sugars of less than 180 mg/dL, with avoidance of hypoglycemia. Hemoglobin A_{1C} levels above 7.5% may be falsely elevated because of uremia, but hemoglobin A_{1C} goals should be measured regularly, preferably with an immunoassay to avoid analytic interference, and a goal of less than 7% should be sought.[91] Diabetes education using a calendar diary is essential.

When adding insulin into the bag of dialysate, limited insulin ultimately reaches the portal system (due to adherence to the plastic bag and tubing and dilution in the dialysate), so that the average dose is often two to three times the previous subcutaneous dose. Doses in type I diabetics may be substantially lower than in type II diabetics.[328] Doses, however, vary greatly and must be individualized.

To determine the initial intraperitoneal insulin dose for CAPD (Table 10–4), add up the total number of units of all types of insulin given subcutaneously and divide this evenly among four 2-liter bags, giving it all as regular insulin. Supplemental insulin is required to account for the dextrose in each exchange. For 1.5% dextrose solution, add 2 units, for 2.5% dextrose solution, add 4 units, and for 4.25% dextrose

solution, add 6 units. Daytime exchanges should be timed to occur 20 minutes before each meal, to allow insulin absorption and dietary hyperglycemia to coincide. Blood glucose should be monitored fasting to adjust the dose in the overnight dwell and at 1 hour postprandial to adjust each daytime dwell as indicated in Table 10–4.[328] As metabolic control improves on CAPD, decreased insulin requirements may result.

In patients on cycling peritoneal dialysis, comparable glycemic control can be achieved. Because of higher ultrafiltration and reduced glucose absorption during the frequent short-dwell cycles, total insulin can be reduced to about 85% of that administered on CAPD.[329] Up to half the total dose can be given in the daytime dwell. Additional subcutaneous injections during the day may be required to help metabolize carbohydrate absorbed with meals.[328] Alternatively, cycling patients can be treated with twice-daily or more frequent subcutaneous dosing. Cycling patients who switch temporarily to CAPD should beware of the risk of hypoglycemia during the longer exchanges, which permit greater insulin absorption.

In patients with rapid peritoneal transport rates (as determined by the peritoneal equilibration test),[305] higher blood sugars reduce ultrafiltration and may also require more insulin. During infection, injuries, or emotional stress, extra insulin should be given, using "sick-day" rules, to prevent ketoacidosis. During episodes of peritonitis, insulin requirements vary widely: they are commonly increased but in some cases are reduced because of hypoglycemia. The insulin dose may also need to be adjusted for variable food intake or physical activity. The insulin dose should be reduced for exchanges prior to a procedure that requires fasting.

Peritonitis

Between 1991 and 2001, rates of hospitalization among peritoneal dialysis patients for peritonitis fell 47%,[9] presumably resulting from improved preventive techniques among peritoneal dialysis patients.[330,331] However, peritonitis remains one of the most common causes of hospital admission in peritoneal dialysis patients, accounting for about 15% of admissions in one recent study.[332] Peritonitis is the main cause of technique failure resulting in transfer to hemodialysis.[302,333] Demographic data in the past have associated diabetes with an increased risk of peritonitis.[334] In one registry, diabetes was an independent predictor of peritonitis,[335] and additional studies have reported worse complications of peritonitis in diabetic patients, including higher mortality rates.[302,336] Although theoretically more prone to peritonitis, diabetic patients in fact have an incidence of peritonitis similar to that of nondiabetic patients,[10,337] recently reported as 105 events per 1000 patient years at risk.[10] Another recent study reported that diabetes was not associated with worse outcomes in nearly 400 episodes of peritonitis.[338] Other data show an increased risk of tunnel infections without more frequent peritonitis.[339] Diabetics have significantly higher rates of hospital admission for peritoneal dialysis catheter complications than nondiabetics.[10] The duration of infection and the frequency of need for catheter removal appear similar in nondiabetic and diabetic patients. Organisms causing peritonitis are similar in these two populations on peritoneal dialysis.[340] Blind diabetic patients may have increased peritonitis rates and more severe disease. Overall, infections other than peritonitis more frequently cause death in diabetic patients on peritoneal dialysis.[341]

Table 10–4 Intraperitoneal Insulin Dosing in Peritoneal Dialysis

- Start CAPD with four daily exchanges each 2 L.
- Add up total subcutaneous insulin dose in units. Add one-fourth of the total as regular insulin to each bag of dialysate.
- For 1.5% dextrose, add 2 units regular insulin per bag.
  For 2.5% dextrose, add 4 units regular insulin per bag.
  For 4.25% dextrose, add 6 units regular insulin per bag.
- Perform each exchange 20 minutes before breakfast, lunch and dinner, and at 11PM before bed.
- Check fasting and 1 hour postprandial blood sugars.
- Adjust insulin dose based on blood sugar as follows:

Fasting Glucose (mg/dL)	1 h Postprandial Glucose (mg/dL)	Insulin Adjustment (units)
	<40	−6
<40	40-80	−4
40-80	80-120	−2
80-180	120-180	0
180-240	180-240	+2
240-400	240-300	+4
>400	>300	variable

- For patients on CCPD, reduce the total daily insulin dose to 85%.
- Give up to half of this dose in the daytime dwell; use the remainder in cycled exchanges.
- Beware of the risk of hypoglycemia when the patient converts from CCPD to CAPD status.

CAPD, continuous ambulatory peritoneal dialysis; *CCPD*, continuous cyclic peritoneal dialysis. (From Tzamaloukas AH, Friedman EA: Diabetes. *In* Daugirdas JT, Blake PG, Ing TS [eds]: Handbook of Dialysis, 3rd ed. Lippincott, Williams & Wilkins, 2001, p 453.)

Chronic carriers of *S. aureus*, with or without diabetes, are at higher risk of exit-site infections and of tunnel infections.[342-344] Furthermore, carriers have a higher rate of *Staphylococcal peritonitis*. In one study, three fourths of diabetic patients on peritoneal dialysis were nasal carriers of *S. aureus* (twice the rate of nondiabetic patients).[342] In another report, diabetics tended to have higher rates of nasal carriage than exit site colonization with *S. aureus*, and nasal carriage was more important prognostically than positive exit-site culture in determining risk of *S. aureus* catheter-related infection. Diabetics were at significantly higher risk of *S. aureus* catheter infection than nondiabetics in this study.[345]

Eradication of the staphylococcal carrier state seems to reduce the risk of peritonitis and catheter loss.[346] In a large study population, of whom 30% were diabetic patients, mupirocin 2% ointment applied daily to the exit site was as effective as oral rifampin in preventing catheter-related *S. aureus* infection.[343] A recent review concluded that with either oral rifampin or mupirocin ointment, there was strong evidence that prophylaxis reduced the rate of exit-site infections, while the evidence for decreased rates of tunnel infections and peritonitis was weaker.[347] Although *S. aureus* catheter infections and peritonitis may be serious, the role of prophylaxis for all diabetic patients undergoing CAPD remains to be determined.[348] There is a growing consensus that at least those diabetic patients who are carriers of *S. aureus* should receive antibiotic prophylaxis.[345]

Initial treatment of peritonitis in diabetic patients should be similar to that in nondiabetic patients[343] and should follow the recent recommendations of the International Society for Peritoneal Dialysis.[349] In patients with residual urine output of greater than 100 mL/day, empiric therapy should consist of a first generation cephalosporin, such as cefazolin, and the third generation cephalosporin, ceftazidime, which can be mixed in the same bag for one exchange per day.[349] Because of the recent increase in vancomycin-resistant enterococci,[350] empiric use of vancomycin is now discouraged. Empiric use of cefazolin once daily intraperitoneally appears to be as effective in treatment of peritonitis as vancomycin.[351] Aminoglycoside exposure accelerates loss of residual renal function in peritoneal dialysis patients[352] and is therefore avoided in patients with urine output greater than 100 mL/day.

Fungal peritonitis is an uncommon but severe complication of peritoneal dialysis and may be caused by a growing list of fungal agents. *Candida albicans* is by far the most common.[353] Catheter removal is necessary in most cases of fungal or mycobacterial infections. Diabetes does not appear to predispose to fungal peritonitis.[340,353] However, diabetes was a risk factor for non-*Candida albicans* peritonitis in a recent, very small series of peritoneal dialysis patients.[354]

Gastroparesis

Diabetic gastroparesis is twice as common (70% vs. 37%) in type I than in type II diabetics.[355] Symptomatic gastroparesis may be aggravated by peritoneal dialysis and is an important cause of hospitalization.[356] Gastric emptying is delayed when the peritoneal cavity is full, even in nondiabetic peritoneal dial-

ysis patients.[357] Gastric emptying is significantly slower with dextrose dialysate than with icodextrin dialysate, suggesting that impaired gastric emptying in peritoneal dialysis is not merely reflecting the effect of increased intraabdominal pressure due to the volume of dialysate.[358] Radionuclide gastric emptying results may not correlate with symptoms. A few small studies have reported delayed gastric emptying in approximately 50% of all CAPD patients even without symptoms.[359] Patients refractory to oral metoclopramide on CAPD may respond to intraperitoneal erythromycin, 100 mg/2 L dialysate, with exchanges 30 minutes before meals.[356] Improvement in the radionuclide gastric emptying study with treatment using prokinetic agents resulted in a significant increase in serum albumin levels reflecting improved nutritional status.[360]

Retinopathy

Although vision is less likely to deteriorate in diabetic patients who have undergone renal transplantation, loss of vision is independent of dialysis modality, having similar progression in patients on peritoneal dialysis and hemodialysis.[201,339] Blind patients have decreased technique survival rates.[361] Newer techniques are being developed to allow visually-impaired ESRD patients to perform peritoneal dialysis independently at home without increased risk of peritonitis.[362]

MALNUTRITION

Some reports show that serum albumin is only weakly correlated with other markers of nutritional status such as BMI, percent lean body mass, and a normalized protein equivalent of nitrogen appearance in peritoneal dialysis patients.[363,364] Whereas hypoalbuminemia predicts risk of mortality in the hemodialysis population, its validity is less established in diabetic patients on peritoneal dialysis.[365,366] A low serum albumin level was the variable most closely associated with death risk in a large national survey that included an analysis of peritoneal dialysis patients, 40% of whom were diabetic.[367] A recent report also proposed low prealbumin as a marker of malnutrition and decreased survival in peritoneal dialysis patients.[368] The 40% prevalence rate of protein-calorie malnutrition in patients on CAPD is greater than that in patients on hemodialysis,[369,370] and almost 10% of these patients have moderate to severe malnutrition. Protein malnutrition may be associated with a twofold increase in cachexia-related deaths in diabetic patients on peritoneal dialysis, compared with nondiabetic patients.[371] In one recent study, diabetic patients on peritoneal dialysis had a tendency toward lower serum albumin concentrations, and hypoalbuminemia was a marker of morbidity, especially related to an increased risk of hospitalization.[365]

Hypoproteinemia may be worse in diabetic than nondiabetic patients on peritoneal dialysis. Protein losses in the dialysate (5 to 15 g/day, two thirds of it albumin)[372] and inadequate protein intake are principal causes.[373] Diabetic patients may have greater peritoneal protein permeability than nondiabetic patients on CAPD.[374,375] The greatest protein losses occur during longer dwells, such as overnight, or during bouts of peritonitis. Ongoing urinary protein losses contribute in some patients. Better dialysis adequacy is associated with higher serum albumin.[376] Greater residual renal function has also been associated with higher dietary protein intake.[377]

Malnutrition may be worsened by increased gastroparesis.[360] Markers of inflammation such as C-reactive protein correlate with a low serum albumin, suggesting that an acute phase response during peritoneal dialysis may also contribute to hypoalbuminemia.[378]

Because CAPD patients are able to increase nitrogen synthesis and become protein anabolic in response to increased dietary protein intake, a minimum daily protein intake of 1.2 g/kg is recommended.[369] Other measures available to improve the nutritional status of CAPD patients (including early initiation of dialysis, more intensive dialysis, nutritional counseling, and intraperitoneal amino acid solutions)[369] have not been specifically tested in diabetic patients. Nutritional supplementation with amino acid-containing dialysis solutions has been effective in inducing protein anabolism[379] and increasing serum albumin, prealbumin, and transferrin concentrations,[380] but has been associated with increased serum urea concentrations and metabolic acidosis.[381] A new peritoneal dialysis solution containing both glucose and amino acids has been shown to increase serum amino acid levels to normal without increasing urea, suggesting improved amino acid utilization for protein synthesis without increased urea.[382] Because inadequate dialysis is a risk factor for severe malnutrition in patients on peritoneal dialysis, an increase in the amount of dialysis delivered may be necessary when residual renal function is lost.[267,383] Transfer to continuous cycling peritoneal dialysis may result in improved caloric intake and diminished protein losses relative to CAPD.

SURVIVAL

Patient survival rates for diabetics on peritoneal dialysis have improved 28% from the cohort of patients on peritoneal dialysis between 1987 and 1991 to the cohort of patients on peritoneal dialysis between 1992 and 1996.[9] However, it remains true that uremic diabetic patients have lower survival rates than nondiabetic patients regardless of treatment modality[9,384,385] (Table 10–5). Differences in mortality rates of diabetic patients on peritoneal dialysis versus hemodialysis have generally been small.[386] According to the USRDS, mortality rates of diabetic patients with ESRD who were treated with peritoneal dialysis were slightly higher than those of patients undergoing hemodialysis.[9] A recent prospective analysis compared mortality in all ESRD patients on hemodialysis versus peritoneal dialysis and found that there was no significant difference in mortality during the first 2 years of therapy; however, after the first 2 years, patients on hemodialysis had a survival advantage.[387] Among patients older than age 65 beginning renal replacement therapy, the mortality over the first year on dialysis was higher for peritoneal dialysis patients than for hemodialysis patients, and this difference was more pronounced among diabetics.[388] A report from Europe looking specifically at type II patients found greater mortality in those on peritoneal dialysis than in those on hemodialysis over 14 months of follow-up.[389] Another recent report found that both diabetic and nondiabetic patients with underlying coronary artery disease had poorer survival on peritoneal dialysis than on hemodialysis.[390] Other studies that have shown a survival advantage for peritoneal dialysis over hemodialysis have attributed this to physician selection of healthier patients for peritoneal dialysis.[391,392] In addition, dia-

Table 10–5 Peritoneal Dialysis Outcomes in Diabetic Patients

- Inferior survival compared with that for nondiabetic patients on peritoneal dialysis (PD)
- Slightly inferior overall survival compared with that for diabetic patients on hemodialysis
- Better survival for young patients receiving PD
- Older diabetic patients (>60 yr) do better with hemodialysis
- Survival rates for patients with type I diabetes are better than those for patients with type II diabetes who are on PD
- Poor technique survival in patients with type II diabetes
- Causes of death similar to diabetic patients receiving hemodialysis

betes was a death risk predictor in a survey that included more than 1500 peritoneal dialysis patients.[367]

Recent data show 2-year survival for patients on peritoneal dialysis at 78%, with technique survival at 2 years of 62%.[393] Increased age, poor nutritional status, and presence of diabetes were predictors of decreased survival.[393] Previous data showed 1-, 2-, and 3-year survival rates for type I diabetic patients on CAPD of 92%, 75%, and 50%, respectively.[394] Survival rates have been better for type I than for type II diabetes at both 1-year (92% vs. 74%) and 2-year (65% vs. 23% vintage on CAPD.[395] Two recent reports demonstrated better early (1 year) survival with worse longer term (>1 year) survival for type II as compared to type I diabetics on peritoneal dialysis.[396,397] Survival rates at 1, 3, and 5 years for type I versus type II diabetics on CAPD were 89% versus 100%, 71% versus 69%, and 58% versus 39%, respectively. Both groups of diabetics had worse survival than nondiabetics, despite sufficient and comparable dialysis adequacies.[396] Long-term survival on peritoneal dialysis is better for type I than for type II diabetics.[398] Ten-year survival of patients started on peritoneal dialysis was 50% for type I diabetics and 11% for type II diabetics, including patients who had changed modality to hemodialysis or been transplanted.[399] In a review of age-adjusted CAPD outcomes at one facility in the United States over 10 years, the median survival in type I diabetes (21 months) did not statistically differ from rates from other major causes of ESRD, whereas type II patient survival was significantly worse (11 months).[400]

Compared to hemodialysis, peritoneal dialysis led to better survival for young patients (< 45 years old), whereas older patients (> 60 years old) with type II disease did better on hemodialysis.[395] Other data support an effect of age on outcomes in patients on CAPD.[339, 401] One report attributed all of the increased mortality in type I diabetics to comorbid cardiovascular disease and in type II diabetics to comorbid cardiovascular disease and increased age.[397] In an analysis of the Case Mix Severity Special Study of the USRDS, which included Medicare patients starting dialysis during 1986 to 1987, higher overall adjusted mortality for CAPD relative to hemodialysis was found among diabetic patients. Increased CAPD mortality was particularly evident in elderly patients with type II disease. In fact, the analysis revealed that younger patients on CAPD may have a lower mortality risk than those

on hemodialysis, particularly because of fewer comorbid conditions. The best survival in peritoneal dialysis is achieved in younger patients who are initially free of cardiac disease and are nonsmokers. No similar relative mortality risk was found for nondiabetic patients selected for peritoneal or hemodialysis in the Case Mix Study.[402] Diabetic patients treated with peritoneal dialysis had higher hospitalization rates than those treated with hemodialysis, except for younger patients less than age 40.[9, 403]

Additional factors have been shown to influence outcomes in diabetic patients on peritoneal dialysis. Early referral to a nephrologist prior to initiation of peritoneal dialysis was associated with better survival in type II diabetics.[404] Survival was better in patients with greater residual renal function, although this was not specifically shown in diabetics.[405] A high peritoneal transport rate has been associated with poorer survival, although it seems to be a marker for diabetes, which is the most important risk factor for mortality in peritoneal dialysis patients, so that a high transport rate may not impose any independent risk for mortality.[406,407] In type II diabetics, better glycemic control prior to initiation of peritoneal dialysis (defined as hemoglobin A_{1C} <10% for at least 6 months prior to starting dialysis) was associated with better survival.[408] Independent predictors of mortality in peritoneal dialysis patients in the CANUSA study included increased age, insulin-dependent diabetes, cardiovascular disease, low albumin, poor nutritional status by global assessment, and lean body mass.[409] Another recent report identified independent predictors of mortality as increased age, diabetes, low albumin, elevated diastolic blood pressure, and increased lipoprotein(a) levels.[410]

Peritoneal dialysis technique survival, defined as remaining on this modality without either death or transfer to hemodialysis, may also be inferior in diabetic patients.[395, 411] Some studies[412] have also shown more frequent technique failure in diabetic patients when defined only as transfer to hemodialysis. However, subsequent reports have found similar technique survival for diabetics and nondiabetics on peritoneal dialysis,[385,413] although technique survival on peritoneal dialysis is worse than on hemodialysis.[385] Technique failure resulting from increased membrane permeability, loss of ultrafiltration, and fibrosis of the peritoneal membrane are hastened by accumulation of AGEs because of high glucose-containing peritoneal dialysis solutions in both diabetic and nondiabetic patients.[385] Few studies have compared technique survival in type I versus type II diabetes. CAPD technique survival rates (defined as removal from peritoneal dialysis or death) in type I diabetics were 75% at 1 year and 60% at 2 years, which were better than for type II diabetics. Type II diabetes is the main risk factor for poor technique survival, which is only 35% at 2 years and 18% at 3 years.[400] Technique survival did not differ between patients with type I and type II diabetes in the recent CANUSA study.[414] For technique survival in that analysis, death was censored.

The causes of mortality in patients on peritoneal dialysis are similar to those associated with hemodialysis. Nearly half of the deaths are cardiovascular. Death from acute myocardial infarction in patients on peritoneal dialysis, for example, is more than twice as common in diabetic patients than in nondiabetic patients. Diabetic patients on peritoneal dialysis also die nearly two times as often from cardiac arrest, septicemia, cerebrovascular disease, and hyperkalemia than do nondiabetic patients on peritoneal dialysis.[9] In addition, their hospital

admission rates and lengths of stay are higher than those of nondiabetic patients.[9] Diabetic patients on peritoneal dialysis require less antihypertensive therapy,[415] have more gastroparesis, and may have an increased risk of lower extremity amputation. Experience with long-term survival is limited, but it is more likely with young age, absence of coronary disease, and good blood pressure control.[361]

TRANSPLANTATION

Although improved care of uremic diabetic patients has resulted in a growing population of diabetic transplant recipients,[416] diabetic transplant candidates remain disadvantaged. Diabetics are less likely to be wait-listed before the start of ESRD therapy,[417] and the percent of ESRD diabetics on the waiting list, compared to all causes, is lower.[418] Nonetheless, a large portion of the patients on the national deceased donor waiting list have diabetes.[419] Although the incidence of ESRD has continued to increase for diabetics and for all patients in the United States, however, the transplant rates have not kept pace, decreasing in 2000 to 3.7/100 patient years on dialysis for diabetics compared to 6.6/100 patient years for all ESRD patients (Figure 10–6). Diabetics comprise 44% of all incident ESRD patients but only 17% of those transplanted. The annual incidence rate decreased by 4.6% between 1996 and 2000. Diabetics comprise about 20% of recipients from both deceased and living donors. Of the incident ESRD population of diabetic patients, 13% received a kidney transplant in 2000.

Nonetheless, relatively low mortality rates have led to continued growth (annual change + 6%) in the number of prevalent diabetic transplant recipients. The number of diabetic recipients in the United States increased from 15,608 to 21,132, of a total of 103,809 recipients in year 2000. With improved short-term success rates, diabetic transplant recipients overwhelm the resources of the transplant center[420] and receive long-term follow-up care by community-based nephrologists.[421] Across the United States, point prevalence in ESRD networks varied somewhat, between 16.5% and 27.2%.[9] Most recipients have type I diabetes. By comparison, in few other countries do diabetic patients account for greater than 10% of the total renal transplant population.[416] Following transplantation, diabetic recipients are roughly one and one-half times more likely to have a hospital admission, with hospitalized days annually increased to 8.1 compared to 5.3 for all recipients. In addition to transplant care, management must address all the potential complications of diabetes. In advance of surgery, the candidate should have been evaluated for factors that could negatively affect transplantation outcomes (see Table 10–2). Postoperative management may be made difficult by the concurrent problems of glycemic control, gastroparesis, impaired wound healing, hypertension, malnutrition, and urinary retention. Insulin therapy, either intravenous or subcutaneous, should continue in the recovery room. Postoperative hyperkalemia is common, especially when graft function is delayed, and may require extra insulin or even acute dialysis.[422] Sodium polystyrene sulfonate, especially in sorbitol, should be avoided initially because of the risk of intestinal necrosis.[423] Given experimental evidence that sorbitol is toxic to bowel mucosa, administration with another vehicle may be indicated.[424,425]

Postoperative conversion to oral medications and fluids may be delayed because of gastric atony and bowel dysfunc-
Figure 10–6 Incidence of ESRD and rate of transplantation (per 100 dialysis patient years), 1995 – 2001. Rates adjusted for age, gender, and race. Population estimates obtained from U.S. census data. tion. The promotility agent metoclopramide may increase cyclosporine levels, and erythromycin, also used for gastroparesis, may precipitate frank cyclosporine[426] or tacrolimus[427] toxicity by decreasing drug hepatic metabolism. Wound complications are more common in patients with diabetes. Because of slower neo-ureterocystotomy healing and coexisting bladder atony, an indwelling catheter should remain in place longer than for the nondiabetic recipient. Despite near doubling of insulin doses on average, glycemic control remains suboptimum in many patients.

Ischemic Heart Disease

Although cardiovascular event rates are markedly higher in dialysis patients,[3] cardiovascular disease (coronary artery

disease, peripheral vascular disease, and cerebrovascular disease) has emerged as the leading cause of death in kidney transplant recipients.[428,429] Transplantation is associated with atherogenesis accelerated by the combined effects of preexisting vascular disease and post-transplant factors. This premature development of atherosclerosis is multifactorial[430] because of traditional cardiovascular risk factors (including diabetes) and to factors uniquely related to chronic kidney disease, dialysis, and transplantation.[431,432]

The cumulative incidence of coronary artery disease over 15 years of transplantation is about 25%.[433] Cardiovascular disease accounts for about half of all deaths in ESRD patients and 17% to 50% of deaths among renal transplant recipients. The prevalence of all cardiovascular types at the time of transplantation was 12.9% in one study.[434] By the time of initiation of chronic dialysis treatment, 25% of patients have a history of ischemic heart disease.[435] Cardiovascular mortality rates in patients undergoing dialysis are nearly 15-fold higher than the normal population.[436] In the USRDS, cardiac mortality is high, with overall in-hospital mortality rates with myocardial infarction of 26%.[437] Diabetes is more prevalent in patients with documented cardiovascular events pre-transplant.[438] Diabetic patients manifest the highest cardiovascular morbity and mortality rates of any group of ESRD patients.[439] Overall mortality rates are two times higher when ESRD is secondary to diabetes mellitus, and the risk of death from cardiovascular disease is over two times higher,[440] with ischemic heart disease (IHD) accounting for most. With glomerulonephritis as a reference level for patients who died with functioning grafts, the relative risk by multivariate Cox proportional hazard regression was 1.93.[441] The risk of death in diabetic transplant recipients ages 55 to 64 years is 20 times that of the general population.[439]

The relationship between ischemic heart disease and markers of risk in transplant recipients has been studied to define high risk patients and the roles of individualized risk factor intervention.[433] Some risk factors for post-transplant cardiovascular disease are the same as for the general population, including gender, age, obesity, and a sedentary lifestyle.[442] Classic cardiovascular risk factors including hypertension, diabetes, smoking, and anemia, account for a large part but not for all of the excessive prevalence of IHD in the ESRD population.[438,443] Additional accepted factors altered by the uremic state include disordered lipid metabolism, secondary hyperparathyroidism, and hyperhomocyteinemia[444]; inflammation, oxidative stress, endothelial dysfunction, and apoptosis-related abnormalities in the vessel wall are under evaluation.[445] Among these, hypertension, hyperlipidemia, hyperhomocysteinemia, and hyperglycemia are modifiable by current treatments.

New IHD events continue to accrue many years after transplantation.[443] Following transplantation, significant risk factors for IHD include age, male gender, hyperlipidemia, delayed graft function, acute rejection, obesity, and diabetes.[446] Women are particularly vulnerable to the cardiovascular consequences of diabetes.[447] The roles of other potential factors such as hypercoagulability are currently being evaluated.[430] At early stages of diabetic nephropathy, coronary risk factors begin to aggregate, including lipids, growth factors,[448] and coagulation factors. In addition, cardiovascular disease in diabetic patients with nephropathy clusters in families, supporting an additional genetic mechanism of risk factor aggregation.[449] The mortality risk from cardiovascular causes in proteinuric type I diabetic patients is higher than in nonproteinuric diabetics.[450-452] Immunosuppressive therapy, particularly corticosteroids, may further aggravate risk factors for atherosclerotic vascular disease in transplant recipients.[439] Recently, decreased renal function has emerged as an additional risk factor for acute coronary syndromes in transplant recipients.[453] Many transplanted diabetic patients have mild to moderate renal insufficiency.[436] A recent study reported that higher rates of heart disease requiring hospitalization were associated with stage III chronic kidney disease, 1 to 3 years after transplantation. The association persisted after correction for other known cardiovascular risk factors.[454]

The high rates of serious and fatal IHD in diabetic transplant recipients underscores the need for a systematic approach that begins long before the development of ESRD. Clinical practice guidelines have recommended that screening tests in general should be based on the individual's risk estimate for IHD.[455] Increased graft and patient survival can be achieved using screening strategies to assign risk stratification and exclude those with significant coronary artery disease.[456] However, the most ESRD diabetic patients with severe coronary artery disease do not have tyical anginal symptoms,[457] although the presence of even asymptomatic coronary disease places ESRD diabetic patients at high risk for subsequent myocardial infarction.[458] Even in asymptomatic diabetic recipients, coronary stenosis over 50% is present in over half.[459]

Because of the high incidence of coronary ischemia and because they are more likely to have coronary ischemia that is unrecognized, screening of diabetic kidney transplant candidates undergo more cardiac screening tests than nondiabetics.[460] All symptomatic diabetic patients and high-risk type I patients require angiography; in all others, diabetes is a coronary risk factor, which will require noninvasive evaluation.[456] For preoperative screening alone, for example, diabetic candidates may have high risk for surgery based on standard criteria.[461] For those otherwise at low risk, the presence of diabetes still requires noninvasive cardiac testing. While most transplant centers use noninvasive cardiac tests to screen diabetic candidates,[462] no single cardiac screening test is superior. Uremic diabetic patients are commonly unable to perform adequately on exercise testing, and accuracy of radionuclide imaging in detecting coronary disease is suboptimal.[463] For example, thallium stress testing has low predictive value because of its high incidence of false-positive results, up to 50% in one study.[464] However, the addition of an imaging modality can increase the sensitivity and specificity of noninvasive testing.[465] Dipyridamole thallium imaging supplemented by echocardiography may be superior.[465] Electron beam computed tomography is of uncertain value at this time.

While therapeutic nihilism continues to affect cardiovascular management in ESRD patients,[464] pre-transplant patients with positive screening tests or with symptomatic coronary disease should undergo coronary angiography (Figure 10–7). One study utilized clinical criteria to define a group of type I patients at low risk of cardiac mortality (age < 45 years, diabetic for < 25 years, nonsmoker, normal electrocardiogram[466]), in whom coronary angiography can be avoided. However, no follow-up verification of low-risk status after transplantation has been reported. In patients with symptoms and significant (> 70%) coronary stenosis, coronary bypass or

Data suggest that noninvasive evaluation or coronary angiography are necessary except for some in low-risk category. (Modified from Williams ME: Management of the diabetic transplant recipient. Kidney Int 1995; 48: 1660. Used with permission of Kidney International.)

angioplasty should be performed, although in the absence of stenting, the latter has a high rate of re-stenosis.[467] In a randomized series, a high rate of cardiovascular events was reported in diabetic patients with chronic renal failure and silent coronary disease that was treated medically (i.e., aspirin, calcium channel blockers), as compared with angioplasty or bypass surgery.[468] No similar studies involving lipid-lowering medical management has been done.

Patients with positive screening tests can nonetheless undergo transplantation if appropriate revascularization is performed. Myocardial revascularization surgery using cardiopulmonary bypass can be performed acceptable morbidity and mortality rates in transplant recipients in general.[469,470] Revascularization of advanced disease in symptom-free patients should probably depend on its location and severity. Patients with severe three-vessel disease or left main coronary disease causing severe left ventricular dysfunction may need to be excluded from transplantation. Further emphasis on risk factor management is needed to reduce cardiovascular mortality in the diabetic transplant recipient.[471]

Dyslipidemia

The prevalence of dyslipidemias in patients with chronic kidney disease is high, and only a minority of dialysis patients have normal lipid levels. Dyslipidemias are present in the majority of transplant recipients and are characterized by high total and LDL-cholesterol. Triglycerides are often increased, and, in some, HDL is low. Diabetes contributes synergistically to these unfavorable alterations in lipid profiles.[472] Transplant recipients may also have other nonclassical lioprotein abnormalities. The association of elevated lipid levels and cardiovascular disease or survival of diabetic transplant recipients, however, may be less obvious than in the general population.[473,474] Lipid values are persistently elevated in the first post-transplant year and may decrease partially thereafter.[475] The hyperlipidemic effect of steroids, which varies widely among patients, may result from stimulation of hepatic very low density lipoprotein synthesis, leading to increased plasma triglycerides and an increase in total serum cholesterol. Cyclosporine has also been implicated as a causative factor in

some studies, although the effect is not well-understood. There is no evidence that tacrolimus or mycophenolate mofetil worsen lipoprotein metabolism. Hyperlipidemia is a significant side effect of sirolimus treatment, leading to remarkable increases in mean total cholesterol (50%), LDL-cholesterol (50%), and triglyceride levels (95%) in one study.[476] Specific data on diabetic recipients are not available.

No consensus exists on the ideal management of dyslipidemia in transplant recipients,[477] and adequate trials in the diabetic recipient have not been performed.[478] Lipid reduction strategies should include improved glycemic control,[479] appropriate exercise, and a lipid-lowering diet. However, dietary modifications, especially control of total caloric intake, may be safe but are generally unsuccessful.[480] Immunosuppressive options in high-risk patients generally include withdrawing prednisone, replacing cyclosporine, and avoiding use of sirolimus.[481] Concomitant cyclosporine may increase systemic exposure of all HMG-coa reductase inhibitors, but may be used safely in reduced doses.[482] Statins do not induce increased blood levels of cyclosporine. A recent single-center retrospective analysis showing improved survival in recipients treated with statins included 21% diabetics in the statin-treated population and 22% in the untreated population.[483]

Bile acid sequestrants may worsen high triglyceride levels, may cause gastrointestinal side effects in transplant recipients, and may further impair cyclosporine absorption in diabetic recipients. Nicotinic acid can lower low-density lipoprotein and increase high-density lipoprotein levels in transplant recipients, but may worsen insulin resistance and glycemic control. Fish oil supplements, an alternative best suited for high triglyceride levels, have not been tested in diabetic patients.

Peripheral Vascular Disease

In addition to coronary artery disease, diabetes mellitus leads to peripheral vascular disease with increased limb amputations.[484] Although less lethal than coronary disease, occlusive peripheral vascular disease also limits the success of renal transplants,[485] resulting in 20 times the increase in minor and major amputation rates in diabetic recipients. Pre-transplant large vessel disease is three times more common in diabetic recipients,[486] and vascular disease detected before transplantation doubles the risk of new disease afterward.[487] Pre-transplant coronary disease is associated with increased risk of peripheral vascular complications afterward and a sevenfold increase in risk of amputations.[452] Vascular calcification is an independent predictor of mortality in diabetic patients.[488] Smoking has a strong negative effect on amputation rates.[489] Many amputations are performed in younger recipients. Diagnostic studies show that abnormal toe/brachial pressures and pulse value recordings can be used to assess resting hemodynamics and peripheral vascular disease after renal transplantation.[490]

Hypertension

The etiology of post-transplant hypertension in the diabetic recipient is multifactorial.[491] While the prevalence of hypertension varies with the time after transplantation and the immunosuppressive regimen, it is likely that recipient factors such as pre-transplant hypertension and diabetes are contrib-

utors.[492] A near doubling of hypertension rates over time, to 80% to 90% of recipients,[493] has been attributed to the use of calcineurin inhibitors. Cyclosporine-treated patients are somewhat more likely to have hypertension (89%) than those receiving tacrolimus (78%).[494] The prevalence of hypertension in diabetes mellitus is about twice that of nondiabetics. Hypertension is present in most diabetics awaiting a transplant[495,496] and persisting post-transplantation. It is possible but not proven that diabetic recipients have more pronounced hypertension as a result of calcineurin inhibitors. The incidence of transplant renal artery stenosis does not appear to be increased.

Hypertension contributes to the high incidence of cardiovascular disease, mortality, and late allograft failure.[491] Even minor elevations of systolic and diastolic pressure may impact on graft survival. However, despite the growing number of diabetic transplant recipients, the impact of post-transplant hypertension has not been studied.

Numerous hypertension guidelines do not directly address the issue of post-transplant hypertension, including in the diabetic recipient.[497] Hypertension treatment goals have not been specified[498] but are based on those for the general population. Recent European practice guidelines mandated goals of less than 125/75 mmHg in proteinuric transplant recipients.[492] Pharmacologic therapy is usually necessary, and most conventional therapies have been demonstrated to be safe and effective in the general transplant population. The most commonly used therapeutic options such as calcium channel blockers and angiotensin converting enzyme inhibitors are equally effective in reducing blood pressure. Proteinuria in the transplant recipient is an indication for ACEI rather than for calcium channel blockers. ACEI slows progression of renal disease in diabetic nephropathy,[12] and retards experimental chronic allograft rejection.[499] Angiotensin receptor blockers are potentially and similarly useful.[500] However, a recent study showing the safety and efficacy in post-transplant patients included only a minority of diabetic recipients.[501] ACEI and ARBs have gained wider acceptance in the diabetic recipient and, when used cautiously, are probably effective[502,503] and may be renoprotective. Hyperkalemia and anemia may complicate their use.[504] Treatment failures of post-transplant hypertension may be common.[505] Twenty-four hour ambulatory blood pressure measurements may become a valuable clinical tool in assessing treatment efficacy. Blood pressure control may be improved when type I patients undergo combined kidney and pancreas transplantation.

Urologic Complications

Arising mainly from technical difficulties during the surgery,[506] urologic complications in general have decreased in renal transplant recipients. They remain almost twice as common in diabetic transplant recipients.[507] Diabetic bladder dysfunction and urinary retention commonly occur. Pre-transplant urologic evaluation, such as voiding cystourethrogram are performed in some centers but are not routinely indicated in the absence of voiding symptoms or urinary tract infections.[508] Two common urologic complications, postoperative urinary leaks and obstruction, have a technical basis not related to diabetes. Urinary fistulas are less common but occur more frequently in diabetic recipients. Urinary retention is managed with bladder retraining, cessation of anticholinergic drugs, and the use of

parasympathetic medications. Emphysematous cystitis may be a sequela to neurogenic bladder or bladder outlet obstruction but responds to early diagnosis and treatment.[509] Long-term graft survival is not affected by surgically corrected urologic complications.[510]

Infectious Disease

Infectious complications after kidney transplantation remain a significant cause of morbidity and mortality for the diabetic recipient. Diabetes mellitus has been shown to be a predisposing factor for post-transplant surgical wound infections,[511] bowel perforations, urinary tract infections, including pyelonephritis,[509] and hospitalizations for sepsis.[512] In a large review of data from the USRDS, patients with ESRD renal transplantation resulting from diabetes was associated with a higher risk of sepsis due to gram-negative rods and to urinary tract infections.[512] Diabetic recipients are also prone to opportunistic infections. Persistent colonization or low-grade infection with *Candida* species is relatively common and can lead to emphysematous cystitis and pyelonephritis, papillary necrosis, renal or perinephric abscesses, and *Candida fasciitis.*[513] Colonization should respond to amphotericin bladder irrigation or oral fluconazole. Upper urinary tract infection requires intravenous amphotericin. Aggressive management is necessary to eradicate torulopsis species infection. Diabetes is the most common associated disease for tuberculosis in kidney transplant patients.[514] While mucormycosis is a rare fungal opportunistic infection, it is frequently associated with diabetes,[515] where it causes pulmonary,[516] cutaneous, or disseminated disease. Aggressive treatment with liposomal amphotericin and surgical resection of all infected tissue is required.[517]

Diabetic Retinopathy

As a consequence of the duration of diabetes and the presence of end-stage renal disease, advanced diabetic retinopathy is present in a high proportion of diabetic transplant recipients. Half of recipients are visually impaired, and visual acuity commonly deteriorates in the year preceding transplantation.[518] Whereas the incidence of sight-threatening complications in nondiabetic survivors of renal transplantation is low,[519] preservation of vision in the diabetic may require laser photocoagulation and vitrectomy. Retinopathy can stabilize in the majority of diabetic patients. Posterior subcapsular cataract formation with extended steroid use imposes significant additional impairment of visual acuity[520] and may account for later vision loss in many patients.[521] Ophthalmologic examination should occur every 6 months.

Fractures

Despite improved treatments of bone and mineral metabolism in end-stage renal disease, increased bone fracture rates in diabetic patients after kidney transplantation have been confirmed in recent studies.[522,523] One or more fractures occurred in about 20% of consecutive kidney recipients over about 4 decades in a cross-sectional study at a single center, with a mean follow-up of 6.5 years.[524] Kidney failure due to diabetes doubled the risk of fractures. The risk for foot or ankle fractures is increased almost fourfold in patients with

type I diabetes. Diabetic patients have increased risk of hospitalization because of fractures and decreased survival.[525] In the nontransplant population without renal disease, some studies have suggested an increased risk for fractures with diabetes[526] related to peripheral neuropathy, propensity to falling episodes, and bone fragility, attributed to low bone mass and decreased bone turnover and cortical osteopenia.[527] Evidence has suggested that fewer fractures and increased bone density occur in type II diabetic patients, but osteopenia places type I patients at risk for fractures. Further risk factors for bone osteopenia in pre-transplant renal failure have been widely studied and include secondary hyperparathyroidism, metabolic acidosis, and risk of low turnover bone disease. When measured by dual-photon absorptiometry, bone density is lower in dialyzed diabetic patients than in nondiabetic patients.[528] Low bone turnover (aplastic) states,[529] associated with about half of cases in one study from a decade ago[530] with increased aluminum accumulation on bone surfaces, have emerged as the most common disorder in diabetic patients with end-stage renal disease.[531] Risk of later fractures is correlated with the duration of kidney failure pre-transplant.[524] The major factor implicated in accelerated bone loss following kidney transplantation is use of glucocorticoids, which reduce intestinal calcium absorption, increase resorption of bone, increase renal calcium excretion, enhance sensitivity to parathyroid hormone, and suppress gonadal hormones.[532] Post-transplant bone loss is predominantly the result of steroid-induced decrease in bone formation. Cyclosporine produces increased bone turnover and severe osteopenia in rats,[533] but its specific effects on bone in humans, particularly when used with steroids, is unresolved.[534] Transplantation in the cyclosporine era, which has been accompanied by lower steroid doses, has increased the risk of foot and ankle fractures.[524]

Because of the high fracture risk, diabetic transplant recipients are suitable for fracture prevention. Few randomized controlled trials have examined preventative states to reduce fractures among kidney transplant recipients in general. High levels of bone loss in the initial 6 months are associated with higher steroid doses. Diminished bone mass in diabetic recipients should be managed by steroid reduction, calcium (1–1.5 g/day), vitamin D supplementation, and exercises to prevent disuse osteodystrophy. In postmenopausal women, estrogen therapy is indicated. Calcitonin attenuates cyclosporine-induced bone loss.[535] Bisphosphonates have been shown, in prospective, randomized, controlled trials to delay post-transplant bone loss,[536-538] but have not been evaluated in diabetic recipients.

Post-Transplant Diabetes Mellitus

As transplant management has increasingly emphasized control of post-transplant complications, post-transplant diabetes mellitus (PTDM) has received additional attention recently as a relatively common and potentially preventable cause of adverse transplant outcomes and cost of care. Also termed new onset diabetes mellitus (NODM), it has recently been recognized as an independent predictor of graft failure and mortality that may impact on immunosuppressive drug selection.

Unlike diabetes mellitus itself, the definition of PTDM has not reached a consensus. Criteria vary from the accepted definition of diabetes (fasting plasma glucose 126 mg/dL, to 2-hr

post-prandial 200 mg/dL in a standard oral glucose tolerance test, to consistent blood glucose levels over 140 mg/dL, to hyperglycemia with clinical symptoms of diabetes, to the requirement for insulin) in patients with no previous diagnosis of diabetes. The rates of detection vary with the definition of the condition used. The incidence is affected by the diabetogenic effects of prednisone, cyclosporine, and tacrolimus. While far less than some historical data show an incidence of up to 46% in patients treated with corticosteroids and azothiaprine,[539] more recent data indicate an incidence on cyclosporine/steroid and tacrolimus/steroid regimens of up to 20%, but more typically 5% to 10%. Concern about an increased risk associated with the use of tacrolimus (even with decreased steroid use) has been confirmed in some but not all studies ranging from 10% to 20%. Most cases occur within the first few months post-transplantation, but a recent large survey of Medicare beneficiaries who received their first kidney transplant between 1996 and 2000 revealed an incidence that increased from 16% to 24% in the interval from 12 to 36 months post-transplant (Figure 10–8).[540]

Although risk factors associated with PTDM among surveys do vary, consistent risk factors unrelated to immunosuppression include age, body mass index, African-American and Hispanic ethnicities, family history of diabetes, and hepatitis C.[540] Most studies have not shown a relationship to the cause of ESRD. Corticosteroids provoke glucose intolerance and diabetes by increasing insulin resistance and may also attenuate insulin secretion from the pancreatic β-cells.[541] The mechanisms for the diabetogenic effect of cyclosporine and tacrolimus are less defined but may involve the same combination of worsening insulin resistance and impaired insulin release. While PTDM might be expected to carry the same prognosis as diabetes itself, recent data have confirmed the risk of graft failure (1.63%), death-censored graft failure (1.46%), and mortality associated with it.[540] Despite the association between PTDM and tacrolimus, the drug was actually associated with improved graft survival in the same study. Management guidelines have recently been published[542] and focus attention on closer monitoring, more intensive glycemic control, including use of insulin, and individualization of the immunosuppressive regimen in patients difficult to control, including cessation of steroids in some cases, and conversion from tacrolimus to cyclosporine.[543] No controlled studies are available. Added Medicare costs are $21,500 per newly diabetic patient following renal transplantation.[544]

Recurrent/De Novo Diabetic Nephropathy

Diabetes mellitus remains the most common cause of end-stage renal disease in transplanted patients and may even be underdiagnosed in patients on the renal transplant waiting list.[545] Small series and large registries of transplanted patients indicate that 5% to 10% of allografts are affected by recurrent disease,[546] on average 36 months post-transplantation, that the half-life of allografts with recurrence is diminished, and rate of graft loss variably increased, ranging from a few up to over 50%.[547,548] Recurrence of diabetic nephropathy is an important problem in kidney recipients. Several series have indicated that recurrent diabetic histologic changes of mesangial expansion, glomerular basement membrane thickening, and arteriolar lesions can be found in nearly all trans-
Figure 10–8 Incidence of new onset, post-transplant diabetes mellitus *(PTDM)* after kidney transplantation in adults. Incidence estimated from Cox proportional hazards model; adjusted for multiple covariates. Bethesda, MD, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2003.)

planted diabetic patients after a few years.[549-551] Nodular glomerulosclerosis is less common and may occur in fewer than 20% of diabetic recipients even as late as 13 years after the procedure.[552,553] However, it remains difficult to accurately determine the incidence of recurrent diabetic nephropathy. Data are generally limited to allograft biopsy series done for clinical indications. Particularly in diabetic patients, renal biopsies to confirm their primary diagnosis are infrequently done. Histologic features may be mixed with those of rejection or drug nephrotoxicity. Some cases may be due to de novo rather than recurrent diabetic nephropathy.

Clinical diagnosis of recurrent disease may develop sooner than previously reported but appears to still occur later than other diseases, between 42 and 118 months in a recent series.[554] As in nondiabetic recipients, the half-life of renal allografts with recurrent disease is diminished compared to those without recurrent disease, and allograft survival is reduced. However, the time course to recurrent diabetic renal failure is slow, with fewer than 10% of recipients with recurrence having graft loss after 13 years in one study.[555] Overall, graft loss attributed to recurrent disease in the UNOS registry data was 2%.[556] Additional combined registry data from two transplant centers indicated that 50% of patients with recurrent diabetic nephropathy lost their allografts.[557] With an increasing incidence of post-transplant diabetes mellitus, de novo diabetic transplant nephropathy is now being recognized. A recent study reported that de novo disease was as prevalent as recurrent diabetic nephropathy and had a similar time of occurrence.[558]

Clinical risk factors that predict de novo or recurrent allograft diabetic nephropathy remain uncertain. Known risk factors do not appear to distinguish those with recurrence from those without, except for a loose relation to glycemic control in

some studies.[559] The role of angiotensin converting enzyme inhibitor/receptor blocker therapy in preventing histologic or clinical recurrence or de novo disease has not been evaluated. Progression of recurrent early diabetic lesions can be delayed by successful pancreas-after-kidney transplantation.[560] Recurrent diabetic nephropathy can be prevented after combined pancreas and kidney transplantation.[561] Long-term randomized studies will be required to further assess the impact of recurrent and de novo diabetic nephropathy and available treatments on allograft and patient survival.

SURVIVAL

The survival benefit of kidney transplant recipients varies with the original cause of ESRD. The increased number of prevalent diabetic transplant recipients (including high risk patients) in the United States reflects prevention of early graft loss[562] and improvement in short-term outcomes.[563] Although recent survival studies have analyzed outcomes in cadaveric or living donor kidney transplants versus kidney-pancreas recipients, data continue to confirm the survival advantage of kidney transplantation over dialysis for diabetic patients,[564] even those who qualify for a transplant.[565] Diabetic recipients have shared in the good outcomes of kidney tranplantation during the past two decades but have also benefited from better perioperative management, a reduction in steroid immunosuppression, and improved cardiovascular screening. Annual death rates for diabetic recipients of cadaveric transplants were half those for diabetics on the waiting list, and about one fourth those for all diabetic patients on dialysis in the United States in one study.[418] Long-term survival of diabetic transplant recipients exceeds that of diabetic patients on chronic dialysis,[566] even when selection bias is eliminated. The 30-day mortality rates are only slightly higher in diabetic than in other recipients.[567] Standard analysis shows patient survival curves that approximate those for nondiabetic patients (Figure 10–9). However, death rates post-transplantation are consistently highest among recipients with diabetic kidney disease, who have the poorest 5-year patient survival following transplantation from deceased donors (68% vs. 80% overall) or living donors (81% vs. 90% overall).[568] Annual death rates for diabetic recipients remain one and one-half times the overall death rates and have not significantly improved over the past

8 years.[569] Diabetes is an important determinant of death with a functioning transplant.

Although the increased number of diabetic transplant recipients (including high-risk patients) in the United States reflects improvements in short-term success rates as a result of prevention of early graft loss, diabetic ESRD patients are also more likely to receive a repeat transplant than those with other ESRD diagnoses.[570] For those type I diabetics wait-listed and previously transplanted, the survival advantage occurs earlier and is twice as great as for nondiabetic ESRD patients. Type II patients are less likely to be relisted.

Graft survival rates are shown in Figure 10–10. When graft loss due to recipient death is censored out, long-term graft survival in the diabetic recipient approaches that in nondiabetic patients. The leading overall causes of graft loss are allograft rejection and cardiovascular death. For example, late (5-year) graft loss is due to death in two thirds of diabetic recipients, twice the number in nondiabetics.[571] For older type II diabetic ESRD patients, the prognosis is worse whether renal replacement is dialysis or transplantation, although elderly patients who lack vascular complications may benefit from transplantation.[572] Risk factors for graft survival for deceased donors and living donor transplants are shown in Table 10–6.

REHABILITATION

A consequence of ESRD for the diabetic patients is deterioration of their psychologic and physical status. Many ESRD patients describe their physical condition prior to transplantation as poor[573] and lack abilities for even self-care at home. Rehabilitation of the dialyzed diabetic patient is marginally successful because of severe vision loss, limb amputation, stroke, and cardiac disability. For the diabetic transplant recipient, the goal of transplantation is improvement in well-being rather than cure of the underlying condition. Compared with dialysis, recipients of successful transplants are better rehabilitated, although diabetic recipients remain more impaired than nondiabetic recipients.[574] This is partly because of the inferior pre-transplantation health status of patients with diabetes. Most diabetic recipients experience a benefit in their general health[575] and may be spontaneously more active post-transplantation, but only one third are able to work.[576] Nondiabetic kidney transplant recipients are

Figure 10–9 Actuarial patient survival estimate by month for 116,811 recipients of first kidney transplants between 1990 and 2001, followed until 12/31/2001 for a death event. Diabetes mellitus vs. nondiabetic primary cause of renal failure. (From U.S. Renal Data System: USRDS 2003 Annual Data Report: Atlas of End-Stage Renal Disease in the United States. Bethesda, MD, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2003.)
twice as likely as diabetics to return to full-time work. Vocational rehabilitation facilitates employment and plays an important role in determining quality of life.[577] Although nondiabetic transplant patients commonly report physical and psychologic quality of life status as similar to healthy controls,[578] the perceived health status is lower among diabetic recipients.[579] Exercise training may improve levels of physical functioning, such as muscle strength and exercise capacity.[580] When compared with patients continued on dialysis, the improvement in health status provided by a successful transplant for the diabetic recipient may actually exceed that of nondiabetic recipients.

SOCIOECONOMICS

Management of ESRD patients costs the Medicare system billions of dollars annually, and ESRD payment costs are growing more rapidly than general Medicare expenditures. ESRD accounts for an increasing percentage of Medicare programs, mostly due to the growing population of patients.[9] Direct expenditures for health care in diabetic patients are also billions of dollars in the United States. In diabetics, management of chronic complications accounts for one third of expenditures, and the annual management costs are about two times those for people without diabetes.[581] Management costs increase as diabetes complications progress. Dialysis increases the cost of diabetes care 11-fold.[582] Patients with diabetes continue to consume the greatest amount of ESRD resources and have the most pronounced growth in health services to Medicare.[9] Current data for the USRDS indicate that although the cost of transplantation in diabetic patients still exceeds that in nondiabetic patients, it is still the least expensive treatment of ESRD, when compared with dialysis[3] and costs fewer dollars per life-year saved.[583] Annualized dialysis costs, which are relatively stable over time, average 19% higher for diabetic patients than for the entire dialysis population.[584] The economic costs of transplantation to diabetic recipients is initially a little increased over that for nondiabetic patients,
Figure 10–10 1994–2000 combined adjusted (Cox proportional hazards) deceased donor and living donor graft survival (months) for patients with ESRD due to diabetes. Probabilities are adjusted for age and race. (From U.S. Renal Data System: USRDS 2002 Annual Data Report: Atlas of End-Stage Renal Disease in the United States. Bethesda, MD, National Institutes of Health, National Institutes of Diabetes and Digestive and Kidney Diseases, 2002.)

but annualized average costs rise to between one third and two thirds higher, largely because of increased hospitalization rates.[3] The Medicare costs of transplantation for diabetics compared to nondiabetics are particularly increased for recipients over age 65. Hospitalization constitutes a significant portion of resource utilization by kidney transplant recipients,[585] and in-patient transplant-related expenditures are 25% higher for diabetic recipients. However, overall annual cost savings, when compared with dialysis, were greater for diabetic than for nondiabetic patients by more than $1300, in one study.[586] The cost benefits of re-transplantation are not as significant.[587]

Table 10–6 Risk Factors for Graft Survival for Deceased Donor Transplants and Living Donor Transplants

Primary Cause of ESRD	Percent of Patients	Hazard Ratio for All-Cause Graft Failure	Hazard Ratio for Death-Censored Graft Failure	Hazard Ratio for Death with Functioning Graft
Deceased donor transplants				
Diabetes	22.1	1.26	0.90	2.02

Nutrition in End-Stage Renal Disease
Tahsin Masud, M.D. • William E. Mitch, M.D.

There is abundant evidence that patients with chronic renal failure (CRF), including those treated by peritoneal or hemodialysis, have decreased body weight and subnormal values of serum proteins.[1–3] The mechanisms for these abnormalities are complex and have not been fully identified, but assigning these abnormalities to malnutrition is misleading, since it suggests that the abnormalities can be overcome simply by supplying more food or altering the composition of the diet. Although the focus of our discussion is geared toward nutrition in end-stage renal disease (ESRD) patients, issues also affecting patients with advanced CRF or acute renal failure (ARF) will be highlighted. We begin with a fundamental question: Why does ESRD state mimic malnutrition? Topics to address are: (1) the etiology of protein-calorie malnutrition (PCM) in renal disease, (2) methods for assessing nutritional status, (3) the strategy for successful nutritional intervention, and (4) recommendations for various nutrients intake for maintenance hemodialysis (MHD) or chronic peritoneal dialysis (CPD) patients. Important questions concerning low-protein diet will be addressed: (1) Does therapy with low-protein diets slow the progression of renal disease? (2) Are low-protein diets safe? and (3) Does delaying dialysis, using low-protein diets, affect patient outcome? Finally, the role of nutritional supplements in ESRD patients, including intradialytic parenteral nutrition (IDPN) will be discussed.

WHY DOES END-STAGE RENAL DISEASE MIMIC MALNUTRITION?

Studies of experimental uremia and investigations of patients with kidney failure have suggested several mechanisms that may account for the abnormalities mistakenly assigned to malnutrition (Figure 11–1).

Hypoalbuminemia

Approximately 63% of patients beginning ESRD therapy were found to have subnormal serum albumin levels (< 3.2 g/dL by bromocresol purple and < 3.5 g/dL by bromocresol green).[1] A low serum albumin level is clinically important because it is the strongest independent predictor of total and cardiovascular mortality in ESRD patients.[2,3] Much has been made of a low serum albumin being an index of malnutrition, yet there are several other causes for a dialysis patient to have a low serum albumin and loss of protein stores.[4] The serum albumin concentration is influenced by age, fluid overload, capillary leakage, and evidence of inflammation, in addition to dietary protein stores.[5,6] Regarding its clinical relevance, there is a strong association among atherosclerosis, a low serum albumin and a high C-reactive protein

(CRP) level in pre-dialysis patients.[7] In dialysis patients, albumin generation and serum albumin levels are negatively correlated with markers of inflammation, including CRP, fibrinogen, and interleukin-6.[8,14] These findings suggest that inflammation, mediated by pro-inflammatory cytokines, decrease serum albumin levels but also cause loss of lean body mass plus the development of cardiovascular disease in kidney disease patients. The decline in protein stores, in this case, is linked to increased protein breakdown initiated by responses to inflammation rather than to an abnormal diet (as would be the case in malnutrition).[9] The reason for emphasizing this distinction is the persuasive evidence indicating that serum albumin increases when dietary protein of patients with renal insufficiency is restricted.[10,11] What is required in such patients is a strategy for attenuating inflammation followed by observation of changes in serum albumin. In summary, a normal or low serum albumin concentration may not accurately reflect total albumin content and should not be used as the sole indicator of protein stores.

Inflammation

Inflammation is ascribed as another cause of the problems attributed to malnutrition. Contact of blood with "foreign" surfaces, like the hemodialyzer membrane or peritoneal dialysate, activates several humoral and cellular pathways, with higher levels of CRP and other pro-inflammatory cytokines.[12–14]

Although cross-sectional studies suggest that dialysis patients have high circulating concentrations of cytokines, neither the source of inflammation nor the mechanism that increases the concentrations of these cytokines has been identified. Moreover, circulating concentrations of CRP and other cytokines are also elevated in elderly patients and in patients with congestive heart failure or diabetes.[15–17] These data, in addition to the observation that patients with chronic renal insufficiency who are pre-dialysis also have elevated concentrations of pro-inflammatory cytokines, indicate that the mechanism driving high circulating CRP concentration and inflammation includes other factors in addition to exposure of the patient's blood to dialysis membranes.[13,18,19]

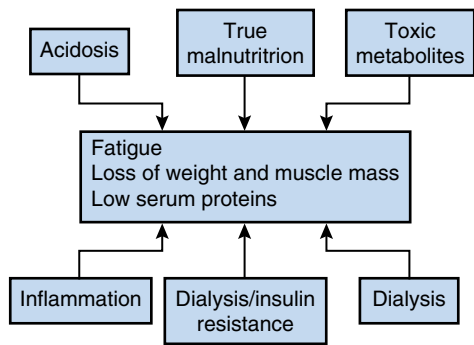
The common thread in models of inflammatory conditions that cause loss of muscle mass is activation of protein breakdown, as has been demonstrated repeatedly in models of sepsis and inflammatory conditions. The administration of TNF-α (and other cytokines) to rodents can stimulate protein degradation in muscle, but it is difficult to assign this response to the action of a single cytokine.[20] To date, cytokine-activated mechanisms that lead to accelerated muscle proteolysis by the ubiquitin-proteasome system have not been identified fully, but, as with acidosis, the catabolic


Figure 11–1 An inadequate diet or "true malnutrition" rarely leads to the fatigue, loss of lean body mass, and low serum proteins associated with loss of kidney function. More commonly, these problems are the result of catabolic mechanisms stimulated by renal insufficiency.

responses depend on the action of glucocorticoids.[21–24] In brief, both the mechanism causing the high concentrations of acute phase reactant proteins and the response of serum albumin to the removal of inflammatory stimuli need elucidation.

Metabolic Acidosis

Metabolic acidosis is common in kidney failure and acts to stimulate the irreversible destruction of essential, branched-chain amino acids. In addition, it accelerates the degradation of protein, especially muscle protein.[21,25] The increased breakdown of muscle protein is a result of activation of the ubiquitin-proteasome proteolytic system, the major system that degrades the bulk of protein in all cells, including muscle cells.[26,27] Recently, we obtained evidence that correcting acidosis in patients treated by chronic ambulatory peritoneal dialysis suppresses the ubiquitin-proteasome system and leads to gain of body weight.[28] There is also evidence that acidosis contributes to the low level of serum albumin in dialysis patients.[29,30] Acidosis in kidney failure, therefore, could contribute substantially to the abnormalities presumed to be caused by malnutrition.

Insulin Resistance

Another cause of the constellation of problems lumped under the diagnosis of malnutrition is resistance to the anabolic action of insulin. Experimentally, acute diabetes mellitus causes rapid loss of body weight and muscle mass due to activation of the ubiquitin-proteasome proteolytic system in muscle.[31] These catabolic responses are rapidly reversed by insulin but are independent of the acidosis of acute diabetes.[32] However, as in acidosis, sepsis, and even starvation, activation of accelerated muscle proteolysis by this system requires glucocorticoids.[33,34] Since diabetes is a common cause of ESRD and kidney failure causes resistance to the hypoglycemic action of insulin, it is likely that diabetes or insulin resistance plays a role in the abnormalities attributed to malnutrition.[35] It is tempting to speculate that the protein catabolism that occurs when patients are dialyzed against a glucose-free bath is related to a reduced stimulation of insulin release.[36]

Another potential cause of ESRD-associated abnormalities in weight, muscle mass, and serum proteins is the combination of accumulated wasted products and metabolic abnormalities caused by the loss of kidney function. Again, this mechanism is not directly linked to an inadequate diet and, in fact, an excess of protein-rich foods should only increase the accumulation of waste products like phosphates, acid, and nitrogen-containing products.[37] To date, there has been no cause-and-effect association found between the accumulation of nitrogen-containing waste products and a specific syndrome, despite intriguing investigations about links between unidentified "middle molecules" and depressed appetite.[38] Overall, evidence supporting this mechanism as a cause of the problems attributed to malnutrition is substantially weaker than for other mechanisms. Finally, Ikizler and colleagues[39] measured whole-body and muscle protein turnover in stable patients dialyzed with modern dialysis membranes. They found that whole-body degradation of protein, including muscle protein, was stimulated during hemodialysis. Because the catabolic response persisted after completion of the dialysis procedure, the authors concluded that the dialysis somehow induced the breakdown of protein.

PROTEIN-CALORIE MALNUTRITION IN RENAL FAILURE

The diagnosis of protein-calorie malnutrition (PCM) in dialysis patients is confounded by the lack of uniform criteria for its diagnosis and the difficulties in separating abnormal nutritional parameters caused by inflammation or complications of uremia. In cross-sectional and longitudinal surveys, the reported prevalence of PCM in dialysis patients varies from 25% to 75%.[40–47] Some ESRD patients have true protein-calorie malnutrition, a condition caused by inadequate nutrient intake, increased catabolism, or increased body requirement of nutrients[2,3] (Table 11–1). As noted, there are other reasons for the loss of protein mass.

Inadequate Protein and Calorie Intake

Anorectic pre-dialysis uremic patients regain appetite after beginning dialysis. It suggests that uremic toxins causing anorexia have been removed by dialysis.[48] Inadequate dialysis, therefore, may result in accumulation of uremic toxins that suppress appetite and cause malnutrition. Several studies in hemodialysis or chronic peritoneal dialysis (CPD) patients report a strong correlation between the dose of dialysis for small molecule removal (Kt/V_{urea}) and protein intake.[49–51] However, even patients with adequate dialysis often have anorexia. Anorexia may be caused by altered taste buds sensation or through complex interaction of various appetite modulators, with serotonin as a central cause of anorexia.[52] Catecholamine and serotonin pathways appear to be involved in the hypothalamic regulation of satiety center and high brain serotonin level, and a lower serotonin/dopamine ratio in the brain will cause anorexia. High plasma levels of anorectics, including tryptophan (a precursor of serotonin), cholecystokinin, leptin, pancreatic polypeptide, cytokines (TNF-α and IL-1), and deficiencies of nitric oxide and neuropeptide Y will each increase intracerebral serotonin.[52]

Table 11–1 Causes of Protein-Calorie Malnutrition in ESRD

Condition	Mechanisms
Inadequate protein or calorie intake	Anorexia: Uremic toxins, inadequate dialysis, absorption of glucose from dialysate, medications
	Diabetic gastropathy
	Dental status
	Volume overload
	Psychosocial factors: Depression, poverty, alcohol/drugs
Increase catabolic response	Low energy intake
	Acidosis
	Insulin resistance
	Inflammation, infection, sepsis
	Glucocorticoids
Increase requirement for protein and energy	Loss of nutrients during peritoneal and hemodialysis
	Increase in resting energy expenditure

Increased Catabolic Response

The maintenance of nitrogen balance in ESRD patients depends on an adequate energy intake.[49,53] Metabolic studies and K/DOQI™ guidelines recommend minimum energy intake of 35 kcal/kg/day,[54] but cross-sectional studies have shown that hemodialysis patients ingest far fewer calories.[55,56] Thus, inadequate energy intake could be an important factor contributing to impaired protein metabolism. Stimulation of protein breakdown by metabolic acidosis, inflammation, insulin resistance, and glucocorticoids have already been discussed.

Increased Requirement for Protein and Energy

Each dialysis session can result in removal of amino acids (about 10 to 12 g), some peptides, and smaller amounts of protein (< 1 to 3 g).[57–60] Significant losses of protein and amino acids have been documented across high-flux membranes that are treated with bleach and formaldehyde.[59,61] In general, the protein losses from reprocessed dialyzers are trivial until the number of reuses exceeds 10.[61] Protein losses in CPD patients are even higher, averaging about 5 to 15 g/day. During episodes of peritonitis, losses may be considerably higher.[62] Much of these losses consist of albumin. There are also immunoglobulins, peptides, and amino acids.[63] Amino acid losses average about 3 g/day.[64] Loss of protein and amino acid is too small to account fully for the increased protein requirements of dialysis patients, but the changes in plasma amino acid concentrations suggest these patients catabolize 25 to 30 g of body protein to compensate for these losses.[63]

Uremic complications can promote protein catabolism to increase dietary protein requirements.[65] The disorders favoring catabolism include resistance to insulin, growth hormone, and insulin-like growth factor-1 and both hyperglucagonemia and hyperparathyroidism.[65] Recent reports suggest that the resting energy expenditure (REE), as measured by indirect calorimetry in patients, is significantly higher in ESRD patients compared to CRF patients not on dialysis.[66,67] Earlier reports concluded that REE in dialysis patients is similar to that of healthy controls and pre-dialysis CRF patients.[68,69] The difference could be the more recent use of more accurate chamber indirect calorimeter. Increased energy requirements could contribute to the development of malnutrition.

ASSESSMENT OF NUTRITIONAL STATUS IN RENAL DISEASES

Since loss of lean body mass is a common problem for patients with ESRD, it is important to use longitudinal assessments of nutritional status to recognize substrate deficiencies early. No single assessment has been defined to evaluate variables that affect nutritional status, so a number of indices are needed to define the nutritional status of patients (Table 11–2).

There must be a medical history for the type of renal disease, comorbid conditions, plus a physical examination. The dietary history should include the amount and patterns of nutrient intake, and a dietitian should obtain information about socioeconomic circumstances that could interfere with a necessary diet. The energy level, appetite, physical activity, medications, and the use of dietary and herbal supplements, alcohol, and illicit drugs must also be documented.[70]

The most common methods for estimating intake in patients with renal disease are dietary recalls, dietary diaries, and determination of protein equivalent of nitrogen appearance. The dietary recall (usually obtained for previous 24 hours) is a simple, rapid method of obtaining a crude assessment of dietary intake.[54] Dietary diaries are written reports of foods consumed during a specified length of time (from 3 to 7 days). This method is not only a more reliable estimate of an individual's intake on average than on a single day, but it is also the only practical way to estimate energy intake. The validity and reliability of dietary interviews and diaries depend on the patient's ability to provide accurate data and the ability of the dietitian to conduct detailed and probing interviews.[54]

Protein Equivalent of Total Nitrogen Appearance (PNA)

Biochemical methods for estimating protein intake are based on the concept that ingested proteins plus the products arising from endogenous protein are metabolized to several

nitrogenous products (e.g., urea, amino acids, or creatinine). In the steady state (neither catabolism nor anabolism), the nitrogenous products that are removed from the body by urine, dialysate, stool, skin, and blood (total nitrogen appearance) are equal to the protein intake (6.25 g protein produces 1 g nitrogen).[71] There is a strong correlation between urea appearance rate (which can be easily calculated from urea dialysate and urine concentration) and total nitrogen appearance, so protein nitrogen appearance can be estimated from the urea appearance rate calculated as the urea accumulated in the body and how much is excreted.

Urea kinetics, calculated from the blood urea nitrogen (BUN), the properties of the dialyzer and the duration of dialysis treatment, is used to calculate protein nitrogen appearance in hemodialysis patients. There are formulas based on a three-BUN or two-BUN measurement.[72,73] The three-BUN method measures pre- and post-dialysis BUN of a single hemodialysis session plus the subsequent pre-dialysis BUN value.[72] The two-BUN method calculates PNA from a single dialysis session, using a computer iteration scheme eliminating need for a third BUN.[73] The two-BUN method is routinely incorporated into formal urea kinetic modeling because fewer BUN measurements are needed and the amount of dietary protein between the dialysis sessions does not influence the measurement. An error involving any of the variables for kinetic modeling will extend to the dietary protein estimates.[74] Graphical nomograms have been developed to estimate dietary protein from a pre-dialysis and post-dialysis BUN samples.[75]

The calculation of protein intake for CPD patient is simpler; it requires only the urea nitrogen excretion in urine and dialysate. Numerous equations proposed for calculating dietary protein were originally developed for chronic ambulatory dialysis patients but also applied to automated peritoneal dialysis patients.[76,77] Protein nitrogen appearance is usually normalized (nPNA) to some function of body weight (e.g., edema-free body weight or body weight derived from the urea distribution space [V_{urea}/0.58]).[54]

There are important limitations in interpreting urea kinetically derived estimates of dietary protein intake. First, in catabolic states (acidosis, infection, etc.), endogenous protein breakdown can increase urea appearance so protein nitrogen appearance will exceed protein intake estimates. Conversely, when a patient becomes anabolic protein nitrogen appearance will underestimate actual protein intake. Second, day-to-day variations in protein intake are reflected rapidly by the protein nitrogen appearance, so single measurement may not tell us about average protein intake over 1 month. Third, protein nitrogen appearance does accurately estimate intake at extremes of protein intake. This is a result of increased nitrogen losses through unmeasured pathways of excretion at higher protein intake and greater endogenous protein catabolism at lower protein intake.[78] Finally, normalizing protein nitrogen appearance to body weight can be misleading in obese, malnourished, or edematous patients. Therefore, K/DOQI™ guidelines for individuals who are less than 90% or greater than 115% of standard body weight, recommend using the adjusted edema-free body weight.[54]

In summary, protein nitrogen appearance reflects approximate protein intake in a stable dialysis patient. However, it should not be used as the sole means of assessing nutritional status, and one must be familiar with potential errors in its calculation and its limitations in interpreting dietary protein intake.

Biochemical Values and Nutritional Assessment

Serum Albumin, Prealbumin, and Transferrin

These proteins are biochemical markers often used to assess visceral protein stores, to monitor the adequacy of responses to a nutritional intervention, and to identify patients who are at risk for complications or are responding poorly to medical/surgical treatment. Besides the limitations of serum albumin as a marker of malnutrition (see previous), prealbumin has a short half-life (2 to 3 days) and is more sensitive to acute changes in protein status. Prealbumin is a retinol-binding protein that circulates in a 1:1 molar ratio to transport the alcohol form of vitamin A. The serum prealbumin level is a powerful predictor of survival in dialysis patients[79] and correlates directly with markers of visceral (albumin and cholesterol), somatic protein stores (creatinine), and recent protein intake.[80] Unfortunately, serum prealbumin is limited by many of the same factors as serum albumin; it is a negative acute-phase reactant. This retinol-binding protein is excreted and metabolized by the kidney in renal failure so it accumulates.[81] There is insufficient evidence to conclude that prealbumin as an indicator of nutritional status is more sensitive or accurate compared to serum albumin.[54]

Serum transferrin also has a short half-life (about 8 vs. 20 days for albumin), but as an indicator of malnutrition, the serum transferrin concentration is frequently reduced in renal failure independently of malnutrition, perhaps due to fluctuation in iron stores.[82] Serum transferrin increases in iron deficiency, in pregnancy, and in the early phases of acute hepatitis; it decreases with certain chronic infections, liver diseases, cancer, or iron loading. Finally, its concentration, like that of albumin, varies with hydration.

In summary, no single serum protein measurement is ideal for detecting malnutrition early, but repeatedly low values generally indicate that there is some degree of protein malnutrition.

Serum Bicarbonate

Dietary protein intake in dialysis patient is an important determinant of acid-base status since metabolism of amino acids, particularly cysteine and methionine, generates protons. Pre-dialysis or stable serum bicarbonate values below 22 mmol/L are indicative of metabolic acidosis in an ESRD patient. Metabolic acidosis affects nutrition by stimulating protein catabolism, and correction of acidosis decreases whole body protein degradation in dialysis patients.[83] Because of the inaccuracies in serum bicarbonate measurements, the reports that acidosis is not associated with malnutrition should be ignored.[84,85] For example, correction of metabolic acidosis in CPD patients improved the nutritional status and reduced hospitalization rates.[86] Oral bicarbonate supplements given to acidotic CPD patients resulted in improved nutritional status judged by subjective global assessment.[87] We recommend that pre-dialysis patients or dialysis patients should have stabilized serum bicarbonate levels above 22 mmol/L.

Serum Potassium

Low serum potassium levels in dialysis patients should raise the suspicion of a poor nutritional intake. Associated with a low serum albumin, low serum phosphorus and magnesium values are commonly found in severely malnourished nursing-home ESRD patients and those maintained on parenteral nutrition.[88] Increasing the dialysis dose may lead to significant hypokalemia in a large proportion of CPD patients, even when achieving DOQI targets.[89]

Serum Creatinine

In dialysis patients, the serum creatinine level is proportional to muscle mass and dietary meat intake.[90,91] The serum creatinine concentration was higher and predicted long-term survival (10–15 years on MHD and 10 years on CPD) compared to values in average-survival (< 5 years) ESRD patients.[92] A direct relationship has been reported between serum creatinine and albumin and prealbumin concentrations.[93,94] Individuals with low pre-dialysis or stabilized serum creatinine values (< 10 mg/dL) should be evaluated for protein-energy malnutrition and wasting of skeletal muscle.[54]

Serum Cholesterol

The serum cholesterol is another marker of increased risk of mortality in ESRD patient.[92,95–97] Surprisingly, it is an independent predictor of mortality in hemodialysis patients who have low-normal nonfasting values of serum cholesterol (< 150–180 mg/dL) compared to those with higher cholesterol levels.[95–98] The same relationship was not observed in CPD patients.[3,95,96] The pre-dialysis or stabilized serum cholesterol concentration is too insensitive to be used for assessment of nutritional status in ESRD patient.

Other biochemical measurements (serum glucose, calcium, and phosphorus) are not useful to assess nutritional status but are of immense importance for diet planning and overall nutritional management of individual dialysis patient.

Assessment of Body Composition

Methods to assess adipose stores and lean body mass range from simple techniques like anthropometrics and creatinine kinetics to utilization of sophisticated technology.

Anthropometry consists of a series of noninvasive, inexpensive, and easy to perform indices including body weight, percent of usual weight, skeletal frame size, body mass index, body fat, and fat-free mass.[54] A decline in anthropometric measurements can detect a loss of lean body mass during long-term evaluations. Unfortunately, very little data are available on how closely subnormal anthropometric values correlate with an adverse clinical outcome. Cross-sectional studies do show a strong linkage between large body size and reduced risk of mortality in hemodialysis patients.[99–101]

The anthropometrics measurement in "healthy" males (including diabetics) and most women on hemodialysis were similar to those of normal adults cited in the National Health and Nutrition Examination Survey (NHANES II) data.[102] However, women with diabetes or African-American diabetics over age 55 had lower triceps skin-fold thickness. There were no differences in anthropometric measurements between hemodialysis and peritoneal dialysis patients. The anthropometrics assessment of patients enrolled in Hemodialysis (HEMO) study revealed that the patients were, on average, lighter with less adipose and muscle tissue in comparison to healthy persons of same ages from NHANES II.[103] Importantly, the HEMO study patients may not be representative of the general ESRD population because patients with serum albumin less than 2.8 mg/dL or those with body weight greater than 85 kg were excluded from the enrollment.[104]

The reliability of anthropometric measurements depends heavily on the skill of the observer, the sites examined (e.g., the circumference of the dominant or nondominant arm when assessing muscle mass), and the degree of hydration. In hemodialysis patients, it is recommended that measures be completed after a treatment, using the arm without the dialysis access. Loss of fat from subcutaneous tissues occurs proportionately, so repeated measures from a selected group of sites in an individual patient can provide reliable information on trends of adipose stores.

Creatinine index is another simple method for estimating fat-free body mass in an ESRD patient.[105,106] There are several limitations of this method. First, rate of creatinine appearance is affected by dietary meat and residual renal function.[54] Second, there is mathematical coupling between weekly creatinine clearance and lean body mass in CPD patients, because both are calculated from the same 24-hour urine and dialysate collection.[107] Finally, the creatinine-based calculation of lean

body mass in CPD patients was found to be highly variable compared to lean body mass based on total body potassium.[108]

Other methods of measuring body composition include bio-electrical impedance, dual-energy X-ray absorptiometry (DEXA), neutron activation, near infra-red interactance, magnetic resonance imaging, and computed tomography (Table 11–3). Each has advantages and disadvantages in ESRD patients.

SUBJECTIVE GLOBAL ASSESSMENT (SGA)

A clinical approach of assessing protein-calorie malnutrition that has recently become popular is subjective global assessment (SGA).[70] SGA is based on evaluating subjective and objective patient information, including medical history and physical examination, gastrointestinal symptoms, body-weight patterns, and patient functional capacity, plus the presence of comorbid conditions that could affect nutritional requirements. The patient is assigned to one of the three nutritional status groups: (1) well nourished, (2) mild-moderately malnourished, or (3) severely malnourished. The SGA method has been used to assess the nutritional status of pre-dialysis[109] and CPD or hemodialysis patients.[110–112] Not all reports agree that SGA has sufficient accuracy for detecting protein-calorie malnutrition. Cooper and colleagues[113] compared SGA with total body nitrogen (neutron activation or "gold standard" marker) for nutritional status. SGA was found to be of limited value in determining malnutrition in patients with ESRD, predicting only 20% to 50% of patients who had evidence of significant nutritional compromise. The SGA did not sufficiently discriminate between mild to moderate and severe degrees of malnutrition.[113] Limitations of the SGA include a heavy reliance on subjective judgment, and SGA may not identify functional impairment due to malnutrition; it also does not identify the type or amount of nutritional support to provide repletion.[114]

In summary, no single parameters have been defined to evaluate the variables that affect the nutritional status of dialysis patient. Consequently, a complete nutritional evaluation is recommended, using all the categories in Table 11–2. A renal dietitian can perform the evaluation at the initiation of dialysis and should monitor post dialysis weights and biochemical parameters monthly. The comprehensive nutritional assessment is repeated every 6 months or more frequently in patients at high risk for malnutrition (e.g., the elderly, those with complicating diseases, etc.).

MANAGEMENT OF NUTRITIONAL ISSUES IN CRF AND ESRD

The goals of dietary therapy for patients with chronic renal failure are: (1) to diminish the accumulation of nitrogenous wastes and limit the metabolic disturbances characteristic of uremia, (2) to prevent malnutrition, and (3) to slow the progression of renal failure.

Protein-restricted diets improve uremic symptoms because they reduce the levels of uremic toxins, most of which result from the metabolism of protein. A low-protein diet also ameliorates specific complications of CRF, including metabolic acidosis, renal osteodystrophy, hyperkalemia, and hypertension, because a diet that is restricted in protein is invariably restricted in the quantities of sulfates, phosphates, potassium, and sodium eaten each day. Those considerations explain why dietary protein restriction has been used for decades to treat chronically uremic patients. Fundamental questions regarding use of low-protein diets in CRF patients are:

- Do they change the progression of renal failure?
- Do low-protein diets cause malnutrition?
- Does delaying the start of renal replacement therapy affect patient outcomes?

LOW-PROTEIN DIETS AND PROGRESSION OF CHRONIC RENAL FAILURE

A number of studies have examined the influence of dietary protein restriction on the progression of renal disease, but

Table 11–3 Assessment of Body Composition in Patients with Renal Disease

Test	Measure	Advantages	Disadvantages	Reference
Bioelectric impedance (BIA)	Total body water, Fat mass, Fat-free mass	Easy and practical in clinical setting	Results influenced by state of hydration	202
		Small coefficient of variation	Technique not validated in amputees	203,204
Dual-energy X-ray absorptiometry (DEXA)	Fat mass, Fat-free mass, bone mineral mass density	Independent of fluid status	Expensive, require large set-up	205,206
		Small coefficient of variation		
Neutron activation	Total body potassium Total body nitrogen	High precision and reliability	Expensive, require large set-up	207,208
		Independent of fluid status		
Near infra-red interactance	Body fat, fat-free mass	Independent of fluid status	Not compared to BIA or DEXA in dialysis patients	209
		Validated for longitudinal assessment		

many of these reports suffer from problems in design, differences in measurement of efficacy, a limited sample size, and the type of diet and degree of compliance with the diet.[115] The randomized, controlled trials that have enrolled only insulin-dependent diabetes patients have shown improved preservation of kidney function in patients assigned to a low-protein diet when compared to patients eating unrestricted amounts of dietary protein.[116–119] The number of diabetic patients studied in these trials was generally small and the duration of follow-up was short. To examine this question in a larger number of patients, meta-analyses have been done in order to combine results from several studies. The results published by Fouque, Pedrini and colleagues[120–122] indicate a significant benefit from low-protein diets in preserving the renal function of diabetic patients.

Trials enrolling nondiabetic and non–insulin-dependant diabetic CRF patients in a randomized fashion have not consistently demonstrated that dietary protein restriction slows progression at least when analyzed according to the diet prescribed. The results of these trials are summarized in Table 11–3. The largest trial in this group was the Modification of Diet in Renal Disease, or MDRD, a study designed to test the effects of dietary protein restriction and different levels of blood pressure control on the progression of renal insufficiency (loss of GFR) in 840 patients.[123] In Study A, patients with GFRs of 25 to 55 mL/min/1.73 m² were randomly

assigned to a usual protein diet (1.3 g/kg/day) or a low-protein diet (0.58 g/kg/day). In Study B, patients with GFRs of 13 to 24 mL/min/1.73 m² were randomly assigned to the same low-protein diet or to a very low-protein diet (0.28 g/kg/day) plus a mixture of ketoacids (to supply essential amino acid requirements). There was no control group eating an unrestricted diet in this group of patients with more advanced renal insufficiency. GFR was measured every 4 months as the renal clearance of [I¹²⁵]-iothalamate and the patients were followed for an average of 2.2 years; the results extrapolated to 3 years for all patients. There was no significant difference in the loss of GFR between the two diet groups in either Study A or in Study B, although there was a trend toward a slower decline in GFR in patients assigned to the lower protein diets.

Do the MDRD study results provide the last word on the influence of low-protein diets in preserving kidney function? Because there are shortcomings of the MDRD study, we do not believe these results demonstrate there is no slowing of the loss of renal function in patients eating a low-protein diet. First, the hypothesis being tested was that eating a protein-restricted diet will slow the loss of residual renal function, but the conclusions of the initial MDRD report[123] were based on the diet assignment, rather than achieved intake (Table 11–3). In fact, when the MDRD study results were analyzed according to compliance with the low-protein diets, there was significant slowing of the loss of GFR and a delay until patients

Table 11–3 Randomized Controlled Trials of Effect of Protein-Restricted Diets on the Progression of Renal Failure

Reference	No. of patients	Mean follow-up (months)	Prescribed protein for randomized groups (g/kg/day)	Actual protein intake (g/kg/day)	Outcome of trial
Jungers et al[210]	14	9	0.6 vs 0.4 plus KA	0.7 vs 0.4 plus KA	Time to dialysis longer and mean slope of $1/S_{cr}$ lower in KA group
Bergstörm et al[211]	16	12-24	Unrestricted vs 0.4 plus EAA	0.86 vs 0.65	Slope of $1/S_{cr}$ and drop in CrCl were similar
Ihle et al[212]	64	18	Unrestricted vs 0.4	>0.75 vs 0.4	Significantly less decrease in GFR and progression to end-stage in low protein group
Rosman et al[213]	239	48	Unrestricted vs 0.4-0.6	No data available	Renal survival better in low protein group after 2 years but no difference after 4 years
Locatelli et al[214]	456	24	1.0 vs 0.6	0.9 vs 0.78	No difference in renal survival
William et al[215]	95	19	>0.8 vs 0.6	1.0-1.14 vs 0.69	Rate of fall of CrCl and $1/S_{cr}$ similar
Klahr et al[123] Study A	585	26	1.3 vs 0.58	1.1 vs 0.77	The intention-to-treat analysis revealed no difference in GFR decline, when analysed by degree of compliance low protein group has significant slowing in GFR
Klahr et al[123] Study B	255	26	0.58 vs 0.28 plus KA	0.73 vs 0.48	No difference in slowing of GFR, on secondary analysis lower protein intake caused slower mean decline in GFR but no independent effect of KA
D Amico et al[216]	128	27	1.0 vs 0.6	1.1 vs 0.8	Low protein group had significant lower risk of progression

required dialysis.[124] Second, the criteria for entering the MDRD study did not include a requirement that patients were, in fact, losing renal function; approximately 15% of the Study A control group had no evidence of progressive loss of GFR, and this would increase the number of patients required to demonstrate a benefit from the dietary manipulations. Another factor that would increase the number of patients to be studied to detect a benefit was the finding that the overall rate of loss of renal function was slower than predicted. In this respect, it is interesting that meta-analyses utilizing results from several studies[120,121] led to the conclusion that dietary restriction was beneficial in preserving residual renal function. Third, there was a disproportionate number of patients (~20%) with polycystic kidney disease, and these patients had no benefit from the dietary restriction or from treating hypertension. Including these patients in the study might have obscured a benefit of the dietary manipulation. Fourth, patients in the MDRD study were given angiotensin-converting enzyme inhibitor therapy in a random fashion. Considering the beneficial effects of these drugs on progressive renal insufficiency,[125] their inclusion would make it more difficult to detect a benefit from the low-protein diet on preserving residual kidney function. Finally, the MDRD study lasted an average of only 2.2 years. This is important because the patients in Study A had an initial rapid loss of GFR just after institution of the low-protein diet, followed by a slower loss of GFR. If this slowing had persisted, it is possible that statistically significant slowing of progression may have been detected in a longer-term study. For example, in other large trials (e.g., the examination of the influence of strict control of hyperglycemia, the DCCT Trial), no benefit was apparent until 4 years of therapy.[126] Likewise, slowing of the loss of renal function in patients with IgA nephropathy during treatment with a fish oil supplement was not apparent until 3 years had passed.[127]

Do Low-Protein Diets Cause Malnutrition?

The finding that dialysis patients often have low levels of serum proteins and evidence of malnutrition has led some to suggest that low-protein diets should be used cautiously or avoided in pre-dialysis patients and that dialysis should be initiated early.[128,129] It is true that if CRF patients are not properly instructed and supervised, there may well be a spontaneous decrease in protein intake and deterioration of some nutritional indices. Another worrisome report is the association between hypoalbuminemia and increased mortality in hemodialysis patients,[130] but hypoalbuminemia in these patients can be linked as much to evidence of inflammation as it is to dietary inadequacy.[8,14,131] In fact, CRF patients treated with low-protein diets were found to have an increase in serum protein concentrations at the initiation of dietary therapy.[132,133] A low-protein diet is also associated with improved survival of CRF patients who subsequently began dialysis.[134] Finally, there is abundant evidence that with proper implementation, a low-protein diet yields neutral nitrogen balance and maintenance of normal serum proteins and anthropometric indices during long-term therapy.[135–137] Once on dialysis, patients treated with supplemented very low-protein diet (SVLPD) rapidly increase their protein intake and gain in lean body mass.[138] Follow-up for 5 years after initiation of renal replacement therapy (MHD and renal transplant), these patients revealed low mortality, correlating to age but not to nutritional parameters at the end of SVLPD therapy.[133]

Does Delaying the Start of Renal Replacement Therapy Affect Patient Outcomes?

NFK K/DOQI™ guidelines for peritoneal dialysis adequacy suggest that chronic dialysis should be initiated at a weekly renal Kt/V_{urea} of 2.0, which approximates a creatinine clearance of 9 to 14 mL/min/1.73 m^2 or glomerular filtration rate (arithmetic mean of the urea and creatinine clearances) of 10.5 mL/min/1.73 m^2. Unless patient has stable or increased edema-free body weight, sound nutritional status and complete absence of clinical symptoms or signs are attributable to uremia.[139] This recommendation was not evidence-based but an opinion relying on flawed or weak arguments.

The rationale given for this suggestion is that optimizing urea clearance once patients are on dialysis is a goal, so why accept much lower levels of urea clearance during the pre-dialysis phase of patient management? There is also concern that CRF patients spontaneously reduce their protein intake as renal function worsens,[128,140,141] and a low serum albumin and low residual renal function at the initiation of dialysis is associated with poor outcomes.[141,142] However, the K/DOQI™ work group did not consider the following facts. First, they assumed equivalence between the solute clearance from residual renal function and peritoneal dialysate. This is not supported by a re-analysis of results from the CANUSA study; the association between total clearance and patient survival was only accounted for by residual renal function not by peritoneal clearance.[143] The differential impact of residual renal clearance and peritoneal clearance on survival was confirmed by the prospective Netherlands Cooperative Adequacy of Dialysis Study of CAPD patients.[144] Second, there is abundant evidence that protein malnutrition is common in dialysis patients,[42–47] suggesting that dialysis therapy could itself be a contributing factor to malnutrition.[39] Finally, those studies reporting negative impact of a low residual renal function on survival at the start of dialysis therapy are flawed by failure to take account of lead-time bias. Lead-time bias refers to the effect whereby measuring survival from the start of dialysis increases apparent survival of those started with more residual renal function, that is, earlier in the course of the disease, than those who start dialysis with less residual renal function.[145] When CRF patients were followed from an estimated creatinine clearance (eC_{cr}) of 20 mL/min, and divided into early and late start groups by the median eC_{cr} (8.3 mL/min) for all patients at the initiation of dialysis, there was no benefit of survival from earlier initiation of dialysis.[146] A Cox proportional hazards model demonstrated a significant inverse relationship between eC_{Cr} at start of dialysis and survival (hazard ratio, 1.1; $P = .02$), that is, patients who started dialysis with a lower eC_{Cr} tended to survive longer.[146] More recently, Beddhu and colleagues[147] examined data from the dialysis Morbidity Mortality Study Wave II to evaluate if beginning dialysis at higher levels of creatinine clearance or GFR (estimated from the MDRD formula) would improve mortality. They found that initiation of dialysis was associated with an increase in mortality for each 5 mL/min increase in GFR. The authors concluded that there is insufficient evidence to advocate early initiation of dialysis.

In summary, there is no substantial evidence that survival improves with early initiation of dialysis in ESRD and that it is associated with a better health-related quality of life.[148]

The results of clinical trials evaluating effect of low-protein diets on the progression of CRF to date have not settled whether such diets will be effective in slowing the loss of residual renal function in a large proportion of patients. When properly applied, these diets do not lead to malnutrition, even in patients with advanced renal insufficiency.[10,11,136–138] For these reasons, we recommend instituting a low-protein diet in all patients who have symptoms attributable to uremia or for patients who exhibit progressive renal insufficiency, despite the proper management of known risk factors for progression such as control of blood pressure, use of drugs blocking angiotensin II responses to minimize proteinuria, hyperglycemia, and so forth. This will require education of the patient and interaction with a skilled dietitian who monitors intake of protein and calories and periodic assessment of the nutritional status of the patient.

DIETARY PROTEIN PRESCRIPTION FOR PRE-ESRD PATIENTS

Based on previous findings, we support the K/DOQI™ recommendations that patients with advanced renal disease (GFR < 25 mL/min), with or without symptoms attributable to uremia or with uncontrolled progressive renal insufficiency, be treated with a well-planned low-protein diet providing 0.6 g protein/kg/day[54] (Table 11–4). For individuals who will not accept such a diet or who are unable to maintain adequate protein-energy intake with such a diet, an intake can be increased up to 0.75 g protein/kg/day. Further increments in protein intake will not only generate more urea

but it will also contribute to metabolic acidosis and renal osteodystrophy through hyperphosphatemia. At least 50% of the protein intake for all these patients should be of high biologic value. The diet should be designed by a nutritionist with an interest in the implementation of diets for CRF patients in order to take advantage of a patient's food preferences and to ensure an adequate intake of calories and vitamins, and so forth.

NUTRITIONAL MANAGEMENT OF DIALYSIS PATIENT

Nutritional management in ESRD patients is primarily directed toward prevention and correction of protein-calorie malnutrition. Management should include dietary counseling, adequate dialysis, avoidance of acidemia, and aggressive medical therapy and nutritional support during acute catabolic illnesses.[149,150] Correctly performed nutritional assessment should point out whether the problem is a result of low nutrient intake, poor assimilation, or increased catabolism. The single most decisive factor influencing protein-calorie nutritional status is probably their intake.[150]

DIETARY PROTEIN PRESCRIPTION FOR DIALYSIS PATIENTS

Hemodialysis patients have increased protein and amino acids losses into dialysate (see previous), as well as increased catabolism from the chronic inflammatory state of uremia, acidemia, or the dialysis procedure itself (e.g., exposure to hemodialyzer membranes, tubing, and catheters).[12–14,39] Measurement of nitrogen balance (NB) is the "gold standard" by which

Table 11–4   Recommended Nutrient Intake in Chronic Renal Failure and Dialysis Patients

	Chronic renal failure and renal transplant	End stage renal disease
Protein* (g/kg of ideal body weight)	GFR (mL/min/1.73 m²) >50 No restriction recommended 25-50 0.6 to 0.75 controlled <25 0.6 For early transplant recipient† For nephrotic patient‡	MHD 1.2 CPD 1.2 to 1.3 Revise goals to 1.0 to 1.1 if serum phosphorus difficult to control
Energy (kcal/kg of ideal body weight)	< 60 yrs old ≥35 > 60 yrs old 30 to 35	< 60 yrs old ≥35 > 60 yrs old 30 to 35
Carbohydrates	35% of non-protein calories	35% of non-protein calories
Fat	Polyunsaturated to saturated ratio of 2:1	Polyunsaturated to saturated ratio of 2:1
Phosphorus (mg)	800-1000 No restriction in transplant recipient if serum phosphorus is normal	800-1000 Individualized
Potassium	Individualized	
Sodium and water	As tolerated, to maintain body weight and blood pressure	As tolerated, to maintain body weight and blood pressure

* At least 50% of proteins should be of high biological value.
† Protein intake of 1.3 to 1.5 g/kg/day while on high doses of steroids.
‡ For nephrotic patients, 0.8 g of protein/kg and add 1 g of protein/g of proteinuria.
CPD, chronic peritoneal dialysis; *MHD,* maintenance hemodialysis.

dietary protein requirements are assessed. There have been only a small number of NB studies performed in hemodialysis patients, and most have shortcomings.[151–154] A small number of patients, short periods of observation, patients that were not always in a steady-state, inclusion of acidotic patients, and reliance on dietary histories for measuring nitrogen intake instead of duplicate diet analysis are some of the weaknesses of NB studies in MHD patients.[65] NB measurements reported in CPD patients suffer from similar limitations. Notwithstanding these limitations, the NB studies suggest that the average protein intake necessary to maintain nitrogen balance in hemodialysis patients is about 1.0 to 1.1 g protein/kg/day and 1.05 to 1.1 g protein/kg/day in CPD patients. The K/DOQI™ work group recommended adding 25% to the average protein intake to obtain safe protein intake (Table 11–4). Some experts believe this is too much protein, especially in anuric peritoneal dialysis patients, and likely to lead to hyperphosphatemia.[155]

ENERGY REQUIREMENTS

Few studies have examined the calorie requirements of CRF patients. In pre-dialysis patients, nitrogen balance with a low-protein diet improves when calorie intake rises; the recommended amount is 30 to 35 kcal/kg/day.[159] The same amount is recommended for dialysis patients. It is important to monitor calorie intake since a diet containing too few calories will compromise the patient's ability to achieve nitrogen balance and lead to loss of muscle mass. Unfortunately, there is no simple method of estimating calorie intake so the clinician must rely on repeated measurements of weight and muscle mass plus input from the dietitian.[159]

Dietary Phosphorus

An elevated serum phosphorus or calcium-phosphorus product, and secondary hyperparathyroidism not only causes renal osteodystrophy in dialysis patient but would also result in vascular and visceral calcification, contributing to the increased risk of cardiovascular deaths in ESRD patients.[156] With these concerns in mind, experts recommend that target serum levels should be 9.2 to 9.6 mg/dL for calcium, 2.5 to 5.7 mg/dL for phosphorus, less than 55 mg^2/dL^2 for serum calcium-phosphorus product, and 200 pg/mL for intact PTH.[157,158] Restriction of dietary phosphorus remains the cornerstone of therapy to prevent hyperparathyroidism and the complications of renal osteodystrophy. The recommended phosphorus allowance for a dialysis patient is 800 to 1000 mg/day and similar or a lower intake should be prescribed for pre-dialysis CRF patients.[158,159] Note that even a slightly elevated serum phosphorus level will stimulate parathyroid hormone production so it is important to initiate dietary phosphorus restriction early in the course of renal failure and, if this strategy is insufficient, an oral phosphate-binder will be needed. For patients who have a high serum calcium-phosphorus product, the initial choice should be a noncalcium containing phosphorus binder. If necessary, aluminum hydroxide should be used for only brief periods (especially in dialysis patients) to reduce the risk of aluminum toxicity. When serum calcium is low, calcium based phosphate binders (carbonate or acetate) should be preferred, because they are effective and cheap. For maximum efficacy, the binder should be taken with food.

Dietary Calcium

The tendency for the calcium intake of CRF patients to be inadequate can be aggravated by decreased intestinal calcium absorption linked to vitamin D deficiency. For this reason and because an excess of phosphates in intestinal secretions will bind calcium, the CRF patient requires an intake of 1.5 g calcium/day.[159] Since dairy products (an excellent source of calcium) are invariably restricted to achieve an adequate phosphorus restriction, eating this much calcium can be difficult. Calcium can be given as a phosphate binder, but calcium carbonate requires a more acidic gastric milieu to be effective; calcium acetate is effective even with gastric atrophy. For hemodialysis patients, pulse doses of vitamin D appear to be beneficial in suppressing parathyroid hormone production. Before beginning vitamin D therapy, serum phosphorus and calcium must be within the normal range in order to prevent hypercalcemia and calciphylaxis. Again, dietary education is critical since dietary indiscretion even by patients who are compliant with phosphate binders, leads to a rise in the calcium-phosphorus product, increasing the likelihood of spontaneous precipitation of calcium and phosphorus throughout the body.

Sodium

Control of blood pressure should be a part of any strategy directed at slowing the progression of CRF.[160] It is easy to achieve a recommended 2-g sodium diet when dietary protein is restricted, and it will potentiate the efficacy of antihypertensive medicines.[161] Moreover, in edematous states, it is difficult, if not impossible, to achieve a net loss of sodium (and hence, extracellular volume) with diuretics, unless dietary sodium is restricted. In dialysis patients, dietary sodium restriction is mandatory to minimize the interdialytic weight gain. Without such therapy, blood pressure is difficult to control and there are more intradialytic problems, including hypotensive episodes and cramps. Patients should be urged to monitor their weight as weight gain invariably signifies fluid retention from dietary indiscretion.

Trace Elements and Vitamin Requirements

In uremia there are significant alterations in the blood and tissue concentrations of trace elements and vitamins. These derangements are due to a decrease in glomerular filtration, impaired tubular function and protein binding of micronutrients. In addition, an inadequate diet or altered gastrointestinal absorption in patients with advanced uremia may limit the absorption of trace elements and vitamins. Dialysis can remove micronutrients, depending on their water solubility, membrane permeability and the gradient between the concentration of an element in serum and its concentration in the dialysate. Inadequate removal may lead accumulation and toxicity (e.g., vitamin A), and water-soluble vitamins can be lost during dialysis. The water-soluble vitamin requirements for dialysis patients are not different from healthy adults. Pharmacologic doses of folic acid are recommended

for lowering plasma homocysteine levels, but whether this decreases cardiovascular risk in renal patients is yet to be established.[162] Vitamin C intake above 100 mg/day can lead to tissue deposition of oxalate crystals and hastening renal insufficiency and increasing the risk of myocardial infarction, shunt failure, and muscle weakness in dialysis patients. Vitamin A and retinol-binding protein plasma levels are increased in renal patients, so vitamin A containing multivitamin preparations for kidney disease patients should be avoided. There is no evidence that vitamin E reduces risk of cardiovascular events and routine supplementation is not recommended.[163] Patients with kidney disease eating an inadequate diet should take a multivitamin preparation that is formulated specifically for renal patients. For dialysis patients, deficiencies of water-soluble vitamins are common due to vitamin losses in the dialysate, poor oral intake and/or altered metabolism.

In summary, the daily requirements for most trace elements and vitamins in renal patients are quite similar to those of healthy adults (Table 11–5).[164]

NUTRITIONAL CARE OF PATIENTS WITH ACUTE RENAL FAILURE (ARF)

ARF, in association with multiple organ failure, has a very high in-hospital mortality rate averaging 40% to 65%.[165–167] In most cases death is due to underlying illnesses such as sepsis, cardiac failure, or hemorrhage rather than electrolyte disturbances or uremia. Evidence of protein losses is quite prevalent in ARF patients for multiple reasons. The main causes are coexisting catabolic illnesses, dialysis related amino acids and protein losses, reduced nutritional intake

and preexisting malnutrition. The predominant feature of hypercatabolism is an increase in skeletal muscle protein breakdown, and the released amino acids are not effectively used for protein synthesis.[168–169] Hepatic uptake of amino acids from the circulation, gluconeogenesis, ureagenesis, and secretion of acute phase proteins are stimulated. Insulin resistance is the major stimulus for decreased protein synthesis and proteolysis. In animal models of uncomplicated ARF, increased muscle protein catabolism and decreased protein synthesis have been documented.[170,171] It is not clear whether increased catabolism is due to uremia or to the associated catabolic illnesses. There is little evidence in humans, that uncomplicated ARF patients have an abnormal nutritional status.[168]

Multiple studies have evaluated the effects of aggressive nutritional supplementation in attempts to reverse malnutrition and improve the prognosis of ARF patients.[172–175] However, the complexity of the disease process has precluded obtaining meaningful and clear-cut results from these clinical studies. Unfortunately, parenteral nutrition in ARF can have significant negative consequences such as fluid overload, mineral and electrolyte disturbances, acid-base disorders, hyperlipidemia, adverse effect of central venous catheter placement and infection, and need for more aggressive dialysis.[168]

Patients with ARF should be closely monitored for changes in nutritional status, and adequate protein and calories are needed. In non-catabolic patients and during the polyuric phase of ARF, a protein intake of 1 g/kg/day is required to achieve a positive nitrogen balance.[176] Larger amounts of dietary proteins will augment the accumulation of unexcreted waste products and prolong the uremic syndrome. A high-protein intake may also stimulate the need for dialysis,

Table 11–5 Comparison of the RDAs for Micronutrients in Healthy Subjects and the Measured Intake by Hemodialysis Patients, with Recommended Intake as the Percent of RDA for ESRD Patients

Micronutrient	RDA in healthy population	Observed intake in HD patients*	Recommended supplement as % of RDA
Zinc	8 mg in women 11 mg in men	N/A	None
Selenium	55 µg	N/A	None
Copper	900 µg	N/A	None
Thiamin	1.1 mg in women 1.2 in men	0.78-2.36 mg	100
Riboflavin	1.1 mg in women 1.3 mg in men	0.69-2.29 mg	100
Folic acid†	400 µg	71-378 µg	200-1000
Vitamin B_6	1.3 mg	0.64-2.14 mg	100
Vitamin B_{12}	2.4 µg	1.2-7.5 µg	100
Vitamin C	75 mg for women 90 mg for men	14-125 mg	120
Vitamin A	700 µg for women 900 µg for men	285-1385 µg	None
Vitamin E‡	15 mg	N/A	None

ESRD, end-stage renal disease; *HD,* hemodialysis; *RDA,* recommended dietary allowance.

which can by itself, stimulate protein degradation.[39] The extent of protein catabolism can be estimated from the urea nitrogen appearance and change in urea nitrogen pool.[168] For critically ill ARF patients on continuous renal replacement therapy (CRRT) amino acid/protein intake of 1.4 g/kg/day is recommended; a higher intake was ineffective in further ameliorating nitrogen balance.[169,177] Use of CRRT in catabolic ARF patients allows better fluid control, but the procedure presents additional nutritional challenges. Loss of amino acids and peptides can reach 6 to 15 g/day, depending upon the filtrate volume and/or dialysate flow, activation of inflammatory reaction through blood-membrane contact, loss of micronutrients such as water-soluble vitamins, and electrolyte derangements.[178,179] Hypophosphatemia and hypomagnesemia can develop in critically ill ARF patients who are receiving parenteral nutrition with restricted phosphate and magnesium content, especially if insulin is present. When regional citrate is used for anticoagulation, bicarbonate and/or lactate concentrations must be reduced to avoid inducing metabolic alkalosis. Moreover, serum ionized calcium should be monitored to prevent extreme derangements in serum calcium levels. The energy requirement in uncomplicated ARF is not different from healthy subject, about 25 to 30 kcal/kg/day. Even in hypercatabolic conditions, such as sepsis or multiple organ failure, energy intake should not exceed 35 kcal/kg/day.[169]

In summary, ARF occurring with critical illnesses induces net protein catabolism, primarily through enhanced proteolysis. Studies that have examined aggressive parenteral nutrition therapy in ARF have not provided conclusive evidence of enhanced survival or recovery of renal function with the therapy. Use of CRRT in critically ill ARF patient allows for liberalization of parenteral nutrition support by easier fluid management, though the procedure can increase catabolism and will require monitoring of electrolyte and acid-base status.

NUTRITIONAL ISSUES IN RENAL TRANSPLANT PATIENTS

A successful renal transplant into a patient with ESRD restores near-normal renal function and is expected to correct the nutritional abnormalities arising from uremia. The renal transplant recipient typically experiences a marked improvement of appetite leading to weight gain. Nevertheless, these patients face many nutritional challenges that demand close dietary monitoring. The commonly prescribed immunosuppressives (corticosteroids, calcineurin inhibitors, and sirolimus) are known to induce metabolic side effects such as protein hypercatabolism, hyperlipidemia, glucose intolerance, hyperkalemia, hypophosphatemia, hypomagnesemia, and obesity. The nutritional status after transplant is also determined by preexisting medical conditions such as protein losses, renal osteodystrophy, hyperlipidemia, and cardiovascular disease. Moreover, these patients suffer from declining renal function due to recurrent acute or chronic rejection, varying degree of proteinuria, hypertension, and poorly controlled diabetes. In early stages of the post renal transplant period the nutritional challenge is to counter the metabolic effects of protein hypercatabolism,

hyperlipidemia, and hyperglycemia. For the stable transplant recipient, the nutritional status should be optimized, including weight gain, obesity, and lipid control. With a failing graft, nutritional management is similar to CRF pre-dialysis patients.

Dietary Protein and Calorie Prescription for Renal Transplant Patients

Early post-transplantation, there is a marked increase in amino acid and protein catabolism due to the use of large doses of steroids plus surgery related stresses. Patients with preexisting malnutrition are at risk for poor wound healing and susceptibility to infection. Based on these concerns, a dietary protein intake of 1.3 g/kg body weight/day is recommended for the early post renal transplant.[180] However, these recommendations are based on only a few nitrogen balance studies.[181] The optimum dietary protein intake for transplant patients on maintenance immunosuppressive therapy is not well-established. Transplant recipients have been shown to maintain neutral nitrogen balance on low-protein intake of 0.6 g/kg/day as long as their energy intake was maintained at least 28 kcal/kg/day.[182] Recently, results of a 12-year follow-up on renal function of transplant recipients consuming protein intake of 0.8 g/kg/day compared to those taking higher protein intake of 1.4 g/kg/day was reported.[183] Those with the lower protein intake maintained unchanged renal function, whereas patients with the higher protein intake lost more than 40% of excretory efficiency. Based on limited available data, it is reasonable to recommend protein intake of 0.8 g/kg/day along with minimal energy intake of 30 to 35 kcal/kg/day for stable renal transplant patient. Those patients with progressive graft failure should have a more stringent protein intake of 0.6 g/kg/day, because there is evidence that a low-protein diet is also associated with a reduction in proteinuria and decreased activity of renin-angiotensin system.[184] During an acute rejection episode requiring treatment with high doses of corticosteroids, protein catabolism increased, yielding high blood urea nitrogen levels. Protein restriction in such patients can lead to severe negative nitrogen balance, so increasing protein intake to 1.2 g/kg/day is appropriate.

Obesity, defined as body mass index (BMI) of more than 30 kg/m^2 or more than 130% ideal body weight, is present in 12% to 40% of recipients within 1 year after renal transplant.[185,186] Obesity is associated with decreased graft survival and increased prevalence of cardiovascular disease after transplantation.[185,187,188] For stable transplant recipients who require weight reduction, a caloric intake of 25 kcal/kg/day along with appropriate dietary and lifestyle measures, including an exercise program, should be recommended. Weight reduction diets in obese, hyperlipidemic transplant recipients cause a modest reduction in cholesterol levels, although "statin" drugs are usually required.[189] The American Heart Association's "one-step" diet is a reasonable initial approach for hyperlipidemic renal transplant patients. This diet, consisting of less than 300 mg of cholesterol per day (with a goal of less than 250 mg/day), 30% total calories as fat, 50% as carbohydrate, and 20% as protein, is easily attainable and is familiar to renal dietitians.[180]

Dietary Phosphorus and Calcium After Renal Transplantation

Hypercalcemia and low normal serum phosphorus levels can be observed after a successful kidney transplant. These biochemical changes are due to persistent hyperparathyroidism, improved PTH sensitivity and increased 1-hydroxylation of vitamin D.[190,191] The parathyroid-induced increase in renal tubular phosphate leak lowers serum phosphorus levels. A phosphaturic action of steroids must also be considered; an increase in serum phosphorus levels after reduction of steroid doses has been reported.[192]

The major improvement over a patient's pre-transplant renal diet is the liberalization of dietary phosphorus. Nevertheless, oral supplements of phosphates are required for periods of up to 1 year after renal transplant. In the absence of hypercalcemia, calcium intake should be around 1000 to 1500 mg/day by diet and supplements.

In summary, a successful renal transplant allows greater dietary freedom and resultant weight gain. Immunosuppressive medications contribute to the protein hypercatabolism, hyperlipidemia, hyperglycemia, and propensity toward weight gain. Protein requirements are high during the early phase, similar to the requirements of healthy adults. With failing graft function, protein restrictions are reinstituted. Further, maintenance of optimal body weight along with changes in lifestyle measures, including an exercise program, should be part of the nutritional management in all renal transplant recipients.

NUTRITIONAL SUPPORT IN DIALYSIS

Despite an aggressive nutritional approach, some ESRD patients have a steady decline in their nutritional status. Unfortunately, dietary counseling is not always successful to maintain an adequate protein and calorie intake.[193] In these circumstances other forms of nutritional intervention have been considered, including oral supplements and enteral or parenteral feeding. There are many commercially available oral nutrient supplements (Nepro®, Magnacal®, Suplena®, etc.) designed specially for renal patients. Use of oral nutritional supplements by malnourished hemodialysis patients have resulted in improvement of serum albumin and prealbumin levels,[193] an increase in protein catabolic rate,[194] and decreased risk of hospitalization.[195] All of these studies were nonrandomized and included a small, selected group of patients that were followed for 3 to 6 months. Two important limitations to long-term use of oral supplements are: (1) A substantial proportion of patients appear to tire of the supplement and will stop taking them, and (2) Medicare does not reimburse for oral supplements, which, when taken on a daily basis, are expensive.[193]

Enteral feeding through nasogastric or gastric tube is usually prescribed for sick dialysis patients, who are incapacitated by neurologic disorders or debilitating illnesses precluding self or assisted oral feeding. There are no data on the efficacy of this nutritional strategy for the prevention or treatment of malnutrition in adult dialysis patients. Tube feeding has been used successfully for many years to provide nutritional support for infants and children treated by dialysis.[193,196]

Intradialytic parenteral nutrition (IDPN) is the provision of nutrients by infusion into the blood stream during the hemodialysis procedure. The benefit may be an improvement in body weight (primarily excess fluid gain), serum markers of nutrition, and a decrease in mortality rates.[197,198] Foulks[199] reviewed all published literature on IDPN use in MHD patients, utilizing an evidence-based approach, and concluded that the data supporting the use of IDPN are weak and a clear recommendation cannot be made. Recently, Pupim and colleagues[200] examined the influence of IDPN on the protein catabolism caused by dialysis. They found that intravenous nutrition increased protein synthesis and decreased protein degradation but only during the dialysis. After dialysis and IDPN, protein degradation increased again. Thus, the influence of IDPN remains controversial. Moreover, this treatment is expensive and its use is severely restricted with Medicare-imposed strict criteria for reimbursement. A National Kidney Foundation position paper on IDPN use gives explicit guidelines for the use of IDPN.[201]

Inflammation in Chronic Kidney Disease

Madhumathi Rao, M.D., F.R.C.P. (U.K.) • Vaidyanathapuram S. Balakrishnan, M.D., M.R.C.P.

The last two decades have seen a rapid evolution in our understanding of the mechanisms underlying the various consequences of the uremic state. Our perception has advanced to include not only the uremic milieu and uremic toxins, but an inflammatory micro-environment that impacts a wide variety of organ systems and physiologic pathways. The "interleukin hypothesis" was proposed in 1983, incriminating interleukin-1 (IL-1) produced during dialysis as the cause of hypotension, fever, and other acute phase responses observed in patients on dialysis.[1] This ushered in an era of study of the role of cytokines as orchestrators of not only acute intradialytic complications, but of the acute phase response and the chronic inflammatory state that exists in patients with chronic kidney disease.

CYTOKINES AND THE ACUTE PHASE RESPONSE

The early observations of endogenous pyrogen (Interleukin-2 [IL-2]), the fever-causing molecule produced by inflammatory cells,[2] and of macrophage migration inhibiting substances produced by lymphocytes upon exposure to antigen,[3,4] led to an awareness of a complex network of cytokines regulating a wide variety of inflammatory and immune responses. Cytokines are polypeptides with a molecular weight of 10 to 45 kDa, with autocrine and paracrine actions. They are highly potent, active at picomolar and femtomolar concentrations, and are synthesized and secreted in response to cellular injury, mainly by—although not restricted to—mononuclear cells, including monocyte-macrophage cell populations and lymphocytes and neutrophils. Cytokines fall into five broad classes according to their salient biologic properties (Table 12–1).[5] Among these categories, the pro- and anti-inflammatory cytokines may be considered the most significant in mediating chronic inflammation in disease states.

The acute phase response is the systemic response to tissue injury and has an important adaptive and defensive role. A more narrow characterization that has emerged in recent years refers to the changes in concentration of a number of plasma proteins, mediated by cytokines produced in response to tissue injury. By definition, the plasma concentration of these acute-phase reactants (APRs) increases (positive APRs) or decreases (negative APRs) by at least 25% during acute inflammation.[6] The most striking increases are seen in levels of C-reactive protein (CRP) and serum amyloid A (SAA), with a 1000-fold or greater rise within a few days of a stimulus. In contrast, some plasma proteins, such as albumin and transferrin, consistently demonstrate a reduction in plasma concentration and therefore represent the "negative" APRs. Although most APRs are synthesized by hepatocytes, some are produced by other cell types, including monocytes, endothelial cells, fibroblasts, and adipocytes.

The acute phase response, including elevated levels of CRP, reflects the generation of pro-inflammatory cytokines. These include interleukin-6 (IL-6), interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), to a lesser extent, interferon-χ, transforming growth factor-β1 (TGF-β1), and possibly interleukin-8 (IL-8). Cytokines operate both as a cascade and as a network, regulating the production of other cytokines and their receptors. The expression of genes for APRs is regulated mainly at the transcriptional level, but post-transcriptional and post-translational mechanisms also participate.[7,8]

The acute phase response is physiologically transient, but chronic inflammatory states are characterized by ongoing tissue injury that provides the repetitive stimuli for cytokine release and persistence of the acute phase response. This is true of the classic inflammatory arthritides, such as rheumatoid arthritis, other collagen vascular diseases, inflammatory bowel disease, chronic infections, and some cancers; a growing body of evidence now places chronic kidney disease (CKD) and end-stage renal disease (ESRD) in the same context. This persistent state of systemic inflammation that represents a sustained activation of the innate immune response presents with systemic manifestations, such as fever, anorexia, fatigue, and lethargy, that characterize many chronic inflammatory illnesses, including CKD. In addition, inflammation associated cytokines mediate the pathogenesis of the anemia of chronic disease and cachexia. Notably, over the last two decades research has established atherosclerosis as an inflammatory process, a concept that takes on additional significance with the observation that cardiovascular disease (CVD) is the most frequent cause of death in patients with CKD of any degree of severity. Cytokine production is also believed to play a role in the bone disease and immune dysfunction seen among uremic patients.

THE CHRONIC INFLAMMATORY STATE IN PATIENTS WITH CHRONIC KIDNEY DISEASE—THE EVOLUTION OF A CONCEPT

Mononuclear cell activation and cytokine production are well-known consequences of blood-dialyzer interactions. The interleukin hypothesis and subsequent research signified that release of pro-inflammatory cytokines was a critical mediator of acute intra-dialytic manifestations in hemodialysis patients. The extent of mononuclear cell activation is dependent on the dialyzer material used and is considered an

Table 12–1 Cytokine Classification

Class of Cytokine	Prototypical Members
Pro-inflammatory cytokines	IL-1, IL-6, TNF-α
Anti-inflammatory cytokines	IL-10
Lymphocyte growth and differentiation factors	IL-2, IL-4, IFN-χ
Hematopoietic colony-stimulating factors	G-CSF, GM-CSF, M-CSF
Mesenchymal cell growth factors	TGF-β1

index of biocompatibility. However, the recognition that the chronic morbidity of renal failure may be a function of a chronic inflammatory process, likely stemmed from the observation that a low serum albumin was one of the most powerful associates of mortality. This observation, borne by several large cross-sectional studies in dialysis patients in the late 1980s, identified hypoalbuminemia as both a marker of the malnourished state and an independent predictor of mortality.[9, 10] Originally attributed to protein-calorie malnutrition and uremic toxicity, it became increasingly clear that a simple deficiency of dietary protein intake, or underdialysis, was insufficient to explain the decline in serum albumin seen in dialysis patients. In addition, interventions such as intradialytic parenteral nutrition have failed to uniformly correct hypoalbuminemia.[11]

Thus, the notion that nonnutritional factors, including inflammation, may be a major cause of hypoalbuminemia was strengthened, and studies in chronic hemodialysis patients noted a high prevalence and coexistence of markers of malnutrition and chronic inflammation. In over 1000 randomly selected dialysis patients, Owen and Lowrie[12] found that the serum concentration of CRP exceeded the upper reference range value (<0.8 mg/dL) in approximately 35% of patients, and a prevalence of 46% was noted by Zimmermann[13] in 288 stable hemodialysis patients. Stenvinkel[14] studied 109 patients with pre-ESRD, and those with malnutrition as judged by a subjective global assessment (SGA) score 2 or greater had significantly higher levels of CRP and fibrinogen. While protein malnutrition can decrease albumin synthesis, this may also occur as part of the acute phase response. Although synthesis of APRs, even after an appropriate inflammatory stimulus, is impeded in protein malnutrition, cytokine release is unimpeded; hence, the inflammatory state is characterized by elevated APRs and pro-inflammatory cytokines in association with hypoalbuminemia.[15] Using this principle, Kaysen and colleagues[16] measured albumin synthesis, fractional catabolic rate, and the distribution of albumin in the vascular and extravascular compartments from the turnover of I-125 human albumin in two groups of hemodialysis patients with serum albumin less than 3.5 g/dL and greater than 4.0 g/dL. Albumin synthesis was significantly reduced in the low-albumin group, and there was a significant negative correlation between serum albumin and both CRP and SAA. Further credence of the impact of inflammation was lent by studies that showed a link between elevated levels of CRP and mortality in patients with CKD. Indeed, Yeun and colleagues[17] showed that inclusion of CRP in a regression model for mortality eliminated serum albumin as a predictor of risk.

Causes of the Inflammatory State in Patients with Chronic Kidney Disease/End-Stage Renal Disease

End-Stage Renal Disease

The causes of the inflammatory state are easier to appreciate in patients with ESRD. Recurrent blood-dialyzer membrane interactions and exposure to dialysis tubing trigger an ongoing inflammatory response, especially with bioincompatible membranes.[18,19] Direct contact of peripheral blood mononuclear cells (PBMC) with dialysis membrane and generation of active complement fragments (C3a, C5a, C5b-9) during hemodialysis play an important role in cytokine induction. Betz and colleagues[20] demonstrated that cuprophan membranes stimulate IL-1 expression in monocytes in the absence of complement. On the other hand, cellulosic membranes can activate through the alternative pathway, the complement cascade, and can generate active fragments able to stimulate cytokine gene expression and secretion by monocytes.

Bacterial contaminants, including lipopolysaccharide (LPS) fragments from poor quality of dialysis water and back-filtration or back-diffusion of contaminants, are another important trigger; indeed, the biologic activities of endotoxin are largely mediated by the cytokines TNF-α, IL-1, IL-6, and IFN-χ, and released from immune cells in response to endotoxin stimulation. Pertosa and colleagues[21] demonstrated that the basal release of TNF-α and IL-6 during hemodialysis was independent of the biocompatibility features of the membrane used but was considerably influenced by the endotoxin content of the dialysate. The contact with the dialysis membrane as well as the interactions with complement fractions, although able to induce a selective cytokine gene transcription in monocytes, does not always automatically stimulate the translation of the specific proteins; LPS or IL-1 is required as a second hit to induce a translational signal.[22]

Finally, the presence of foreign material in vascular accesses, such as polytetrafluoroethylene (PTFE) grafts, or intravenous catheters and their propensity to harbor chronic or recurrent latent infection are additional reasons for the inflammatory state in dialysis patients.[23]

Patients undergoing peritoneal dialysis have their unique set of factors that may enhance chronic inflammation, including episodes of overt or latent peritonitis or PD-catheter related infections and the constant exposure to PD solution, which may include bioincompatible substances or endotoxin.[24]

Chronic Kidney Disease

There is evidence that reduction in renal function per se may play a role in the genesis of inflammation in patients with CKD who are not yet on dialysis, through several mechanisms. Decreased clearance of pro-inflammatory cytokines may enhance overall inflammatory responses. The serum half-lives of pro-inflammatory cytokines, TNF-α and IL-1, are greater in animals without than with renal function.[25] In humans, declining renal function may also affect the levels of additional inflammatory molecules; serum CRP and IL-6 levels are inversely correlated with creatinine clearance.[26] In addition, with renal failure, other molecules that accumulate may provoke an inflammatory response. Advanced glycosylated end products (AGE), for example, clearly initiate inflammation in patients with renal failure.[27]

Volume overload and vascular congestion in patients with renal insufficiency may result in altered permeability of the gastrointestinal tract with accumulation of gut endotoxins that stimulate monocytes toward increased release of pro-inflammatory cytokines.[28] Other comorbid conditions in renal patients may be independently associated with an acute phase response and mechanisms that enhance the development of inflammation. Systemic autoimmune conditions and unrecognized persistent infections may all be contributors to inflammation among patients with decreased renal function.[29]

Oxidative Stress

Oxidative stress results from an imbalance between reactive oxygen species production and antioxidant defense mechanisms. Neutrophils obtained from patients with varying degrees of decline in GFR (creatinine clearance 6 to 35 mL/min/1.73 m^2) appear to exist in a primed state and show enhanced oxidative burst response upon stimulation by formyl peptides.[30] Factors that lead to neutrophil priming may be retained uremic toxins in pre-dialysis patients and LPS contamination of the dialysate in ESRD.[31] Dialyzer membrane bioincompatibility results in leukocyte activation and production of reactive oxygen species.[32] Pro-inflammatory cytokines, produced in response to either contact with membrane or endotoxin, contribute to this primed state.[33] Antioxidant defenses are also impaired in uremic patients who show diminished levels of reduced glutathione, selenium and vitamin E; hemodialysis contributes further to diffusive losses of hydrophilic vitamins such as ascorbic acid.[34] Data are beginning to emerge linking inflammation and oxidative stress in dialysis patients. Positive correlations between elevated CRP levels and plasma thiobarbituric acid reactive substances (TBARS) and plasma F$_2$ isoprostane levels, both measures of lipid peroxidation, and a negative correlation with plasma α-tocopherol levels have been shown.[35,36] These observations are consistent with the hypothesis that markers of inflammation and oxidant stress in dialysis patients are associated, and inflammation is associated with a depletion of antioxidants.

CYTOKINES AND THEIR REGULATORY NETWORKS

Classically, the immune system has been divided into innate and adaptive components. The former comprises the nonspecific resistance to pathogens, and the latter is characterized by antigen specificity and immunologic memory. The mammalian innate immune system consists of plasma proteins (such as complement), cells (such as neutrophils, macrophages, and natural killer cells), and physical barriers. The innate immune system recognizes and responds to a restricted set of highly conserved structures common to different pathogens. These pathogen-associated molecular patterns (PAMPs) include, among others, LPS, peptidoglycan, bacterial DNA, lipotechoic acid, mannans, and glucans. A family of receptors called "toll" receptors appear to initiate the innate immune response. At least 10 mammalian toll receptors have been identified, of which toll-like receptor–4 (TLR-4) is important in LPS recognition and responsiveness. TLR-4 defective mice show endotoxin hyporesponsiveness as well as

an increased susceptibility to infection by gram-negative organisms. Recognition results in the release of inflammatory cytokines (IL-6, TNF-α, IL-1β) that mediate the biologic activities of LPS, and in concert with costimulatory molecules, initiate the adaptive immune response. Thus, cytokines produced in response to cellular injury are one of the major classes of compounds in this scheme that initiate and mediate inflammatory responses for both the innate and adaptive immune systems. They activate neutrophil chemotaxis and phagocytosis and modulate mononuclear cell function in T-cell immune regulation.[37,38]

Both IL-1 and TNF-α sequentially induce the production of IL-6, feedback upon each other, and initiate other cascades. Several of the metabolic effects of IL-1 and TNF-α are thought to be mediated by IL-6, which also appears to be the major mediator of the acute phase response in ESRD patients.[39,40] IL-10 provides a physiologic mechanism to limit the inflammatory response after its initiation and effector functions for defense have been accomplished. After a latency of 8 to 12 hours, the initial secretion of IL-6 and TNF-α is followed by IL-10 production by stimulated monocytes. TNF-α of itself up-regulates IL-10 production, and IL-10 downregulates and inhibits production of TNF-α, IL-1 β, and IL-6, providing an efficient autocrine feedback mechanism for controlling the very redundant pro-inflammatory cytokine production by monocytes. The precise mechanisms by which IL-10 mediates these inhibitory effects have not been determined; however, both transcriptional and post-transcriptional mechanisms have been proposed.[41–44]

Several inhibitors of cytokines have been characterized. The same cells that synthesize IL-1, TNF-α, and IL-6 also produce specific inhibitors: IL-1 receptor antagonist (IL-1 Ra), soluble TNF receptors (sTNFR), and soluble IL-6 receptors (sIL-6R). These inhibitors antagonize the biologic functions of their specific cytokine and extend their circulating half-lives. Whereas IL-1Ra acts as a competitive inhibitor of IL-1 binding to its type-I and type-II receptors, without agonist activity, sTNFR's and sIL-6R's are the extracellular ligand binding domains of their cell surface receptors that are shed upon stimulation and bind directly to the cytokine.[5,45]

Cytokine Dysregulation in Chronic Kidney Disease/End-Stage Renal Disease

Several studies have demonstrated elevated circulating levels of pro-inflammatory cytokines in patients on HD, although others have not corroborated this observation.[40,46] The reasons for variability among these studies could relate to different methodologic and biologic factors that affect the measurement of cytokines in HD patients.[47] Moreover, plasma levels of cytokines do not necessarily reflect cytokine synthesis in HD patients or inflammatory states. Measurement of cytokine synthesis by peripheral blood mononuclear cells (PBMC) probably offers a consistent method of assessing cytokine production in dialysis patients. Transcriptional activation of interleukin-1 (IL-1) in PBMC has been observed following a single passage through an unsubstituted cellulose dialyzer.[48] Consequently, PBMC isolated from patients on chronic HD demonstrate increased spontaneous IL-1 synthesis on incubation, despite the absence of exogenous stimuli. In contrast, in mononuclear cells isolated from healthy subjects, neither IL-1 protein nor mRNA for IL-1 is demonstrated by

using Northern hybridization, and these cells fail to show evidence of IL-1 synthesis even after incubation for 24 hours.[49] Furthermore, PBMC from HD patients are "primed" to produce increased levels of IL-1 and TNF upon *in vitro* stimulation.[50–52] When stimulated with endotoxin, these cells synthesize as much as fivefold more IL-1 as compared to mononuclear cells from healthy subjects.[53] Similar results have been reported for the synthesis of TNF and IL-6.[54,55] Girndt and colleagues[56] used the cytoflow technique, a single-cell detection of cytokine production to measure the activation state of circulating monocytes. This technique revealed that only 15% to 20% of circulating monocytes were capable of cytokine production in healthy individuals, even after stimulation by endotoxin. In contrast, some 50% of circulating monocytes in HD patients were primed for cytokine production.

It has been proposed that counter-regulatory mechanisms may be insufficient to limit the heightened state of inflammation in patients with ESRD. The inflammation-limiting effect of IL-10 is functional in HD patients, although higher levels of the cytokine are needed to downregulate the overproduction of pro-inflammatory cytokines. Unlike TNF-α and IL-6, where higher levels are derived from a higher number of cytokine producing cells, IL-10 secretion is mainly enhanced by a higher level of secretion per single cell.[56] A transcriptional defect has been observed in IL-10 synthesis and may partly explain why the required elevation of IL-10 production appears to be limited in a significant proportion of ESRD patients.[57] There is evidence that monocytes differentiate into populations that mutually exclusively express either IL-6 or IL-10, and this may further contribute to the cytokine imbalance seen in ESRD.[56]

Cytokine-specific inhibitory proteins such as IL-1Ra and sTNFR are also elevated in HD patients. The molar ratios of plasma IL-1Ra:IL-1β range from 3:1 to 4:1 and the molar ratios of plasma sTNFR:TNF range from 13:1 to 38:1. Exposure to cuprophan membranes increases the peripheral blood mononuclear cell (PBMC) content of IL-1Ra, and the production of IL-1Ra upon endotoxin-stimulation by several-fold higher compared to undialyzed patients with CRF, CAPD patients, or healthy controls. However, in vivo studies have shown that a 1000-fold excess of IL-1Ra is required to block the hemodynamic effects of IL-1. Therefore, it appears unlikely that the levels of IL-1Ra and sTNFR observed in patients on HD are sufficient to block the systemic effects of IL-1 and TNF produced during dialysis. Therefore, such elevated plasma levels of inhibitory proteins are more likely to be "footprints" of IL-1 and TNF, respectively, or markers of monocyte activation produced during dialysis.[58] Indeed, elevated levels of IL-1 Ra have been shown to correlate with adverse cardiovascular events in HD patients.[59]

Genetic Factors

Circulating cytokine levels vary considerably among ESRD patients, and one may speculate that genetic factors, such as polymorphisms in genes encoding pro-inflammatory cytokines, may be involved in determining the individual inflammatory reaction in response to a given insult. Polymorphisms are the existence of two or more alleles at significant frequencies in a population, that may take the form of insertions/ deletions (I/D), minisatellites and microsatellites

(dinucleotide, trinucleotide, and tetranucleotide repeats), and single nucleotide polymorphisms (SNPs). In this respect, a number of different cytokine polymorphisms might be of interest, serving as markers of susceptibility to or severity of disease.

In humans, the interleukin gene cluster on chromosome 2q12-14 contains the loci for IL-1α, IL-1β, their receptors, and IL-1Ra.[60] Specifically, for IL-1α, a genetic association exists between a promoter polymorphism and juvenile rheumatoid arthritis and early-onset Alzheimer's disease.[61,62] A second IL-1α variation within intron 6, a 46 bp tandem repeat (VNTR), also influences gene expression.[63] In addition, IL-1α and IL-1β genotypes are significantly associated with the severity of periodontal disease, whereas an IL-1Ra polymorphism contributes to the susceptibility to severe sepsis.[64,65] Several variants of IL-1β and IL-1Ra have been associated with chronic renal failure and diabetic nephropathy in Caucasians and African-Americans.[66–68] Berger and colleagues[69] recently reported that IL-1 gene polymorphisms are highly related to both plasma levels of CRP and fibrinogen in patients referred for angiography.

The human TNF-α gene maps to chromosome 6 (p21.1-21.3) within the human leucocyte antigen complex.[70] There are a number of different polymorphisms in the promoter region of TNF-α and also at least one in the coding region. The polymorphism at position -308 in the promoter region consisting of a G (-308G) in the common (wild-type) allele and an A (-308A) in the uncommon allele, modifies gene expression.[71] The TNF-α -308A allele has a prevalence of approximately 30% in the general white population.[72] *In vitro* studies show that the presence of this allelic variant displays increased gene transcription as compared with the wild-type allele and is associated with increased secretion of TNF-α from macrophages *in vitro* and elevated TNF-α blood levels in vivo. The TNF-α -308A allele has also been associated with adverse outcome in a variety of infectious and inflammatory diseases, including cerebral malaria, meningococcal disease, the sepsis syndrome, and celiac disease.[72–75] The TNF-α promoter gene is in linkage disequilibrium with several HLA alleles that may also be involved with the control of TNF-α secretion or that may be independent risk factors for the development of meningococcal disease or other forms of sepsis.[76]

Several SNPs have been identified within the IL-6 promoter region, the best studied being the -174G/C SNP. The C/C genotype has been related to higher levels of plasma IL-6, particularly after stresses such as surgical procedures.[77,78] In the general population, the C-allele has been associated with higher levels of CRP and has been linked to hypertension, coronary heart disease, and left ventricular hypertrophy.[79]

There is a large interindividual variation in IL-10 response to inflammation, at least 70% of which may be explained by genetic factors.[80] Indeed, the SNPs identified in the promoter region of the IL-10 gene are related to IL-10 expression and have been linked to the risk of both SLE[81] and inflammatory bowel disease.[82] Moreover, Girndt and colleagues[84] have recently shown that the IL-10-1082 SNP was associated with an increased risk of cardiovascular events[83] and immune dysfunction, characterized by poor rates of seroconversion after hepatitis-B vaccine in hemodialysis patients.

The human TGF-β1 gene is sited on chromosome 19 (q13.1-13.3) and at least seven polymorphic sites have been

described, including three each in the promoter and coding regions.[85] Grainger and colleagues[86] demonstrated that the concentration of total TGF-β1(active + acid activable latent) in plasma was predominantly under genetic control with a heritability estimate of 54%. The presence of the C-509T promoter region polymorphism explained 8.2% of the additive genetic variance of total TGF-β1 concentration. In a study of lung transplant recipients, Awad and colleagues[87] showed that stimulated lymphocytes from patients homozygous for the G allele at the +915 position of the signal sequence (codon 25) produced higher levels of TGF-β1 compared to heterozygous patients (G/C). In a study of heart transplant recipients, Aziz and colleagues[88] showed that the codon 25 G/G genotype was associated with plasma levels about one and a half times higher than the G/C genotype. TGF-β appears to have a protective role in atherogenesis, and low plasma levels have been associated with clinical disease.[89] In a recent study of hemodialysis patients from Italy, serum levels of TGF-β1 were lower in patients with atherosclerotic disease, although there was no demonstrable relationship to TGF-β1 genotypes.[90] The ECTIM study showed an association between the G/C genotype at codon 25 and the risk of myocardial infarction.[85] Yokota and colleagues[91] showed that male subjects with the T allele at the +869 position of the signal peptide sequence region (genotypes T/C or T/T at codon 10), had a threefold higher risk of MI, and lower TGF-β1 levels, compared to males with the C/C genotype. Several other studies have been negative for an association between coronary disease and coding or promoter region polymorphisms in population groups without CKD.[92,93]

The innate immune system is the first line of defense against bacterial lipopolysaccharide (LPS). Two polymorphisms of the human TLR-4 gene, Asp299Gly and Thr399Ile, have been recently characterized.[94] These are associated with impaired bacterial endotoxin-induced signaling and the capacity to elicit inflammation. TLR-4 receptor mutations have been associated with an increased risk of gram-negative infections and gram-negative shock.[95] TLR-4 expression has been noted to be up-regulated in both human and murine atherosclerotic lesions.[96] These observations suggest that defects in TLR-4 signaling may exert opposing effects in the pathogenesis of gram-negative infections and atherosclerotic disease. This is especially significant in the context of microbial disease with organisms such as *Chlamydia pneumoniae* and *Helicobacter pylori* being implicated in the pathogenesis of atherosclerotic disease. Kiechl and colleagues[97] recently described an association between the Asp299Gly TLR-4 polymorphism (diminishing the inflammatory response to gram-negative pathogens) and a decreased risk of atherosclerosis in nonrenal patients.

Myeloperoxidase (MPO), another component of the defense system, is a hemoprotein expressed in polymorphonuclear leukocytes and monocytes that catalyzes the production of hypochlorous acid, enhancing the antimicrobial activity. MPO has recently been linked to several diseases, such as atherosclerosis and Alzheimer's disease.[98] A highly functional SNP that affects the transcription of MPO is located in the promoter region (463G/A)[99] and may be of interest due to a recent description of an association between this SNP and the presence of coronary artery disease.[100]

Another polymorphism that might contribute to different inflammatory responses is the C825T polymorphism in the GNB3 gene, encoding the ubiquitously expressed β3-subunit of the G proteins, which is involved in immune cell function in humans. In a preliminary prospective study including 228 HD patients, higher CRP levels and higher mortality were seen in T homozygotes, suggesting that the C825T polymorphism might influence mortality rate in HD patients.[101]

Consequences of the Inflammatory State in Patients with Chronic Kidney Disease/End-Stage Renal Disease

Hypoalbuminemia and Malnutrition

The reasons for malnutrition in dialysis patients are multifactorial and include disturbances in protein and energy metabolism, hormonal derangements, poor intake due to anorexia, and nausea and vomiting related to the uremic toxicity. Associated comorbidity (diabetes mellitus, diffuse vascular disease) and complications (pericarditis, infection, congestive heart failure) can also contribute to malnutrition. Thus poor nutrient intake, protein, and amino-acid losses during dialysis and catabolic stresses summarize the main mechanisms underlying dialysis-related malnutrition. The inflammatory response and cytokines mediate many of these mechanisms.[46,102,103]

TNF-α and IL-1 directly suppress appetite. Animal studies suggest that direct effects of these cytokines on the hypothalamic satiety center explain this anorectic effect. IL-6 and TNF-α induce muscle breakdown in rats and lead to a wasting illness similar to prolonged starvation and are known mediators of cancer cachexia.[104,105] These cytokines have both antianabolic and catabolic actions on muscle, upregulating ubiquitin-proteasome-mediated proteolysis and freeing amino acids for the synthesis of defensive proteins such as the APRs, ferritin, and CRP.[106,107] An established metabolic effect of chronic inflammation is cytokine-mediated hypermetabolism. Increased resting energy expenditure (REE) is observed in most of the chronic inflammatory states, again placing dialysis patients at increased risk for negative energy balance.[108] Chronic inflammation also produces insulin resistance and disrupts the growth hormone and insulin-like growth factor I axis, leading to decreased anabolism and increased leptin concentrations, which may induce anorexia due to its central effects.[109]

In the dialysis population, the most consistent relationships have been demonstrated between IL-6 and indices of malnutrition. Since both IL-1 and TNF-α sequentially induce the production of IL-6, some of their metabolic effects are thought to be mediated by IL-6. It is also notable that whereas most other cytokines function via paracrine/autocrine mechanisms, the major effects of IL-6 are a consequence of its concentration in the circulation and can take place at sites distinct from its site of secretion. IL-6 downregulates albumin synthesis, and the relationship between elevated levels of IL-6 and hypoalbuminemia has been noted by several investigators.[39] Kaizu and colleagues[110] reported that hemodialyzed patients with high plasma IL-6 concentration had lower serum albumin levels and greater weight loss over a 3-year period than patients with low plasma IL-6. Moreover the circulating IL-6 concentration was inversely correlated with serum albumin, cholinesterase, and mid-arm muscle area. In a more recent study these investigators showed a significant inverse association between IL-6 and measures of muscle wasting, using the

creatinine generation rate from a creatinine kinetic model and thigh muscle area measured by computed tomography.[111] Bologa and colleagues[112] showed that in addition to the inverse correlation with serum albumin, higher levels of circulating TNF-α and IL-6 were also associated with lower levels of serum cholesterol. IL-6 remained the strongest predictor of mortality in this cohort, even after adjustment for potential confounders such as older age, hypoalbuminemia, and lower body mass index (BMI). While serum cholesterol was not a significant predictor of mortality, nonsurvivors were noted to have significantly lower levels of serum cholesterol. The link between elevated levels of circulating IL-6 and mortality has also been noted in patients with normal renal function and in the elderly.[113,114] Pecoits-Filho and colleagues[115] showed a strong predictive value of elevated IL-6 levels for poor outcome in an incident dialysis population that was starting either HD or PD.[115]

The Malnutrition-Inflammation-Atherosclerosis (MIA) Syndrome

Cardiovascular causes account for almost 50% of the reported causes of dialysis patient deaths in all age groups.[116,117] Considering that most dialysis patients die of atherosclerotic cardiovascular diseases, it is significant that hypoalbuminemia and other nutritional indicators are strong risk factors for early death. Several recent epidemiologic studies have demonstrated that inflammation per se may play an important role in the development of atherosclerosis and death from ischemic heart disease and cerebrovascular disease.[118] A series of recent publications mirror these associations between cardiovascular risk and a host of inflammatory biomarkers, including cytokines, cell adhesion molecules, and downstream players, such as CRP and SAA, in patients both with and without renal disease.[119] Experimental evidence suggests an important role of IL-6 in the atherosclerotic process. Injection of recombinant IL-6 exacerbates early atherosclerosis in ApoE-deficient mice, and increased IL-6 expression is found within the fibrous plaques of atherosclerotic lesions.[120,121] IL-6 is also an independent predictor of the progression of carotid atherosclerosis in patients on dialysis treatment,[122] and baseline levels of plasma IL-6 appear to predict patient survival similar to the reported associations for albumin and CRP.[112,115] Thus, the chronic inflammatory state contributes to malnutrition and atherosclerotic cardiovascular disease, both of which are strong predictors of mortality in dialysis patients. Foley and colleagues[123] found that among hemodialysis patients, a 1.0 g/dL fall in mean serum albumin was independently associated with the development of de novo and recurrent cardiac failure, de novo and recurrent ischemic heart disease, cardiac mortality, and overall mortality, the magnitude of increased risk ranging from 2.2 to 5.6.

There is thus considerable evidence for strong interactions between CVD, malnutrition, and a chronic inflammatory state, and nutritional and inflammatory markers are closely linked to CVD in CKD patients. Stenvinkel and colleagues[14] have therefore suggested the existence of a syndrome consisting of malnutrition, inflammation, and atherosclerosis (MIA syndrome) in patients with CKD. Elevated levels of pro-inflammatory cytokines could be the link between the high prevalence of inflammation, malnutrition, and CVD in patients with CKD. The MIA syndrome has also been invoked to explain the "reverse epidemiology" or "risk-factor paradox" seen in dialysis patients.[124] PEM and inflammation change many nutritional measures in the same direction. In contrast to the general population, where markers of overnutrition are associated with increased risk of CVD, markers of undernutrition such as low body mass index (BMI), reduced serum cholesterol, or creatinine concentration correlate with increased morbidity and mortality, including a higher risk of cardiovascular events and death, in dialysis patients. A similar reversal is also apparent for the relationship between plasma total homocysteine (tHcy) and cardiovascular risk. Homocysteine may induce vascular damage and promote atherogenesis by inducing platelet activation, oxidative stress, endothelial dysfunction, and hypercoagulability.[125] Although in the general population there is strong evidence that a mildly elevated plasma tHcy is an independent and graded risk factor for atherosclerosis,[126,127] in patients with ESRD, findings have been inconsistent, with some studies showing paradoxically lower levels in association with CVD.[128] Several studies have shown that tHcy levels are lower in malnourished ESRD patients as a direct consequence of PEM. Moreover, albumin is an important binding site for tHcy, and there is a direct relationship between serum albumin levels and tHcy. Thus, the presence of the MIA syndrome would be expected to confound the relationship between plasma tHcy and vascular disease.

Cardiovascular Disease

Atherosclerosis as an inflammatory lesion

In contrast to the traditional view that atherosclerosis is an acellular lesion composed of lipid deposits, recent understanding of the biology of atherosclerosis reveals the atheromatous lesion to be a site of active inflammation. Cytokines play differential roles in the pathogenesis and evolution of the lesion with pro- and anti-atherogenic effects influencing plaque characteristics and clinical outcomes. The classical pro-inflammatory cytokines, IL-1, TNF-α, and IL-6, typically mediate pro-atherogenic processes, whereas IL-10, an anti-inflammatory cytokine is considered anti-atherogenic, although this may be an oversimplification. Pro-atherogenic mechanisms include local effects on endothelial cells, VSMCs and monocytes, as well as various metabolic and coagulant mechanisms. IFN-χ and TGF-β1, mediate either pro- or anti-atherogenic effects depending on the stage of evolution of the lesion. The balance between pro- and anti-atherogenic cytokines probably depends, in part, upon the balance between the T_H1 and T_H2 lymphocyte subpopulations within the atherosclerotic plaque.[129]

The earliest stages of atherogenesis are associated with an enhanced expression of pro-inflammatory cytokines. Several pathologic processes that cause endothelial injury, including modified LDL, free radicals, hemodynamic stress, hypertension, or infectious microorganisms, stimulate cytokine release. Cytokines alter endothelial function, enhancing the expression of leukocyte adhesion molecules and chemokines. A strong positive correlation has been demonstrated between IL-6 levels and soluble intercellular adhesion molecule −1 (ICAM-1). Moreover, they interact with platelets and coagulation and fibrinolytic systems that are activated following endothelial injury. Monocyte and T-cell recruitment and migration of vascular smooth muscle cells (VSMCs) into the sub-intimal region are promoted, leading to the formation of foam cells

and, eventually, the "fatty streak," which is the first macroscopic manifestation of atherosclerosis. Foam cells represent a rich source of cytokines, chemokines, growth factors, colony stimulating factors and proteolytic enzymes. IL-1, TNF-α, and IFN-χ, in turn, increase the expression of CD40 and CD40-ligand (CD40L), cell-associated members of the TNF-TNF receptor family. Subsequent ligand binding of CD40 by CD40L augments the surface expression of E- or P-selectin, ICAM-1, and vascular cell adhesion molecule −1 (VCAM-1) on cells found in plaques. These findings highlight the role of the foam cell in the plaque microenvironment and the potential auto-regulatory, positive feedback loops that determine the chronic nature of atherosclerotic inflammation.[129]

Further plaque advancement depends upon the subintimal microenvironment. Replication and activation of both VSMCs and mononuclear phagocytes promote plaque growth and fibrous cap formation. Plaques composed of a lipid-rich core with numerous inflammatory cells, in particular, macrophages, are termed "vulnerable" because they are more prone to rupture. Pro-inflammatory cytokines, TNF-α and IL-1, stimulate the expression of matrix metallo-proteinases (MMPs) that degrade extracellular matrix (ECM). This weakens the fibrous cap that overlies the lipid core of the plaque and renders it more prone to rupture by hemodynamic stresses. The direct contact of blood coagulation mechanisms to tissue factor triggers thrombosis. When the prevailing fibrinolytic mechanisms outweigh the procoagulant pathways, a limited mural thrombus rather than a sustained and occlusive blood clot develops. Healing takes place with resorption of the mural thrombus and the elaboration of growth factors, such as platelet derived growth factor (PDGF) from platelets and TGF-β1 from VSMCs, macrophages, and activated platelets. TGF-β1 is the most potent stimulus known for interstitial collagen synthesis by VSMCs and appears to exert an important plaque stabilizing effect. A stable plaque has a thick fibrous cap, a smaller lipid pool, fewer inflammatory cells and a dense ECM, and is less prone to disruption.[129] Apart from increasing ECM synthesis, TGF-β1 increases the expression of tissue inhibitors of MMPs, TIMPs,[130] and interacts with the fibrinolytic cascade. Plasmin is the most important physiologic activator of TGF-β1, which, in turn, upregulates the expression of plasminogen activator inhibitor-1 (PAI-1).[131–133]

Inflammation and Other Cardiovascular Disease

Congestive heart failure is common among ESRD patients, and over 50% of such patients have evidence of PEM and hypoalbuminemia.[134] In its most serious form, cardiac cachexia is defined as the loss of more than 10% of lean body mass.[135] Plasma levels of TNF-α, IL-1, and IL-6 have been reported to be elevated in cardiac failure, presumably triggered by factors such as low tissue perfusion, hypoxia, hepatic congestion, and bowel wall edema.[136,137] Inflammatory cytokines are, in part, responsible for anorexia, increased muscle proteolysis, and increased resting energy expenditure. They also have a depressant action on the myocardium, thus inducing myocardial dysfunction. Stenvinkel and colleagues[138] evaluated cardiac troponin T (cTnT), a highly sensitive and specific marker of myocardial damage in ESRD patients starting dialysis and an independent predictor of mortality. They demonstrated positive correlations between cTnT and IL-6, and CRP, respectively, suggesting an association between inflammation and cTnT levels. Cardiac calcification of either coronary vessels or valves has been previously considered a passive degenerative process, but more recent studies have indicated the involvement of active inflammation. A recent study in a peritoneal dialysis cohort showed a significant relationship between cardiac valve calcification and elevated CRP, hypoalbuminemia and malnutrition assessed by SGA, even after adjustment for serum PTH and Ca-P metabolism.[139] Another study in peritoneal dialysis patients showed that the presence of coronary artery calcification measured by the Agatston score showed higher levels of IL-6, TNF-α, and CRP, although these associations did not retain significance on multivariate adjustment.[140]

Triggers for Inflammation

The traditional lipid-centric view contributed tremendously to progress in understanding the pathophysiology of atherosclerosis. The current model links inflammation to the role of lipids and dyslipidemia. Oxidative modification of low-density lipoprotein (LDL) yields biologically active compounds that induce the expression of adhesion molecules, chemokines, and pro-inflammatory cytokines.[141] Pro-inflammatory cytokines such as IL-1 and TNF-α inhibit the activity of lipolytic enzymes (lipoprotein lipase, hepatic triglyceride lipase, lecithin-cholesterol acyltransferase) that are responsible for the catabolism of triglyceride-rich apo-B containing lipoproteins and HDL.[142,143] Indeed, given that plasma levels and synthesis of these cytokines are elevated in dialysis patients, it follows that the uremic lipoprotein profile resembles the abnormalities seen in patients with acute infection, severe trauma, and myocardial infarction. The protective effect of HDL stems partly from its role in reverse cholesterol transport and in the transport of significant antioxidant enzymes (platelet activating factor acetyl hydroxylase and paraoxonase).[141] However, in the presence of inflammation, SAA associates with HDL, displacing apoA-I and redirecting HDL cholesterol from the liver to the macrophage for use in tissue repair, or even converting it to a nonfunctional or pro-inflammatory particle.[144] Lipoprotein (a) (Lp[a]) is another APR; IL-6 responsive elements have been identified in the 5′ flanking regulatory region of the apo(a) gene on chromosome 6.[145] Concentrations of Lp(a) increase during the acute phase response,[146] depending upon the size of the apo(a) isoform, which is inherited as an autosomal codominant trait.[147] Lp(a) is an LDL-like particle in which an apolipoprotein(a) (apo[a]) moiety is linked via a disulfide bond to apoB-100.[148] There is extensive homology between Lp(a) and plasminogen.[149] Lp(a) binds avidly to endothelial cells, macrophages, fibroblasts, and platelets, as well as the subendothelial matrix, where it may promote proliferation of VSMCs and chemotaxis of human monocytes.[150,151] By virtue of its structural homology to plasminogen, it competes for binding to plasminogen receptors and inhibits fibrinolysis at sites of tissue injury. It may also induce production of PAI-1 and inhibit secretion of tissue plasminogen activator (TPA).[152,153] Lp(a) also has the ability to deliver significant quantities of cholesterol to sites of vascular injury, 40% of its mass being represented by cholesterol. It is thus a highly atherothrombotic lipoprotein, triggering inflammatory, antifibrinolytic, and lipid mediated pathways in vascular injury. A recent meta-analysis of 27 prospective studies with a mean follow-up of 10 years showed that

individuals with Lp(a) concentrations in the top tertile, had a risk ratio for coronary heart disease 1.6 times (95% CI: 1.4 to 1.8) that of individuals with Lp(a) concentrations in the bottom tertile. Adjustment for conventional risk factors did not diminish this association.[154]

Infectious agents, such as *Chlamydia pneumoniae, Helicobacter pylori,* herpes simplex virus, and cytomegalovirus, have been implicated in various epidemiologic studies as etiologic for atherosclerosis, of which the associations with *C. pneumoniae* have been the strongest.[155] The organism has been demonstrated within atherosclerotic lesions by immunostaining or PCR[156,157] and may potentially mediate both local effects and stimulate the production of IL-6 and the acute phase response.[122]

Other factors that may trigger inflammatory signals involved in atherogenesis include advanced glycosylated end products (AGE) that occur as a result of sustained hyperglycemia. AGE-modified proteins can augment the production of cytokines and other inflammatory pathways in endothelial cells.[158] Adipose tissue is an important source of pro-inflammatory cytokines, such as TNF-α and IL-6, and thus potentiates atherogenesis independent of its relationship to the metabolic syndrome and insulin resistance.[159]

C-Reactive Protein

CRP is the prototypical APR produced by the liver in response to various pro-inflammatory cytokines, namely IL-6, IL-1, and TNF-α. IL-6 binding elements are present in the promoter region of the CRP gene in hepatocytes.[160] Human CRP is a pentameric protein encoded by a gene on chromosome 1. It acts as an opsonin for bacteria, parasites, and immune complexes and can activate the classical pathway of complement. In addition, it binds to and effects the clearance of nuclear material from necrotic tissue and therefore provides a protective mechanism against the initiation of nuclear-antigen specific autoimmunity.[7]

Data from the Physician's Health Study first called attention to the importance of CRP as a marker of risk of MI in, apparently, healthy individuals.[118] In a recently reported meta-analysis of 14 prospective long-term studies of CRP and the risk of nonfatal myocardial infarction or death from coronary heart disease, the combined adjusted risk ratio was 1.9 (95% CI 1.5–2.3) among individuals in the top tertile of baseline CRP concentrations.[161] CRP also predicts recurrent events and mortality in patients with coronary, cerebrovascular, and peripheral vascular disease.[162] CRP has emerged as a remarkably robust marker of cardiovascular risk and meets the criteria required for clinical utility as a surrogate for cytokine stimulation. It is relatively stable from day to day in a given individual, with a plasma half-life of 19 hours and relatively constant fractional clearance rates in both healthy individuals and diseased states. It has a standardized and reproducible assay and adds to estimates of risk already provided by established markers.[163] The recent guidelines of the American Heart Association (AHA) address the potential role of CRP in cardiovascular risk assessment.[164]

There is evidence that CRP may be more than a marker of disease, playing a direct role in the pathogenesis of atherosclerosis. The protein is markedly upregulated in atheromatous plaques, the majority of foam cells beneath the endothelium showing positive staining for CRP. It promotes LDL cholesterol uptake by macrophages, binding to LDL and VLDL in a calcium-dependent fashion. It may induce the expression of intercellular adhesion molecules by endothelial cells and the production of tissue factor, an activator of the coagulation pathway, by monocytes. Indeed, it has been suggested that high CRP concentrations and the extent of its deposition in the atherosclerotic plaque may be associated with plaque vulnerability and occurrence of acute thrombotic events.[162,163]

Patients with CKD and ESRD show elevated CRP levels in keeping with the underlying chronic inflammatory state.[9,13] There is a close correlation between changes in plasma levels of IL-6 and levels of CRP.[115,165] The inverse relation with serum albumin levels among ESRD patients has already been discussed. Bergstrom and colleagues[166] were the first to show that elevated CRP was a strong predictor of mortality in HD patients, and later studies have supported this observation. Zimmermann[13] showed that all-cause mortality was 4.6-fold, and cardiovascular mortality was 5.5-fold higher among patients in the highest quartile of CRP compared to the lowest quartile. Yeun[17] also identified CRP levels as the most powerful predictor of all-cause and cardiovascular mortality. Similarly, Iseki and colleagues[167] showed a poorer survival among patients with an elevated CRP compared to those with normal levels. Mirroring the observations in the general population, hemodialysis patients with elevated serum CRP and serum amyloid A levels were shown to have significantly higher serum levels of Lp(a) and fibrinogen, and both were predictors of CVD and death.[13] The Cardiovascular Risk Extended Evaluation in Dialysis (CREED) study showed that CRP was an independent predictor of the number of atherosclerotic plaques in the carotid arteries of a chronic HD cohort.[168] Among patients with CKD, Stenvinkel[14] showed strong associations between inflammation (high CRP) and increased carotid intima media area and presence of carotid plaques. In a recent secondary analysis of the Modification of Diet in Renal Disease (MDRD) data, Menon and colleagues[169] showed that among patients with CKD and glomerular filtration rate (GFR) less than 60 mL/min/1.73m^2, CRP was inversely related to serum albumin, and patients with a high CRP level had a 1.73-fold increase in the odds of CVD.

Anemia and Unresponsiveness to Erythropoietin

Erythropoiesis is regulated by cytokines, and chronic inflammatory conditions characterized by high circulating cytokine levels often manifest anemia that is hyporesponsive to erythropoietin (EPO).[170] A significant proportion of dialysis patients show EPO resistance even after known causes such as iron deficiency, hyperparathyroidism, or aluminum overload have been excluded,[171] and altered cytokine production may be responsible for suppressing bone marrow erythropoiesis, EPO production, or impairing iron utilization. Serum ferritin is an APR and patients with refractory anemia due to inflammation characteristically have paradoxically elevated levels of ferritin. IL-1 and TNF-α inhibit EPO production *in vitro*; the inhibitory effect on erythroid colony formation in bone marrow cultured with uremic serum was reversed by the addition of specific anti-TNF-α antibodies.[172] Goicoechea[173] and, more recently, Kalantar-Zadeh[174] have shown in patients undergoing chronic HD, a significant and direct correlation between EPO dose and peripheral blood mononuclear cell (PBMC)

associated TNF-α and IL-6 production and serum IL-6 levels, respectively.

Bone Disease

Cytokines such as IL-6 appear to play a role in regulating osteoblast/osteoclast interactions. Il-6 is produced by osteoblasts in response to parathyroid hormone (PTH) and may induce osteoclastogenesis and bone resorption. Indeed, some of the effects of calcitriol in bone may be mediated by IL-6. IL-1 and TNF-α also appear to exert osteoclastic effects. In addition, IL-1 upregulates the expression of the extracellular calcium-sensing receptor mRNA, inhibiting PTH secretion *in vitro.*[175]

IL-1, IL-6, and TNF-α stimulate β-2 microglobulin (β-2MG) release by leukocyte and endothelial cells.[176] They play an important role in the pathogenesis of amyloid bone disease in patients dialyzed with cellulosic membranes where complement activation and cytokine release culminates in enhanced β-2MG generation.[177,178]

Immune Dysfunction

Uremic patients on dialysis demonstrate an increased susceptibility to infections, which account for up to 15% of the mortality in this population.[117] Dysfunction of phagocytic cells related to blood-dialyzer interactions with bioincompatible cellulosic membranes, complement activation, and altered cytokine production are some of the nonspecific defects in host defenses. The immune system in HD patients is characterized by deficient effector function towards bacterial and viral infections. Other manifestations of this cellular immune defect include extended survival of skin allografts, marked decrease in delayed type hypersensitivity responses to cutaneous antigens, and reduced seroconversion after vaccination.[179] Part of the underlying defect is an impaired costimulatory signaling of antigen presenting cells towards T-lymphocytes.[180] Girndt and colleagues[181] showed in dialysis patients, a correlation between inflammatory activation, measured as the *in vitro* production of IL-6 and TNF-α by PBMC upon stimulation with LPS, and immunodeficiency, measured as nonresponsiveness to hepatitis B vaccination. The higher production of pro-inflammatory cytokines appeared to correlate with impairment of immune function and a higher production of IL-10, an anti-inflammatory cytokine, with good immune function. An intact counter-regulatory effect of IL-10 for reducing monokine synthesis thus appears to be necessary for immunocompetence. Indeed, Kimmel and colleagues[40] showed that elevations in pro-inflammatory cytokines such as IL-1 and TNF-α were independently associated with mortality, and circulating levels of IL-2 and IL-12, cytokines critical for T-cell growth and function, and T-cell number and function, were independently associated with survival. Related observations emerged from analyses of over 20,000 chronic dialysis patients in the Fresenius Medical Care data system. Total lymphocyte count was associated, albeit weakly with proxies for body protein content (albumin, creatinine) and inversely with death risk. Total neutrophil count, a crude marker of systemic inflammation, on the other hand, was inversely associated with proxies for body protein content and directly with death risk.[182] These findings underscore the intricate relationships between malnutrition, immune function, and clinical outcomes in ESRD patients with chronic inflammation as a unifying pathophysiology.

Metabolic Effects

TNF-α and IL-6 induce insulin resistance, and both cytokines cause dyslipidemia. Both TNF-α and IL-6 appear to be closely related to the control of body composition.[183,184] TNF-α is over-expressed in the adipose and muscle tissues in obese compared to lean subjects. IL-6 is also expressed in adipose tissue, and IL-6 deficient mice develop obesity.[185] TNF-α blocks the action of insulin in cell culture as well as in experimental animals.[186] The elevated levels of inflammatory cytokines such as TNF-α, IL-1β, and IL-6 are believed to mediate, in large part, the hyperglycemia with insulin resistance and profound negative nitrogen balance in the sepsis syndrome.[187] In a sample of patients from a population survey, serum IL-6 concentrations were higher in subjects with impaired glucose tolerance and type II diabetes than in the control subjects.[188] The dyslipidemic effects associated with the acute phase response that have been discussed earlier in this review, include elevation of circulating concentrations of Lp(a) and triglycerides, conversion of HDL into a proatherogenic form, and oxidation of LDL.

Inflammation as a Therapeutic Target

At the patient level, several questions remain and might be of clinical significance, such as the temporal patterns of the development of the inflammatory state and the identification of subsets of patients at greater risk for developing the inflammatory state and its consequences. A suggested approach to the management of the inflammatory aspects of the uremic state is schematized in Figure 12–1. At the current state of knowledge, we do not have a robust evidence base to propose specific strategies to counter inflammatory processes. However, within the framework of existing clinical guidelines there exists considerable potential to modify clinical outcomes.

Anti-inflammatory or anti-cytokine strategies (anti-TNF-α antibodies, soluble TNF-α receptors, and IL-1Ra) have been found to be extremely effective in limiting the inflammatory consequences of certain diseases, such as rheumatoid arthritis.[189] In the context of the patient with CKD, however, such therapies would be limited by the fact that there is no single target in the inflammatory response; the inflammatory state is already established in response to multiple factors and consists of the activation of multiple mediators. It can be argued that interventions should be directed to block the inflammation inducing stimuli upstream, such as the use of ultrapure water for dialysate, biocompatible membranes, and correction of acidosis. Clearance of larger molecules by dialytic or adsorbent therapies are potential avenues for the removal of β2-MG, leptin, or other proteins that potentiate the inflammatory response. Preliminary studies with an adsorbent column (BetaSorb) have shown that in addition to very efficient β2-MG clearance, there was a marked decrease in the ability of uremic serum to stimulate TNF-α production from a monocytic cell line.[190]

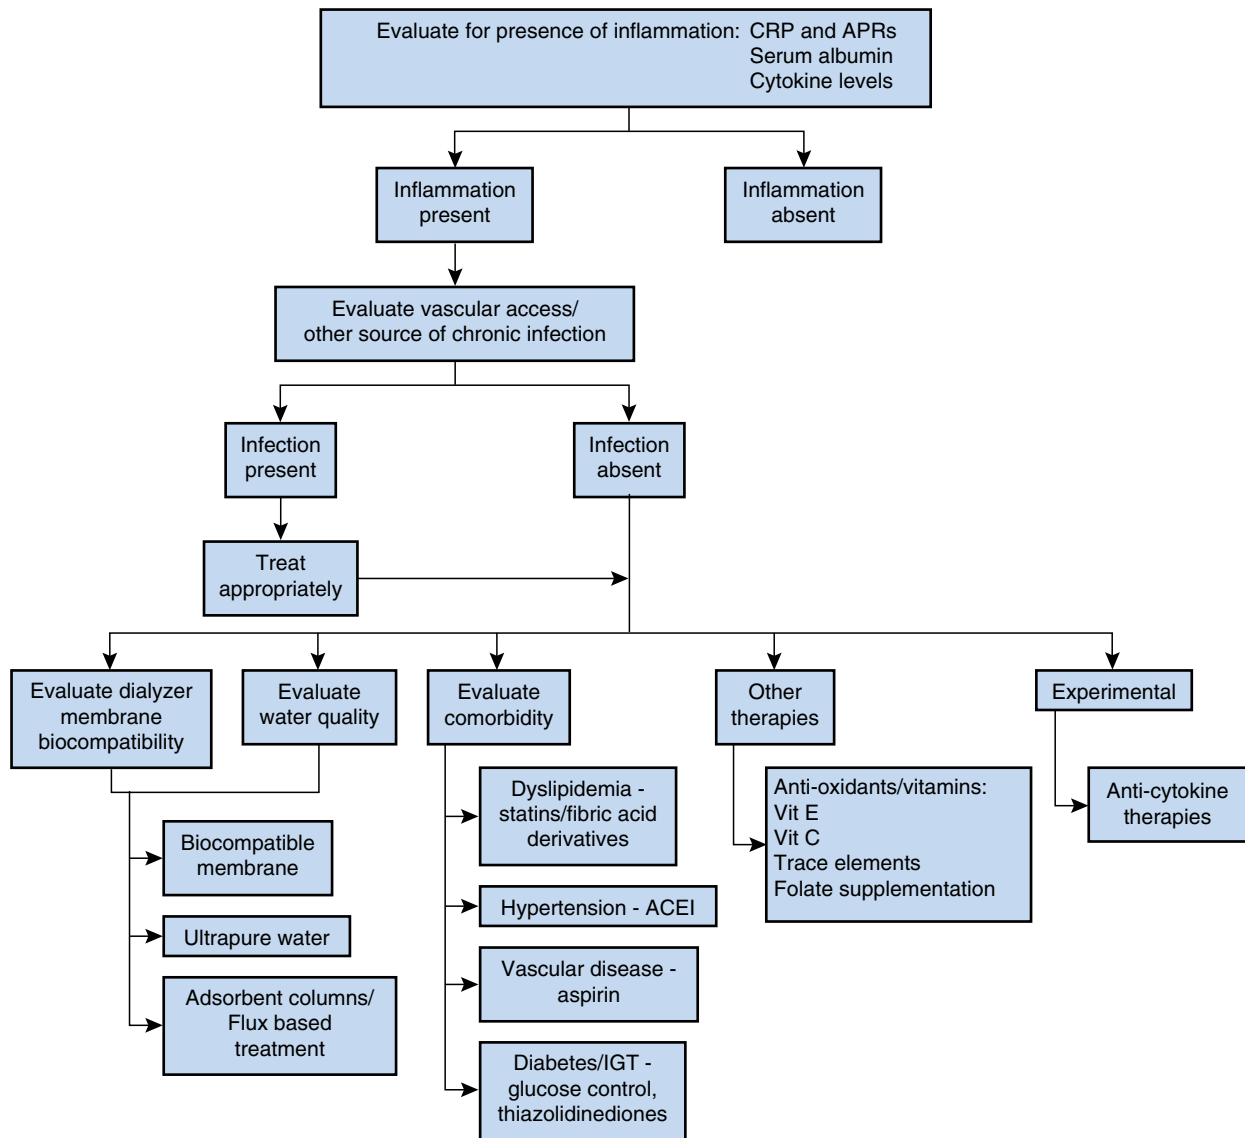
Observations from recent clinical trials have shown that HMG-CoA reductase inhibitors and ACE inhibitors appear to have anti-inflammatory effects beyond their lipid-lowering actions and antihypertensive actions, respectively.[191–193]


Figure 12–1   Management of inflammatory aspects of the uremic state in the patient with chronic kidney disease.

Aspirin is now known to reduce cardiovascular risk in direct relation to baseline levels of CRP.[118] The antioxidant and anti-inflammatory effects of vitamin E have been explored in several studies, such as the SPACE trial with benefit on cardiovascular end points.[194] The other group of drugs that may have beneficial effects on plaque biology, apart from their primary therapeutic indications include the fibric acid derivatives and thiazolidinediones that activate peroxisome proliferation activating receptor isoforms α and χ, respectively.[195] Thus, although there is some evidence that therapeutic avenues targeting chronic low grade inflammation might mitigate the cardiovascular consequences, malnutrition, and increased mortality among patients with kidney disease with evidence of systemic inflammation, prospective studies are required to evaluate these novel strategies and to define optimal therapeutic approaches.

Sleep Disorders in Chronic Kidney Disease and Transplantation

Daniel Norman, M.D. • Robert Thomas, M.D.

OVERVIEW

Sleep and Sleep-Breathing: A Primer for the Nephrologist

The human sleep-wake cycle is primarily generated through interactions of the circadian system and a sleep homeostat. These two separate but interacting oscillatory processes mediate much of sleep or wake propensity at any given point in time. Sleep debt increases during wakefulness and dissipates during sleep. At the same time, the suprachiasmatic nucleus of the hypothalamus generates a wake or arousal signal that increases in strength throughout the biologic day, peaking in the evening hours at approximately 2200 hours, to keep us awake despite an increasing sleep debt in the evening hours. The strength of this signal then declines during the biologic night to reach a minimum at approximately 0600 hours, which coincides with the nadir of body temperature to help keep us asleep as we "pay off" our sleep debt into the early morning. In the absence of this circadian arousal signal, sleep-wake consolidation is lost, and the monophasic sleep-wake cycle is replaced by a polyphasic sleep-wake cycle.

Many protective mechanisms are compromised during sleep. The upper airway, a dynamic structure that serves functions in speech, swallowing, and respiration, is particularly vulnerable during sleep. Most patients with obstructive sleep-disordered breathing (SDB) have an anatomic predisposition (a smaller airway that is longer and laterally compressed) to airway collapse. However, during wakefulness, protective mechanisms maintain an open airway by increasing the activity of tongue and pharyngeal dilator muscles. These protective mechanisms can fail during sleep, with subsequent collapse of the pharyngeal airway behind the palate, tongue, or both. Control mechanisms are also important, because for any given anatomic abnormality, there is a wide spectrum of clinical disease. Disordered breathing events occur only during sleep, even in patients with the most severe obstructive disease. Instability of respiratory control can lead to periodic breathing with variable respiratory effort, and complete or partial obstruction can occur at the nadir of the ventilatory cycle. As a result, instability of respiratory control may contribute, in some individuals, to the development of obstructive disease. Such interactions of anatomy and control may be most important in populations with a high prevalence of mixed disease, including chronic renal failure and congestive heart failure.

Upper airway narrowing during sleep fluctuates continuously within a population and across nights within an individual. Predominantly obstructive and nonobstructive disease (central apneas; periodic breathing, including Cheyne-Stokes, hypoventilation) each has characteristic appearances on sleep studies. A polysomnogram, otherwise known as a sleep study, typically records information on sleep timing, staging, respiratory effort, air flow, muscle tone, oxyhemoglobin saturation, and limb movements. Apneas are complete or nearly complete cessations of airflow, and hypopneas are events of lesser severity. Study interpretation will typically include indices of the frequency of breathing disturbances during sleep, such as a respiratory disturbance index (RDI), an apnea-hypopnea index (AHI), or an oxygen desaturation index (ODI) (often the number of 4% desaturations per hour of sleep). There is still much uncertainty regarding the physiologically appropriate method of scoring abnormal breathing during sleep and phenotyping of the scored abnormality. When associated with desaturations and clinical symptoms, a count of 5 or more events per hour of sleep is considered a reasonable threshold to treat; when scoring regardless of desaturations, counts of close to 20 are at the upper end of normal. However, counts do not clearly reflect severity of individual events, because they do not necessarily reflect the duration, impact on sleep, and degree of autonomic activation at arousal from each event. The criteria used to score these events are especially relevant, because methods used in the older literature may not be comparable with the most recent. It is important to recognize that virtually all studies on sleep-breathing in the renal failure population used the less-sensitive thermal air sensors (thermistors) rather than the more sensitive nasal cannula-pressure transducer technique. This tends to underestimate diagnostic severity and overestimate therapeutic efficacy. In the absence of symptoms, the application of scoring results is even more problematic, but a count greater than 15 respiratory events that have oxygen desaturation per hour of sleep may be a reasonable threshold to recommend treatment in healthy and asymptomatic individuals.

Sleep in Renal Disease

Sleep disorders are very common in the setting of renal disease. Questionnaire-based studies have reported a prevalence of sleep disorders in 43% to 86% of patients with end-stage renal disease (ESRD) (vs. 12% of healthy controls).[1–4] Sleep symptoms become more frequent with the introduction of hemodialysis (HD),[3] are similar in prevalence among patients on hemodialysis or peritoneal dialysis,[1,5] and increase with the duration of dialysis therapy.[4] Sleep-related complaints are also more common with advanced age, male gender,[6] and increased caffeine intake.[1,6] Among HD patients, reports of daytime sleepiness are more common in those on the morning versus afternoon or evening dialysis shifts, and morning-shift patients also report the fewest hours of nightly sleep.[4]

Hemodialysis may result in the production of sleepiness-inducing cytokines,[7] and napping during the dialysis sessions is a very common occurrence.

Common sleep disorders in patients with renal disease include insomnia, circadian rhythm disturbances, obstructive and central sleep apnea, restless legs syndrome (RLS), and periodic limb movement disorder (PLMD). Sleep apnea is estimated to be 10 times more prevalent in patients with ESRD than in the general population.[8] In a study of an unselected series of patients with ESRD, 70% reported symptoms of excessive daytime somnolence and 31% demonstrated evidence of sleep disordered breathing (AHI = 5 events/hr).[9] Parker and colleagues[10] studied stable hemodialysis patients, excluding subjects if interview revealed symptoms of sleep apnea, RLS or PLMD, and then found that of the 46 "asymptomatic" participants, 33% displayed abnormal levels (defined by mean sleep latency < 8 min) of objective sleepiness by multiple sleep latency test (MSLT), 50% had evidence of sleep apnea (defined by a respiratory disturbance index of > 5 events/hr), and 50% had evidence of PLMD (PLM index > 5 events/hr).

Consequences of Abnormal Sleep in Renal Failure

Earlier data had to be extrapolated from work with the non-ESRD population, but there is now a body of research on the effects of sleep disorders directly related to patients with ESRD. A recent study by Bliwise and colleagues[11] reported that median survival among morning-shift HD patients is double that of afternoon-shift patients, and others have demonstrated that individuals undergoing morning HD have the fewest hours of nightly sleep[4] and are sleepier than those dialyzed at other times of the day.[2] PLMD predicts increased mortality risk among hemodialysis patients,[12] and after adjusting for age, sex, and number of years on dialysis, the presence of restless legs syndrome was associated with an astounding 80% greater risk of mortality over 2.5 years of follow-up in one surveyed series of hemodialysis patients.[13]

Cardiovascular Consequences

Obstructive sleep apnea is now accepted as an independent risk factor for the development of hypertension, arrhythmias, congestive heart failure, and stroke.[14] Given its high prevalence in this population, it is likely to play a significant role in cardiovascular morbidity in patients with renal disease.[15] Data from the Sleep Heart Health Study demonstrated clear associations between sleep apnea and the development of hypertension.[16] Episodic hypoxia causes surges in blood pressure, heart rate, and sympathetic activity in patients with sleep apnea and is associated with a loss of the normal "dip" in blood pressure seen in normal individuals during the night.[17] Patients with chronic renal failure show a similar blunting of the normal blood pressure decline at night,[18] and this blunting tends to become more severe in pre-dialysis patients as renal failure worsens.[19,20] A lack of normal blood pressure decline at night is a known predictor of end-organ damage in hypertensive patients,[21] a phenomenon to which SDB likely contributes. When patients who lack normal nocturnal decline in blood pressure are studied by polysomnography, many are found to have unrecognized sleep apnea.[22] Episodic hypoxia causes progressive increases in blood pressure in animal studies, mediated in part through rennin-angiotensin system activation, via increased renal sympathetic nerve activity.[23] A prospective study by Covic and colleagues,[21] using ambulatory blood pressure monitoring, demonstrated that lack of normal nocturnal blood pressure decline is surprisingly common among patients with ESRD (67% were nondippers), and that only the consistent nondippers in this cohort developed left ventricular dilation and hypertrophy by echocardiography over a 12-month period of follow-up. Another study demonstrated that lack of nocturnal decline in blood pressure in hemodialysis patients was associated with nocturnal hypoxemia, and that greater degrees of nocturnal hypoxemia were associated with greater left ventricular wall thickness and greater incidence of concentric hypertrophy.[25] In a study over 32 months of 50 uremic patients on dialysis without pre-existing pulmonary disease, nocturnal hypoxemia was a significant predictor of the incidence of cardiovascular events: each 1% decrease in average nocturnal oxyhemoglobin saturation associated with a 33% increase in risk of fatal and non-fatal cardiovascular events.[26] Thus, there is ample evidence that the nocturnal hypoxemia and sympathetic activation associated with SDB are physiologically detrimental to the ESRD patient.

Renal Consequences

The pathophysiologic changes associated with SDB, especially the intermittent, severe hypertensive surges, can also damage the kidneys. Compared with daytime blood pressure-matched controls who have a more normal decline in nocturnal blood pressure, nondippers have a faster rate of decline in renal function due to hypertensive nephrosclerosis.[27] Nocturnal hypertension also relates to the rate of decline in renal function in patients with IgA nephropathy.[19] Subnormal nocturnal blood pressure decline has also been linked to degree of urine albumin excretion within the normoalbuminuric range in patients with type I diabetes[28] and correlated with urine albumin excretion in microalbuminuric and normoalbuminuric patients with type II diabetes mellitus.[5] Microalbuminuria, in turn, is a strong predictor of total mortality and cardiovascular mortality and morbidity in this patient population.[29] Cross-sectional studies of type I diabetic patients with microalbuminuria have shown that the nocturnal blood pressure often fails to fall normally during sleep. A recent prospective study demonstrated that the increase in systolic blood pressure during sleep preceded the development of microalbuminuria and was thought to perhaps play a causative role in its development.[30] Among patients with obstructive sleep apnea syndrome, proteinuria correlates with both apnea hypopnea score and time spent with oxyhemoglobin saturation less than 90%.[31] Sklar and colleagues[32–34] demonstrated that 64% of obese apnea subjects had proteinuria (> 46 mcg/min), versus 14% of obese non-apnea subjects, and that apnea patients demonstrate reversibility of proteinuria following treatment of sleep apnea. Glomerular hyperfiltration is decreased by positive airway pressure treatment.[34] Other studies, however, suggest a lesser role for sleep apnea in the development of clinically significant proteinuria, but they do show links between arousal index and urine protein/creatinine ratio.[35] Natriuresis and diuresis decrease by approximately 50% in patients with severe sleep apnea with effective nasal continuous positive airway pressure (CPAP) therapy.[36]

Sleep apnea is also cited as a potential contributor to poor compliance with dialysis.[37] A questionnaire study demonstrated that 20% of the hemodialysis patients had prematurely discontinued dialysis at least once in the past. Self-reported premature discontinuation rates correlated significantly with self-reported sleep problems, sleep onset latency, diminished total sleep time, symptoms of restless legs, and transferrin saturation (which is indirectly linked to RLS).[13]

Sleep Disordered Breathing in the Post-Transplant Population

Perfect blood pressure control is an important goal after renal transplantation. Although there are reports of dramatic improvement in sleep disordered breathing in some patients following kidney transplantation,[38] (see later text) residual sleep apnea can compromise this goal and not be obvious by daytime office blood pressure measurements. The prevalence of significant SDB in unselected post-transplant patients is not known, but preliminary evidence suggests that "cure" cannot be taken for granted.[39] Does SDB-related sympathetic activation exacerbate that induced by cyclosporine and tacrolimus? Clearly, more research is needed in this area.

Metabolic and Infectious Consequences

Sleep deprivation in animal studies results in impairment of host defenses and invasion of bacteria into normally sterile body tissues, with bacterial overgrowth in the intestine and invasion in mesenteric lymph nodes apparent by day 5.[40] In humans, sleep deprivation increases C-reactive protein levels, an independent marker of adverse cardiovascular outcome.[41] Treatment of sleep apnea with CPAP results in diminution of the elevated levels of C-reactive protein and interleukin-6 found in patients with sleep apnea.[42] Severe SDB is associated with the "metabolic syndrome," and intermittent hypoxia models of sleep apnea worsen insulin resistance in animal[43] and human[44] studies, and improvements in insulin resistance in patients with sleep apnea have been shown following CPAP therapy.[45] Could the consequences of severely fragmented sleep amplify some of the metabolic abnormalities, especially increased inflammatory markers and cytokine activation, so commonly seen in ESRD? The metabolic consequences of sleep disorders, particularly sleep-disordered breathing is becoming increasingly recognized. These include insulin resistance, endothelial dysfunction, lipid peroxidation, and cytokine dysregulation.[46–49] Specific research on metabolic changes before and after therapy of sleep apnea in patients with ESRD may be forthcoming.

Quality of Life Consequences

Post-dialysis fatigue is reported in greater than half of patients on hemodialysis.[50] CAPD patients with sleep apnea (respiratory event index > 20/hr) score higher on the depression and anxiety scales of the Minnesota Multiphasic Personality Inventory II tests than those without sleep apnea.[38] Multivariate analyses of a cohort of adult hemodialysis patients revealed that sleep disturbances were linked to levels of pain, depression, and physical functioning.[51] The periodic leg movements (PLM) index correlates to Health & Functioning and Family subsets of quality of life indices in HD patients.[52]

The percentage of ESRD patients with a professional activity is significantly higher (63%) for those with ODI less than 15 than those with ODI greater than 15 (21%).[53] A study of 46 HD patients by PSG, MSLT, and questionnaires revealed that 30% have abnormal levels of daytime somnolence, 32% have a mean sleep latency less than 8 minutes, and 13% have a mean sleep latency less than 5 minutes, demonstrating objective measures of severe daytime somnolence.[52] In these studies, MSLT score correlated with quality of life measures, but total recorded sleep time and Epworth Sleepiness Score did not, demonstrating the difficulty in identifying those with the greatest potential degree of impact from sleep disturbances.[52]

Medication use for symptom relief is common. Of those with RLS, 50% report taking a sedative, and frequency of sedative use correlates with severity of RLS.[2] Regular use of hypnotics or minor tranquilizers is reported by 39% of the HD population, with greater frequency of use among females than males.[4] The short- and long-term effects of increased sedative use among this population are largely unknown.

SPECIFIC DISORDERS: ETIOLOGY, DIAGNOSIS, AND MANAGEMENT

Sleep-Disordered Breathing

Prevalence

Polysomnographic studies have revealed sleep apnea prevalence rates of between 50% and 70% among patients with ESRD.[54] This is significantly greater than the prevalence in the general population, which in wide-scale studies ranges from 2% to 8%.[55,56] The prevalence of sleep apnea in ESRD does not seem to relate to the modality of therapy (HD vs. PD) and is often mixed (central and obstructive) in etiology.[54] Pfister and colleagues[53] studied 38 patients with ESRD by overnight ambulatory oximetry, revealing that 47% of ESRD patients (vs. 3% of healthy controls) have an ODI greater than 15. Of those ESRD patients who reported on questionnaire "excessively loud snoring," 88% had an ODI greater than 15, versus 13% of those without. ODI greater than 15 was found in 77% of those who were overweight, and those who had a systolic blood pressure greater than 140. Wadha and colleagues'[57] study of 30 randomly selected ESRD patients (half on HD, half on PD), demonstrated 53% to 60% had sleep apnea (RDI > 5 events/ hr), with the majority of events being obstructive. Similarly, Kimmel and colleagues[58] found that 9 of the 16 ESRD patients with symptomatic sleep apnea studied by overnight polysomnogram had primarily obstructive physiology, whereas in the remaining 7, greater than half of the respiratory events were of the central type. In other series, however, such as Pressman and colleagues'[59] study of eight ESRD patients referred to polysomnography for sleep complaints, central and mixed sleep apnea were more common than obstructive disease.

Mechanisms

There have been a large number of hypotheses proposed to explain the high prevalence of sleep apnea in patients with renal disease. Certainly, part of the explanation stems from the presence of confounders (age, diabetes, tobacco use, and obesity) common to patients with renal disease that are known

risk factors for sleep apnea. Many other contributors to the increased prevalence of sleep apnea in renal disease have been proposed, however, including: (1) anemia, (2) ineffective clearance of endogenous substances/opioids that destabilize breathing, (3) diminished upper airway muscle tone from uremic neuropathy, (4) respiratory control instability due to uremic toxin effects on the central nervous system, (5) airway narrowing secondary to volume overload, (6) osmotic disequilibrium from hemodialysis, and (7) chronic metabolic acidosis/compensatory respiratory alkalosis, with an altered pCO_2 threshold (which may increase propensity for central sleep apnea).[38,58,60,61] Many of these proposed mechanisms, however, need further investigation and may be contradicted by other studies that demonstrate no correlation between some of these factors (i.e., degree of azotemia, bicarbonate concentration, or hematocrit) and severity of sleep apnea.[59] The use of testosterone in some patients to stimulate erythropoiesis has been proposed as another potential link between ESRD and sleep apnea but is not supported, because respiratory event indices are not associated with serum testosterone levels and do not change 2 months after discontinuation of testosterone supplements.[62]

Effects of Treatment in End-Stage Renal Disease

Fein and colleagues[63] described complete reversal of sleep apnea in one patient with uremia after the initiation of dialysis. However, adequacy of dialysis, as evaluated by Kt/V, correlates neither with the presence of sleep complaints on questionnaire nor with the number of respiratory events per hour on polysomnography in patients on HD or CAPD.[64] Kimmel and colleagues[58] found no correlation between carbon dioxide tension or plasma hydrogen ion concentration and number of disordered breathing events in a series of 13 ESRD or chronic renal insufficiency (CRI) patients who had both arterial blood gas analysis and polysomnography. Mendelson and colleagues'[65] polysomnographic study of 11 HD patients both on the day before and on the day of dialysis did not show a decrease in number of respiratory events on the nights following dialysis (132 events to 138 events per night on pre- and post-dialysis nights, respectively) or in level of oxyhemoglobin desaturation, but the study did show a smaller percentage of disordered breathing time comprised of central events on nights following dialysis versus nondialysis nights. When Kimmel and colleagues[58] compared hemodialysis patients with patients within "weeks to months" of initiating dialysis (mean serum creatinine and creatinine clearances of 6.8 mg/dL and 9.8 mL/min, respectively), no significant differences were found in the number of disordered breathing events or level of oxyhemoglobin desaturation between the two groups. Interestingly, two patients with chronic renal insufficiency were restudied by polysomnography after initiation of hemodialysis. One, who had clinically significant sleep apnea (defined as >30 total respiratory events on overnight study), continued to have sleep apnea but fewer events on the repeat study (numbers were not published). The other patient with CRI studied twice did not meet criteria (he had 5 total nocturnal respiratory events only) on the initial study but did meet criteria (>30 events overnight) for clinically significant sleep apnea on repeat study 18 months after the initiation of hemodialysis.[58] Although these results seem to refute a causative role for uremia in the development of sleep apnea, it is possible that the adequacy of dialysis achieved among patients involved in these studies was not sufficient to demonstrate a change in apnea frequency or severity.

Hanly and colleagues[66] studied 14 patients with ESRD by polysomnography during conventional, 4 hours at a time, thrice-weekly hemodialysis, and then again after switch to 8-hour nightly hemodialysis. Mean AHI was 25/hr on conventional hemodialysis, and dropped to 8/hr on nocturnal hemodialysis, and stayed lower at 13/hr 2 days after nocturnal hemodialysis was discontinued. Among the subset of 7 of the 14 patients having clinically significant sleep apnea, defined as AHI greater than 15 events per hour, transition to nocturnal hemodialysis was associated with an even more dramatic drop in AHI (from greater than 40/hr, to 9/hr on nocturnal hemodialysis, and to 19/hr 2 days after its discontinuation).[66] The changes described in transition to nocturnal hemodialysis were accompanied not only by a fall in serum creatinine concentration, but also by elevations in serum bicarbonate concentration and transcutaneous pCO_2.[66] The better treatment of metabolic acidosis and resultant movement of pCO_2 away from the apneic threshold may be partly responsible for the decline in AHI, by limiting central sleep apnea and periodic breathing (both thought to be linked to pCO_2) that, in turn, affect upper airway stability and may predispose to obstructive events.[66] The type of dialysate buffer used in hemodialysis may also have an impact on the type and severity of sleep apnea observed, as Jean and colleagues[67] demonstrated that in 10 HD patients studied polysomnographically after 6 HD sessions with either an acetate or bicarbonate buffer, and then again after six sessions with the other, the total number of respiratory events (from 114 to 64), particularly central apneas (from 33 to 3) and hypopneas (from 114 to 64), declined on the night following bicarbonate buffer HD. This change occurred despite no significant difference in arterial pH, pCO_2, and bicarbonate levels after dialysis with each of the two buffers, and was speculated to represent possible alteration of chemical ventilatory control by acetate buffers.[67]

In a study of 11 patients on peritoneal dialysis with polysomnography on two subsequent nights, one with and without PD fluid in the abdominal cavity, 6 were found to have clinically significant sleep apnea, and, although the total number of respiratory events, the distribution of these events between REM and NREM sleep, and the mean percentage of total disordered breathing time comprised of obstructive events did not change between the two nights, the degree of desaturation and wake after sleep time increased, and total sleep time decreased on nights with dialysate instilled versus empty nights.[68] The apneic patients had a significantly lower waking PaO_2 with dialysate instilled compared to empty nights, suggesting that they may have poor ability to compensate for the fluid load in the abdomen that could, in part, predispose them to sleep disordered breathing or greater oxyhemoglobin desaturation.[68]

Transplantation

Several case reports demonstrate significant improvements—and at times, resolution—of central and obstructive sleep apnea in dialysis patients after renal transplant.[38] Some of these cases have been quite spectacular, with patients with

pre-transplant AHIs greater than 50 per hour manifesting post-transplant AHIs less than 10 per hour, accompanied by resolution of snoring, daytime somnolence, and nocturnal dyspnea.[39] Another striking example is a case report of a patient with severe sleep apnea, with pre-transplant polysomnography demonstrating an ODI of 133 per hour, and mean- and nadir-oxyhemoglobin saturations of 85% and 52%, respectively, who spent almost half of his total sleep time prior to transplantation with oxyhemoglobin saturations less than 80%. By the time of discharge from hospital following cadaveric kidney transplantation, this patient reported complete resolution of sleep-related symptoms, and on follow-up study, showed an ODI of 6 per hour and mean- and nadir-oxyhemoglobin saturations of 94% and 80%, respectively, demonstrating spectacular improvement in what had been primarily (88%) obstructive sleep-disordered breathing shortly after transplantation.[69] An ongoing study of the effects of transplantation on sleep-disordered breathing has been less impressive (Bertrand Jaber, M.D., personal communication), and resolution should not be taken for granted.

Standard Therapy

Nasal positive airway pressure (PAP) remains the optimal treatment for most patients with sleep apnea. Single night titration of nasal CPAP resulted in improvement in subjective sleep quality, number of awakenings and morning alertness, and objective measures, including reduction in stage I sleep, elevation of oxyhemoglobin saturation nadir (from mean of 79.5% pre-CPAP to 90% with titration), and a drop in apnea/hypopnea index (from mean 64/hr pre-treatment, to 6/hr during titration).[59] Given the known association of ESRD and mixed physiology disease, the failure rate and the need for bilevel ventilation could be expected to be high, but systematic large treatment trials have not been published. Weight reduction, avoidance of supine posture during sleep, maximizing nasal patency, avoidance of alcohol or other sedatives, are often-cited adjuncts in the treatment of sleep apnea but do not substitute for PAP therapy. Dental devices and surgical options also exist but have variable success rates and are less often used. A diet with high concentrations of branched-chain amino acids may improve central sleep apnea in chronic renal failure patients but appears to worsen obstructive disease and warrants further study.[70]

Restless Legs Syndrome and Periodic Limb Movement Disorder

Prevalence

Walker and colleagues'[2] questionnaire-based study of unselected patients in a hemodialysis unit indicates a prevalence of RLS in the HD population of 57%. Among these patients, 48% report severe symptoms, an equal proportion believe that RLS causes delays in their sleep onset, and a full 74% report excessive daytime somnolence.[2] Though RLS severity does not seem to correlate with serum creatinine levels, HD patients with RLS tend to have higher pre-dialysis urea and creatinine concentrations.[2] Restless legs symptoms have been associated with nocturnal awakening, sleep-onset latency, diminished total sleep time, pruritus, and the use of medications as sleep aids.[13] Periodic limb movements of sleep is a disorder that is characterized by rhythmic movements (usually the lower) of extremities during sleep that is often seen in patients with restless legs syndrome but may exist independently as well. PLM by sleep study in CAPD population is more common in those with higher intact PTH levels,[38] suggesting a possible contributor may be altered calcium homeostasis. Although it was previously thought to be a prevalent cause of sleep disruption, many in the sleep field now question the significance of PLMD role in sleep disturbance, because limb movements may be just a marker for arousals related to respiratory effort.[71] The presence of "significant" PLM (>25/hr) on PSG in CAPD patients is not predicted by sleep complaints, and is in fact less common in those who report leg twitching at night than those who do not.[38] Pressman and colleagues'[59] study of ESRD patients with symptomatic sleep apnea demonstrated a trend toward decline in PLMS with arousal during single night of CPAP titration study. The presence of PLMs by sleep study is related to mortality, with patients with ESRD who have a PLM index greater than 80 per hour and a median survival of 6 months.[12] In one study, PLM index actually appeared to be a better predictor of mortality in this population than more traditional indicators, including serum albumin concentration, hematocrit level, and urea reduction ratio.[53]

Mechanisms

Despite similar polysomnographic measures of sleep macro-architecture (total sleep time, sleep efficiency, sleep latency, time spent awake, time spent in various sleep stages), uremic patients with RLS have significantly higher PLM indices during sleep and wakefulness and poorer subjective sleep quality compared to nonuremic patients with RLS symptoms of similar severity, indicating that uremia itself may (perhaps through increased excitability) contribute to greater impact of RLS on sleep.[72] Iron deficiency and abnormal iron transport mechanisms to the central nervous system are thought to be involved in the etiology of many cases of RLS and PLMD and are likely to play some role in the high prevalence of these disorders in patients with ESRD.[73] Magnetic resonance imaging utilizing special sequences can quantify iron in the basal ganglia but remains a research tool. Serum ferritin levels less than 50 mcg per liter are often used as an indirect marker and may indicate a prospect for improvement with iron replacement therapy.[73] Other potential contributors in patients with ESRD include uremic peripheral neuropathy[73] and spinal cord pathology, because spinal cord flexor withdrawal reflex excitability during sleep is increased in idiopathic RLS associated with renal failure.[74]

Effects of Treatment in End-Stage Renal Disease

Roger and colleagues[75] demonstrated that of the 55 ESRD patients studied, 40% had RLS and that treatment with erythropoietin in the affected group did result in a substantial improvement in symptoms. In addition, there have been some case reports of resolution of restless leg syndrome in a number of patients with ESRD after kidney transplantation,[76,77] but in a substantial proportion of these patients, RLS may gradually reappear.[77]

Standard Therapy

Guidelines for therapy of RLS in patients with renal disease are now available. Intravenous iron was an original treatment for RLS, and appropriate repletion of iron stores is still very important in this patient group.[73] In the hemodialysis population, correction of anemia through iron supplementation (including intravenous) and recombinant human EPO results in significant reduction of PLMS, arousing PLMS, and improves daytime alertness.[78] Levodopa/carbidopa is effective for the treatment of RLS in this population,[79] but although it lowers PLMS indices, there is conflicting data on whether it causes subjective improvement in sleep quality.[80,81] There is now a clear preference for the newer dopamine agonists, such as pramipexole, pergolide, cabergoline, and ropinirole over levodopa/carbidopa as first-line therapy, because levodopa/carbidopa is associated with greater risk for augmentation of symptoms over time. (Augmentation refers to development of increased symptoms that start earlier in circadian time that temporarily respond to an increased dose.) The newer dopamine agonists, though generally well tolerated, are still not ideal. Pergolide therapy results in subjective improvement in restless legs symptoms, quality of sleep, and lowers PLMS indices, but it does not necessarily result in less interrupted sleep by polysomnography.[82,83] Pramipexole has few side effects, reduces severity of restless legs symptoms, and significantly lessens PLM while awake and PLM of sleep,[84] but does not significantly change sleep latency, sleep efficiency, or total hours of sleep time by pretreatment and posttreatment polysomnography.[84] Opioids are effective but are usually reserved for patients who fail dopamine agonist therapy.[85,86] Clonazepam, despite its widespread use in RLS, has extremely limited data supporting its efficacy[87,88]; thus it and other benzodiazepines are also considered second-line therapies.[89] Gabapentin may be an effective option for restless legs syndrome in hemodialysis patients who do not respond to other therapies, but needs further study.[73,90] Table 13–1 lists medications used for the treatment of RLS/PLMS, along with information on dosing and common side effects. Clinical trials are ongoing with several newer antiepileptics, such as levetiracetam (Keppra), so further choices may be available.

Insomnia and Circadian Rhythm Abnormalities

Insomnia is a rather nonspecific complaint from the pathophysiologic standpoint (difficulty initiating and maintaining sleep, poor subjective sleep quality, nocturnal awakenings), but 45% of hemodialysis patients reported it, and rates increase with age, morning hemodialysis, greater than 12 months duration of dialysis, and serum PTH levels.[91] Polysomnographic studies of stable HD patients not on sedatives, who report no symptoms of RLS or sleep apnea, reveal diminished total sleep times and sleep efficiency compared to age-matched norms.[9] Patients often sleep during hemodialysis. Mean daytime melatonin levels are increased for patients with CRF (whether on conservative therapy, HD, PD, or post-transplant) versus healthy controls,[92] and the normal nocturnal rise in melatonin concentration seen in healthy controls was reportedly absent in all HD patients and 80% of post-transplant patients.[92] Deficiency in nocturnal pineal synthetic enzyme activity and diminished renal clearance or degrada-

tion of melatonin are described as potential etiologies for the lack of nocturnal surge and elevated daytime levels of melatonin, respectively, in patients with renal disease.[92] Vaziri and colleagues[93] demonstrated an attenuation of the normal decline in serum melatonin and little change in its principle metabolite, 6-sulfatoxymelatonin in the morning hours in patients with ESRD, with no significant clearance of either compound with HD. In animal models of CRF using 5/6 nephrectomy, Vaziri and colleagues[94] demonstrated an attenuated nocturnal surge in serum melatonin that was partially restored by the administration of erythropoietin to correct anemia. However, in patients with ESRD, insomnia, delayed sleep onset, and night-time arousals are not directly linked to serum melatonin concentrations, possibly due to the supraphysiologic range that often exists in this population.[95] While altered melatonin physiology may be one contributor to the high prevalence of insomnia in patients with ESRD, multiple other factors are likely to exist, including side effects of various medications, reduced nocturnal sleep drive secondary to daytime naps (i.e., during HD sessions), restless legs symptoms, and prolonged sleep latency from sleep-onset respiratory instability.

MANAGEMENT ISSUES AND CHALLENGES FOR THE FUTURE

Screening for Sleep Disorders

Despite a surprisingly high prevalence, our ability to identify those at highest risk for sleep disorders among patients with ESRD remains limited. Of ESRD patients with "excessively loud snoring," 88% have ODI greater than 15, but so do 38% without, and more than half of ESRD patients with an ODI greater than 15 deny excessively loud snoring by questionnaire.[53] Thus, snoring is not a particularly useful screening tool. Parker and colleagues[9, 96] confirmed work done by others to demonstrate that the Epworth Sleepiness Scale (ESS), an often used questionnaire-based method for assessing sleepiness, correlates poorly with the MSLT score (an objective measure of sleepiness used in the laboratory). Patients with ESRD have significantly higher levels of sleepiness by validated questionnaires (Epworth Sleepiness Scale and Visual Analog Scale), but these scores do not correlate with ODI.[53] Questionnaire screening for restless legs syndrome in patients on chronic dialysis is also problematic, with both low sensitivity and specificity.[97] Others have demonstrated that questionnaire-based screening of patients with ESRD for symptoms of sleep apnea is equally inaccurate.[9] One possible practical approach is to assume that all patients have abnormal sleep until proven otherwise and to use screening tools to stratify disease severity. The latter could include limited polysomnography, including nasal pressure-based airflow detection and oximetry (unfortunately not covered by Medicare in the United States, but this limitation does not exist elsewhere), and a restless legs severity questionnaire.

Management Challenges and Sleep Disordered Breathing

Management of sleep and SDB in ESRD poses unique challenges. It seems that everything that could go wrong with the

Table 13–1 Medications for Restless Legs Syndrome and Periodic Limb Movements of Sleep

Agent/Class	Usual Dose (mg)	Dose Adjustment in Renal Failure	Notes/Precautions	Common Side Effects
Dopamine Agonists				
Bromocriptine	1.25 –15 mg qhs	Unknown–liver metabolism predominates	Rarely used for this indication. Rare reports of seizures, serositis/fibrosis, and cardiac arrhythmias	Same as for pergolide
Cabergoline	0.25–2 mg qhs	Unknown	Same as for pergolide	Same as for pergolide
Carbidopa/ levodopa	25/100 mg qhs– 100/400 mg tid	Unknown–no major dose adjustment needed	Higher chance of augmentation phenomena (see text) than other dopamine agonists. Absorption reduced if ingested with iron salts, increased clearance if taken with pyridoxine (B_6)	Dyskinesia, nausea, orthostatic hypotension, hallucination, insomnia
Pergolide	0.05 mg qhs–1 tid	Unknown	Rare reports of serositis/ fibrosis. Rare cardiac arrhythmias	Same as for levodopa, plus somnolence, peripheral edema, nasal congestion
Pramipexole	0.125 mg qhs– 1.5 tid	Renal clearance– very long $t_{1/2}$ in ESRD, start at half tablet of 0.125 mg qhs, increase slowly to minimum necessary dose	Same as for pergolide. Daytime somnolence, "sleep attacks"	Same as for pergolide
Ropinirole	0.25 mg qhs–1 tid	Unknown–liver metabolism predominates	Same as for pergolide	Same as for pergolide
Sedative/Hypnotics				
Clonazepam	0.25–4 mg qhs	Not needed–liver metabolism predominates	Probably best avoided—there are superior medications available	Confusion, somnolence, tolerance
Oxazepam	10–40 mg qhs	Unknown–may need longer time to reach steady state levels in ESRD		Same as for clonazepam
Temazepam	7.5–30 mg qhs	Unknown but has 80%–90% renal clearance		Same as for clonazepam
Triazolam	0.125–0.5 mg qhs	Not needed	Duration of action too short	Same as for clonazepam
Zaleplon	5–20 mg qhs	Unknown–liver metabolism predominates		Same as for clonazepam
Zolpidem	5–20 mg qhs	No dosage adjustment necessary Additional dosing not necessary after HD		Same as for clonazepam

Continued

Table 13–1 Medications for Restless Legs Syndrome and Periodic Limb Movements of Sleep—Cont'd

Usual Agent/Class	Dose Adjustment Dose (mg)	in Renal Failure	Notes/Precautions	Common Side Effects
Opiates				
Codeine	30–180 mg qhs	Decrease dose by 50% for ESRD		Sedation, pruritis, confusion, constipation, nausea
Hydrocodone	5–30 mg qhs	Unknown–6%–20% excreted unchanged in urine		Same as for codeine
Methadone	2.5–30 mg qhs	Recommend low doses due to likely prolonged $t_{1/2}$		Same as for codeine
Morphine	5–30 mg qhs IR, 30 mg qhs– 30 mg tid CR	Decrease dose by 50% for ESRD	Controlled–release forms provide longer duration of action	Same as for codeine
Oxycodone	5–10 mg IR, 10 mg qhs–20 mg bid CR	Suggest decreasing dose by 50% in ESRD	Controlled–release forms provide longer duration of action	Same as for codeine
Propoxyphene	150–250 mg qhs	See note to right	AVOID use in patients with renal insufficiency–active metabolite, norpropoxyphene accumulates	Same as for codeine
Tramadol	50–100 mg qhs	Renal excretion occurs, so recommend lowest possible doses. Only 7% removed by HD, so additional dosing not necessary	Potential for augmentation phenomenon	Same as for codeine
Other				
Clonidine	0.1–1 mg qhs	None		Dry mouth, dizziness, constipation, sedation
Ferrous sulfate	325 mg qd– 324 mg tid	None	Indicated for patients with serum ferritin levels < 50 mcg/L Consider IV iron if refractory	Constipation, dark stools, nausea
Gabapentin	300–900 mg tid	Renal clearance, dialyzable. 100 qhs –300 tid, with additional 100–200 dose post-HD		Sedation, fatigue, dizziness, somnolence, ataxia

Adapted from Earley CJ: Restless legs syndrome. NEJM 2003; 348:2103-2109. Dosing guidelines should not substitute for clinical judgment. In all cases, lowest initial dose with very gradual titration is recommended because of increased risk for adverse effects from accumulation of active compounds.

sleep system does so in these patients. The effects of weight change and body fluid distribution in the interdialytic interval are not known, but some change in positive airway pressure requirements may occur. Auto-adjusting PAP machines would, in theory, be optimal, but currently available machines do poorly in patients with mixed obstructive and central disease and thus would not be appropriate for many patients with CRF. Bilevel PAP can both stabilize and destabilize breathing in such patients, but some will clearly benefit. Stabilization of respiratory control may be required as an adjunct to support the upper airway; options include additional oxygen (even in the absence of severe desaturations) and cautious use of benzodiazepine hypnotics. Carbon dioxide is a strong stabilizer of periodic breathing, but use of a dead-space mask (with or without PAP) and addition of CO_2 into the PAP circuit remain investigational. Fragmented

sleep-wake cycles, an inevitable consequence of napping and excessive time in bed, result in more time spent at the sleep-wake interface, where sleep and breathing are often unstable. This can make falling asleep with PAP quite difficult, and a tight and consistent sleep schedule is critical. Those with predominantly periodic breathing and mild obstruction may gain clinical benefit by sleeping with supplemental nasal oxygen. Nocturnal hemodialysis may improve some of the respiratory abnormality, perhaps by correcting hypocapnia and the resultant periodic breathing and respiratory instability. However, in the reports of patients using this dialysis regimen, sleep quality (arousal index) remained elevated, and the measure of respiration was not nasal pressure, which might have exaggerated the apparent benefit.[66] Nocturnal HD only marginally improves excessive daytime sleepiness.[98] The reality is that the only real option for significant SDB in this population is PAP.

Management Challenges: General

Table 13–2 outlines some of the major challenges faced in the treatment of sleep disorders in patients with renal disease. Periodic limb movements are so common in CRF patients that if persistent even after treating bothersome restless legs, the focus should be on first optimizing SDB management rather than trying to treat "PLM disorder." Iron deficiency and anemia should be managed appropriately. One study of recombinant human erythropoietin therapy in 10 CRF patients to correct anemia found reductions in PLMS, arousals from sleep, and sleep fragmentation, while allowing for more subjectively restorative sleep and improved daytime alertness.[78] A cautious trial of dopaminergics or low-dose opiates may be considered, at the risk of adding to the complexity of the medical management with questionable benefit. Daytime sleepiness/fatigue has numerous causes in ESRD, and after optimizing sleep and dialysis, a cautious trial of a stimulant such as methylphenidate or the wake-promoting drug modafinil could improve quality of life. The latter is now FDA approved as an adjunct to treat persisting daytime symptoms after best current PAP therapy, and most CRF patients with SDB may well qualify. There is, however, no data on efficacy or safety in this population. Napping is common during dialysis and in renal failure patients in general. Excessive napping is disruptive to nocturnal sleep, but a consistently timed mid-afternoon nap of 20 to 40 minutes could allow improved alertness in the late afternoon and evening. Nontraditional methods such as accupoints massage should be rigorously evaluated before acceptance in this population.[99] The implications of high melatonin levels, if any, are unknown.[93, 95]

Management Challenges: The Future

There are numerous unanswered questions in the management of SDB and sleep in CRF. Can more intensive dialysis normalize sleep? From the experience with congestive heart failure, optimizing therapy can improve but does not eliminate the problem. Can appropriate SDB management improve the high mortality in dialysis patients, or can glucose tolerance and blood pressure control be improved? There are little data, and more studies are forthcoming. Does the nocturnal hemodynamic stress inevitably associated with SDB contribute to early renal injury and the development of microalbuminuria? SDB is common and probably pathogenic in preeclampsia (increased risk during pregnancy in those with renal failure), contributing to nocturnal hypertension—could early treatment of disordered breathing reduce this risk or its fetal consequences? The management of SDB in CHF is gaining popularity at least in concept, but the reality is far away outside the research setting. As more patients are referred to sleep centers by cardiologists, we may be able to draw on such experiences for the management of SDB in patients with ESRD. Given the large number of patients and high prevalence of sleep disorders within both of these groups, target-population specific clinics managed by nurse practitioners or clinical nurses and supervised by sleep-medicine trained physicians may be necessary to significantly impact the CRF or CHF populations. Such clinics could be within a heart failure or dialysis program. Laboratory support will also be critical and may require administrative and technical creativity beyond what exists today. Could dialysis centers double as sleep laboratories (at least for diagnostic testing) at night?

There have been a multitude of publications,[100,101] at times redundant, describing the problems of sleep, sleep-disordered breathing, and sleepiness in the end-stage renal failure population. Enough said. Management and outcome trials are long overdue.

Table 13–2 Sleep Medicine: Clinical Challenges in the End-Stage Renal Disease Patient

Insomnia	Always multifactoria—a comprehensive treatment approach is required. Use of sedative-hypnotics without workup is inappropriate.
Excessive daytime sleepiness	Fatigue is so common in patients with ESRD that clinical sleepiness/fatigue scales may have less clinical predictive value. Short of some type of objective sleep-breathing assessment, the contribution of disordered breathing during sleep cannot be estimated.
Restless legs	High probability of abnormal iron status and likely contribution from "uremic toxins." Medications may need adjustment in relation to dialysis. Many antidepressants, especially the serotonin re-uptake inhibitors, may induce or worsen RLS.
Sleep-wake cycle fragmentation	Napping during dialysis will contribute to fragmented nocturnal sleep.
Sleep-disordered breathing	High probability of complexity—obstructive disease and periodic breathing. SDB may contribute to depressed mood. Positive airway pressure may only partially control the disease. Fluctuating weight associated with intermittent dialysis could result in varying positive pressure requirements. Automatic pressure adjusting devices do not work well if there is coexisting periodic breathing.

The Pediatric Patient with Chronic Kidney Disease

Bradley A. Warady, M.D. • Vimal Chadha, M.D.

Although uncommon in children, chronic kidney disease (CKD) can be a devastating disorder with the potential for serious long-term ramifications (Table 14–1). Reference to CKD includes the spectrum of disease ranging from mild kidney damage with normal solute clearance to end-stage renal disease (ESRD). Despite some basic similarities with the abnormalities seen in adults, CKD in childhood is, in fact, characterized by many unique features not experienced by the adult population. For instance, growth and cognitive development are two of the major characteristics of childhood. Unlike adults who have completed their physiological and intellectual maturation, infants and young children are in the formative phase of their neurodevelopment and physical growth, both of which may be adversely affected by CKD during this particularly vulnerable period. This is especially pertinent because a substantial percentage of the pediatric CKD population develop renal insufficiency very early in life as a result of congenital or inherited disorders (*vide infra*). Additional CKD related clinical manifestations, such as renal osteodystrophy, poor nutrition, anemia, and cardiovascular disease, are also characterized by features unique to the pediatric population. Most significant is that suboptimal management of these and other related issues may be associated with an increased risk for subsequent morbidity and possibly even mortality. This chapter is, in turn, designed to highlight issues associated with the provision of optimal clinical care to children with advanced CKD (or chronic renal insufficiency [CRI]), as defined by a creatinine clearance less than 75 mL/min/1.73m^2), irrespective of the primary renal disorder. It is equally important to mention that this chapter will, on the other hand, not address disease-specific (e.g., renal tubular disease, renal stone disease, nephrotic syndrome) treatment related issues.

DIAGNOSIS AND EVALUATION OF CHRONIC KIDNEY DISEASE

To improve the detection and management of CKD, guidelines have recently been developed by the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (K/DOQI).[1] The diagnosis of CKD is established based on the presence of kidney damage and level of kidney function (glomerular filtration rate [GFR]), irrespective of the specific type of the underlying kidney disease (diagnosis) (Table 14–2). Kidney damage is defined as structural or functional abnormalities of the kidney, initially without a decreased GFR, which may lead to a decreased GFR over time. Among patients with CKD, the stage of the disease is defined by the level of the GFR, with higher stages (e.g., Stage 5) representing lower levels of GFR

(Table 14–3). In the pediatric literature and as noted previously, CRI is defined by a creatinine clearance less than 75 mL/min/1.73m^2, a value that falls within Stage 2 CKD. The rationale for including individuals with a normal GFR within the CKD population is that substantial kidney damage often occurs before the GFR declines and these individuals are at increased risk for adverse outcomes associated with CKD. As the frequency of complications of CKD begin to increase when the GFR falls below 60 mL/min/1.73m^2, individuals with a GFR below this level are characterized as having CKD, even without any other evidence of kidney damage.

Although the level of GFR has been recommended as the primary criterion for defining and staging CKD, an important caveat should be recognized when using these definitions in young children. In children, the normal level of GFR varies according to age, gender, and body size. Whereas the normal GFR in young adults is approximately 120 to 130 mL/min/1.73m^2, the normal value is much lower than this in early infancy, even when corrected for body surface area. It subsequently increases along with the increase in body size for up to 2 years.[2] Hence, the GFR ranges that are used to define the five CKD stages by K/DOQI in Table 14–3 apply only to children 2 years of age and older. The normal range of GFRs at different ages is given in Table 14–4.[2–4]

As per the K/DOQI guidelines, estimates of GFR are the best means of assessing the level of kidney function in children and adolescents in the clinical setting, and the GFR should be estimated from prediction equations that take into account the serum creatinine concentration, the patient's height, and the patient's gender. The Schwartz formulas are, in turn, widely used in pediatric practice.[5–7] The GFR is calculated as follows:

$$C_{Cr} \text{ (mL/min/1.73m}^2) = 0.55 \times \text{Height (cm)}/S_{Cr} \text{ (mg/dL)}$$

(The constant is 0.45 for infants <1 year of age and 0.7 for adolescent boys)

The validity of these formulas as a means of estimating GFR is compromised in the child with markedly diminished renal function because of the inherent increase in creatinine secretion that occurs in this situation. Alternative methods of assessment, such as the cimetidine clearance[8] or the clearance of cystatin C,[9] may provide the most accurate means of estimating renal function in this select population.

DEMOGRAPHICS

Whereas the exact incidence of CKD in children is not known, the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) has recently characterized this

Table 14–1   Potential Clinical Consequences of Chronic Kidney Disease in Children

Table 14–2   Definition of Chronic Kidney Disease

1. Kidney damage for ≥ 3 months, as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, manifest by either:
   - Abnormalities in the composition of blood or urine
   - Abnormalities in imaging studies
   - Abnormalities on kidney biopsy
2. GFR < 60 mL/min/1.73m^2 for ≥ 3 months, with or without kidney damage

Table 14–3   K/DOQI Stages of Chronic Kidney Disease

Stage	Description	GFR (mL/min/1.73m^2)
1	Kidney damage with normal or increased GFR	>90
2	Kidney damage with mild decrease in GFR	60–89
3	Moderate decrease in GFR	30–59
4	Severe decrease in GFR	15–29
5	Kidney failure	<15 or dialysis

Table 14–4   Normal GFR in Children and Adolescents

Age (Sex)	Mean GFR ± SD (mL/min/1.73m^2)
1 wk (males and females)	41 ± 15
2–8 wk (males and females)	66 ± 25
>8 wk (males and females)	96 ± 22
2–12 yr (males and females)	133 ± 27
13–21 yr (males)	140 ± 30
13–21 yr (females)	126 ± 22

population.[10] The 2003 annual report has information on 5384 patients with CRI, defined and as mentioned previously as a calculated creatinine clearance of 75 mL/min/1.73m^2 or lower. Sixty-five percent of patients in the CRI registry are males, 62% are white, and 19% are African-Americans. Twenty percent of the CRI patients are less than 24 months of age and 17% are toddlers (2–5 years). Almost one half of the cases are accounted for by patients with the diagnoses of obstructive uropathy (23%), aplasia/hypoplasia/dysplasia (18%), and reflux nephropathy (8%). Apart from focal segmental glomerulosclerosis (FSGS) that accounts for 8% of cases, none of the other primary diseases account for more than 5% of the total population. The prevalence of FSGS among blacks is twice that of the other races combined (16% vs. 6%). Likewise, the registry of the United States Renal Data System (USRDS) has recently revealed that the rate of glomerulonephritis as a primary cause of pediatric renal insufficiency in blacks and other non-white patients has more than doubled over the past 20 years, as have the rates of cystic, hereditary, and congenital diseases.[11]

GROWTH FAILURE

Growth failure is one of the most onerous and visible clinical manifestations of CKD in children, and patients often fail to achieve a final adult height consistent with either population norms or their own genetic potential. According to the NAPRTCS registry, more than one-third of children with CKD are less than the 3rd percentile (standard deviation score [SDS] of −1.88) for height upon entrance to the registry.[10] Overall, patients with CKD are nearly 1.5 SDS below age and sex specific norms for height, while the youngest patients (0–1 year) are the most severely growth retarded portion of the population, with a mean height SDS of −2.35 at baseline.[10]

Likewise, the European Study for Nutritional Treatment of Chronic Renal Failure in Childhood found that one third of the height deficit experienced by children at 3 years of age in association with early onset CKD occurs during fetal life and an additional one third during the first postnatal months.[12] This is an important issue since one third of postnatal statural growth overall is attained during the first 2 years of life, and any insult to growth that occurs during this time may have a profound impact on final adult height. The height deficit may be alleviated to a small extent by "catch up growth" in those patients who entered the NAPRTCS registry at 0–1 year of age and who at 2-year follow-up had a mean delta height SDS of 0.67.[10] Pubertal growth is also often adversely affected in the setting of CKD. The onset of puberty is delayed by an average of 2.5 years, the duration of the pubertal growth spurt is 1.6 years shorter in duration than normal, and the pubertal growth spurt is approximately only 50% of that experienced by normal children.[13]

In addition to its negative influence on the achievement of a normal final adult height and the potential association between poor growth and social issues, such as job availability and the ability to find a spouse, poor incremental growth in association with CKD has been associated with an increased risk of morbidity and mortality in children.[14] Furth and associates,[15] utilizing data from the NAPRTCS, demonstrated that children with significant growth failure, as reflected by a height SDS more negative than −2.5 at the time of dialysis initiation (and thus reflective of care provided during the period of CKD), had a significantly increased risk of hospitalization and twofold higher risk of death compared to patients with normal growth (height SDS > −2.5). In a similar manner, analysis of data from the U.S. Renal Data System (USRDS) on 1112 subjects less than 17 years of age revealed that growth failure is associated with a more complicated clinical course and an increased risk of death for children on dialysis.[16]

The more severely growth retarded patients also had more hospital days per month of dialysis and were less likely to attend school full-time.[16] Although these studies do not suggest that poor growth is the immediate cause of poor patient outcomes, growth retardation may possibly serve as a surrogate for suboptimal clinical care in children with CKD. Therefore, delineation of the optimal management of growth retardation in children with CKD may be crucial to the establishment of clinical treatment standards, which may, in turn, reduce the burden of hospitalization and mortality in these patients.

Although multiple factors such as protein energy malnutrition, acidosis, extensive salt and water losses, and secondary hyperparathyroidism may contribute to growth failure, perturbations of the growth hormone/insulin-like growth factor (GH/IGF) axis is the predominant factor contributing to the impaired growth associated with CKD, particularly in those patients outside the period of infancy.[17–22] Normally, growth hormone (GH) release from the pituitary gland is stimulated by growth hormone releasing hormone (GHRH) from the hypothalamus. The GH is bound by GH receptors within the liver with the subsequent production of IGF-1. The majority of IGF-1 is bound to acid labile subunit and insulin growth factor binding protein 3 (IGFBP–3) in a ternary complex, and a portion of the remaining free (bioactive) IGF-1 stimulates cartilogenous growth in bone.[23] In patients with CKD, there is an increased pulsatile release of GH from the pituitary gland due to a less active negative feedback loop to the hypothalamus. In addition, the metabolic clearance rate of GH is reduced, resulting in a rise in the circulating GH concentration.[24,25] However, despite the presence of the elevated GH concentration, GH receptor downregulation within the liver and defects in postreceptor signal transduction result in decreased IGF-1 synthesis by the liver.[26–28] Furthermore, the bioavailability of IGF-1 is reduced as a result of elevated IGF binding proteins (IGFBP). Increased circulating levels of IGFBP-1 and IGFBP-2 are inversely correlated with residual GFR and height[29] and probably contribute directly to the resistance to the anabolic and growth promoting effects of GH and IGF-1.[30] Thus, renal failure is not a state of GH or IGF-1 deficiency but instead a state in which the regulation and bioavailability of components of the GH/IGF/IGFBP system are altered.

Recognition that recombinant human GH (rhGH) treatment improves the height velocity of children with CKD has dramatically changed the therapeutic approach available to correct and/or prevent the growth retardation associated with renal insufficiency.[13,22,31–33] Recombinant GH is approved for the treatment of growth failure in children with CKD at a daily dosage of 0.05 mg/kg given by subcutaneous injection. Children who are Tanner stage I, II, or III and with a height SDS of −1.88 or worse and/or a height velocity SDS more negative than −2.0 are candidates for rhGH treatment.[33] A simple approach to the use of rhGH is provided in Figure 14–1.[34] Preparation is no longer produced. Proper management of malnutrition, correction of acidosis, and control of renal osteodystrophy is essential to maximize growth potential and should always precede treatment with rhGH. It is noteworthy that treatment with rhGH is most effective when prescribed to those with CKD, prior to the need for dialysis,[35] and the treatment response is positively correlated with the initial degree of growth retardation.[13] Whether individualization of the dose can best be guided by IGF-1 levels will soon be studied.

Historically, there has been a concern that the acceleration of growth that results from rhGH treatment during the prepubertal years might be offset by an earlier onset and/or shorter duration of pubertal growth.[36] However, long-term follow-up results of the German Study Group for Growth Hormone Treatment in Chronic Renal Failure has revealed that the onset of the pubertal growth spurt was actually delayed in boys treated with rhGH (although not in girls), and the duration of the growth spurt was no different from controls.[13] Although the prepubertal bone maturation was slightly accelerated in children treated with rhGH, the rhGH induced prepubertal growth stimulation was sufficient to override this effect.[13] Most significant was the finding that those patients who received rhGH grew significantly better than those patients who did not receive rhGH, and only the former group of patients had a normal mean final adult height. Remarkably, despite these results, less than 30% of prepubertal children with CRI in the NAPRTCS registry, who also have a height SDS more negative than −1.88, have received rhGH, a finding that suggests the need for additional education of patients and health care providers.

As mentioned earlier, prior to initiating rhGH therapy, patients should be evaluated for preexisting or worsening osteodystrophy radiographically, along with an assessment of an intact PTH level. Additionally, baseline hip X-rays should be obtained due to the theoretic, increased risk of slipped capital femoral epiphysis and avascular necrosis of the femoral head associated with rhGH therapy. Any limp and/or hip or knee pain should be carefully evaluated. An ophthalmologic evaluation should also take place because of the reported but rare treatment related complication of pseudotumor cerebri. Recent database evaluations have revealed rhGH usage to be safe, as reflected by an adverse event profile no different than that noted in a population of children with CKD and no history of rhGH usage.[37] Finally, the height velocity of patients receiving rhGH should be closely monitored, with the weight related dose modified every 3 to 4 months to maintain the standard dosing regimen. Typically, rhGH is discontinued when the child has closed epiphysis, has achieved a target height percentile, or when adverse events such as severe hyperparathyroidism, pseudotumor cerebri, active neoplasia, or slipped capital femoral epiphysis occurs. If discontinued for reasons other than closed epiphysis, reinstitution of rhGH should be considered, if the height velocity significantly decreases and the reason for discontinuing the drug has resolved.

NEUROLOGIC AND EDUCATIONAL DEVELOPMENT

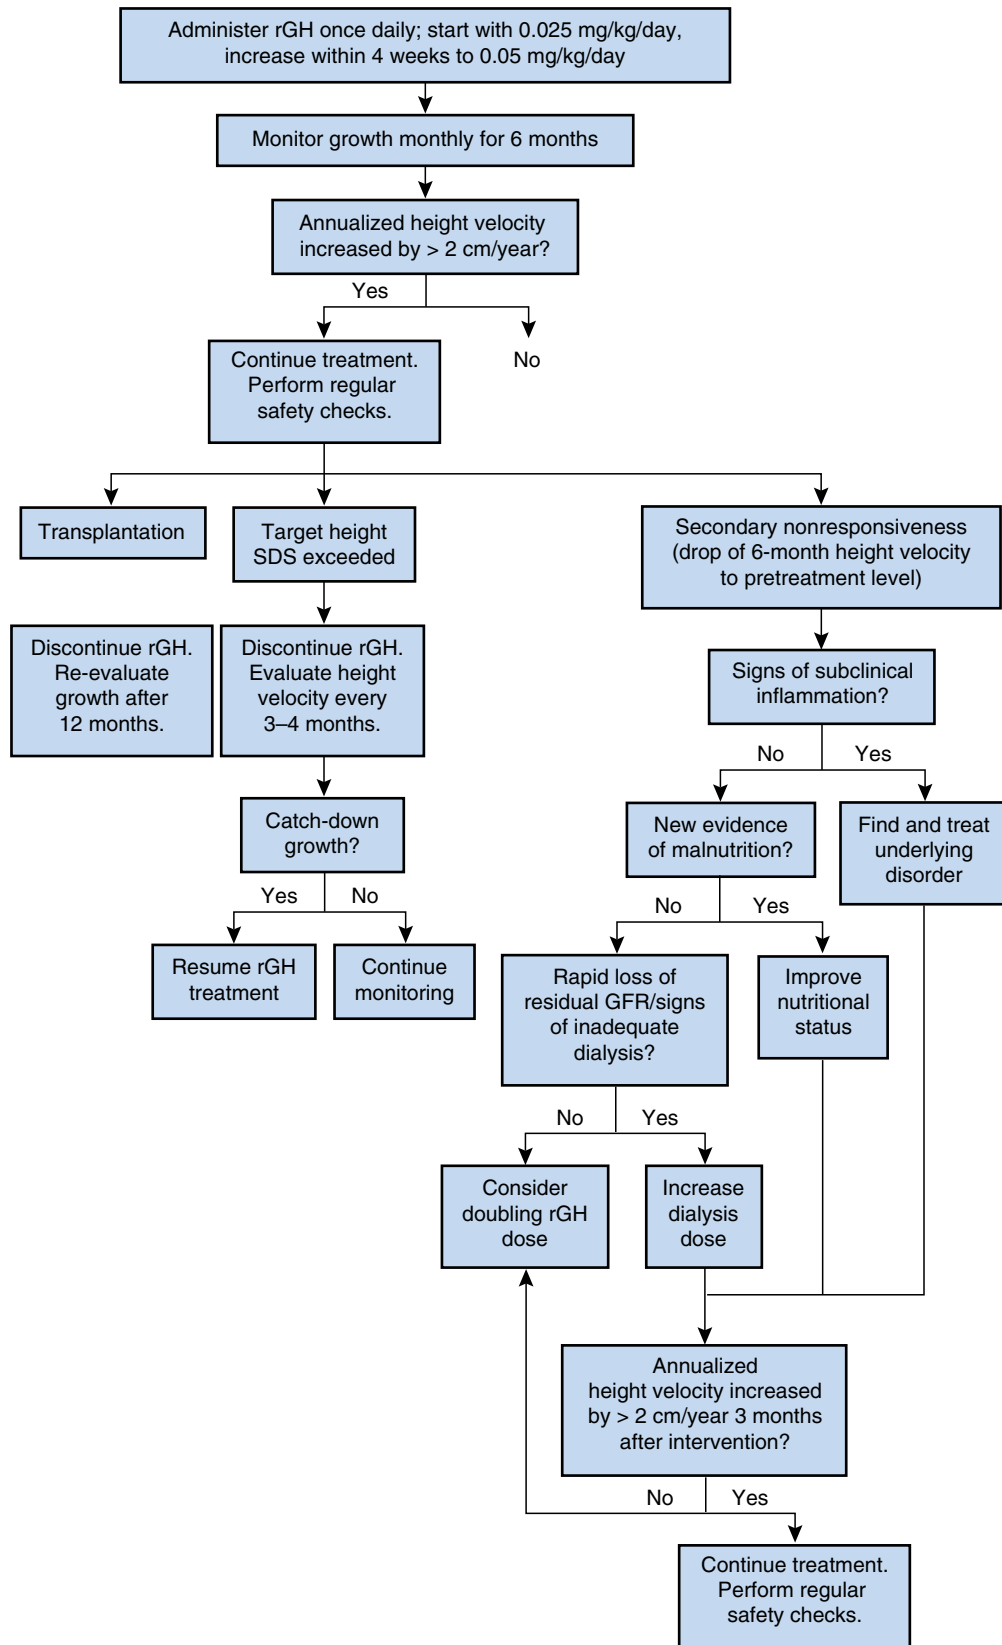
The majority of brain growth occurs during the first 2 years of life. A seminal report on the developmental outcome of children with CKD during infancy demonstrated a high prevalence of mental dysfunction, microcephaly, and seizures.[38] Thankfully, this has been supplanted by more favorable outcomes resulting from the aggressive treatment of malnutrition, often with the use of supplemental tube feeding, and the avoidance of aluminum-containing compounds.[39,40] Nonetheless, there continues to be evidence that neurologic functioning and development are adversely affected by the uremic state. In some studies, verbal performance and memory skills


Figure 14–1 Management of rGH therapy.

have been shown to be significantly affected, leading to substantial impairment of school functioning. The duration of renal insufficiency appears to be a factor in neurologic dysfunction, with the worst performance occurring in those with the longest duration of uremia. Nevertheless, the prevalence of neurocognitive impairment, its magnitude, and the specific risk factors that contribute to its development (including metabolic factors) remain largely unknown. To that end, a multicenter, comprehensive prospective study designed to assess the neurocognitive status of children with CKD and risk factors associated with a poor neurocognitive outcome has recently been funded by the National Institutes of Health (NIH) in the United States. This study will include extensive neuropsychological, behavioral, and neuroimaging testing on 600 children over a 5-year period of time. Until this study is completed and we have a better understanding of this complex issue, it is prudent to effectively manage the metabolic derangements and malnutrition associated with CKD aggressively and to enroll active participation of experts in behavioral and developmental pediatrics and neurology for appropriate evaluation and early intervention when deemed necessary.

NUTRITIONAL ISSUES

Protein energy malnutrition is a common problem in patients with CKD and is one of the major contributors to the poor growth seen in these patients, especially during the first few years of life. Since energy intake is the principle determinate of growth during infancy, malnutrition has the most marked negative effect on growth in children with congenital disorders leading to CKD.[41,42] In fact, only in infants has maximizing caloric intake been noted to be an effective means of improving height velocity in association with CKD.[43] As mentioned previously, suboptimal nutrition is also likely to contribute to an impaired neurocognitive outcome in the youngest patients.[44–46] The provision of inadequate nutrition during the period of CKD has resulted in a low body mass index (BMI) in a substantial percentage of children at dialysis initiation, primarily those less than 9 years of age.[11] A low BMI during dialysis has previously been associated with an increased risk for mortality in pediatric patients. Similarly, in a cohort of 1700 children initiating dialysis from 1995 through 1998, the risks of hospitalization and death were two times higher in patients with hypoalbuminemia as compared to those initiating dialysis with a normal serum albumin.[47] Finally, the 2003 annual report of the USRDS has revealed that 49% of pediatric patients start dialysis with a serum albumin level below the test's lower limit; the number drops to 44% for whites but reaches 59% for blacks and 79% for blacks with secondary glomerulonephritis.[48] Thus, the provision of adequate nutrition and the prevention of protein energy malnutrition are necessary to promote optimal growth and development in children with CKD, while hopefully minimizing the physiological and biochemical consequences of uremia.

The assessment of the nutritional status of children with CKD requires the evaluation of multiple indices, as there is no single available measure that alone can assess a patient's nutritional status accurately (Table 14–5).[49] A variety of physical

Table 14–5 Indices Used for Nutritional Assessment

  - protein equivalent of total nitrogen appearance (PNA)
  - Bioelectrical Impedance Analysis (BIA)
  - Dual Energy X-ray Absorptiometry (DEXA)
  - Subjective Global Assessment (SGA)

measurements, anthropometric assessments, and serum studies are routinely performed; special studies such as bioelectrical impedance and DEXA are more often deemed to be research tools in nature. The formula for calculating the normalized protein equivalent of total nitrogen appearance (nPNA) in children, which is reflective of the dietary protein intake, is different from the calculation in adults, as it takes into account the child's anabolic state and the higher nonurea-N excretion.[50] The calculation is as follows:

$$\text{Protein intake (g/kg/day)} = [\text{urea-N excretion (g/kg/day)} \times 15.39] - 0.8$$

The origin of malnutrition in children with CKD is multifactorial (Table 14–6); however, an inadequate voluntary dietary intake is considered a major contributing factor, especially in infants.[51] Nausea and vomiting are common in infants and children with CKD, with delayed gastric emptying and gastroesophageal reflux being detected in as many as 70% of patients with these problems.[52] Medical management with antiemetic medications (metoclopramide, domperidone) and antacids (H-2 blockers, proton-pump inhibitors) or surgical intervention (Nissen fundoplication) is frequently required. Additionally, whey predominant formulas can be used in these patients with resultant benefit because they have been shown to stimulate gastric emptying.[53,54]

Adolescents are the other patient group who appear to be particularly vulnerable to malnutrition due to their poor eating habits. They skip meals, favor fast foods, and in the presence of imposed dietary restrictions, find it difficult to meet the nutritional requirements of normal pubertal growth and development. They may benefit from individualized counseling and from having a special rapport with the renal dietitian.

Table 14–6 Causes of Protein-Energy Malnutrition (PEM) in Children with Chronic Kidney Disease

- Inadequate food intake secondary to
  – anorexia
  – altered taste sensation
  – nausea/vomiting
  – emotional distress
  – intercurrent illness
  – unpalatable prescribed diets
  – impaired ability to procure food because of socioeconomic situation
- Chronic inflammatory state
- Catabolic response to superimposed illnesses
- Possible accumulation of endogenously formed uremic toxins and/or the ingestion of exogenous toxins
- Removal of nutrients during dialysis procedure
- Endocrine causes such as
  – resistance to the actions of insulin and IGF-1
  – hyperglucagonemia
  – hyperparathyroidism

Energy

A number of studies have shown that the majority of pediatric patients with CKD exhibit an inadequate energy intake,[55–59] and the intake progressively decreases with worsening renal failure.[59] In a large, prospective study of growth failure in 120 children between the ages of 18 months and 10 years with CKD, the spontaneous energy intake was less than 80% of the recommended dietary allowance (RDA) for age in greater than 50% of the more than 400 food records obtained, with the poorest results reported in the oldest patients.[60] Whether the energy intake should more appropriately be referenced to height remains unanswered. Nevertheless, since maximizing caloric intake has been noted to be particularly effective in improving height velocity in infants with CKD, with only a rare report of a similar experience in older children,[17,42,43] the provision of adequate energy intake early in life is clearly most crucial.[61] Infants with CKD requiring fluid restriction, or those who have a poor oral intake, may require a greater caloric density of their milk formula than the standard 20 kcal/oz. Aggressive enteral feeding should be considered if the nutritional intake by the oral route remains suboptimal, despite all attempts at oral supplementation. The use of enteral support has repeatedly resulted in the maintenance or improvement of SD scores for weight and/or height in infants and young children with CKD.[51,62] Nasogastric (NG) tubes, gastrostomy catheters, gastrostomy buttons, and gastrojejunostomy tubes have all been used, with encouraging results, to provide supplemental enteral feeding to children with renal disease. The feeding can be given as an intermittent bolus or, more commonly, by continuous infusion during the night (Figure 14–2).[34]

Current experience suggests that the energy intake of children with CKD should be at least equal to the RDA for normal children of the same chronologic age (Table 14–7).[33,63] Dietary therapy should provide 50% of total calories from primary complex carbohydrates, and the remainder of the non-protein calories should be from fat, with a polyunsaturated/saturated ratio of 2:1. Energy supplementation in excess of the RDA is not recommended in the absence of malnutrition (Figure 14–3).[34]

Protein

Low-protein diets reduce the generation of nitrogenous wastes and inorganic ions that might be responsible for many of the clinical and metabolic disturbances characteristic of uremia. Moreover, low-protein diets decrease the development of hyperphosphatemia, metabolic acidosis, hyperkalemia, and other electrolyte disorders. A large number of clinical trials and experimental studies have examined the impact of dietary protein restriction on the rate of progression to ESRD in adults,[64–70] and indeed, such a diet can retard the progression of renal failure or delay the onset of maintenance dialysis therapy.[71–75] Accordingly, it is recommended that a low-protein diet (0.6 g/kg/day) be considered in adults with significant CKD who are not yet undergoing dialysis.

Pediatricians, on the other hand, are rightly concerned about the potential for harmful effects of severe dietary protein restriction, particularly as it pertains to the growth of infants and young children with CKD. Experimental studies in young animals have, in fact, shown that a decrease in dietary protein intake during the normally rapid period of growth that is sufficient to slow the deterioration of renal function, does adversely affect growth.[65,76] As a result, very few studies of dietary protein restriction have been conducted in children with CKD.[77–80] In one such study, Uauy and associates[79] reported a negative impact of a modest protein restriction on the growth of infants with CKD during the feasibility phase of a multicenter trial. In a seminal 1997 investigation of more than 100 children with CKD, the European Study Group for Nutritional Treatment of Chronic Renal Failure in Childhood found that a reduction in dietary protein intake to a "safe amount" (0.8 to 1.1 g/kg ideal body weight/day) in pediatric patients (2–18 years of age) for 3 years did not interfere with the children's growth, but it also did not influence the progression of renal insufficiency.[80] In conclusion, current data suggest that moderate dietary protein restriction has no beneficial effect in terms of preventing the progression of renal insufficiency, but, on the contrary, such interventions may be associated with a loss of growth velocity, particularly in infants. Thus, current recommendations are to provide 100% of the RDA for healthy children of the same gender and chronologic age (Table 14–7).[33,81] It is advised that at least 50% of the total protein intake come from proteins of high biologic value such as those from milk, eggs, meat, fish, and poultry.

Lipids

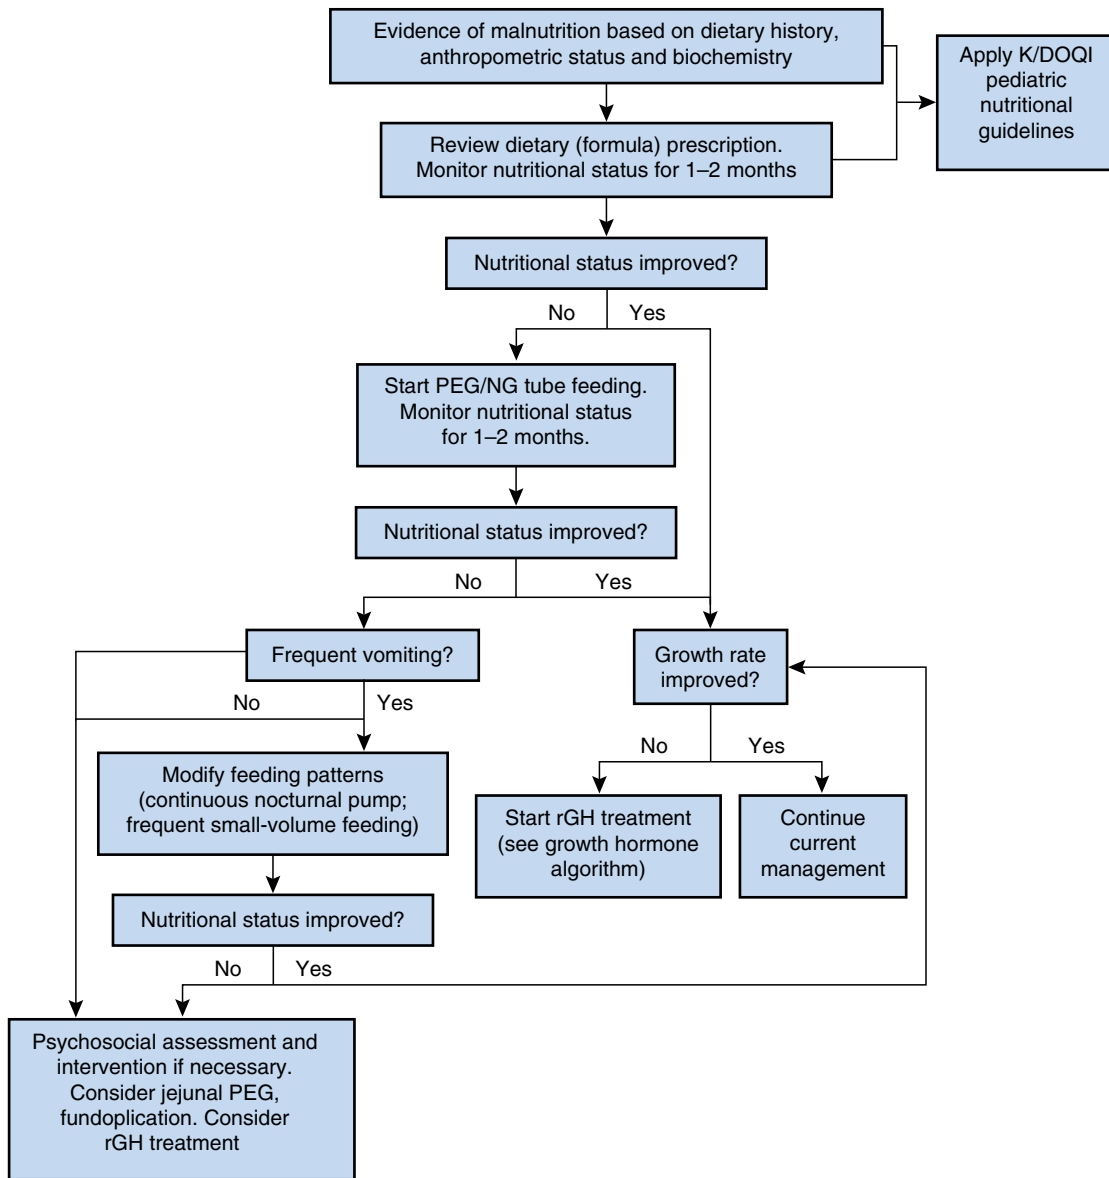
Hyperlipidemia is a frequently recognized complication of CKD in children.[82] Uremia is associated with an increase of triglyceride-rich lipoproteins that are atherogenic and likely to increase the risk of cardiovascular disease among children with CKD.[83–85] There is also some evidence that an abnormal lipid status may hasten the progression of renal disease itself.[86] It is important to note that even with a near normal total cholesterol concentration, individual lipoprotein species often


Figure 14–2   Management of malnutrition with growth failure in infants.

Table 14–7   Estimated Energy Allowances and Recommended Dietary Protein (g/kg/day) for Infants and Children with Chronic Kidney Disease[33,81]

	Age (Years)	Energy (kcal/kg/day)	Protein (g/kg/day)
Infants	0.0–0.5	108	2.2
	0.5–1.0	98	1.6

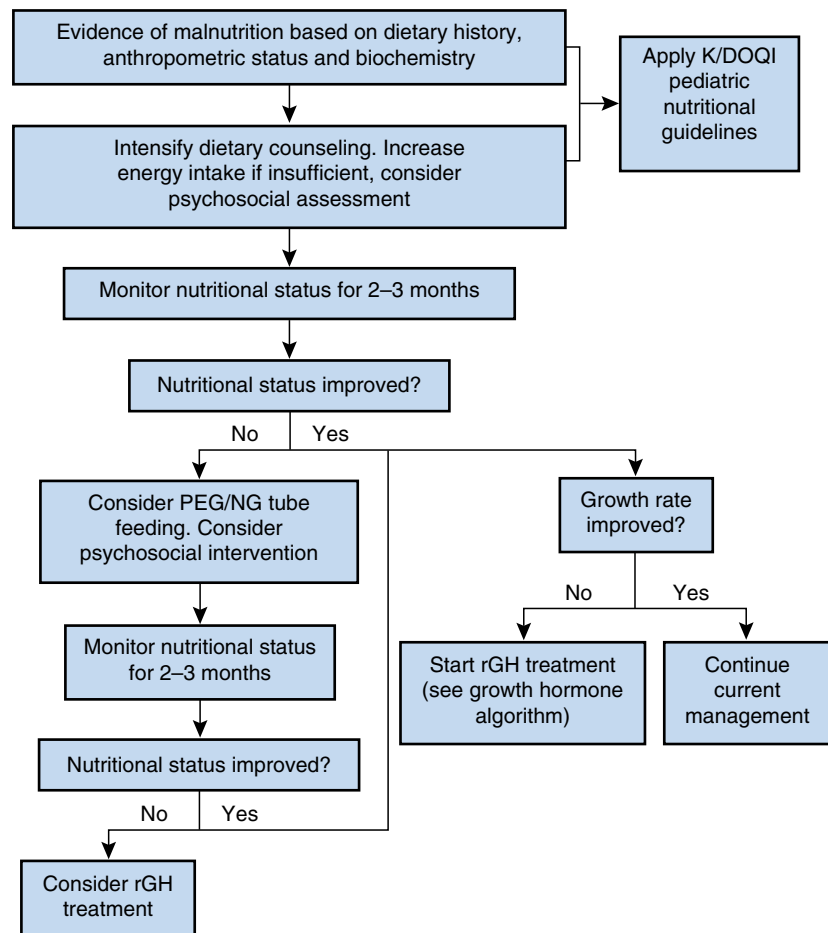
Females	11–14	47	1.0
	15–18	40	0.8
	18–21	38*	0.8

*Based on RDA and increased physical activity.

reveal an abnormal pattern, being characterized by a low HDL-cholesterol and high VLDL, IDL, and variable LDL-cholesterol.[87,88] The extent of the abnormality in these values typically parallels the degree of renal impairment. The Friedewald formula, which is commonly used by laboratories to approximate LDL-cholesterol levels as part of a lipid profile, tends to underestimate the true LDL concentration in uremic individuals.[89,90] Plasma ultracentrifugation, available through many commercial laboratories, remains the "gold-standard" technique to measure the various density classes of lipoproteins, while routine, low resolution screening tests in this population may fail to detect dyslipidemia.[86]

The metabolic abnormalities that accompany the dyslipidemia of uremia are complex. Insulin resistance uniformly occurs and is independently associated with disturbances of lipid metabolism.[91] Unlike what occurs in children with nephrotic syndrome, lipoprotein synthesis in patients with

Figure 14–3 Management of malnutrition with growth failure in school children and adolescents.


CKD does not appear to be significantly exaggerated; however, studies consistently demonstrate impaired catabolism of triglyceride-rich lipoproteins.[92] The amount and activity of hepatic triglyceride lipase (HTGL) is decreased in uremic individuals,[93] while decreases in lipoprotein lipase (LPL) function are less consistently noted, despite a clear increase in the concentration of apoC-III, an inhibitor of LPL.[94,95]

The optimal management of dyslipidemia in children with CKD is not clearly defined. Of interest, only 44% of children with ESRD even underwent evaluation of their lipid status in 2001.[48] Treatment of malnutrition related to renal insufficiency is essential and should supersede any potential rise in lipid levels that might result from it. Correction of metabolic acidosis, vitamin D therapy, and correction of anemia with erythropoietin each seem to have some normalizing effect on dyslipidemia in children with renal failure.[96–98] Fish oil has been shown to reduce hypertriglyceridemia in a small group of children with ESRD,[99] and there are reports of statin usage in children with nephrotic syndrome.[100–102] Nevertheless, there is currently not enough data to support the regular long-term usage of the standard lipid lowering therapies such as statins and fibrates in children of all ages, despite their frequent usage in adults. In the absence of substantial safety and efficacy data related to statin therapy in children, the recommended therapeutic approach for children with Stages 2 to 4 CKD generally consists of dietary and lifestyle modifications.

In patients with markedly elevated serum triglyceride levels, the dietary carbohydrate intake should be decreased from 50% to 35% of the total caloric intake. The remainder of the nonprotein calories should be supplied as fat with a polyunsaturated to saturated ratio of greater than 2:1. The child should be encouraged to ingest complex carbohydrates in lieu of simple sugars and concentrated sweets and to use unsaturated fats such as oils and margarines from corn, safflower, and soy. Plant stanol esters in the form of dietary supplements reduce intestinal cholesterol absorption and may provide a safe and effective means of reducing serum cholesterol.[103] Lipid-lowering drugs may be used judiciously in selected patients, such as in adolescents with Stage 5 CKD and either an LDL greater than or equal to 130 mg/dL or a combination of a fasting triglyceride level greater than or equal to 200 mg/dL and a non-HDL cholesterol of greater than or equal to 160 mg/dL.[104,105]

Acid-Base and Electrolytes

Infants and children normally have a relatively larger endogenous hydrogen ion load (2–3 mEq/kg) than do adults (1 mEq/kg), and metabolic acidosis is a common manifestation of CKD in children and an important negative influence on growth. Studies performed in adults and children have shown that chronic acidosis is associated with increased

oxidation of branched-chain amino acids,[106] increased protein degradation,[107] and decreased albumin synthesis.[108,109] Persistent acidosis also has detrimental effects on bone because it alters the normal accretion of hydroxyapatite into bone matrix and causes bone demineralization as the bone buffers are increasingly used for neutralizing the excess acid load. Thus, it is recommended that the serum bicarbonate level should be maintained at or above 22 mEq/L by supplementing with oral bicarbonate.[33]

Whereas in healthy people the body's sodium balance is maintained by alterations in urinary sodium excretion, sodium requirements in children with CKD are dependent on the underlying kidney disease and the degree of renal insufficiency. Children who have CKD as a result of obstructive uropathy or renal dysplasia are most often polyuric and may experience substantial urinary sodium losses despite advanced degrees of CKD. Signs of sodium depletion are subtle and may include listlessness and hypercalcemia. The growth of these children may also be hampered if ongoing sodium and water losses are not corrected. Fine and associates[110] demonstrated poor weight gain in animals deprived of salt with a resultant decreased extracellular volume, bone mass, and fat mass. In turn, the beneficial effect of sodium and water supplementation on the linear growth of 24 young children with CKD has been reported.[19] In contrast, children with CKD resulting from primary glomerular disease, or those who are oliguric or anuric, typically require sodium and fluid restriction to minimize fluid gain, edema formation, and hypertension. The fluid intake is usually a fraction of the calculated maintenance volume adjusted for the degree of oliguria. A reasonable sodium intake is 3 to 4 g/day, initially. These patients should be advised to avoid processed foods and snacks from fast-food restaurants. The sodium content of other food items should be checked carefully on food labels, and the sodium content of medications may need to be monitored.

Potassium homeostasis in children with CKD is usually unaffected until the glomerular filtration rate falls to less than 10% of normal. However, children with renal dysplasia, post-obstructive renal damage, severe reflux nephropathy, and renal insufficiency secondary to interstitial nephritis, often demonstrate renal tubular resistance to aldosterone action and may manifest hyperkalemia, even when their creatinine clearance is relatively well preserved.[111] The hyperkalemia experienced by these children is exacerbated by volume contraction (and can be particularly common in salt losers), and the majority of the patients respond to salt and water repletion. In patients who are persistently hyperkalemic, dietary potassium intake should be limited. As potassium is infrequently listed on food labels and cannot be tasted, a list of foods rich in potassium such as chocolates, french fries, potato chips, bananas, green leafy vegetables, dried fruits, and orange juice should be provided to patients and their families. Altering the methods of food preparation, such as soaking vegetables before cooking, helps decrease potassium content. In the case of infants and young children being fed milk formula, the potassium content of the formula can be reduced by incorporating the potassium exchange resin sodium polystyrene sulfonate (Kayexalate).[112] Attention should also be paid to medications such as potassium sparing diuretics, cyclosporin, and angiotensin converting enzyme inhibitors, because they may cause or exacerbate hyperkalemia. If constipated, the patient should be treated aggressively as significant quantities of potassium are eliminated through the gastrointestinal route in patients with CKD.

Vitamins and Micronutrients

Vitamins and minerals are essential for normal growth and development, and either a deficiency or an excess amount can prove harmful. Unfortunately, the vitamin and mineral needs of pediatric patients with CKD are not clearly defined and the limited data that are available are derived from patients undergoing maintenance dialysis. Children with CKD are prone to develop vitamin deficiencies because of anorexia and dietary restrictions, while they are also at risk to develop toxic levels of vitamins when the renal clearance is significantly impaired.

The provision of adequate quantities of vitamin B_{12} and folic acid is imperative for effective erythropoiesis. More recently, raised doses of supplemental folic acid (2.5 mg/day) have been suggested by some for children with CKD because folic acid has been shown to decrease the elevated homocysteine level that is commonly seen in patients with renal failure, and this is a potential risk factor for cardiovascular morbidity and mortality.[113,114] Further study of this issue in children is clearly warranted.

Vitamin C is necessary for the formation of collagen. However, an excessive intake of vitamin C in the dialysis population may result in elevated oxalate levels as an end product of vitamin C metabolism and lead to the development of significant vascular complications.[115] Vitamin A levels are reported to be elevated in patients undergoing PD despite the lack of vitamin A supplementation. The elevated levels are a result of the loss of the kidneys' normal ability to excrete vitamin A metabolites.[116] Since elevated levels of vitamin A can be associated with the development of hypercalcemia and complications related to a high calcium-phosphorus product, it is important to avoid the use of vitamin supplements that include vitamin A in patients with Stage 5 CKD. The status of vitamins C and A in children with early stages of CKD has not been well studied.

Since most infant milk formulas, including Similac PM 60/40 are fortified with both water-soluble and fat-soluble vitamins, the majority of infants with CKD receive the dietary reference intakes (DRI) for all vitamins (including vitamin A) by dietary intake alone and do not require vitamin supplementation. The current K/DOQI guidelines recommend an intake of 100% of the DRI for water-soluble vitamins as a reasonable starting point for children undergoing maintenance dialysis therapy. Supplementation should be considered if the dietary intake alone does not meet or exceed the DRI, if measured blood vitamin levels are below normal values, or if clinical evidence of deficiency is present.[33] There are no specific recommendations for children with CKD.

Aluminum, copper, chromium, lead, strontium, tin, and silicon levels have all been noted to be elevated in patients with CKD, reflecting the fact that their clearance is dependent on an adequate glomerular filtration rate.[117,118] Aluminum salts were commonly used in the 1970s and early 1980s as a phosphate binder and were found to cause severe toxicity manifested by encephalopathy with seizures, osteomalacia, and microcytic anemia, even in children with mild renal insufficiency.[119,120] Subsequently, the use of aluminum containing phosphate binders was discontinued. The Growth Failure in

Renal Disease Study[121] showed that serum aluminum levels were elevated only in children taking antacids containing aluminum, which provides 1000 times more aluminum than environmental exposure, which is approximately 3 to 5 mg/day. Aluminum absorption is enhanced by citrate, an important issue for those children with CKD receiving alkali therapy as treatment for metabolic acidosis. Other trace elements have not been as well studied in children; however, zinc levels have been shown to be low in malnourished children and should be monitored and supplemented as necessary.[117] Copper deficiency, although rare, has been associated with ineffective erythropoiesis.

Carnitine

Carnitine is an essential compound in the oxidative process of fatty acids,[122] and the kidney is the major site for its synthesis in humans.[123] Although patients undergoing prolonged dialysis are at risk for carnitine deficiency because carnitine is removed both by hemodialysis and peritoneal dialysis,[124,125] there is little information on the carnitine status of children with CKD. Carnitine has been proposed as a treatment for a variety of metabolic abnormalities in pediatric patients with ESRD, including dyslipidemia and anemia, as well as for treatment of intradialytic hypotension in patients receiving hemodialysis. However, there is currently insufficient evidence to support the routine use of carnitine in either the pediatric CKD or dialysis patient population. Of interest, recent data from the USRDS has revealed that fewer than 2% of pediatric dialysis patients were evaluated for the presence of carnitine deficiency in 2000 to 2001, and only 4% of pediatric patients received supplemental carnitine.[48]

ANEMIA

Anemia is a frequent complication of CKD in children and adults.[126–130] Studies in the adult population have provided substantial evidence that anemia is an important predictor of patient morbidity and mortality. Anemia is strongly associated with cardiovascular disease and is present early in the course of CKD, long before the need for renal replacement therapy arises.[131] The anemia of CKD is associated with a number of physiological abnormalities, including decreased tissue oxygen delivery,[132–134] increased cardiac output, cardiac enlargement, ventricular hypertrophy, congestive heart failure,[135–138] decreased cognition and mental acuity,[139] and impaired immune responsiveness.[140,141] In addition, anemia may play a role in growth retardation and decreased intellectual performance in pediatric patients.[142,143] These poor outcomes stress the importance of anemia management in children with CKD.

Unfortunately, anemia management in children with CKD has received remarkably little study. Data from the 2003 report of the USRDS has revealed that the mean hemoglobin at dialysis initiation in 2001 was only 9.1 g/dL for all pediatric patients (9.3 for whites and 8.9 for blacks), reflective of suboptimal anemia management during the period of CKD.[48] Although the mean hemoglobin varied from state to state, it did not exceed 9.8 g/dL in any of the 50 states.[11] The presence of anemia was most striking in the 0- to 4-year age group and in those who subsequently received chronic hemodialysis.[11]

Similarly, the NAPRTCS has revealed that the mean hematocrit (Hct) of children with CRI at entry into the registry is only 33.5%, despite the fact that a hematocrit of 33% to 36% is recommended by K/DOQI. In addition, less than 20% of all children with CRI and followed by NAPRTCS had received recombinant human erythropoietin (rHuEPO) 48 months after the baseline evaluation.[10] A hematocrit less than 33% has also been found to be associated with an accelerated rate of progression towards ESRD in the NAPRTCS registry.[10,144,145] Finally, in a more recent NAPRTCS study, Warady and Ho[146] determined that a hematocrit less than 33% at dialysis initiation was associated with a greater mean number of hospitalization days during the initial year of dialysis as well as with a significantly greater probability for a hospitalization of 30 days or more during that year when compared to patients with an Hct greater than 33%. Most important was the finding that the presence of anemia at dialysis initiation was associated with an estimated 52% greater risk of death.

The anemia present in association with CKD is primarily caused by a decrease in the renal production of erythropoietin.[147] Additional factors that may cause or contribute to anemia include iron deficiency,[148] hyperparathyroidism,[149] acute and chronic inflammatory conditions,[150] aluminum toxicity,[151] folate and vitamin B_{12} deficiency,[152] hypothyroidism,[153] and hemoglobinopathies such as α-thalassemia.[153] In turn, the standard workup of anemia should be initiated when Hgb is less than 11 g/dL (Hct <33%) and initial blood work should include red blood cell indices, reticulocyte count, and iron parameters such as serum iron, total iron binding capacity (TIBC), and serum ferritin. The percent transferrin saturation (TSAT) is calculated as the serum iron × 100 divided by the TIBC. The value and validity of additional diagnostic tests to address the iron status, such as the reticulocyte hemoglobin content and the percent hypochromic red blood cells, awaits further study in pediatrics. When deemed appropriate, testing to evaluate for the possible contribution of the etiologic disorders noted previously should be performed.

Finally, recombinant human erythropoietin (rHuEPO) has been used for the treatment of CKD related anemia since 1986.[154,155] Despite compelling evidence regarding the benefits of rHuEPO, its use in the pediatric CKD population continues to be low, particularly in the context of the severe degree of anemia noted in patients younger than 5 years of age at dialysis initiation.[11] The USRDS has revealed that only 37% of all pediatric patients have received rHuEPO before starting dialysis, and black children were less likely than whites to receive pre-ESRD rHuEPO therapy.[48] The target range for Hgb (Hct) for rHuEPO therapy is 11 to 12 g/dL and 33% to 36%, respectively.[156] Supplemental iron should be administered to maintain a TSAT of greater than or equal to 20% and a serum ferritin level of greater than or equal to 100 ng/mL.[156] While iron is typically provided by the oral route, intravenous iron supplementation can be an efficient means by which iron stores can be enhanced in children with CKD. Levels of TSAT greater than or equal to 50% or serum ferritin greater than or equal to 800 ng/mL are not associated with any further benefit and may require modification of iron therapy. The average dosage of rHuEPO is 150 units/kg/wk given by the subcutaneous route; younger patients (<5 years) frequently require higher doses of up to 300 units/kg/wk given in two to three doses. There are limited data regarding the use of longer acting erythropoietin in children.[157] The response to rHuEPO is

monitored by measuring Hgb/Hct every 1 to 2 weeks following the initiation of treatment or following a dose increase or decrease, until a stable target Hgb/Hct and rHuEPO dose have been achieved; monitoring is then recommended to occur every 2 to 4 weeks.

RENAL OSTEODYSTROPHY

Bone disease is a universal complication of CKD, and it encompasses a spectrum of skeletal disorders ranging from the high-turnover lesions of secondary hyperparathyroidism to the low-turnover adynamic bone disease.[158] Although similar factors are involved in the pathogenesis of renal osteodystrophy in adult and pediatric patients with CKD, growth retardation and the development of bone deformities are complications that occur only in children. A number of factors such as disturbances in calcium and phosphorus homeostasis, reduced synthesis of the active form of vitamin D (1,25-dihydroxycholecalciferol), altered metabolism of parathyroid hormone (PTH), and impaired renal clearance of PTH fragments play critical roles in the pathogenesis of renal osteodystrophy.

Over the past decade, the availability of first generation immunometric PTH assays have allowed characterization of the spectrum of renal osteodystrophy in adult and pediatric patients receiving maintenance dialysis therapy.[159–161] Historically, it remained largely unexplained why the concentrations of intact PTH had to remain well above the normal range for healthy individuals (10–65 pg/mL) to maintain normal bone turnover and to prevent the development of adynamic bone disease in adult and pediatric patients treated with dialysis. However, a recent series of studies by D'Amour and associates demonstrated that the first PTH-IMAs detected not only the intact hormone, but also PTH fragments truncated at the amino-terminus, for instance, PTH (7–84).[162–165] The more recently developed second generation immunometric PTH assay (second PTH-IMA) uses a detection antibody raised against the first four amino-terminal amino acids and recognizes only PTH (1–84) and possibly PTH fragments that are truncated at the carboxyl–terminus, but not the PTH (7–84).[166–168] First generation PTH-IMAs thus overestimate the true concentration of PTH (1–84) in serum or plasma, both in patients with ESRD and those with normal renal function, by including PTH (7–84).[164,167,169,170] In patients undergoing dialysis therapy, the PTH concentrations measured with the 1st PTH-IMA are on average 40% to 50% higher than those measured with second PTH-IMA.[166,168–171] Recent data do indicate that one or more PTH (1–84) fragments, such as PTH (7–84), actually antagonize the calcemic actions of PTH (1–84) and may modulate bone metabolism through a receptor distinct from the type I PTH/PTHrP receptor.[168–170,171] Nevertheless, a high degree of correlation (r = 0.977) has been observed between the PTH results determined by the first and second PTH-IMAs in patients with ESRD.[167,169,173]

The levels of PTH that are associated with normal rates of bone formation in pediatric patients with different degrees of renal insufficiency before dialysis therapy are not clearly defined. Although additional data on this subject are clearly needed, recent guidelines from K/DOQI have recommended intact PTH values of 30 to 70 pg/mL and 70 to 110 pg/mL in adult patients with CKD Stages 3 and 4, respectively. It is likely

that the pediatric work group will soon make similar recommendations.[174]

Although it is well recognized that phosphorus retention in patients with advanced CKD plays a central role in the development and maintenance of secondary hyperparathyroidism (HPT) by causing hypocalcemia and reducing the rate of conversion of 25-hydroxyvitamin D3 to 1,25-dihydroxyvitamin D3,[175] a deficit of calcitriol synthesis has also been shown to be a major factor in the development of HPT.[176,177] In fact, a study involving a large number of adult patients with CKD revealed that HPT developed at a time when the serum calcium and phosphorus were still normal.[178] Thus, the current belief is that calcium, phosphorus, and calcitriol play an integrated role and all are important in the pathogenesis of HPT.

Along the same lines, although dietary phosphorus restriction is the usual first line approach to the management of HPT, phosphorus restriction alone may not be very effective in suppressing PTH, if the calcium intake is inadequate.[178] Apart from having an independent effect on parathyroid gland activity,[178] dietary calcium may also be a signal to upregulate the vitamin D receptor density in the parathyroid glands.[179,180] Thus, the appropriate dietary intakes of calcium, phosphorus, and vitamin D are crucial for the management of HPT in patients with CKD.

Adequate dietary calcium intake during childhood is necessary for the development of optimal peak bone mass.[181] The current recommendation is that patients with CKD should achieve a calcium intake of 100% of the DRI[182] (Table 14–8). Infants and young children usually meet the DRI for calcium with the consumption of adequate volumes of breast milk/formula. Unfortunately, the largest source of dietary calcium for most persons are dairy products which are also rich in phosphorus; in turn, phosphorus restriction universally leads to a decreased calcium intake. In these situations, calcium supplementation may be required as low phosphorus, high calcium foods such as collards, dandelion greens, kale, rhubarb, and spinach usually do not make up a substantial part of a child's diet. Several products fortified with calcium such as fruit juices and breakfast foods are commercially

Table 14–8 Recommended Calcium Intake for Children with Chronic Kidney Disease

Age (Years)	DRI (mg/day)	Recommended Maximum Intake (mg/day)
0.0–0.5	210	420
0.5–1.0	270	520
1–3	500	1000
4–8	800	1600
9–18	1300	2500*

DRI, dietary reference intake.
Recommended maximum intake: preliminary recommendation by a pediatric workgroup developing guidelines for the management of dietary calcium intake in children with CKD.
(From Baker SS, Cochran WJ, Flores CA, et al: Committee on Nutrition, American Academy of Pediatrics, Policy Statement: Calcium requirements of infants, children and adolescents [RE 9904]. Pediatrics 1999; 104: 1152–1157.)

available, and limited studies have suggested that the bioavailability of calcium from these products is at least comparable to that of milk.[183] Calcium can also be supplemented in medicinal forms such as carbonate, acetate, and gluconate salts of calcium that are commonly used as phosphate binders. When used for calcium supplementation alone, ingesting these products between meals maximizes calcium absorption.[184] Chloride and citrate salts of calcium should be avoided as the former may lead to acidosis in patients with CKD, and the latter may enhance aluminum absorption.

On the other hand, excessive calcium intake in conjunction with activated vitamin D analogues can lead to (1) hypercalcemia, (2) adynamic bone disease, and (3) systemic calcification. In the adult K/DOQI guidelines, it is recommended that the elemental calcium intake from phosphate binders should not exceed 1500 mg/day and that the total elemental calcium intake should not exceed 2000 mg/day in an attempt to maintain a normal serum calcium and a calcium × phosphorus product less than 55 mg^2/dL^2.[174] In the absence of definitive pediatric studies, the K/DOQI pediatric work group is likely to recommend a maximal calcium intake of two times the DRI for age, except for ages 9 to 18 years (both genders), where two times the DRI (2600 mg) exceeds the Tolerable Upper Intake Level (UL) of 2500 mg.[182] The serum calcium phosphorus product should probably be kept below 60 mg^2/dL^2 in all but possibly the youngest (<3 years) children who naturally have a "high" serum phosphorus level.

The dietary phosphorus intake in children with CKD should be restricted to less than 800 mg/day if a normal phosphorus level is to be achieved, with recognition that dairy products and high-protein foods are the main sources of dietary phosphorus.[185] However, strict dietary phosphorus restriction is often impractical and ill advised because it may lead to an inadvertent poor protein intake. In addition, extremely low phosphorus diets are typically unpalatable. Although young infants may be effectively managed by a low-phosphorus containing milk formula such as Similac PM 60/40 (Ross Laboratories, OH) and Good Start (Nestlé Company, Switzerland), most other patients require oral intestinal phosphate binders to control hyperphosphatemia. Phosphorus control is particularly difficult in vegetarians because for the same total quantity of dietary protein delivered, the phosphorus content is greater in protein derived from vegetable sources versus animal protein. Whereas food labels rarely state the phosphorus content, chocolates, nuts, dried beans, and cola soft drinks are rich in phosphorus and should be avoided; nondairy creamers and certain frozen nondairy desserts may be used in place of milk and ice cream.

Aluminum hydroxide and carbonate were widely used as phosphate binders in the past, but their use was abandoned once they were found to be associated with severe toxicity in adults and children with renal insufficiency.[119,120] Currently, calcium-containing salts (Table 14–9) such as calcium carbonate and calcium acetate are commonly used as phosphate binders, with the latter often reported to be a more effective binder than the former.[186] To be maximally effective, their intake should coincide with that of meals or snacks. The optimal timing for the administration of binders with tube feedings has not been clearly defined. As noted above, calcium containing phosphate binders also serve as an important source of supplemental calcium. More recently, excessive calcium intake in the form of phosphate binders has been implicated as one of the factors responsible for the development of coronary-artery calcification in young adults who started dialysis as young children.[187–189] These findings have focused attention on calcium and aluminum free phosphate binders such as Sevelamer hydrochloride (RenaGel),[190–192] although no calcium-free phosphate binder is currently approved by the FDA for use in children. On rare occasions and for very restricted periods of time, a closely monitored low-dose (<30 mg/kg/day) of aluminum containing phosphate binders may be tried as a last resort for those patients in whom hyperphosphatemia remains uncontrolled, despite the previously recommended medical/dietary management. Finally, in contrast to the successful pretreatment of milk with ion-exchange resins to decrease potassium content, studies on the pretreatment of milk with calcium acetate to reduce the phosphate content found the procedure ineffective.[193]

In the absence of 1∝-hydroxylation of vitamin D, synthetic 1,25 dihydroxyvitamin D (the active metabolite) or dihydrotachysterol (requires only hepatic hydroxylation for activation) is used in pediatric patients with CKD. These

Table 14–9 Calcium Content of Common Calcium-Based Binders[174]

Compound	Brand Name	Compound Content (mg)	% Calcium	Elemental Calcium (mg)
Calcium acetate	Phoslo	667	25	167
Calcium carbonate	Chooz (Gum)	500	40	200
	TUMS EX	750	40	300
	TUMS Ultra	1000	40	400
	LiquiCal	1200	40	480
	CalciChew	1250	40	500
	CalciMix			
	Oscal 500			
	TUMS 500			
	Caltrate 600	1500	40	600
	NephroCalci			
Calcium citrate	CitraCal		Not recommended	
Calcium acetate/	MagneBind 200	450/200		113
magnesium carbonate	MagneBind	300/300		76

preparations are often started early in the course of CKD on the basis of an elevation of the intact serum PTH and serum alkaline phosphatase levels. As suggested previously, one of the serious complications associated with the use of these activated vitamin D metabolites is the development of hypercalcemia. Several newer noncalcemic vitamin D analogues, such as paricalcitol (19-nor-1, 25-dihydroxyvitamin D_2)[194] and doxercalciferol (1∝-hydroxyvitamin D_2),[195] selectively depress the parathyroid gland with a lower incidence of hypercalcemia when compared to current agents. Pediatric studies with these medications are currently underway.

CARDIOVASCULAR DISEASE

Systemic atherosclerosis and cardiovascular disease (CVD) are usually viewed as unique problems of adulthood, and adult patients with CKD suffer significantly increased rates of morbidity and mortality secondary to CVD, compared to the general population.[196] Nonetheless, the systemic process of atherogenesis begins during childhood, and many pediatric patients with CKD presumably undergo years of accelerated atherosclerosis as they mature toward later life.[197] To be sure, children with renal insufficiency have a high prevalence of traditional risk factors for CVD. As noted in the NAPRTCS registry, 38% to 78% of these children are hypertensive, and as many as 60% to 90% develop hyperlipidemia.[82] In addition to these traditional risk factors, children with CKD may amplify their cardiovascular risk due to a number of uremia-related factors, including anemia, hyperhomocysteinemia, malnutrition, chronic inflammation, and hyperparathyroidism.[114,198,199] Thus, the combination of traditional and uremia-related risk factors may initiate and accelerate CVD in the pediatric population with CKD. In fact, CVD is now recognized as the second most common cause of death in children with ESRD,[48,85,200,201] and the cardiovascular mortality rate reported in children and young adults on chronic dialysis is almost 1000 times higher than in comparably aged individuals without renal disease.[85]

As mentioned previously, hypertension is a common consequence of CKD and may be a presenting sign in children and adolescents. A significant association between hypertension and progression of CKD in adults has been shown in a recently conducted review of 26 studies by K/DOQI.[202] Similarly, a retrospective analysis of pediatric patients with CRI from the NAPRTCS database demonstrated a high prevalence (48%) of hypertension and a close correlation between hypertension and the progression of renal failure.[203] In the latter study, hypertension predicted the progression of CRI independently of other known risk factors such as baseline kidney function, age, race, and primary kidney disease. The study also revealed that systolic, but not diastolic blood pressure, remained an independent predictor for the progression of renal failure. An earlier study by Wingen and associates[80] has also shown that systolic BP and moderate proteinuria were significant risk factors for the progression of renal failure in children.

The question of whether hypertension is the cause or merely a marker of the progression of renal disease was addressed even before ACE inhibitors became available. Several clinical studies in adults with diabetic nephropathy have demonstrated that lowering BP to the upper normal range[204] or lower[205] results in a slowing of the loss of renal function as well as a simultaneous decrease in proteinuria. A beneficial effect of lowering BP has also been demonstrated in adults with nondiabetic renal diseases.[206] The ACE inhibitors seem to offer better preservation of renal function than other antihypertensive agents,[207] especially in patients with proteinuria.[208] This evidence of renoprotection by ACE inhibitors, as well as their antihypertensive efficacy with few side effects has, in turn, led to the widespread use of these agents in pediatric renal patients despite few published pediatric data. The impact of BP management on the progression of renal failure is, however, currently being examined in a European pediatric multicenter study. In this 3-year trial, children with CRI treated with an ACE inhibitor (ramipril) are randomized to a target BP below the 50th percentile or between the 50th and 95th percentile on the basis of 24-hour ambulatory BP monitoring standards. The results of this trial should become available later this year. Twenty-four–hour ambulatory blood pressure monitoring (ABMP) is being used in the trial because this technique has been found to be superior to clinic BP measurements in predicting end organ damage.[209, 210] It is also useful for the detection of abnormal nocturnal BP changes, which are predictive of cardiovascular mortality in patients with CKD.[211] Although limited ABPM data exist presently in pediatrics, its use is likely to become more widespread following the availability of normalized reference values in children[212] and its application in the European study and the U.S. multicenter CKD study.

The number of reviews of cardiac function and structure in children with CKD are limited, but the few that do exist provide in vivo evidence of cardiac morbidity in this population. However, the exact timing of the onset of the cardiovascular abnormalities during the course of CKD in children is not known. It is likely that the pathophysiological processes probably start early, as echocardiographic studies of children have revealed an increased left ventricular mass (LVM) in 22% of children with renal insufficiency, 30% of those treated with dialysis, and 63% of those who have received a kidney transplant.[213] In a cohort of 140 young adult patients from the Netherlands with ESRD onset at age less than 14 years, evidence of increased LVM was found in 47% of males and 39% of females, diastolic dysfunction in 13% and aortic valve calcification in 19% of all patients.[214] An important correlation has also been observed between LVM and decreasing renal function in children with CKD, suggesting that uremia itself may lead to a progressive increase in LVM.[215] It is important as well to note that there is a significant correlation between anemia and CVD because the LVM is reduced in children after correction of anemia with erythropoietin.[216] Another echocardiographic study of children initiating maintenance dialysis (26 HD, 38 PD) showed left ventricular hypertrophy (LVH) in 75% of the children, and the severity of LVH correlated with the duration of renal insufficiency prior to the institution of dialysis.[217] In adults, long-standing cardiac hypertrophy ultimately leads to maladaptive LVH, diastolic and systolic dysfunction, and may eventually lead to cardiac failure and death. Therefore, the LVH that begins during childhood CKD may be a key risk factor for future cardiac disease in young adults with ESRD.

A small autopsy series of children with ESRD or status-post kidney transplantation has also provided evidence of pathologic changes in the intima of the coronary arteries,[218] and the

recent cross-sectional studies that detected coronary artery calcification by electron-beam computed tomography in young adults lend support to the possible presence of accelerated coronary artery disease in pediatric/young adult patients with CKD.[187, 188] Despite this growing evidence, congestive heart failure still appears to be much more common in children than atherosclerotic heart disease.[11]

In summary, early evaluation and an aggressive management approach to include effective blood pressure control, anemia management with erythropoietin, control of dyslipidemia, prudent use of calcium salts as phosphorus binding agents, and 1,25 dihydroxyvitamin D3 for secondary hyperparathyroidism are essential to decrease CVD morbidity and mortality. The role of folic acid and anti-inflammatory therapy to treat elevated homocysteine levels and markers of inflammation in children awaits further study.

PREVENTION OF PROGRESSION OF CHRONIC KIDNEY DISEASE

The major health consequences of CKD include not only the progression to kidney failure, but also all of the associated manifestations noted earlier. Recent evidence indicates that these outcomes can be improved by early treatment.[219] Therefore, there is a need to understand the mechanisms involved in the progression of CKD and to determine reliable and early biomarkers that correlate with disease progression. The latter are necessary to follow the early success or failure of applied interventions to preserve renal function and to slow the progression of renal insufficiency.

There is experimental as well as clinical evidence that the response to a loss of renal mass and the subsequent progression to CRI in children is different from that seen in adults. In young animals in whom maturational growth is occurring, injury after renal ablation is often more severe than that seen in adult animals.[220] A reduction in renal mass has been associated with the development of proteinuria and hypertension, both of which are established risk factors for renal disease progression in humans. The presence of glomerular hypertrophy and subsequent glomerulosclerosis is substantial, especially in the deep nephrons of the young rat. This increased sclerosis is postulated to be related to factors unique to the young growing kidney, which is characterized by centripetal growth and differentiation. In humans, a similar response to injury is observed in the juvenile kidney. For example, as many as 33% of children develop microalbuminuria after undergoing unilateral nephrectomy for Wilms' tumor.[221]

As protein leaks through the diseased glomeruli, it injures the tubular cells and thereby causes interstitial inflammation and subsequent fibrosis.[222] Albumin has autocrine and paracrine effects on tubular cells in culture media.[223] The presence of microalbuminuria in adult diabetic patients is associated with a 10-fold higher risk of progression to overt nephropathy.[224] Severe proteinuria is also associated with a faster progression of renal deterioration in adult patients with glomerular diseases,[206] and results from the Modification of Diet in Renal Disease (MDRD) study supports the concept that proteinuria is an independent risk factor for progression of CRI in adults.[225] At the same time, reduction of proteinuria, independent of blood pressure, is associated with a subsequent beneficial effect on progression of CKD in adults.

Although proteinuria is an established biomarker of CKD progression, diseases involving a high filtered load of albumin such as minimal change nephrotic syndrome are not typically associated with the presence of renal insufficiency, suggesting that the assessment of glomerular proteinuria with only albumin may not be optimal. On the other hand, the urinary excretion of IgG and β1-microglobulin predicts the clinical course better than the extent of proteinuria in membranous nephropathy.[225] Evidence of tubular injury and dysfunction, manifested by abnormal amounts of small urinary tubular proteins, may also be useful biomarkers of progression of renal disease. Retinol binding protein (RBP) and *N*-acetyl-glucosaminidase (NAG) have been shown to be markers of proximal tubular damage and dysfunction. RBP is much more sensitive than NAG for the early detection of tubular impairment.[226] In children with vesicoureteral reflux, evidence of tubular dysfunction as measured by urinary RBP and NAG is frequently noted in patients who have renal scarring, evidence of damage that usually precedes the development of albuminuria. Proteomics and the new methodologies of protein profiling are recent and exciting scientific developments to study urinary proteins and have the potential for identifying clinically useful biomarkers that predict the progression of renal disease.[227] These investigative techniques will be an important component of the multicenter pediatric CKD study.

CONCLUSIONS

In conclusion, the development of CKD during childhood frequently results in a variety of clinical manifestations that can have a lifelong impact on the pediatric patient. To optimize therapy at present, an aggressive diagnostic and management approach designed by a multidisciplinary team is absolutely essential. Future investigative efforts will likely make possible additional therapeutic options to delay or even to prevent the progression of CKD, clearly the desired outcome for children and adults alike.

Modality Options for End-Stage Renal Disease Care

Gihad E. Nesrallah, M.D., F.R.C.P.C., F.A.C.P. • Peter G. Blake, M.B., F.R.C.P.C., F.R.C.P.I. • David C. Mendelssohn, M.D., F.R.C.P.C.

Over the last decade, the end-stage renal disease (ESRD) population in the United States and Canada has doubled in size and continues to grow at an alarming rate.[1,2] The exponential rate of growth in the ESRD population has been slowed to some extent by advances in pre-ESRD care, but this should hardly be viewed as reassuring. Projections from the United States Renal Data System (USRDS) database estimate that the ESRD population will exceed 2.2 million by the year 2030 in the United States alone. In 2001, caring for patients with ESRD cost $15.4 billion in U.S. funds, consuming 6.4% of the total Medicare budget.[1] The need for dialysis systems that maximize patient outcomes while controlling cost has never been more apparent.

Transplantation has established itself as the superior mode of renal replacement therapy (RRT), both with respect to outcomes and cost-effectiveness.[3,4] The ESRD population, however, continues to grow out of proportion to the supply of donor organs, thus limiting ESRD management mainly to the realm of the various dialytic therapies. In-center hemodialysis (HD) is the most prevalent and generally the most costly form of RRT in use, consuming the majority of the ESRD budget in most developed countries. Home hemodialysis, though associated with a greater up-front cost, is cost-effective in the long-term when compared to in-center HD.[5] Self-care and home hemodialysis have been estimated to cost 58% as much as in-center HD, and peritoneal dialysis (PD) remains highly cost-effective, costing as little as 53% as much as in-center HD in the United States.[6] In particular, the recent relative decline in utilization of PD in the United States and in Canada remains difficult to understand on the basis of outcomes and cost analysis.[7]

It is reasonable to conclude that the ESRD modality distribution in a given country will have profound and fundamental consequences for patients, stakeholders, and funding bodies. Thus, modality options must be viewed in parallel, on both a systems level and on an individual patient level. It has never been more incumbent upon the nephrology community to devise modality selection and distribution strategies that take into account patient preference, cost, and effectiveness, while keeping pace with current trends in ESRD management. The purpose of this chapter is to outline the relative merits and limitations of the various RRT options from both a patient and system perspectives, to describe the various factors that influence modality selection, and to propose a strategy for delivering cost-effective care to the ESRD population in the years to come.

OPTIONS FOR RENAL REPLACEMENT THERAPY

It is the bias of the authors that there are no perfect ESRD therapies. There has been an unfortunate tendency in the past to cast dialysis therapies in a competitive light. The tragic truth is that all dialysis therapies are burdensome and imperfect, and all these therapies must be improved. Dialysis therapies should be considered as complementary, and suitable patients without contraindications to any form of dialysis therapy should be presented with a menu of choices. Ideally, these informed patients should be encouraged to select the method that suits their personal situation in the least burdensome way.

This section is intended to provide a general overview of the relative merits and shortcomings of the existing ESRD treatment options.

Peritoneal Dialysis

Peritoneal dialysis involves the transport of solutes and water across the peritoneal capillaries and membrane into a dialysate, which has been infused into the peritoneal cavity. Solutes, including uremic wastes, potassium, and acids, diffuse along their concentration gradients into this fluid, and water follows the osmotic gradient created by hypertonic solute, usually glucose, in the dialysate. Solutes are carried along with ultrafiltered water in a process known as *solvent drag*. The net result is translocation of solute and fluid from blood into the dialysate, though transport of both water and solute may occur in the reverse direction, depending on membrane characteristics and dwell time. The dialysate is changed at regular intervals so that these solutes are removed and the concentration and osmotic gradients may be restored.

The two principal techniques are continuous ambulatory peritoneal dialysis (CAPD) and automated peritoneal dialysis (APD). The former involves manual exchanges typically performed every 6 hours, thus four times daily. In CAPD, fluid is always present in the abdominal cavity. APD is usually performed primarily overnight during sleep and requires a cycler machine to automate the fluid exchanges. APD can be further subdivided into continuous cycler peritoneal dialysis (CCPD), which involves the use of daytime dwells and nocturnal intermittent peritoneal dialysis (NIPD) in which exchanges are only performed overnight and the patient is "day-dry." Daytime exchanges and dwells occurring at various intervals,

and lasting for various lengths of time, are becoming increasingly common, while NIPD is in decline.

The peritoneal dialysis procedure requires a functioning peritoneal dialysis catheter, of which there are various types. These may either be inserted percutaneously or surgically, and may be placed well in advance and buried in the abdominal wall until they are needed.

PD is usually a chronic, home-based dialysis therapy. Use of PD for acute dialysis in hospital is now rare,[8,9] and hospital-based chronic PD therapy like IPD (intermittent PD) is no longer commonly employed because of high cost, low clearance of uremic toxins, and poor patient outcomes. For purposes of the discussions in this chapter, PD is used to mean chronic, home-based therapy.

Advantages of Home Peritoneal Dialysis

The peritoneal dialysis procedure is fairly simple as compared with hemodialysis and does not require the same level of technical expertise. The equipment is simple and portable, thus making it practical both in the acute and chronic settings. It may be administered around the clock, and reasonable clearances may be obtained, albeit not as efficiently as with hemodialysis. It avoids the use of vascular access catheters, and thus avoids complications such as bleeding (associated with anticoagulation), air embolism, thrombosis, and bacteremia. Because ultrafiltration occurs slowly, there is a lower risk of hypotension, especially in patients with severe heart failure who might not tolerate HD.[10] Thus, PD may also be of potential value to the hemodynamically unstable patient and may also theoretically limit ischemic injury to already failing kidneys in the setting of acute renal failure.

Slow solute and water clearance limit the use of peritoneal dialysis in acute situations such as drug intoxications, life threatening hyperkalemia, and severe pulmonary edema. The insertion of a peritoneal dialysis catheter requires an appropriate peritoneal cavity and abdominal wall, free of malignancy, infection, and adhesions. This is not always feasible in the acute situation, though it is not uncommonly done in the pediatric patient population.[11]

As a home-based therapy, PD is taught to patients and possibly other loved ones or caregivers over a 1- to 2-week training period. For the independent patients, this encourages responsibility for their own care. It offers a more liberal diet than HD and is more flexible in scheduling, which confers advantages to many patients who want to stay employed while on dialysis.

For diabetic patients, PD delays the use of suboptimal vessels for hemodialysis access and provides an intraperitoneal route for insulin administration, which often avoids the need for injections.

Complications and Limitations of Peritoneal Dialysis

In the United States, the hospitalization rate for PD patients is similar to that of HD patients, though their total days in the hospital are greater.[1] Peritoneal dialysis-related complications range from metabolic abnormalities to technical and infectious complications.

The most common symptom noted by patients undergoing peritoneal dialysis is abdominal distension. This is a function of the patient's size and the dwell volume as well as, to some extent, the degree to which the patient has acclimatized to their volume of intra-abdominal fluid. Excessive distension may occur if drainage is inadequate as fluid accumulates in the abdominal cavity. Various abdominal wall hernias are associated with PD, especially with increasing age and body mass index.[12] These may necessitate a technique change (to APD or HD) or occasionally, surgical intervention.

Catheter-related complications include pericatheter leaks, obstruction (inflow or outflow failure), kinking, and pain associated with fluid drainage. Infection of the exit site, tunnel, or peritoneal cavity may occur, and may occasionally require catheter removal or change.[13] While hospitalizations due to hemodialysis-related vascular access-associated infections continue to rise, the reverse has been seen with respect to PD-catheter–associated infections.[1] Metabolic complications of PD include hypernatremia (which may result from frequent exchanges where free-water is lost in excess of sodium, or excessive sodium sieving occurs)[14] and hyperglycemia, due to absorption of dextrose most commonly occurring in diabetic patients.[15]

Finally, protein losses through the peritoneum can be substantial and may preclude the use of peritoneal dialysis in extremely sick and catabolic patients.[16]

PD is a less durable therapy than HD. There are many reasons why a PD patient will eventually transfer to HD, including infection, inadequate dialysis (especially as residual renal function is lost), and failure to thrive.

Hemodialysis

Hemodialysis is the most widely used dialysis modality worldwide. The basic dialysis procedure involves the removal of excess water and solutes from blood passed along a semipermeable membrane within a dialysis filter, as blood is passed through an extracorporeal circuit. Diffusive loss of solute is promoted by the countercurrent passage of a dialysis solution of appropriate electrolyte composition along the opposite side of the semipermeable membrane. Convection, or ultrafiltration, is a process by which water and small solutes dissolved in it are drawn across the membrane by the application of hydrostatic forces.

In its most common form, hemodialysis is a treatment center-based therapy administered three times weekly for periods ranging from 2.5 to 5 hours. Most commonly, it is performed in full-care facilities, including hospitals and free-standing dialysis centers but can also take place in an assisted-care, self-care, or home-based setting, where supervised patients provide varying amounts of their own treatment.

Advantages of Hemodialysis

Hemodialysis is capable of achieving greater small solute clearance and water removal in a shorter period of time than peritoneal dialysis, thus it is more efficient. Rapid clearance is desirable in acute renal failure with its various metabolic derangements, because it is in the setting of intoxication with dialyzable substances and in life-threatening hyperkalemia and pulmonary edema.

Especially for dependent patients, center-based HD allows the responsibility of care to fall on the provider team instead of on the patient and family. The ease of insertion of temporary and semipermanent dialysis catheters makes this an easy

option for acute renal failure or for initiation of an unprepared new patient with ESRD.

Complications and Limitations of Hemodialysis

Because HD is an intermittent therapy usually delivered three times per week, many dietary restrictions are necessary. Transportation of patients from where they live to the dialysis facility can be an important challenge.

Setting up and running a hemodialysis unit requires specially trained nurses and technicians and can only be done in specialized centers. It also requires an appropriate water supply, though portable water treatment systems are now widely available. It also usually requires a large capital investment and space for patient treatment and support areas.

Hemodialysis carries with it all the complications of vascular access, including the line insertion and/or surgical procedures and systemic anticoagulation. The high blood flow rates used in a typical hemodialysis procedure require the presence of an adequate cardiac output, occasionally limiting the use of hemodialysis to relatively hemodynamically stable patients and those with reasonable cardiac function.

The hemodialysis procedure is generally well tolerated. Certain conditions may, however, predispose patients to various complications. Patients who begin dialysis with very high blood concentrations of urea and other solutes may experience symptoms related to a rapid drop in serum osmolarity, which can cause cerebral edema. Symptoms can include headache, nausea, vomiting, and in severe cases, seizures, obtundation, and coma. Hypotension is another common hemodialysis complication that results from a rate of intravascular volume removal that exceeds the rate of plasma refilling from the interstitium. This most commonly affects patients with large interdialytic weight gains or impaired cardiac function, as well as those on antihypertensives to control high blood pressure between dialysis treatments. Restless legs, nausea, vomiting, and headache are not uncommon symptoms on dialysis even in the absence of disequilibrium. Leg cramps are quite common, especially when excessive fluid is removed. Less common acute complications include dialyzer reactions, arrhythmias, seizures, hemolysis, and cardiac tamponade.

Home-Based Hemodialysis

In the early days of dialysis in the 1960s and 1970s, home-based hemodialysis was a significant modality. Utilization has dramatically declined to a current rate of only 1% to 2% in the United States and in Canada. This decline was mainly due to technical complexity and caregiver burnout.

However, there is a recent surge in interest in home hemodialysis.[17,18] New patient-friendly machines are being developed by the dialysis industry; these may allow more patients to qualify for and to select home hemodialysis. Home helpers (caregivers) are no longer a requirement.

Conventional home HD utilizes a thrice weekly schedule that mimics intermittent, center-based HD. Recently, the menu of choices has expanded, such that daily (or 5–6 days per week) home HD is attracting increasing attention and excitement.

Home HD shares many advantages of home PD, with flexible diet and scheduling. It is, however, considerably more technically complex. Training requires 4 to 8 weeks, and the complexity precludes its use in many patients. From a health care system perspective, an important advantage is that fewer dialysis nurses and technicians are required to sustain patients on home hemodialysis than on center-based HD, and the capital cost and space requirements are much less. Nephrologists are enthusiastic about an increased role for home HD in the future.[19–21] Delays in approval of adequate public funding of daily home HD in the United States and in Canada are currently limiting the potential growth of these new modalities.

Frequent Hemodialysis Regimens

Frequent HD regimes are ideally suited to the home environment. Daily HD, however, has been successfully applied to an older and sickly center-based population with excellent results.[22] The potential negative financial consequences of this full care, center-based approach are very substantial. The direct cost of daily dialysis is much greater than the cost of thrice weekly, and the incremental requirements for skilled personnel and space are high. At the time of writing, there are no funded programs outside of research settings of which we are aware. Nonetheless, from a theoretic point of view, the comments below apply to both home-based and in-center daily HD.

In 1978, Kjellstrand and associates[23] acknowledged the "unphysiology" of dialysis as a major limitation of the conventional thrice-weekly intermittent hemodialysis regimen. The intermittency of the conventional hemodialysis regimen is associated with large osmotic and fluid shifts, which are insults that are associated with unpleasant symptoms and adverse outcomes, such as left-ventricular hypertrophy. Given that normal kidneys perform so many physiologic functions, and that they do so on a continual basis, it can be understood why the term "renal-replacement therapy" could be viewed by some as an overstatement when applied to conventional, intermittent thrice-weekly hemodialysis.

Frequent dialysis has evolved from the belief that more dialysis treatments per week result in smaller osmotic, electrolyte, and fluid shifts per treatment, while delivering overall more efficient solute clearance. Because of the large volume of distribution of many solutes, they are often cleared from the blood within the first hour of dialysis, with diminishing returns towards the end of a 3- or 4-hour dialysis treatment. This is followed by a rebound phenomenon, where solutes such as urea, for example, redistribute themselves as they shift from the intracellular space to the vascular compartment. Shorter, more frequent dialysis capitalizes on the high rate of solute clearance that is achieved in the first hours of a dialysis and does so twice as frequently as conventional dialysis, removing more uremic waste per unit time and causing less fluctuation in serum levels of various electrolytes and other solutes.

Various terms have been applied to describe frequent dialysis regimens, including "quotidian-" and "hemeral-" dialysis. Frequent dialysis can be delivered in various forms, the most common of which are high-efficiency (hemeral) short-hours daily dialysis and long-hours, slow nocturnal dialysis. Typically these regimens are administered between 5 and 7 days a week. Short-hours daily dialysis typically consists of 1.5- to 2.5-hour runs with blood and dialysate flow rates similar to those used in intermittent HD. Slow nocturnal dialysis is usually given over a 6- to 8-hour period, with slower blood and dialysate flow rates, while the patient sleeps.

The benefits of the various quotidian dialysis regimens are protean and can only be described briefly here. From the patient's perspective, improved quality of life and an improved overall sense of well-being have been universally observed in studies of quotidian dialysis. Rather than spending the better part of each post-dialysis day recovering from their last treatment, quotidian dialysis patients reported no longer feeling "washed-out" after their treatment. On the contrary, many are able to disconnect from their dialysis circuits and immediately go about their regular days' activities.[24] Since these are largely home-based therapies, patients enjoy greater independence and flexibility and are often able to return to work. Because of improved volume control, blood pressure is well-controlled with little or no medication.[25–27] This has been shown to promote regression of left-ventricular hypertrophy, an independent predictor of mortality. Calcium and phosphate balance are more easily regulated, and patients, particularly on long nocturnal dialysis, may actually require phosphate supplementation to maintain a neutral phosphorus balance.[28,29] Patients typically have lower calcium-phosphate products, with less need for calcium-based phosphate binders. Small solute clearance is markedly improved, with less post-dialysis rebound in urea and electrolyte concentrations.[30]

The major limitation to the use of these modalities, at least in the home setting, is that the patient must be able to learn and perform the dialysis procedure either independently or with assistance, thus limiting quotidian dialysis to a smaller subset of the ESRD population. One theoretic disadvantage is direct cost, given that the dialysis materials used must double, and that each dialysis machine is used to treat one patient only instead of the many patients who might be treated with it in a dialysis unit. There is, however, increasing evidence that, in addition to improving all of the previously mentioned biochemical and physiological parameters and quality-of-life, quotidian home dialysis actually results in a net cost savings, even when the large up-front cost of the dialysis machine and its installation are accounted for.[31–33] This is largely attributable to the reduction in nursing costs, drug costs, and fewer hospitalizations.

As growing evidence accumulates, quotidian dialysis therapies may emerge as the treatment of choice for suitable ESRD patients for whom renal transplantation is not immediately available. Also, frequent in-center therapies await further evaluation with respect to efficacy and cost-effectiveness. A recent report shows that patients with high comorbidity have improved outcomes with daily in-center HD compared to conventional HD.[22]

Finally, since most quotidian dialysis studies to date have been small, they have not been adequately powered to assess survival. Theoretically, a treatment that promotes regression of LVH and improves blood pressure, anemia, nutritional status, and the calcium phosphorus product should confer some survival advantage over conventional thrice-weekly dialysis, but larger-scale prospective randomized trials will be needed to confirm this. At the time of this writing, such studies are planned and their findings are eagerly awaited.

Preemptive Renal Transplantation

It is with virtual unanimity that renal transplantation is accepted as the treatment of choice for end-stage renal disease.

As compared with dialysis, transplantation has been shown to improve quality of life, reduce mortality, and to reduce the cost of caring for patients with ESRD.[34] With the ever-growing size of the CKD population, there has been an increasing relative shortage of donor organs. This has underlined the need to continue to develop strategies that will improve long-term graft and patient survival, and to do this in a cost-effective manner. Preemptive transplantation offers the potential to improve these important outcomes while containing costs. This section will review evidence for transplantation as a dominant strategy in ESRD care and will present a rationale for vigorously promoting preemptive transplantation where possible.

Survival

Transplantation has long been thought to improve survival in patients with ESRD. Factors that have been shown to impact on long-term patient survival include, but are not limited to, the source of the allograft, patient age, comorbid conditions, gender, race, and degree of immunosuppression. Patients with hypertension, diabetes, advanced age, and those who smoked or received kidneys from cadaveric donors have less favorable outcomes than patients without these factors.[35]

Earlier trials showing improved survival with transplantation were limited by selection bias, since they compared transplant patients with patients still on dialysis, who were presumably older and carried a greater burden of comorbid illness.[35–37] A more recent study attempted to overcome this problem by comparing patients who underwent transplantation with patients awaiting transplantation, groups that are more similar with respect to baseline demographics and comorbidity.[38] This longitudinal survival study, which included over 200,000 patients on dialysis (of whom 23,275 were transplanted), showed that despite a transient increase in early mortality post-transplantation, there was a 42% to 82% reduction in long-term mortality among cadaveric renal transplant recipients as compared with their waiting-list counterparts (Figure 15–1). The survival benefit was greatest in younger patients, Caucasians, and younger patients with diabetes, though elderly patients had improved outcomes with transplantation as well. Comparisons between peritoneal dialysis and hemodialysis transplant recipients have not demonstrated any significant differences.[39]

Quality of Life

Although there are no prospective randomized controlled trials to address the issue of quality of life (QOL) in transplantation, it is generally agreed upon that transplantation offers the best possible QOL of any form or renal-replacement therapy. In one study in which an SF-36 questionnaire was completed by renal transplant recipients, patients on peritoneal dialysis or hemodialysis, and healthy control subjects, transplant patients rated their perception of health higher than either dialysis patient group in six out of eight scales. Transplant patients scored lower on only two and higher on one out of eight scales as compared with healthy subjects.[40] These findings were corroborated in a similar study that also used covariate analysis to control for case-mix.[41] A large meta-analysis that included 218 smaller studies and 14,750 patients found statistically significant pre- to post-transplant improvements in
Figure 15–1 Adjusted relative risk of death among 23,275 recipients of a first cadaveric transplant. The reference group was the 46,164 patients on dialysis who were on the waiting list (relative risk, 1.0). Patients in both groups had equal lengths of follow-up since placement on the waiting list. Values were adjusted for age, sex, race, cause of end-stage renal disease, year of placement on the waiting list, geographic region, and time from first treatment for end-stage renal disease to placement on the waiting list.

physical functional QOL, mental health/cognitive status, social functioning, and overall QOL perceptions.[42]

Cost-Effectiveness

USRDS financial data from 2001 (Figure 15–2) depict the relative per-patient per-month costs of incident transplant events, functioning graft care, and dialysis.[1] Despite the increased upfront cost of transplantation, the overall financial benefits are substantial, with graft maintenance costs around one-quarter to one-fifth less than dialysis costs. Given that transplantation provides both improved quality of life and better survival than any other form or renal replacement strategy, and given its
Figure 15–2 PMPM expenditures, by modality: Prevalent patients. (From USRDS Annual Report, 2002.)

lower overall cost, transplantation must be viewed as a dominant strategy. The cost-effectiveness of transplantation is limited only by the donor organ supply.

Preemptive Transplantation

In the traditional approach to ESRD care, patients with progressive chronic kidney disease would eventually begin some form of dialysis and, if appropriate, would subsequently be evaluated and listed for transplantation. If a patient were fortunate enough to have a suitable and willing living donor, the option of transplantation prior to the initiation of dialysis, that is, preemptive transplantation, exists. In some countries, this concept has been broadened to include the use of cadaveric-donor kidneys. These two strategies differ with respect to their financial and ethical implications, as will be discussed below. Preemptive transplantation rates vary internationally. In Austria, Germany, and Ireland, preemptive transplantation is hardly practiced at all.[43] In the United States, approximately 25% of all live donor transplants are performed prior to initiation of dialysis.[44,45] In Sweden, on the other hand, preemptive transplantation is the standard of care for children and makes up about 70% of all transplants in the pediatric population.

Proposed Benefits and Limitations of Preemptive Transplantation

Preemptive transplantation offers many theoretic advantages. The first and most obvious of these, from the patient perspective, is the potential to avoid dialysis and its associated morbidity and inconvenience. In addition, the patient can avoid vascular access surgery. From a financial perspective, avoiding dialysis spares both the cost of vascular access surgery and the cost of dialysis itself. Preemptive transplantation may also limit the amount of time away from employment, as compared with dialysis, thus conferring an economic advantage to both the patient and to society. One case-control study from the United States compared matched patients who were on dialysis for a minimum of 6 months prior to transplantation, with patients transplanted preemptively. Patients in the preemptive transplant group were more likely to be employed 6 months post-transplant.[46]

Many clinical benefits to preemptive transplantation have been proposed. The most important of these are improved graft and patient survival, which are discussed in more detail in the following section. The potential for improved cardiovascular health (discussed below) and the avoidance of blood transfusion (particularly in hemodialysis) also make preemptive transplantation attractive.

The most frequently cited potential disadvantage to preemptive transplantation is that of noncompliance with immunosuppressive therapy. It has been argued that having never had to suffer the inconvenience and morbidity associated with dialysis, or the unpleasant symptoms associated with advanced chronic kidney disease, such patients might be less inclined to endure the burden of a rigorous drug regimen and its associated side effects. One small study that failed to show any benefit to preemptive transplantation attributed this failure to noncompliance in the preemptive transplant group.[46] Most studies, however, have failed to demonstrate any significant differences in compliance between preemptive and nonpreemptive transplant recipients.[47,48]

Biochemical and Immunologic Factors in Preemptive Transplantation

There are many theoretic reasons why preemptive transplantation may confer both improved patient and graft survival. Patients transplanted before the initiation of dialysis are less likely to have ESRD-related complications, including cardiovascular disease, malnutrition, and chronic inflammation. The associations between these various factors are numerous and complex.

Many biochemical indices have been correlated with adverse outcomes in patients with ESRD. High levels of C-reactive protein, abnormal lipoprotein profiles, and low serum albumin, for example, have all been associated with an increased risk of death in patients on dialysis.[49] Additionally, atherogenic endothelium-related molecules, such as tissue plasminogen activator, von Willebrand factor, endothelin, and homocysteine, for example, are present in higher levels in patients on maintenance hemodialysis than in healthy subjects.[50–53] Because many of these factors increase with time on dialysis, patients who undergo transplantation prior to the initiation of dialysis may theoretically have a lower risk of cardiovascular and renal allograft vascular injury.

Preemptive transplantation has been associated with a lower incidence of acute rejection. A large retrospective cohort study using USRDS data found a 52% reduction in the rate of allograft failure in the first post-transplant year, and further reductions in subsequent years in patients who received preemptive transplantation from a living donor, as compared with matched cohorts who received living donor transplants after the initiation of dialysis. This was partially attributable to reductions in acute rejection episodes and points to the known immunologic differences between dialyzed patients and CKD patients not yet on dialysis.[54] Hemodialysis has, for example, been associated with improvements in T-cell proliferation,[55] as well as changes in cytokine expression, which may thus result in increased rejection rates.[56]

Another fundamental difference between patients who are dialyzed and those who are not is the level of residual renal function (RRF). The idea that RRF may protect the graft from hyperfiltration injury (and vice versa) has been proposed.[57]

Waiting Time on Dialysis: A Strong Predictor of Transplant Outcomes

Although early studies showed favorable outcomes for patients undergoing preemptive transplantation, it was not initially clear whether or not time on dialysis itself independently predicted the poorer outcomes observed in patients transplanted after the initiation of dialysis.[47,58] This was largely because of the inability to exclude selection bias and the possibility that healthier patients had been chosen for preemptive transplantation in earlier studies. In a study by Cosio and associates[59] time on dialysis was found to correlate inversely with patient survival but occurred independently of confounders, such as patient age and comorbid factors. This study, however, also showed that patients who had been on dialysis for longer periods of time had a greater prevalence of left-ventricular hypertrophy (LVH), suggesting that the deleterious effect of a longer time on dialysis was at least, in part, due to the development of LVH, a known independent risk factor for cardiovascular death. In this study, death-censored graft survival was not significantly different between the preemptive and nonpreemptive groups.

A later analysis of data from the USRDS showed not only that time on dialysis was associated with reduced graft and patient survival, but also that death-censored graft survival was worse with increasing time on dialysis.[60] This further strengthened the hypothesis that time on dialysis was an independent predictor of graft loss. This was true for both cadaveric and living donor transplants. This study also showed that the magnitude of the effect of time on dialysis was the same across all major comorbid disease groups, arguing against the view that cumulative disease burden (such as cardiovascular disease) was the main cause of poorer graft survival in patients with longer wait times.

Finally, in an attempt to quantify the impact of time of dialysis on graft and patient survival, Meier-Kriesche and associates[61] analyzed data from 2405 kidney pairs harvested from the same donor and transplanted into one patient with a short waiting time and another with a long waiting time. This controlled for unknown base-line donor characteristics. Using a Cox proportional hazards model, they quantified the risk of time on dialysis on graft function and found overall adjusted 10-year living donor graft survival to be significantly different at 75% and 49% for patients transplanted before 6 months and after 24 months of dialysis, respectively (Figure 15–3). A similar trend was observed for cadaveric transplants (Figure 15–4). Preemptive cadaveric transplantation offered the same graft survival as a living donor transplant done after 24 months of dialysis.

Preemptive Transplantation with a Living Donor

Despite efforts to increase the availability of donor organs worldwide, the supply of cadaveric kidneys has failed to meet the demands of the growing ESRD population. The living donor pool was once restricted to closely-related family members who were more likely to share HLA antigens, thus lowering the risk of rejection. With modern advances in immunosuppressive therapy, HLA compatibility has become less of a limiting factor in long-term graft survival. The living donor pool has been broadened to include not only extended relatives, but also unrelated donors, with long-term outcomes comparable to those seen in living related donor transplants, and superior to cadaveric donor transplants.[62] The living donor pool is, in fact, the most rapidly growing source for renal allografts in the United States.[1]

Kidneys from living donors offer many advantages over grafts from cadaveric donors, including improved long-term graft function and a markedly lower incidence of delayed graft function (DGF). This is partly attributable to differences in warm ischemic time.

Based on current evidence, living donor preemptive transplantation offers outcomes that are at least equivalent to and likely superior to any other known form of renal replacement therapy. Living donor preemptive transplantation offers not only the best possible outcome to patients with CKD, but also makes use of the largest growing organ donor pool in the developed world and likely minimizes ESRD costs. Where possible, it should thus be promoted as the treatment of choice for patients with ESRD.
Figure 15–3 Unadjusted graft survival in 21,836 recipients of living transplants by length of dialysis treatment before transplant.
Figure 15–4 Unadjusted graft survival in 56,587 recipients of cadaveric transplants by length of dialysis treatment before transplant.

Preemptive Cadaveric Renal Transplantation

In the case of preemptive cadaveric renal transplantation (PCRT), there are certain logistic concerns that cannot be ignored. The most important of these is that it is often difficult to accurately predict when renal replacement therapy will be required. Owing to the unpredictability of organ availability, it can often be very difficult to time transplant surgery optimally. If the patient is listed for transplantation early, and a cadaveric organ becomes available, then they will have lost many months of native organ function. This also translates to more months of dialysis therapy for a patient already on dialysis who might have otherwise received that organ. From an ethical perspective, this may seem unfair because the patient already on dialysis may be seen as being more "entitled" to receive that same donor kidney. Conversely, one must be prepared to deal with long waiting times, and dialysis may ultimately need to be started before an organ becomes available. This makes it difficult to appropriately time vascular access surgery, or else results in the use of temporary catheters. This, however, may not be much of a problem in countries where

the cadaveric donor pool is well matched to the size of the transplantable population. In most developed countries, however, cadaveric kidneys are in short supply, making PCRT not only unethical, but also impractical.

Circumstances have been described in which PCRT may be justifiable. It has, for example, been suggested that growth is better preserved in children who are transplanted early as compared with those treated with chronic dialysis.[63] Some have argued that a patient with dependent family members such as young children should be offered every opportunity to remain employed, and that avoiding dialysis in such a patient justifies PCRT.[43] Others have argued that optimization of HLA matching may be an indication for early listing on the cadaveric donor list. This would allow for highly selective donor matching and would be justified on the basis of improved long-term graft survival.[47]

In countries where the organ supply is more easily met and wait times are estimated to be less than 1 year, PCRT may be a feasible option. Belgium and Austria, for example, have annual cadaveric kidney donor rates equal to the yearly demand. Under these circumstances, it is recommended that patients be listed when the GFR is less than 15 mL/min.[43]

Preemptive Transplantation in Developing Countries

In addition to improved graft and patient survival, preemptive transplantation may offer advantages specific to the developing world.[64] The transmission of infectious diseases is of particular interest. In countries where the incidence of hepatitis B and C is high, a strategy that minimizes blood transfusion is desirable, because liver disease with hepatitis B-antigen positivity, for example, is associated with increased morbidity and mortality in renal transplant patients.[65,66] Other infectious diseases, such as tuberculosis, are more prevalent in dialysis patients as well[67] and are of even greater importance in the developing world. Such infections can complicate, if not preclude, transplantation. Finally, cost is often the greatest barrier to receiving renal replacement therapy in developing countries, and many countries have no publicly funded dialysis system.[68] The cost-effectiveness of preemptive transplantation might make it available to a proportion of the CKD population in countries where financial resources are scarce.

OUTCOMES WITH HEMODIALYSIS AND PERITONEAL DIALYSIS

Modality Comparisons

Any evaluation of the relative merits of HD and PD must, of course, take into account outcome data. Although some comparative studies have addressed hospitalization rates and measures of quality of life, the most frequent and objective end point is patient survival.[69,70]

Methodologic Issues

The complexities of comparative modality studies cannot be well understood without first taking into account methodologic issues. The results are hugely influenced by the type of analysis that is done.

The first and most important point to make is that all existing comparative studies are observational, and most are based on retrospective analyses of large national registry databases. There are no successfully completed randomized controlled trials comparing HD and PD, and none is ever likely to be done, given the stark differences between the two modalities and the consequent unwillingness of most patients to be randomized to one or another. This point was highlighted by the recent thwarted attempt of investigators in the Netherlands to perform a randomized trial.[71] All the evidence that we have is therefore based on suboptimal experimental design with major potential for confounding and bias.

The first methodologic challenge that comparative studies face is the need to correct for the biases in modality selection that occur at the initiation of dialysis. In some countries, such as Italy and Spain, data suggest that PD patients tend to be older with more comorbidity.[72] However, detailed data from the United States and Canada suggest the opposite to be the case in those countries.[73,74] U.S. patients starting PD tend to be younger and to have less comorbidity than their HD counterparts. They are, however, more likely to be Caucasian rather than black, and to be diabetic, both adverse prognostic factors. Other baseline characteristics that are sometimes adjusted for

include residual renal function, nutritional measures, body size, and serum albumin. Additional ones that are rarely adjusted for because of lack of information but that may be important include level of education, adherence, motivation, social supports, and socioeconomic status.

With regard to the mortality analysis itself, a variety of other issues arise. Some comparative studies are "intent–to–treat" (ITT) and others are "as treated" (AT). Both approaches are valid and answer related, but distinct, questions. The first asks whether initial modality allocation effects ultimate outcome and so is important to the clinician advising the patient on initial modality selection. The AT analysis is an attempt to answer the fundamental question as to which modality is inherently superior. It is now customary to do both ITT and AT analyses in comparative studies in order to maximize the overall robustness of the analysis, as well as to answer the two distinct questions.[73] Some studies use hybrids of the two methodologies by censoring the ITT analysis at the time of a modality switch.[75] A related but somewhat distinct issue is whether the analysis looks at incident or prevalent dialysis patients. An incident analysis is always preferred.[76] Patterns of early dropout may lead to biases in purely prevalent analyses.

Another important point is when to begin the modality comparison. The first day of dialysis might seem appropriate, but early mortality on dialysis is likely more related to preexisting comorbidity than to the modality chosen. Also, acutely ill patients and urgent starts more often initiate with HD rather than with PD. Accordingly, it is customary to start the comparison 60 or 90 days post-initiation. Waiting longer until 4 or 6 months post-initiation may introduce a bias against PD for reasons that will shortly be discussed. Work by Foley[77] and other authors[74] suggest that this issue has a marked influence on comparative mortality analyses. Again, a good compromise is to perform the analyses at a variety of start points, that is, 0, 60, 90, 120 days, and so forth.[76] Unfortunately, registries such as the USRDS do not have data prior to 90 days post-initiation.

A number of observers have noted that the relative hazards of mortality between HD and PD are not consistent with time. It is therefore misleading to use the Cox proportional hazards model in a comparative analysis, precisely because mortality rates are not "proportional." Foley[77] has argued that the best technique to get around this is to use repeated Cox analyses starting, for example, at 0, 12, 18 months, and so forth. The reasons for this disproportionality are controversial. One is the already mentioned tendency in many centers for urgent, sicker, more acute starts to use HD as initial therapy. This may explain the higher mortality seen with HD early on. Even among more elective starts, there is a clear trend in North America for PD patients to be younger, and to have less comorbid conditions and adjustments for these characteristics may be incomplete.[73] An additional explanation, however, is that superior preservation of residual renal function in PD patients may be playing a role in the first 1 to 3 years on that modality. This is difficult to prove, but the survival advantages of residual function are well recognized and the observation is plausible. Conversely, in later years of PD, more patients are anuric and at greater risk of volume overload, hypertension, and low clearance. In some cases, gradual membrane deterioration occurring with time on PD may also predispose to fluid overload. Another explanation for the trend for long-term HD

patients to do relatively better than those on long-term PD, is the possible cumulative atherogenic effect of the peritoneal dialysate glucose.[78]

One more feature of comparative mortality studies that needs to be taken into account is that the results are often outdated by the time they are published. Both HD and PD are constantly changing. Recent changes in HD include more widespread use of high flux membranes, a tendency to deliver higher clearances, the greater use of central catheters as long-term access, and some fall off in the practice of membrane reuse. In PD, recent changes include much greater use of automated cyclers, widespread use of polyglucose solutions, and higher delivered clearances.[79–81] Comparative analyses, based in registry data, are frequently 4 to 8 years out of date by the time they are published.[73,82,83] In the context of changing practices and of apparently declining mortality rates, this places a question on the relevance of the results to contemporary practice.

Results of Comparative Studies

The majority of published data comparing PD and HD mortality has come from the United States and Canada, although there has been some contributions from Europe.[84–86]

A landmark, but flawed study, by Bloembergen and associates[82] from the USRDS, published in 1995, set off the present controversy in this area. This analysis covered a 3-year period in the late 1980s and assigned patients each year to the modality they were using on January 1. On average, this methodology leads to the omission of the first 9 months of time on dialysis, the period when PD does best in comparative studies. Not surprisingly, therefore, the results showed superior survival on HD (Relative Risk [RR] 1.17), particularly in older patients, in females, and in diabetics. A similar analysis covering the early 1990s omitting less of the early time on dialysis, was carried out by Vonesh and associates.[87] This showed that the advantage for HD was of borderline significance, was getting less with time, and was again concentrated in older female diabetics.

Collins and associates[75] used more contemporary data from the mid-1990s to address this issue. A more appropriate ITT analysis of incident dialysis patients was used with censoring occurring after transplantation or modality switch. This study looked at patients beginning 90 days post-initiation of dialysis and covered the 2 subsequent years. This is the period where PD tends to do best and the results showed a substantial advantage for PD in nondiabetics of all ages and also in younger diabetics (Figure 15–5). Only in older female diabetics did HD have the advantage. The contrasting results of the Bloembergen and Collins studies may partly be explained by a change in relative mortality rates between the two modalities over a 10-year period, but it largely reflects the huge influence of the time period after initiation of dialysis that has been covered by the study. Analyses dominated by incident patients always show PD as looking better than those dominated by prevalent or longer-term patients.

In Canada, analyses by Fenton and associates[74,88] from the Canadian Organ Replacement Register (CORR) performed in the early and mid-1990s showed a consistent advantage for PD in all groups except older diabetics. This was the case with both ITT and AT methodologies (Table 15–1). The mortality advantage for PD again tended to lessen with time and by 3

years post-initiation there was no difference. Correction for comorbidity was incomplete in all these United States and Canadian registry-based studies. The Fenton data for Canada had more adjustment for comorbid conditions than did the Collins or Bloembergen studies, but all were limited.

Murphy and associates[76] from Canada used a prospective cohort of almost 1000 patients with detailed comorbidity data to get around this issue. They found that much of the apparent PD survival advantage was removed once more complete adjustment was done, taking into account degree or severity of comorbidity as well as numbers of comorbid conditions.

Comparative mortality data from Denmark and Italy have shown similar patterns of an early advantage for PD followed by a later tendency for HD to do better.[84] New data from the Netherlands showed no difference in survival between PD and HD during the first year but then saw a tendency for HD patients to do better than PD patients, especially those over the age of 60.[86]

By the beginning of the 1st decade of this century, it appeared that some consensus had thus been reached on

comparative mortality data with a convergence of findings internationally.[89] In general, PD appeared to have an early advantage, most marked in young and nondiabetic patients and related to a variety of factors, including, perhaps, unmeasured baseline case mix differences and better residual renal function preservation. With time, risks equalized and then started to favor HD. The duration of the advantage for PD was least in older diabetics, particularly in those who were female. The advantage for PD was also of shorter duration in the United States compared to Canada and Europe. These findings gave some credence to the notion that PD was particularly suitable as an initial modality with patients subsequently being switched to HD, either electively or as problems arise. This approach, which has been sometimes described as "PD first" has been used to varying degrees in a variety of countries.[90–92]

Recent Analyses

In 2003, however, new analyses based on USRDS data reopened the modality controversy.[73,83] Two papers from the same group looked at over 100,000 incident dialysis patients from the mid-1990s and examined the effect on comparative mortality of the presence or absence of coronary heart disease (CHD) and congestive heart failure (CHF). The analysis was more sophisticated than that of previous USRDS studies in that it used both ITT and AT methodologies. More importantly, it redid the analysis at 6-month intervals to deal with the issue of nonproportional hazards. Of 108,000 patients studied, 87% were on HD and 13% were on PD. At baseline, 26% had overt CHD, 74% did not. Over 2 years, the mortality rate for those with CHD was 34% on HD and 36% on PD, whereas for the larger group without CHD, it was 23% on HD and 18% on PD.[73] However, after adjustment for a variety of baseline demographic, comorbid, and laboratory test characteristics, diabetic patients with CHD had a 23% higher mortality risk than those on PD, whereas those without CHD had a 17% higher risk (Figure 15–6).[73] Among nondiabetics, those with CHD had a 20% higher mortality risk, whereas those without CHD had a 1% lower risk on PD.[73] Results for those with and without CHF were generally similar.[83]

These studies have raised the concern that PD might be problematic in the 25% to 35% of ESRD patients who have clinically overt cardiac disease at initiation, and indeed in diabetic patients in general, also. The notion of PD as a more atherogenic therapy has thus gained some credence.[78] However, the weakness of this type of analysis must be remembered. The completeness of the adjustments for potential confounding factors is always in doubt. Baseline data come from "Medical Evidence Forms" filled in at initiation of dialysis, and the reliability of these has been questioned.[93] No information on the severity, as distinct from the presence and absence, of comorbidity is provided. Furthermore, the data from these studies are already 5 to 7 years old and come from a period when use of antiatherogenic lipid lowering therapy was less common in ESRD patients and when there was less emphasis on glucose sparing strategies in PD in these studies.[73,83] The majority of patients without overt cardiac disease did well on PD.

Recent evidence suggests that PD mortality and technique failure rates in North America continue to fall impressively.[81,94,95] Furthermore, it is uncertain how much these data

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

Figure 15–6 Adjusted Cox survival curves for new ESRD patients with coronary artery disease treated with peritoneal dialysis (PD) versus hemodialysis (HD). Adjusted for age at study start, sex, race, cause of ESRD, hypertension, congestive heart failure, peripheral vascular and cerebrovascular disease, tobacco use, chronic lung disease, AIDS, neoplasm, serum albumin, body mass index, hematocrit, estimated GFR, and pre-ESRD erythropoietin use. *P = .0001. (From Ganesh et al: Mortality differences by dialysis modality among incident ESRD patients with and without coronary artery disease. J Am Soc Nephrol 2003; 14[2]:415-424.)

can be extrapolated to ESRD populations outside the United States. Nevertheless, the data do merit attention and should be a "call to arms" to PD practitioners to focus particularly on management of cardiac risk factors and disease in the PD population. Greater use of cardioprotective and lipid lowering medications and more attention to volume status are required. A focus on reducing exposure to the potentially harmful effects of hypertonic glucose by using alternative solutions, especially in patients who are diabetic, obese, or who have overt cardiac disease, would seem desirable.[78]

Conclusion

How do all these data help the clinician when approaching modality selection in the individual patient? All this published evidence is observational, predominantly retrospective, and registry-based and so is prone to confounding. In general, the apparent benefits for one modality over the other in these studies are modest compared to the influence of other larger factors such as age, diabetes, and heart disease. Modality decisions should therefore be based primarily on the personal preferences and social circumstances of the patient concerned. These are of greater relevance to the individual patient. PD may have particular advantages in younger and in nondiabetic patients, but this does not mean all such patients should be directed to PD. Similarly, HD may have apparent advantages in older diabetic patients and in those with overt cardiac disease, but this does not mean that all such patients should be placed on HD. The apparent advantages for one or other modality in these patient subgroups are too modest, are based on evidence that is too unreliable and are too dated to justify such an approach. Rather, the patient should be exposed to information about each modality, and, as far as possible, an

informed choice should be made. Regardless of the chosen modality, greater attention should be focused on reducing cardiovascular risks with appropriate medications, lifestyle adjustments, and modifications in the dialysis prescription.

Modality selection in many settings is, of course, complicated by resource issues.[96] In many jurisdictions, the rising cost of ESRD care in general and the lower general cost of PD compared to HD adds an additional complexity to the modality selection process.[91,92] The notion of PD as a preferable initial therapy for many patients with a subsequent elective switch to HD, if problems arise, is an attractive and potentially cost-effective strategy that takes economic data as well as patient outcomes into account and tries to give the patient the best of both modalities.[90] The advent of new home HD modalities also provide opportunities for an integrated home-based approach, using both PD and home HD for provision of renal replacement therapy.[97]

PATIENT ISSUES IN MODALITY SELECTION

Given that (1) all dialysis modalities are imperfect, (2) outcomes are similar with the two dominant forms of treatment (center-based HD and home PD), and (3) costs are lower with home-based dialysis, then it seems reasonable to promote a dialysis modality distribution that reflects these factors. In theory, this would lead to a greater proportion of patients using home dialysis therapies (PD and HD). There are, however, a myriad of factors that interact to cause marked deviations from what one might consider to be an ideal distribution of dialysis modalities.

For the sake of this discussion, we will divide these factors into patient-related factors and system-related factors. In fact, there is often considerable overlap, and in a given patient and/or health care system, many factors may be operating simultaneously.

It is generally agreed that the majority of patients could do either home PD or center-based HD. However, in a minority of patients, there are strong medical or social issues that might cause the provider to recommend, or even insist upon, one form of treatment and not another.

Patient Preference

There is also a general agreement that if a patient has no strong indication for or against a certain form of therapy, that patient preference should be the prime determinant of modality selection. Indeed, recent surveys of nephrologists in Canada, in the United States, and in Europe all show this strong opinion.[19–21, 98]

Allowing patient choice to drive modality selection raises some interesting ethical issues. Utilitarian considerations could be used to justify mandating a less costly form of dialysis for suitable patients. In this way, scarce resources could be used to treat more patients and/or to deliver more expensive and presumably higher quality of care.

On the other hand, the prime imperative in the minds of nephrologists seems to be autonomy in that competent and informed patients should make up their own mind about competing treatment methods, especially when outcomes are not proven to be different. This position is likely strengthened by the realization that forcing patients to take responsibility for a technical, home-based therapy when they do not want to could lead to complications and undermine the likelihood of a successful outcome.

Indeed, there is evidence that empowering patient choice would not lead to an imbalance of modality distribution in favor of more expensive therapies. It has been shown in several studies in Canada, in the United States, and in Europe that patients given appropriate education will choose a method of home dialysis about 50% of the time.[99–102] This has important implications for global costs of dialysis and for modality distribution in most jurisdictions in the Western world.

In practice, the ideal of empowerment of patient choice may not always be a reality. Consider the example of the United States, where more than 90% of its prevalent dialysis patients are on HD and only 8% on PD. Although American nephrologists say that patient preference is the most important determinant of modality decisions,[21,98] recent USRDS Wave II data suggest that only 25% of the selected HD patients recall ever having PD discussed as a modality option.[103] One can speculate that this heavy reliance on HD may be excessive in some regions, limiting patient choice and constraining some patients to treatment regimes that might limit their independence and compromise their lifestyle. Furthermore, this apparent lack of empowerment of patient choice is contrary to ethical principles valued by nephrologists and serves to drive up the overall cost of ESRD care.

The Canadian Society of Nephrology takes on the issue of whether providers should be educating patients in a completely unbiased way and allowing free choice of modality, or whether providers are allowed to promote home dialysis first. The Canadian Society of Nephrology (CSN) policy articulated in a document called "Principles of ESRD Care"[104] states that providers should be encouraging patients to choose less expensive home-based therapies, although they must not be made mandatory.

Medical Factors Affecting Initial Choice of Modality: Indications and Contraindications

Although the list of medical and social contraindications to one form of dialysis is long, in practice most patients will not have an absolute indication or contraindication. It is of interest to note that there are few contraindications to center-based HD, more to home PD (medical and social), and most to home HD (especially social). Indeed, the aging of the dialysis population is a well described phenomenon. Although age per se is not felt to be a contraindication for home dialysis therapies,[19–21] age is associated with many medical and social comorbidities that make home dialysis difficult or impossible. This is one reason why home dialysis has been in decline.

In a prospective cohort study of incident HD and PD patients, the Choices for Healthy Outcomes in Caring for End-Stage Renal Disease (CHOICE) Study Investigators observed significant differences between these groups with respect to comorbidity burden.[105] Using the Index of Coexistent Diseases (ICED) to measure comorbidity across 19 medical conditions, they found that overall, PD patients had fewer and less severe comorbid illnesses at the initiation of dialysis. The incidence and severity of heart failure, arrhythmia, other heart conditions, gastrointestinal disease, respira-

tory conditions, and physical impairment were substantially lower in PD patients, even after adjusting for other factors affecting modality selection. This finding is corroborated by at least one other recent study.[106] The authors concluded that patients with a heavier burden of illness were less likely to choose (or be chosen for) PD, instead assuming a more dependent role with center-based HD.

To date, no reasonable evidence exists to favor one modality over another on the basis of gender or race. CAPD is generally preferred over hemodialysis in the pediatric patient population for various reasons, including improved nutritional status, higher hematocrit, lower transfusion requirements, better blood pressure control, and avoidance of vascular access, which can be difficult to secure in small children.[107] Peritoneal dialysis has also been associated with better growth indices in infants and young children.[108,109] Children on PD are almost twice as likely to be enrolled in school than their hemodialysis counterparts.[110]

The major medical issues that must be considered by the treatment team are self-explanatory and will not be described in detail. For PD, major medical contraindications include inflammatory bowel disease, ischemic bowel disease, acute diverticulitis, intra-abdominal abcess, colostomy, ileostomy, pregnancy, malnutrition, multiple abdominal adhesions, high grade proteinuria, severe diabetic gastroparesis, severe hypertriglyceridemia, advanced COPD, Le Veen shunt, ascites, ventriculo-peritoneal shunt, and recent renal allograft. Less certain but important considerations include obesity, history of diverticulitis, severe low back pain, hernias, multiple abdominal surgeries, blindness, and hiatus hernia with reflux esophagitis.[111]

For center-based, intermittent HD, the major medical contraindications include inability to secure vascular access, refractory heart failure, prosthetic valve disease, and problems on HD. Other considerations include infectious disease (HIV, hepatitis B or C), and contraindications to heparin use.

Technique Failure and Modality Change

While peritoneal and hemodialysis are not vastly different with respect to long-term patient survival rates, they differ greatly with respect to technique survival. Hemodialysis is a relatively robust therapy. However, technique failure in peritoneal dialysis is a significant issue and has been defined as any situation requiring a switch to hemodialysis for greater than 3 months.[89] This definition excludes patients who have required a short time off PD for peritonitis or a catheter change.

Technique survival in CAPD has improved over the last decade. A Canadian study documented a 20% reduction in technique failure from the 1980s to the 1990s, accounted for largely by lower peritonitis rates.[94] Improvements in sterile technique, including the introduction of Y-transfer sets as well as better patient education are likely major contributors here. Indications for switching from peritoneal dialysis to hemodialysis, as outlined in the NKF-DOQI guidelines, are summarized in Table 15–2.

SYSTEM ISSUES IN MODALITY DISTRIBUTION

There is an astonishing international variation in modality distribution.[1] Countries like Japan utilize peritoneal dialysis (PD) in only 3.9% of dialysis patients, whereas in other countries (Mexico, Hong Kong, New Zealand) it is the dominant modality.

Similarly, dialysis modality distribution is markedly different in Canada and in the United States. Canada is a relatively high user of PD by international standards and had 22.3% of its prevalent patients on this therapy in the year 2000.[2] However, the percent utilization of PD has been falling steadily the past 8 years from a peak of 37.5% in 1992. PD utilization in Canada also varies markedly by province with the highest penetration in New Brunswick at 40.5% and the lowest in Alberta at 17.3% (preliminary 2000 data).

The situation in the United States is such that PD utilization is only 8.4% in 2001 and has fallen each year from a peak of 14.7% in 1993.[1] There is also significant geographic variation, such that network 16 (AK, ID, MT OR, WA) has 12.4% PD utilization, whereas network 2 (NY) has only 6.5%.

There is similar international variation in the use of home hemodialysis. Australia and New Zealand do quite well in this regard with more than 10% of prevalent patients, but most of the rest of the world struggles at around 1% to 2% utilization of home hemodialysis (HD).

Nonmedical Factors and Modality Options

Given that outcomes on hemodialysis and peritoneal dialysis are similar, and that the medical factors described above apply to only a minority of patients, then there must be other important factors that impact on modality decisions for individual patients and, hence, lead to the wide variations in modality utilization described previously. The relative degree

Table 15–2 NKF/DOQI Guidelines: Indications for Switching from Peritoneal Dialysis to Hemodialysis

Consistent failure to achieve a target Kt/V_{Urea} and C_{Cr} when there are no medical, technical, or psychosocial contraindications to HD.

Inadequate solute transport or fluid removal. High transporters may have poor ultrafiltration and/or excessive protein losses (relative contraindication, obviously discovered after initiation and the first PET).

- Unmanageably severe hypertriglyceridemia.
- Unacceptably frequent peritonitis or other PD-related complications.
- Development of technical/mechanical problems.
- Severe malnutrition resistant to aggressive management (relative).

to which these nonmedical factors impact upon modality decisions and modality distribution varies from country to country. This section discusses the most important of these factors.

Financial/Reimbursement

In a classic article on nonmedical factors that impact on ESRD modality decisions, Nissenson and associates[112,113] conclude that financial and reimbursement factors stood out as the most important one in nearly every country or region studied. However, it is a complex issue, because physicians and facilities may have different financial interests. Furthermore, there is confusion in discussions about dialysis economics because it is necessary to distinguish the effect of cost from the effect of funding. In the end, it is funding that will impact more on modality decisions.

PD is less costly than center HD in North America and in Europe.[6,114–116] Intermittent home HD is similarly much less costly than center HD, and data suggest that slow nocturnal dialysis is also less costly than center HD.[32]

In some developing countries the least expensive dialysis modality is used predominantly.[117] Often this is PD if the solutions are manufactured locally. Mexico is a good example, with greater than 90% PD utilization. However, some countries like India impose import duties on PD fluid produced elsewhere. This artificially inflates the cost of PD to a level higher than HD, effectively denying a useful therapy to its citizens.

Most Western European nations predominately utilize HD, especially if there is a private or mixed public and private dialysis system.[112,113,118] Publicly funded ESRD delivery systems tend to devote less money to ESRD programs and have higher PD utilization rates but lower ESRD incidence rates. Nations with private funding tend to use HD in more than 90% of cases, possibly because the investment in private ownership of HD facilities produces incentives to keep them full. An additional factor is physician reimbursement systems, which often pay nephrologists more generously for center-based HD. Indeed, in some countries, home-based therapies have no physician fee at all.

In Canada's case, public funding of dialysis services and prohibition of private ownership of facilities has led to relatively high rates of PD utilization. As for the United States, with its high utilization of PD, reimbursement rates for facilities and physicians do not favor either modality. It is therefore not immediately clear why this modality distribution exists. The lack of an existing local PD infrastructure, the less expensive marginal costs of adding an additional patient to a preexisting HD program, and the incentive to keep HD units operating at full capacity are economic explanations that have been advanced.[28] Finally, recent USRDS Wave II data suggest that only 25% of the selected HD patients recall having PD discussed as a modality option, while conversely 68% of PD patients remember discussions regarding HD as an option.[103] One can speculate that the extreme American reliance on HD may be unjustified and contrary to patient preferences.

Resource Availability

Resource limitations can be both capital and human. Lack of capital in underdeveloped countries leads to no public fund-ing of dialysis and very low treatment rates. Similarly, lack of HD facilities or machines can lead to pressures that increase PD utilization. High PD utilization in Canada in the early 1990s was felt to result from centralization of dialysis treatment centers in university centers and excessively tight government control of capital funding of HD expansion.[112] As HD demand exceeded supply in provinces like Ontario, PD utilization rose to levels that were felt by the providers to be beyond reason.[119,120] Lack of trained personnel (physicians, nurses, technologists) can all impact upon available choice of modality.

Social Issues

Many social problems can limit the availability of patients to manage a home dialysis method. Severe poverty and poor hygienic conditions preclude home dialysis therapy. In marginal situations, especially in the elderly who are frail or have many comorbid conditions, support is essential. If support from family members or other loved ones, or from home care nursing, is not available, then home dialysis is not an option. Unsuitable housing and water supply may also contraindicate home dialysis. Drug abuse and/or noncompliance may interfere with the ability of patients to prosper on home dialysis.

On the other hand, living long distances from HD centers can make center HD impossible, and a home dialysis option may be the only viable strategy.

Cultural Habits

It is described that certain ethnic groups share internal values and perceptions that impact on acceptability of a dialysis therapy choice.[112,113] Chinese patients may be more averse to needle puncture and may place more emphasis on the duty and honor of caring for elderly parents. Both factors tend to encourage home PD. Japanese culture seems to prefer receiving care at clinics and hospitals, rather than at home.

Late Referral and Suboptimal Predialysis Care

There seems to be little doubt that late referral to a nephrologist has numerous negative consequences. This topic has been the subject of several recent reviews.[121–126]

The potential benefits of earlier referral include (1) discovery and treatment of reversible causes of renal failure, (2) slowing the rate of decline of progressive renal insufficiency, (3) managing the multiple comorbid conditions and cardiovascular risk factors associated with chronic renal failure, and (4) facilitating efficient entry into ESRD programs of all patients who might benefit.[127,128] Of special significance to policy makers and funders are the observations that it may be possible to increase patient survival,[129–136] increase the use of native AV fistulas,[137–140] achieve better vocational outcomes,[141] increase utilization of more cost-effective home and community-based dialysis modalities,[102,106,142–145] improve quality of life,[146,147] decrease hospital utilization,[130,136,137,139,148] and reduce health care costs.[142,149] Physicians interested in home dialysis should note that patients referred early and adequately educated about dialysis modalities seem more likely to choose home HD or PD.[100–102,112,145,150]

Nephrologists' Attitudes, Opinions, Educational Deficits, and Biases

It is stated that a lack of training and experience of nephrologists and nurses and physician bias impacts upon modality selection.[112] In an attempt to examine nephrologists' opinions and biases, we have done a series of studies in Canada, in the United States, and in the United Kingdom.[19–21] These are published separately, but for the purposes of this chapter, the study data is lumped together in order to highlight the remarkable degree of similarity between them.

We used a very simple survey methodology. We sent a mailed questionnaire to the Canadian Society of Nephrology membership and achieved a 66% response rate. Similarly, we surveyed a random sample of the National Kidney Foundation Council on Dialysis and reported a 47% response rate, and a sampling of the Renal Association of Great Britain and Ireland with a response rate of 63%.

In one set of questions, we asked the physician respondents: What are the most important factors controlling or affecting modality decisions? The single most important factor in all three countries is patient preference. Outcome data is ranked second, costs to the patient and health care system is reported to be a neutral factor, and reimbursement both to facilities and physicians is reported to be not important. This is a survey methodology so there may be limitations in terms of respondents wanting to report socially desirable answers rather than reporting truthfully. Nonetheless, the answers are remarkably similar across three different countries with different modality distributions.

Another question asked of the nephrologist: Suppose you are consulted by a state or province with 10 million people, and you are to give advice to government about planning dialysis systems in the future. No rationing is to occur. Given these seven dialysis modalities, what percent would you assign to each one in an ideal system? Figure 15–7 shows that if the prime criteria was to maximize survival, wellness, and quality of life, a form of HD was recommended for 63%, 67%, and 62% of patients in Canada, in the United States, and in Europe, respectively. Home HD was recommended for 9%, 12%, and 11%, whereas PD was recommended for 37%, 33%, and 38% in the three countries, respectively.

Figure 15–8 shows results from a similar question, but this time the respondents were asked to maximize outcomes based on the prime criteria of cost-effectiveness. The results changed only slightly. In Canada the HD:PD ratio recommended is now 57:43, in America it is a 60:40 split, and in Europe it is 56:44. Home hemodialysis is now recommended for 12%, 16%, and 10%, respectively. The results are surprisingly similar between these three physician groups who practice in three different countries, with three different health care systems and with three different current PD utilization rates.

In a subsequent study, we looked specifically at the issue of physician bias.[151] Nephrologists unfamiliar with PD are thought to have a negative attitude toward PD, which is transmitted to patients and impacts on choice. We performed a secondary analysis on our survey database to compare physicians who practice only or mainly hemodialysis, to the physicians who practice only or mainly PD. The hypothesis being tested was that the doctors who practice mainly or only hemodialysis will show marked preferences for HD in their answers, compared to the doctors who practice only or mainly PD. Of the 50 or
Figure 15–7 Optimal modality distribution recommended by Canadian, American, and European nephrologists based on maximization of survival, wellness, and quality of life.
Figure 15–8 Optimal modality distribution recommended by Canadian, American, and European nephrologists based on maximization of cost-effectiveness.

60 questions in this survey, Table 15–3 shows only the answers that are statistically significantly different. In other words, most answers are not statistically significantly different. In fact, even in the ones that are statistically different, they are not very different in terms of the number ranking.

Table 15–3 Differences Between Nephrologists Based on Dialysis Practice

	Factor	All or Mainly HD	Both HD and PD (mixed)	All or Mainly PD	P
	No. of respondents	117	232	16	
General factors	Cost to health care system	2.42 ± 0.11	2.78 ±0.07	2.94 ± 0.22	.001*
Patient-Related factors	Cognitive impairment	1.55 ± 0.06	1.84 ± 0.05	2.29 ± 0.18	.0001*
Influencing choice of HD or PD	Poor coordination	1.84 ± 0.06	2.00 ± 0.05	2.47 ± 0.21	.007
	Insufficient IQ	1.91 ± 0.06	2.08 ± 0.05	2.29 ± 0.21	.008
	Poor motor strength	2.09 ± 0.06	2.27 ± 0.05	2.71 ± 0.17	.003

HD, hemodialysis; PD, peritoneal dialysis. (Adapted from Charest AF, Mendelssohn DC: Are North American nephrologists biased against peritoneal dialysis? Perit Dial Int 2001; 21[4]:335-337.)

Age is an example of a difference where hemodialysis doctors feel that greater than 70 years is more of a factor against PD than the PD doctors, but the difference is not large. The biggest difference is related to a weight contraindication to PD. Doctors who do mainly hemodialysis believe that the upper limit for PD should be 98 kg, whereas doctors who do mainly PD say 108 kg.

We then looked again at the optimal system design question. Surprisingly, the hemodialysis doctors and the PD doctors answered these questions very similarly. Concerning the percent PD in the optimal distribution with maximization of survival, wellness and quality of life, 32% was recommended by the HD doctors, whereas 45% was recommended by the PD doctors. Similarly, when framing the question around cost-effectiveness, the recommendations become even more similar with PD utilization suggested at 41% by the HD doctors and at 40% by the PD doctors. Although there is a difference in opinion about optimal modality distribution between nephrologists who do mainly HD compared to those who do mainly PD, the 32% to 45% PD recommendation is 3.5 to 5 times higher than current rates of PD utilization in the United States. An independent published survey of American nephrologists shows very similar results, including emphasis on patient preference in modality decision making, relative underutilization of PD, and no difference between nephrologists who do all HD compared to those familiar with PD.[98]

From the primary and secondary analysis of our surveys, we conclude that nephrologists' attitudes toward PD and home HD are in fact quite positive, and that there is no evidence of significant widespread bias against PD. We acknowledge certain limitations within this survey methodology, but to try to establish the optimal dialysis modality distribution is a very hard question to probe with more rigorous research designs. For example, there will never be a randomized controlled trial of PD versus HD.

A useful guide to medical and nonmedical factors that influence modality selection is shown in Table 15–4. Originally drafted by Hamburger and associates,[152] it has recently been updated and expanded by Shetty and Oreopoulos[111] and presents indications and contraindications to hemodialysis and peritoneal dialysis from the home peritoneal dialysis-perspective.

TIMING THE INITIATION OF DIALYTIC THERAPY IN PATIENTS WITH CHRONIC KIDNEY DISEASE

In everyday clinical practice, nephrologists and their patients are commonly faced with the decision about when to initiate dialysis. On occasion, the decision is straightforward, as in the setting of acute renal failure with acute metabolic or volume-related complications. In the setting of slowly progressive chronic kidney disease, however, the decision-making process is more complex and requires the consideration of several clinical, biochemical, and psychosocial factors.

Absolute Indications for Initiation of Dialysis

The absolute indications for initiation of dialysis are more typically observed in the setting of acute renal failure, and include:

1. Neurologic complications, such as encephalopathy, sensory neuropathy, and motor neuropathy
2. Uremic serositis, including pericarditis and pleuritis
3. Metabolic abnormalities refractory to medical management, including hyperkalemia and metabolic acidosis
4. Volume overload refractory to medical management

When present in the setting of CKD, these complications reflect either an acute or chronic exacerbation in renal function but may also result from failure to recognize pending complications before they occur.

Relative indications for dialysis may be present late in the course of CKD but may also complicate acute renal failure and include symptoms, such as fatigue, weakness, insomnia, anorexia, nausea, vomiting, itching, and weight loss.

To date, no large prospective randomized trials have identified an ideal renal functional threshold at which to initiate renal replacement therapy in patients without uremic symptoms. The many small observational and often retrospective studies that have addressed this question have generated numerous opinions, each focusing on different measures of nutritional status, residual renal function, or clinical parameters. Unfortunately, many of the studies addressing this issue

Table 15–4 Dialysis Modality Selection Guide

Medical Considerations	Demographic Considerations	Psychosocial Considerations
PD Strongly Indicated		

Vascular access difficult to establish
Refractory chronic heart failure
Prosthetic valvular disease
Problems on HD (e.g., severe
   headache or asthenia post-HD)
	Age 0–5 years	Long way from center
		Strong patient preference
		Strong need for autonomy, independence,
		   or control

PD Preferred		

Cardiovascular diseases/HTN
Chronic disease:
   Known bleeding disorder
   Multiple myeloma
   Labile diabetes
   HIV positive
   Hepatitis B or C positive
Transplant candidates
Transfusion problem (X-match
   or Jehovah's Witness)
	Age 6–16 years	Active lifestyle
		Variable schedule
		Travel
		Needle anxiety
		Demand for flexible diet

PD or HD Equally Preferred		
Diabetes mellitus Chronic, stable angina Peripheral vascular disease Polycystic kidney disease Scleroderma	Both sexes All races Nursing home residents	
PD Not Preferred but Possible with Added Considerations		
Large size (obesity) History of diverticulitis Severe low-back pain Hernias Multiple abdominal surgeries Impaired manual dexterity Blindness Hiatus hernia with reflux esophagitis	Severe depression Drug abuse Social support needed Poor compliance	
Questionably Indicated for PD (Relative Contraindications)		
Malnutrition Multiple abdominal adhesions Ostomies Proteinuria >10 g/day Severe diabetic gastroparesis Severe hypertriglyceridemia Advanced COPD Ascites Patient with patent LeVeen shunt Patient with ventriculoperitoneal shunt Transplant within 1 month Upper limb amputation	Chronic poor hygiene Dementia Dementia Concern about body image Homeless Small home without place to store the supplies	
Contraindicated for CAPD		
Severe inflammatory bowel disease Acute active diverticulitis Active ischemic bowel disease Abdominal abscess Starting dialysis in the 3rd trimester of pregnancy	Severe active psychotic disorder or manic-depressive Marked intellectual disability with no helper	

(Modified from Hamburger R et al: A dialysis modality decision guide based on the experience of six dialysis centers. Dial Transplant 1990; 19:66-69.)

have been limited by variations in patient compliance, comorbidity burden, referral-time bias, and starting-time bias.[153]

There has recently been attention focused on an earlier, timely, or healthy start to dialysis.[124,154,155] The argument in favor of an early start begins with the recognition that morbidity and mortality on dialysis is too high and has not been dramatically altered by interventions directed at improving dialysis care. One factor that might contribute to this is that patients become ill while waiting to start dialysis, and that dialysis then becomes a salvage-from-illness type of therapy that does not work very well. Earlier starts might protect against the spontaneous reduction of dietary protein intake associated with late stage progressive CKD, and possible malnutrition (clinical or subclinical) at onset of ESRD, which is known to be an adverse prognosticator. Furthermore, it is noted that many patients start dialysis at a level of residual renal function that corresponds to less clearance of uremic toxins than would be delivered by an adequate dose of dialysis.

Early retrospective work by Bonomini and associates[156,157] recognized significant differences among patients with varying levels of GFR at the initiation of dialysis, showing that an earlier start was associated with improved survival, increased employment, and reduced hospitalization. Nonetheless, proponents of this early start proposition acknowledge the lack of prospective data to validate the hypothesis, but argue forcefully that "although critics of these recommendations may perceive them to be needlessly aggressive, the high morbidity, mortality and costs associated with ESRD call for urgent and bold measures to improve the quality and quantity of life in these patients."[124] To an extent, these arguments influenced some recent North American guidelines about initiation of dialysis.[158,159]

The other side of the dialysis initiation coin is that early dialysis may be more costly and exposes patients to more dialysis-related complications and limitations in lifestyle. Indeed, one study shows only a modest benefit to an early start,[160] four studies have shown no benefit,[131,161–163] and three show worse outcomes.[164–166] Given that it would take a rather large trial to prove any benefit to an early start, the incremental benefit is likely small and would be unlikely to justify the increased cost and inconvenience of an early start approach.

In the absence of any absolute indications, the decision to start dialysis is a dynamic process that largely consists of serial clinical assessments and laboratory investigations. Although it is generally agreed upon that dialysis should be started when significant uremic symptoms develop, there is significant variability in the levels of renal function at which patients will report such symptoms.[162] This observation may partially account for the fact that up to 23% of patients started on dialysis in the United States between 1995 and 1997 began with a GFR of less than 5 mL/min, a level well below any recommended targets.[167] The impact that this may have on outcomes is debatable but serves to illustrate that there may be some value in serially calculating residual renal function through CrCL or GFR formulas in the pre-ESRD setting.

The Importance of Nutritional Status in Patients Starting Dialysis

The relationship between nutritional status at the initiation of dialysis and survival is well established.[168] Progressive chronic renal failure is associated with spontaneously reduced protein intake and a deterioration in nutritional status. This is further exacerbated in patients with protein-losing nephropathies. Low levels of biochemical markers, such as albumin, prealbumin, and creatinine have been associated with adverse outcomes in ESRD patients.[169,170] Fleischmann and associates[171] compared 1346 hemodialysis patients of various levels of body mass index (BMI) and found an inverse relationship between BMI and 1-year survival. Patients with the lowest BMIs also had a greater frequency of hospitalization and lower levels of biochemical markers such as albumin. It has thus been argued that dialysis should be initiated before lean body mass is lost.

When to Initiate Dialysis: Current Guidelines

Many professional organizations have offered guidelines for the initiation of dialysis in asymptomatic patients. Although the various recommendations vary with respect to GFR or nPNA thresholds, there is a general consensus that the focus should be on the overall clinical impression and not on these objective measures. The presence of uremic symptoms should take precedence over any laboratory parameters.

The Canadian Society of Nephrology (Table 15–5) recommends following the glomerular filtration rate (GFR) calculated as the mean of the urea and creatinine clearances determined by 24-hour urine collection.[159] At low levels of GFR, this has been shown to correlate well with inulin clearance, a gold standard for GFR quantification.[172] The CSN argues that the concept of using Kt/V as an estimate of residual renal function is foreign to most nephrologists.[159]

The NKF/DOQI's most current recommendations are largely derived from the peritoneal dialysis literature and were last updated in the year 2000. Applying these recommendations requires a calculation of the residual weekly urea clearance as expressed as renal Kt/V_{urea}, as well as the nPNA, using

Table 15–5 Canadian Society of Nephrology Clinical Practice Guidelines: Initiation of Dialysis

1. When the GFR is less than 120 L/wk per 1.73 m² (0.2 mL/s or 12 mL/min), look for symptoms or signs of uremia or evidence of malnutrition. If there is evidence of uremia or if the PNA is 0.8 g/kg per day, or if there is clinical malnutrition (SGA), recommend dialysis. The GFR value of 120 L/wk corresponds to a CCr of approximately 0.3 mL/s or 18 mL/min and a weekly Kt/V of 2.0 (evidence: level IV – case-series with historical controls).
2. If there is no evidence of uremia or malnutrition, increase the frequency of observation to monthly and recommend dialysis when indicated (uremia or malnutrition) (opinion).
3. When the GFR is less than 60 L/wk per 1.73 m² (0.1 mL/s or 6 mL/min), recommend initiation of dialysis (opinion).

(Adapted from Churchill DN, et al. The Canadian Society of Nephrology Practice Guidelines, 10 (Suppl 3):S289-S297, 1999.)

methods that have been described extensively.[158] A summary of their recommendations is provided in Table 15–6. A proposed algorithm is presented in Figure 15–9.

The methods proposed by both CSN and NKF/DOQI are not used in routine clinical practice, and the guidelines also show approximate conversions to more widely available markers of renal function like calculated CrCl (Cockcroft Gault formula) or calculated GFR (MDRD formula).

The CSN and NKF/DOQI guidelines recommended thresholds for initiating dialysis are based on very low-level evidence and largely reflect opinion. The more recent Renal Physicians Association (RPA) guidelines reflect that there is insufficient evidence to recommend initiating renal replacement therapy based solely on the specific level of GFR.[173] Instead, the RPA guidelines emphasize the importance of early referral to a CKD program, early counseling about modality options, early referral for transplant assessment, and timely referral for vascular access placement.

INTEGRATED CARE

The epidemic growth rate of ESRD and its attendant enormous costs threaten to outstrip society's ability to pay for it. Modality distribution is an important modifier of dialysis costs. Nephrologists cannot solve the dialysis dilemma of growth and high cost, but they do have an obligation to treat the most patients in the best way possible, for the lowest societal expenditure. In theory, it is possible that there is an optimal dialysis modality distribution, which allows for the treatment of the maximum number of patients, with the highest quality of care and the best possible outcomes, at the lowest cost. Nephrologists must seek to define and promote such an optimal modality distribution.[117,174] In this way, they are credible

as advisors to health care policy and funding bodies. Advocating unlimited growth of a dialysis system that is not the most cost-effective will only lead to an inability to influence health care policy decision makers.

Hemodialysis and peritoneal dialysis have traditionally been viewed as competing modalities. Proponents of an integrated care approach to ESRD management, however, maintain that these modalities should rather be viewed as complementary, and that each has its appropriate place in the management of ESRD. This strategy provides each patient with the form of renal replacement therapy that yields the maximum benefit at each stage of their disease.

The Traditional Integrated Care Approach: A Rationale

Arguments in favor of the integrated care approach rest on the following premises[175]:

- Given the freedom to choose, many patients will select a given treatment modality on the basis of lifestyle.
- PD and HD differ in technical and medical terms such that valid arguments exist for using them in a PD first sequence in suitable patients.
- Evidence suggests that patients who have experienced more than one dialytic modality have a survival advantage with a PD first strategy.
- PD is more cost-effective than in-center HD

Traditionally, proponents of the integrated care concept have suggested that hemodialysis and peritoneal dialysis should be presented to patients in an unbiased way so that patient preference would dictate modality selection. Patient education obviously lies central to the self-decision process. One study showed that when provided with adequate information about

Table 15–6 NKF/DOQI Guidelines for Initiation of Dialysis

Guideline 1
When to Initiate Dialysis–Kt/V_{urea} Criterion
Unless certain conditions are met, patients should be advised to initiate some form of dialysis when the weekly renal Kt/V_{urea} ($K_r t/V_{urea}$) falls below 2.0. The conditions that may indicate dialysis is not yet necessary even though the weekly $K_r t/V_{urea}$ is less than 2.0 are:

1. Stable or increased edema-free body weight. Supportive objective parameters for adequate nutrition include a lean body mass >63%, subjective global assessment score indicative of adequate nutrition and a serum albumin concentration in excess of the lower limit for the lab, and stable or rising.
2. Nutritional indications (see Guideline 2).
3. Complete absence of clinical signs or symptoms attributable to uremia.

A weekly $K_r t/V_{urea}$ of 2.0 approximates a renal urea clearance of 7 mL/min and a renal creatinine clearance that varies between 9 to 14 mL/min/1.73 m^2. Urea clearance should be normalized to total body water (V), and creatinine clearance should be expressed per 1.73 m^2 of body surface area. The GFR, which is estimated by the arithmetic mean of the urea and creatinine clearances, will be approximately 10.5 mL/min/1.73 m^2 when the $K_r t/V_{urea}$ is about 2.0.

Guideline 2
In patients with chronic kidney failure (e.g., GFR <15 to 20 mL/min) who are not undergoing maintenance dialysis, if protein-energy malnutrition (PEM) develops or persists despite vigorous attempts to optimize protein and energy intake, and there is no apparent cause for malnutrition other than low nutrient intake, initiation of maintenance dialysis or a renal transplant is recommended.

(Adapted from National Kidney Foundation, K/DOQI Clinical Practice Guidelines for Peritoneal Dialysis Adequacy, 2000. Am J Kidney Dis 2001; 37[Suppl 1]:S65-S136.)

treatment options, patients were more likely to select CAPD over hemodialysis and were typically satisfied with that decision.[176] Younger patients, especially those who are employed, opt for home-based therapies in favor of in-center HD.[177,178] Home therapies may be preferred over in-center dialysis by the geriatric patient population as well, particularly when adequate education is provided.[179]

With appropriate unbiased predialysis counseling, a greater proportion of patients would thus select PD as the initial modality, thus reaping the proposed benefits of the PD-first approach. The potential benefits of PD over HD are largely confined to the first 2 years on dialysis, and following this period, or following technique failure, patients could switch to HD.[92] This has obvious economic benefits, as well

as numerous clinical benefits and implications for quality of life.

Van Biesen and associates[90] published the first-ever large series evaluating the effectiveness of an integrated care approach. In this study, the charts of 223 HD and 194 PD patients were reviewed and assessed for survival in an intention to treat analysis. Patients initially treated with PD, who subsequently switched to HD, had improved survival as compared with those who started with and remained on HD. Of the patients who remained on their initial modality for more than 48 months, PD patients had reduced survival as compared with their matched HD counterparts. Although this study was retrospective, it was concluded that patients who start with PD and switch to HD in a timely fashion, do at least as well as patients initially treated with HD.

Reformulating the Integrated Care Concept

As we move forward into the new millennium, it is imperative that ESRD management strategies keep pace with evolving technical innovations. The "PD-first" integrated care approach as described earlier, has in several important ways failed to achieve this. A reformulation of this concept has been recently proposed.[97]

First, it is well established that renal transplantation, particularly preemptive transplantation, offers patients the best possible outcomes with respect to survival and quality of life. Unquestionably, transplantation should be promoted as the first-line treatment for ESRD, and any integrated care algorithm should reflect this.

Second, although dialysis-related technologies have advanced over the last decade, technique-changes in PD and conventional thrice-weekly HD have not significantly improved any patient-related outcomes. Emerging home-based hemodialysis therapies such as short daily, and slow nocturnal (collectively known as "quotidian" dialysis therapies) have gained increasing acceptance[17,18] and appear to offer superior intermediate outcomes over conventional in-center thrice-weekly hemodialysis.[17,26,180] Evidence that these therapies are cost-effective has begun to emerge,[31–33] and it is likely that they will soon be accepted as a significant component of dialysis treatment strategies. Indeed, nephrologists believe that home hemodialysis should compromise more than 10% of an optimal modality mix.[19–21] This figure represents much higher utilization than what currently exists in most jurisdictions.

Finally, many of the proposed benefits of a PD first-strategy, however, may apply to quotidian or three times weekly home hemodialysis regimens as well, and both share many potential benefits over in-center HD. These are summarized in Table 15–7 and discussed in detail later. On this basis, it is proposed that all home-based therapies (PD and HD) should be regarded as equivalent, and that these should all be promoted as second-line therapies after preemptive transplantation.

Proposed Benefits of Home-Based Therapies

Survival

A general discussion of survival outcomes comparing PD and HD has been presented earlier in this chapter. To date quotid-

Table 15–7 Important Shared Advantages of PD and Home Quotidian Dialysis

- Excellent volume and blood pressure control.
- Patient independence and employment.
- Liberalization of dietary intake.
- Allowance for an incremental dialysis start strategy.
- Reduced risk of hepatitis and other parenteral exposures.
- Reduced erythropoietin requirements.
- Possible reduction in the risk of long-term complications of dialysis, such as amyloidosis.
- Preservation of residual renal function.
- Improved transplant-related outcomes.
- Preservation of vascular access sites (PD only).
- Possible early survival advantage over intermittent HD (PD). Survival advantage with quotidian dialysis seems plausible, but awaits confirmation.
- Cost-effectiveness.

ian hemodialysis has not been studied with respect to mortality advantages. Unfortunately, quotidian dialysis studies have been too small to address this issue. What is known is that quotidian dialysis improves several intermediate outcomes that are associated with an increase in the risk of death. These include anemia, the calcium-phosphorous product, left-ventricular hypertrophy, and nutritional status. It is the authors' opinion that quotidian dialysis will prove to be effective in conferring a survival advantage, but this awaits confirmation in either a large prospective trial or a quotidian dialysis registry.

Treatment Costs

Numerous studies have compared the relative costs of HD and PD.[6,114,115] Although dialysis delivery costs are easily underestimated due to various intangible costs and difficult-to-quantify hospital and organizational costs, it is certain that PD is less costly than HD.[181] A Canadian study estimated CAPD to cost approximately 60% as much as hospital-based hemodialysis.[114] A cost-utility analysis showed PD to be more cost-effective over a 5-year period and across all age groups in Sweden.[96]

Quotidian dialysis has also proven to be cost-effective.[32,33] One cost-comparison study found that despite the up-front cost of purchasing and installing one dialysis machine per patient, and despite a doubling in the cost of disposable materials, short-hours daily and long-hours nocturnal home hemodialysis cost less than conventional in-center dialysis and actually resulted in an increase in quality-adjusted life years.[33] Even if direct costs of daily home hemodialysis are similar to the costs of center-based HD, there are important secondary gains that make them crucial. These include that they do not require new "bricks and mortar" and minimize the capital and operating costs of expanding infrastructure in health care facilities or other locations. Perhaps more important is that they do not rely as much on highly trained dialysis nurses and technicians, who are in short supply in many parts of the world.

Improved Employability

Julius and associates[177] examined a nondiabetic cohort of patients receiving various dialysis modalities. Using logistic regression analysis and controlling for baseline demographic variables, it was found that on CAPD patients were more likely to be employed than their HD counterparts. It should not be inferred that treatment with PD increases employability, but rather that it is possible that patients who are able to perform their own dialysis procedure are more likely to be able to work as well. A study by Garcia-Maldonado[182] evaluated cognitive function using the standardized written test and found that PD patients have better cognitive function than their HD counterparts. PD patients in this study, however, had higher hematocrit levels, which likely accounted for some of the difference.

The freedom and flexibility in treatment schedule offered by home dialysis therapies has also permitted many patients to return to work. In the London Daily/Nocturnal Hemodialysis study, 40% of unemployed patients who switched from conventional in-center dialysis to quotidian dialysis were able to resume full-time employment.[24]

Quality of Life

Patients receiving home-based therapies generally enjoy a higher quality of life (QOL) and greater autonomy than their in-center counterparts. It is intuitively obvious that autonomy impacts on quality of life, but it is not possible to design a prospective study to evaluate this in patients requiring RRT. Autonomy is also important with respect to modality selection. A retrospective series showed that when a program was forced to offer only CAPD (because it could no longer accommodate more hemodialysis patients), quality of life scores were reduced as compared with patients who could choose between HD and CAPD.[183]

It is difficult to assess whether patients prefer PD over HD. One study by De Vecchi and associates[184] attempted this by administering a questionnaire to patients who had experienced both HD and PD for 6 months. Patients were initially allowed to freely choose between PD and HD. A greater proportion of patients had selected CAPD over HD as their initial modality (76% vs. 24%). The reasons for choice of CAPD were: more free time (21%), more freedom (67%), better well-being (44%), less worry (5%); for HD they were: more free time (53%), better well-being (39%), less worry (13%), no need for a peritoneal catheter, and fewer clinical complications (19%). Most patients who had experienced both HD and PD had often switched from one to the other because of technique failure or other complications. Under such circumstances, it is not surprising that patients preferred their current modality.

A discussion on quality of life cannot be complete without addressing the impact of RRT on caregivers. Patients receiving home-based therapies may have varying degrees of dependency on their caregivers, occasionally requiring assistance with all aspects of dialysis delivery, though most quotidian home dialysis patients are independent or minimally assisted. Caregiver burnout is not unheard of and may occasionally necessitate a switch to in-center therapy.

Patients who switch from conventional hemodialysis to quotidian dialysis universally prefer the latter, reporting improved well-being, reduced treatment-associated anxiety, less treatment associated symptoms, such as dizziness and dyspnea. Quotidian dialysis patients may also enjoy an unrestricted diet, which impacts heavily on overall quality of life.[185]

Renal Transplantation

Although long-term graft survival is similar in patients initially treated with PD and HD,[186] PD-treated patients may enjoy certain benefits in the post-transplant period. Delayed graft function (DGF), defined as renal dysfunction requiring renal replacement therapy in the first post-transplant week, is a strong negative predictor of long-term graft function.[187,188] The odds of DGF are lower in patients receiving PD, as is the incidence of oliguria.[189] It has been hypothesized that this could be due to greater hydration in PD patients.[190] The effects of quotidian dialysis on graft function have not yet been explored.

A greater incidence of inadvertent blood loss among HD patients has been associated with greater blood transfusion and erythropoietin requirements when compared with PD.[191] This same study showed a corresponding increase in panel reactive antibodies and increased transplant wait times. Lower blood transfusion rates have also been associated with a lower incidence of hepatitis C among PD patients.[192]

Some have suggested that peritoneal dialysis may indirectly confer some mechanical advantages during ureterovesical anastomosis. Since patients with increased residual renal function are less likely to have atrophic bladders, their anastomoses are theoretically less likely to leak.[193] This, however, has not been evaluated in any scientific way. The potential impact of quotidian dialysis on transplant-related outcomes has not yet been reported.

Preservation of Residual Renal Function

In the early 1990s, Faller and Lameire[194] demonstrated that the loss in total Kt/V in CAPD patients over time was due to a loss of residual renal function (RRF) and not attributable to changes in peritoneal membrane transport characteristics. In this study, the contribution of RRF to the total clearance fell from a predialysis level of 21.6% to less than 3% over a period of 7 years. Subsequent studies have corroborated this finding.[195]

Preserving RRF may be advantageous in many ways. Of greatest significance is the positive impact on survival. The CANUSA study not only demonstrated that the progressive loss in clearance over time was due to the loss of RRF, but that it was specifically the decline in RRF that was associated with decreased patient survival and not the a decline in peritoneal clearance.[196] The ADEMEX and NECOSAD-2 studies reinforced this point, demonstrating that total small solute clearance alone did not predict survival, but that RRF did.[197,198]

The explanation for this finding is not straightforward, as residual renal function may confer numerous metabolic advantages over and above small solute clearance, and hemodynamic factors are likely to be present as well. Extracellular fluid volume (ECFV) control is likely an additional factor. It is well established that cardiovascular mortality is increased in dialysis patients, and that LVH is a major independent predictor of cardiovascular death.[199,200] Residual renal function has recently been associated inversely with the development of

LVH.[201] Higher levels of RRF have also been associated with lesser degrees of ECFV-expansion.[202] The volume-expanded state in patients with low RRF is thus associated with LVH and cardiovascular death. These observations at least partly explain the reduced mortality observed among PD patients as compared with HD patients in the first 2 years on dialysis, when RRF is at its highest.

Improved volume regulation has the added benefit that patients may liberalize their fluid and dietary intake. Indeed, nutritional status tends to be better in patients with preserved RRF. Micronutrient and total caloric intake, for example, is greater in patients with higher levels of renal urea clearance.[203] This has been shown to be associated with improved survival.[204] RRF has also been associated with positive nitrogen balance, reflecting higher dietary protein intake.[205] Other important metabolic effects of RRF include increased middle- and large-molecular weight solute clearance and improved renal endocrine function.[206,207]

Cardiovascular Disease

Cardiovascular disease is the leading cause of mortality among ESRD patients, thus it is imperative that any strategy designed to improve outcomes in this patient population must take cardiovascular risk management into account. In addition to traditional cardiovascular risk factors, one must consider the factors related to kidney failure itself and dialysis. These include hyperhomocysteinemia, anemia, malnutrition, lipoprotein (a), inflammation, and an elevated calcium-phosphorous product.

The relative merits of the various dialytic modalities with respect to cardiovascular disease remains somewhat controversial, and discussions in this area are complex. There are cardiovascular concerns that may relate to PD therapy. The atherogenicity of glucose-based dialysate has been implicated, particularly with respect to its effect on lipid profiles, the production of advanced glycosylation end products, and oxidative stress. Lipoprotein (a), which is also associated with CAD, is markedly elevated in CAPD patients.[208] A recent series documented markedly greater levels of total cholesterol, triglycerides, and lipoprotein (a) and lower HDL levels in PD patients as compared with their HD counterparts.[209] Not surprisingly, both HD and PD patients have elevated LDL levels. Although lipid lowering drugs have proven effective in reducing LDL levels in CAPD patients, no prospective studies to date have conclusively shown any mortality benefits to their use in dialysis populations.

Blood pressure control varies from one dialytic modality to another. One study by Saldanha and associates[210] demonstrated a 7.8% decrease in blood pressure 6 months after switching from HD to PD. This was associated with a drop in ideal body weight, suggesting that improved volume status was a contributing factor. A Japanese survey found systolic blood pressure to be 8 mmHg lower on average in patients on PD versus HD.[211] These findings, however, have not been entirely consistent throughout the literature.[212] Such studies are likely confounded by numerous factors, including aggressiveness with antihypertensive therapy and volume control, as well as the level of residual renal function, though Saldanha's study also documented a reduction in antihypertensive medication in subjects that switched to PD.

Homocysteine levels tend to be high in dialysis patients. A study by Moustapha and associates[213] documented an almost twofold higher level in HD patients versus PD patients. Plasma folate levels were also found to be lower in HD patients, suggesting that folate is removed to a greater degree by HD than by PD. Homocysteine is markedly improved by treatment with both short-daily and long-nocturnal dialysis.[25]

Quotidian dialysis offers a unique approach to cardiovascular risk factor management. Hypertension is unquestionably better controlled with quotidian dialysis than with conventional HD or PD. Quotidian dialysis patients require less antihypertensive medication, and over time even experience regression of left-ventricular hypertrophy.[214,215] Over time, this may translate into an increased survival advantage. Reductions in the calcium-phosphorous product that have been observed in quotidian dialysis have yet to be shown to translate into mortality reduction. Such is also the case with improvements in homocysteine and lipid profiles.

Some have suggested that arrhythmias are more common in conventional HD than in PD. Canziani and associates[216] documented a marked increase in the incidence of severe cardiac arrhythmias in patients treated with PD relative to their HD counterparts. Not surprisingly, these patients also had a greater degree of LVH, a known precipitant of ventricular arrhythmias. Data from the USRDS database have shown that thrice-weekly hemodialysis is associated with greater incidence of sudden cardiac death on Mondays and Tuesdays than on any other days of the week.[217] The supposition here is that following a 72-hour interval between dialysis treatments, electrolyte abnormalities such as hyperkalemia and volume overload are likely to occur. By virtue of its continuous nature, peritoneal dialysis is less likely to expose patients to these insults and is thus not associated with an increase in sudden cardiac death.

Despite these numerous intermodality differences, some clear conclusions can be drawn: (1) quotidian dialysis offers what appears to be the best potential cardiac protection via reductions in LVH, calcium-phosphate product, and blood pressure; and (2) volume control is likely a key factor in preventing LVH and can be achieved to some extent using any modality provided that vigilance is applied.

Anemia Management

It is fairly well-established that treatment of anemia in ESRD improves quality of life, increases exercise capacity, improves sleep disturbances, prevents LVH, and has been associated with improved cognitive function.[218,219] More importantly, hemoglobin levels in excess of current DOQI targets (>12 g/dL) have recently been associated with reduced hospitalization rates, with no increased risk of death, as had previously been thought to be the case.[219]

Hemodialysis patients are constantly faced with modality-associated blood loss; thus, it is not surprising that on average, PD patients achieve their hemoglobin targets more easily than do HD patients. This difference may also be partially accounted for by greater residual renal function, though no study to date has confirmed this. Ultimately, PD patients tend to have higher hemoglobin levels, with reduced erythropoietin requirements resulting in lower anemia management costs. Canadian data from 1998, when most erythropoietin was

1) Timely referral
2) Slow rate of progression
3) Manage CV risks and comorbidities
4) Timely preparation
5) Timely initiation

Figure 15–10 A reformulated version of integrated care. (From Mendelssohn DC, Pierratos A: Reformulating the integrated care concept for the new millennium. Perit Dial Int 2002; 22[1]:5-8.)

administered subcutaneously, showed that PD patients received on average 6000 units per week as compared with the 8000 units per week received by their HD counterparts.[220] Additionally, and not surprisingly, the prevalence of intravenous iron preparation usage has been up to nine times greater in HD patients.[220] Quotidian dialysis has also been associated with reduced erythropoietin requirements, and thus substantial cost savings.[27]

THE INTEGRATED CARE CONCEPT REVISITED

In view of the previous discussion, it is apparent that many reasonable arguments favor the use of home peritoneal and home-based quotidian hemodialysis as first-line dialysis therapies for patients who cannot be preemptively transplanted. The approach that is proposed takes into account patient autonomy, important clinical outcomes, including survival and cardiovascular disease, new technologies, and advocates maximizing the use of cost-effective therapies. A proposed algorithm is depicted in Figure 15–10. In summary, a modern integrated care approach should comprise the following principles:

1. Early referral to CKD programs should be promoted, because it is associated with improved outcomes and preservation of renal function.
2. CKD care should include aggressive medical management to delay the progression of chronic renal failure, reduce cardiovascular disease burden, and control the complications of chronic renal failure.
3. Preemptive living donor transplantation should be promoted as the first-line treatment for ESRD.
4. Patients who are not eligible for preemptive transplantation should receive timely, adequate, and unbiased education regarding the complete array of renal replacement therapy options available, including home based hemodialysis and home peritoneal dialysis.
5. Suitable patients should be actively encouraged to select a home-based dialysis modality as their initial therapy.

6. Patients initially treated with home dialysis might be switched to another modality, when and if required.

Based on these concepts, we believe that home hemodialysis is an important option that must be included in public discussions about the optimal dialysis modality distribution at the system level. At the patient level, when it is available, it must be promoted as an excellent initial dialysis choice. Unfortunately, home HD may not be available in many jurisdictions. Perhaps this is why home HD is not always included in discussions about integrated care. Indeed, some recent detailed publications do not even mention home HD.[90,175,193] However, nephrologists believe that home HD is currently underutilized and that it should be a significant part of an optimal modality mix. Where it is not available, nephrologists should advocate locally for adequate funding mechanisms, infrastructure, and other system enhancements in order to increase its availability.

In conclusion, end-stage renal failure modality treatment issues are complex, but fundamental, and affect both costs and outcomes. This chapter has tried to set out the issues in a way that highlights the controversies, that promotes a sound rationale for current clinical decision making, and that sets the stage for future well designed studies.

Hemodialysis

Chapter 16

Principles of Hemodialysis

Jane Y. Yeun, M.D. • Thomas A. Depner, M.D.

Hemodialysis is a life-sustaining treatment without which more than a million patients throughout the world would die within a few weeks.[1] This dependence on an extracorporeal blood device is both the fulfillment of hopes by some and the dashing of dreams by others and highlights the need for an in-depth understanding of all aspects of hemodialysis, including the human reactions to it. Before one can configure hemodialysis optimally, one must understand its target, the uremic syndrome. This chapter reviews the physical, chemical, and clinical principles of hemodialysis as they relate to the treatment of uremia, starting with historical milestones and ending with projections for the future. The discussions include brief notes of comparison to other modalities, such as peritoneal dialysis and hemofiltration; these and other topics are abbreviated in this chapter as they are reviewed more extensively in other chapters.

FUNDAMENTAL CONCEPTS

Historical Development

Hemodialysis was originally termed *extracorporeal dialysis* because it was performed outside of the body. Several early pioneers laid the foundation for therapeutic dialysis. Graham[2] (1805–1869), a professor of chemistry in Scotland, invented the fundamental process of separating solutes using semipermeable membranes *in vitro* and coined the word "dialysis." In 1916, Abel[3] in the United States dialyzed rabbits and dogs with a "vividiffusion" device using celloidin membranes and a leech extract called hirudin as an anticoagulant. Abel was the first to apply dialysis to a living organism and to use the term "artificial kidney." In Germany, Georg Haas[4] first used the artificial kidney to dialyze a human in 1924. His attempts were only marginally successful because toxicity from his crude anticoagulant limited his ability to prolong flow in the extracorporeal circuit.

In view of these previous failures, it was not at all certain in 1944 that Willem Kolff's use of extracorporeal dialysis as a human life-saving treatment for patients with renal failure would be successful. Three major advances aided his efforts in the nearly 20 years since Hass's work: the invention of cellophane, the discovery of antibiotics, and the availability of heparin as an anticoagulant. Through his keen interest in kidney failure and his aptitude for mechanics, Kolff[5] and his patients ultimately met with success. Kolff[6–8] is often called the "father of hemodialysis" because his method became accepted as the standard for temporary replacement of kidney function in patients with short-duration acute renal failure.

Attempts to apply hemodialysis to patients who had more prolonged or permanent loss of kidney function were limited because the artery and vein used for blood access had to be tied off after each treatment. In 1960, Belding Scribner,[9] working with Quinton and Dillard at the University of Washington in Seattle, developed a blood access device for repeated dialysis using plastic tubes inserted into the artery and vein. This device, known as the Scribner shunt, and the more permanent arteriovenous (AV) fistulas later introduced by Brescia and Cimino[10] in Italy allowed hemodialysis to be repeated for many years as a life sustaining treatment. For their pioneering work in the field of artificial organs, Kolff and Scribner[11] were granted the prestigious Lasker Clinical Medical Research Award in 2002.

Renal Replacement Therapy

Available Modalities

After the success of hemodialysis, other forms of extracorporeal renal replacement therapy were attempted, including *hemofiltration* and *hemodiafiltration*. These methods rely primarily on convective filtration of the blood instead of diffusion. Several forms of *intracorporeal* dialysis were attempted, including dialysis of the pleura and pericardium, diarrheal therapy, and dialysis of loops of bowel, but the most successful intracorporeal modality has been *peritoneal dialysis*. The most promising renal replacement therapy is *renal transplantation* because it can restore normal or near-normal renal function, including potential functions not yet discovered, with the least inconvenience to the patient.

Hormone Replacement

Modern studies of kidney physiology show that the kidney, like other body organs, has an endocrine function, that is, it

produces hormones that act on distant organs.[12] Currently recognized nephrogenic hormones include erythropoietin, thrombopoietin, calcitriol, prostaglandins, and renin. This improved understanding of renal endocrinology led dialysis providers to launch a massive effort to replace erythropoietin and calcitriol, both deficient in patients with kidney failure. The past few years have seen additional advances in endocrine replacement for ESRD patients: (1) the development of dar-bepoietin, a derivative of erythropoietin with added glycopro-teins that reduce the frequency of administration, (2) the development of calcitriol analogues with comparable sup-pressive effects on the parathyroid gland but lesser effects on gastrointestinal absorption of calcium. See Chapters 14 and 15 for further discussion of hormone replacement.

Psychologic Support

Providers of dialysis have been slow to focus attention on the patient's reaction to kidney loss and dialysis and to develop a better understanding of kidney failure from the patient's perspective. The patient's initial depression on learning about failure of the kidneys, the subsequent denial, often fol-lowed by anger and rejection of medical and surgical treat-ments, and the negative attitude toward renal replacement therapy are now recognized as expected responses that are more intense in younger patients. A common source of frus-tration for otherwise well-intentioned caregivers, these psy-chologic reactions to kidney failure and dialysis are undergoing active investigation using quality of life meas-ures developed specifically for dialysis patients. Poor quality of life is associated with higher levels of comorbidity, includ-ing malnutrition, anemia, poor quality of sleep, delayed ini-tiation of dialysis, and low level of physical function[13-18] that can adversely impact mortality.[19-21] Because formal psychi-atric counseling is considered too expensive for public fund-ing in some countries, it is important for all caregivers to be aware of these stresses and to receive guidance in dealing with them.

Prevention and Management of Medical Complications

Successful management of hemodialysis-dependent patients requires anticipation and prevention of problems rather than simply reacting to crises. Current approaches include attempts to reverse the psychologic effects of kidney loss as discussed previously, preventing anemia and bone disease, monitoring the patient for signs of malnutrition, measuring blood flow in peripheral AV access devices, expecting hypotension during dialysis in patients with concentric ven-tricular hypertrophy, adjusting medication doses appropri-ately, and monitoring the quality of dialysate water. Water quality is especially important because the patient is exposed to large volumes that may contain toxic substances, such as aluminum or bacterial endotoxin (see Chapter 5). Several recent publications documenting higher hospitalization rates,[22] morbidity,[23,24] and mortality[25] in patients with chronic kidney failure referred late to nephrologists have highlighted the importance of preemptive care in patients with end-stage renal disease (ESRD). In the United States, the National Kidney Foundation (NKF) has published a series of clinical practice guidelines and practical recommendations,

with the ultimate goal of improving the quality of life for dialysis patients.[26-29]

Definitions

Dialysis is the passage of molecules in solution by *diffusion* across a *semipermeable membrane.* Essential elements of this process are a *solvent* containing dissolved *solutes* and the membrane that contains *pores* through which some or all of the solutes move by diffusion (Figure 16–1A). The molecular kinetics of diffusion are both solute and membrane specific. Solute characteristics that affect movement across a particular membrane include concentration, molecular weight, shape, charge, and lipid solubility. Membrane characteristics that determine permeability to a particular solute include the aver-age effective pore size; the number, geometry, and distribution of pores within the membrane; membrane surface area and thickness; and surface characteristics, such as charge and hydrophilicity. The solvent itself may also move by diffusion if its chemical activity is not balanced across the membrane. Although solutes may move in both directions across the membrane, it is customary to refer to the compartment con-taining more vital substances that one wishes to preserve as the *dialyzed compartment* and to the solution in the other, usually larger, compartment as the *dialysate.*

The concept of molecular diffusion is critically important to the definition of dialysis. Solutes pass through the membrane down an *electrochemical gradient* caused primarily by a differ-ence in concentration across the membrane (Figure 16–1A). This concentration gradient, which is the driving force for dif-fusion, may also be dissipated by the dialysis (i.e., the molecu-lar concentration gradient tends to fall with dialysis).

In the absence of an electrochemical gradient, solutes may also pass through pores in the membrane by *filtration,* a process of *convection.* The driving force for filtration is *pressure,* either *hydraulic* or *osmotic,* that is unbalanced across the membrane (Figure 16–1B) and independent of dialysis. During filtration, solute passively accompanies the solvent from one compart-ment to the other, causing no change in solute concentration. Convective movement may occur in the opposite direction to diffusive movement and, even in the same direction, convective movement may interfere with dialysis (i.e., the two fluxes may not be additive when they occur simultaneously).

Hemodialysis means literally "dialysis of the blood." This form of dialysis is distinguished by its location outside the body and by the continuous flow of blood across the dialyzer membrane. Therapeutic hemodialysis is most often used to treat kidney failure by equilibrating the blood against an iso-osmotic dialysate. Vital solutes are added to the dialysate at concentrations designed to mimic those normally maintained by the native kidney (Figure 16–1A and Table 16–1). The resulting dialysate is essentially a physiologic salt solution that, in addition to creating a gradient for removal of unwanted solutes, reproduces another vital function of nor-mal kidneys, that of maintaining a constant physiologic con-centration of extracellular electrolytes.

Demographics

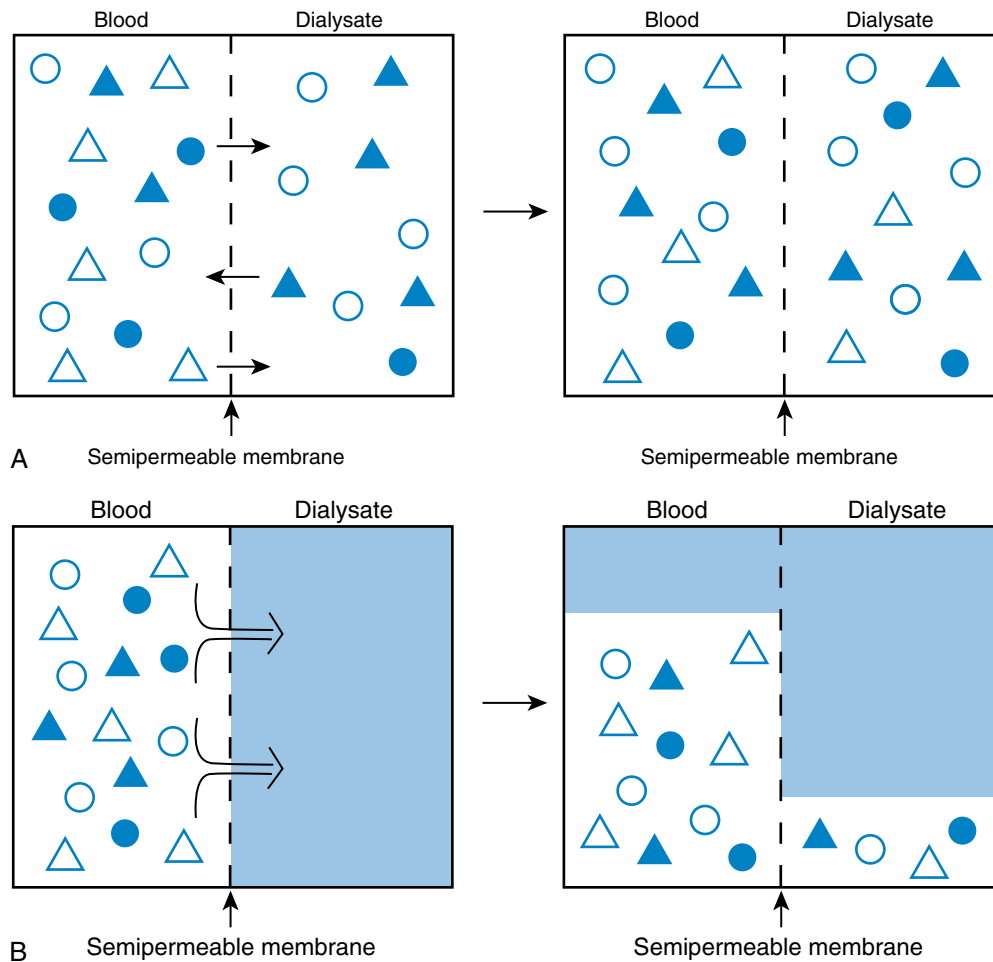
According to the Centers for Medicare and Medicaid Services, at the end of 2001, there were 406,081 patients in the United States with ESRD.[30] Of these ESRD patients, 28% had func-


Figure 16–1 **A,** Diffusion across a semipermeable membrane. Solutes with higher concentrations in the blood compartment, such as potassium (*solid circles*) and uremic toxins (*open triangles*), diffuse through the membrane into the dialysate compartment. Conversely, solutes with higher concentration in the dialysate, such as bicarbonate (*closed triangles*), diffuse into the blood compartment. Solutes, such as sodium and chloride (*open circles*), with concentrations nearly equivalent in the two compartments, move little across the membrane. **B,** Convection across a semipermeable membrane. Hydrostatic pressure applied to the blood compartment causes the solvent to flow across the membrane into the dialysate compartment, bringing along solutes. As a result, for solutes with a sieving coefficient close to 1, there is no change in concentrations in the blood compartment with time.

tioning kidney transplants, whereas the remainder was maintained on dialysis. Both the prevalence and the incidence of ESRD vary greatly with age (Figure 16–2). The high incidence-to-prevalence ratio reflects a high mortality rate, especially in older age groups. The incidence is higher for men (404/million) than for women (280/million) (Figure 16–3), and the disease shows an ethnic predilection for African-Americans and Native Americans (Figure 16–4). The causes of ESRD are listed in Table 16–2. Since 1980, the percentage of patients with diabetic kidney disease has increased from near 0% to 45% of patients initiating dialysis in 2001, primarily because of increased acceptance of diabetic patients into dialysis programs. Before 1980, the reported outcome of diabetic patients receiving long-term hemodialysis was so poor that maintenance hemodialysis was not recommended.[31] Today the mortality rate remains higher than the average, but diabetes mellitus has become the most common cause of ESRD.[30] Mortality rates for patients with diabetic kidney disease also

rise with age, but a higher mortality rate is apparent in younger type I diabetic patients, as shown in Figure 16–5.

The cause of the high ESRD mortality documented in the United States, compared with other countries, is controversial.[32] Speculation ranges from delivery of relatively inadequate dialysis or more liberal acceptance of patients in the United States to inadequate records of mortality kept in other countries. Although the survival of dialysis patients has slowly improved in the last 10 years, it remains greater than 20% per year in the United States. Statistics from the United States Renal Data System (USRDS) show a 79% 1-year survival, 65% 2-year survival, and 38% 5-year survival.[30] Causes of death[30] are listed in Table 16–3. Greater than 50% are due to cardiovascular disease, but it is unclear whether the uremic milieu, coexisting medical illnesses, or dialysis itself accounts for the high mortality (see Chapter 12). Seventeen percent of deaths in the United States occurred after voluntary withdrawal of dialysis, presumably because the patient's quality of life was

Table 16–1 Solutes Present in Dialysate

Component	Concentration (mEq/L)
Sodium	135–145
Potassium	0–4.0
Chloride	102–106
Bicarbonate	30–39
Acetate	2–4
Calcium	0–3.5
Magnesium	0.5–1.0
Dextrose	11
pH	7.1–7.3

not sufficient to justify its continuation. This relatively high withdrawal rate probably reflects the ready availability and aggressive approach to initiating dialysis in the United States by all parties involved in that decision, including the patient.

As shown in Figure 16–6, the incidence of ESRD in the United States has steadily increased,[30] most likely as a result of aging of the population and increasing acceptance of dialysis for older patients as part of their Medicare entitlement. The most recent analyses of the USRDS data suggest a leveling off in the rate of rise in the incidence (Figure 16–6).

UREMIA: THE TARGET OF HEMODIALYSIS

Uremia is the clinical state or syndrome that is reversed by dialysis therapy, and it literally means "urine in the blood." Whether or not urine output falls, all patients with uremia accumulate solutes, collectively known as *uremic toxins*. It is this accumulation of solute, the most abundant of which is *urea*, that justified the application of dialysis as a treatment for uremia.[4] From another perspective, the concept of uremia as a state of intoxication by substances normally eliminated by the kidney is supported by the success of therapeutic dialysis.

Clinical Syndrome

Although not all patients exhibit all of the symptoms and signs of uremia, the monotony of the clinical syndrome in patients with widely divergent causes of kidney failure indicates that the syndrome is the consequence of the kidney failure per se, not the underlying disease. Nearly every organ system is involved, but the most highly targeted are the gastrointestinal tract and the central nervous system. Early symptoms include dysgeusia, loss of appetite, nausea, weight loss, inability to concentrate on a mental task, lethargy, daytime sleepiness, pruritus, and menstrual irregularity in women. Unfortunately, these symptoms are not specific. They appear in most patients only at an

Data from USRDS: Excerpts from the United States Renal Data System 2003 annual data report. Am J Kidney Dis 2003; 42:S37-S181.

advanced stage of kidney damage (80% to 90% loss of nephrons). Far advanced symptoms and signs include uremic serositis with pericarditis, once the harbinger of death due to uremia; central nervous system suppression leading to uremic coma; overt peripheral neuropathy; and uremic fetor due to volatile amines emitted in the breath.

Fluid accumulation, which is subtle in most patients, contributes to hypertension that eventually leads to cardiac hypertrophy and diastolic dysfunction. The latter may precipitate congestive heart failure. Because cardiovascular disease is the most common cause of death in hemodialyzed patients, increasing attention has been focused on this aspect of the uremic syndrome and on blood pressure and other risk factors for cardiovascular complications, especially in the early phases of kidney failure (see Chapter 12).

Uremic Toxins

Most of the solutes known to accumulate in uremia (Table 16–4) are low in molecular weight and consequently are dialyzable.

Some originate from food (e.g., sodium and phosphorus), whereas others are products of metabolism (e.g., urea, uric acid, and hydrogen ion). Routine clinical measurements include serum levels of the electrolytes sodium, potassium, bicarbonate, and chloride; the nitrogenous substances urea, creatinine, and uric acid; and other substances, such as magnesium, calcium, phosphate, and intact parathyroid hormone. Serum pH is not usually measured, but the serum bicarbonate concentration inversely reflects acid accumulation in the patient. Serum aluminum and β_2-microglobulin levels are useful in some patients. Outside of these readily available solute levels, serum levels of the other solutes in Table 16–4 are not clinically useful.

Although urea is a poor marker of native kidney function, it has special significance in ESRD patients because it is the most abundant solute to accumulate and because its accumulation results from both generation (from protein catabolism) and failure of renal excretion. Because urea generation is an index of protein nutrition, monitoring urea levels is potentially doubly important. However, this dual origin of urea complicates interpretation of any measured level, rendering it nearly useless unless additional measurements are taken to identify the rela-

tive contributions. Mathematical models of urea kinetics applied to serum urea concentrations measured before and after dialysis treatments allow separation of protein catabolism from the contributions of dialyzer and native kidney function. As discussed in more detail subsequently, this modeling process currently forms the basis for quantifying and prescribing hemodialysis (see Quantifying Hemodialysis).

Other substances proposed as uremic toxins include carbamylated proteins from posttranslational modification by high concentrations of urea and cyanate,[33,34] advanced glycation end products from the Maillard reaction between 3-deoxyglucosone and the terminal NH_2 groups of proteins,[35-37] β_2-microglobulin,[38] uric acid,[39] p-cresol,[39, 40] parathyroid hormone,[41,42] granulocyte inhibiting proteins,[40] hydrogen ion and metabolic acidosis,[43] homocysteine,[44-46] other organic and phenolic acids,[47] advanced lipoxidation end products,[48, 49] and advanced oxidation protein products.[48, 49] Some of these substances have been linked with specific diseases:

- β_2-microglobulin and advanced glycation end products with amyloidosis[35,38,50,51]
- Advanced glycation end products and parathyroid hormone with heart disease[36,37,41,42]
- Uric acid, p-cresol, and granulocyte inhibiting protein with immune dysfunction[39,40,52]
- Phenolic acids, dicarboxylic acids and guanidines variably with inhibition of erythropoiesis, shortened red blood cell life span, and neurologic symptoms in animals[47,53]
- Both phenolic acids and dicarboxylic acids with impaired protein binding of drugs[47]
- Advanced lipoxidation end products, advanced oxidation protein products, and homocysteine with atherosclerosis[46,48,54]

These substances are thought to evoke their toxicity by (1) progressive bulk accumulation (e.g., β_2-microglobulin and advanced glycation end products), (2) upsetting the oxidation-reduction balance (e.g., uric acid and p-cresol), (3) binding to vital signaling and transport proteins (e.g., phenolic acids), (4) altering second messengers, and (5) altering nitric oxide production.[49,55,56] Traditional hemodialysis applied 3 days per week may remove some of these uremic toxins more slowly or not at all because they are larger in size, are not readily available to the dialyzer (sequestered in remote com-

Figure 16–6 Incidence of ESRD in the United States with time. (Adapted from USRDS: Excerpts from the United States Renal Data System 2003 annual data report. Am J Kidney Dis 2003; 42:S37-S181.)
Table 16–4 Solutes That Accumulate in Uremia and Their Proposed Toxicity (If Known)

Solute	Proposed Toxicity
Low molecular weight (<500 daltons)	
Sodium	Volume overload
Potassium	Arrhythmia, muscle weakness
Hydrogen ion (metabolic acidosis)[43]	Degrades protein (activates ubiquitin proteasome); alters vitamin D and parathyroid hormone levels
Urea[65,66]	None
Creatinine	None
Phosphate	Osteodystrophy
Magnesium	Muscle weakness
Uric acid[39]	Disturbs calcitriol production and metabolism; ? immune dysfunction
Guanidines[47]	Immune dysfunction
Hippuric acid[47]	Muscle weakness; neurologic symptoms; decreases drug binding to albumin
Indoxyl sulfate[47]	Displaces drugs bound to albumin; glomerulosclerosis
p-cresol[39]	Immune dysfunction
Oxalic acid[47]	Tissue deposits; inhibits endothelial cell replication and migration
3-carboxyl-4-methyl-5-propyl-2-furanproprionic acid[47]	Displaces drugs bound to albumin; inhibits erythropoiesis; inhibits mitochondrial oxidation
4-hydroxybenzoic acid (phenolic acid)[47]	Platelet dysfunction; shortened red cell survival; neurologic symptoms
Quinolinic acid[47]	Inhibits erythropoiesis; seizures in mice
Homocysteine[44]	Accelerated atherosclerosis
Middle (500–5000 daltons) and high (5000–50,000 daltons) molecular weight	
Parathyroid hormone[41,42]	Inhibits mitochondrial oxidation; hypertrophic cardiomyopathy; cardiac fibrosis; immune dysfunction
β_2-microglobulin[35,38,50,51]	Dialysis amyloidosis
Carbamylated proteins[33,34]	? Accelerated atherosclerosis
Advanced glycation end products[35-37]	Dialysis amyloidosis; accelerated atherosclerosis
Granulocyte inhibitory proteins[40]	Immune dysfunction

Some of the low-molecular-weight solutes behave similarly to middle-molecular-weight solutes because of significant protein binding.

partments),[57] or are protein bound.[58,59] However, if the total duration of hemodialysis or hemodiafiltration is increased and administered over 6 days per week, removal of larger or sequestered molecules and even some protein-bound substances improves significantly.[60-62]

Despite its importance as a measure of dialysis adequacy, urea itself has demonstrated little toxicity in experiments where urea was added to the dialysate to prevent its removal.[63,64] Similarly, although all other solutes mentioned accumulate in kidney failure, their levels are well below that necessary to evoke toxic responses in animals and in humans, even when measured in patients with overt signs of uremia, such as pericarditis or uremic coma.[65,66] Even after decades of research, investigators are unable to identify a single toxin or a group of toxins responsible for the immediate life-threatening uremic syndrome that is quickly reversed by dialysis.[47, 63, 65-69] Because dialysis does little more than remove fluid and dialyzable solutes, the uremic syndrome must result from a rapid accumulation of known and unknown toxins in aggregate, perhaps each at subtoxic levels.

Residual Syndrome

It is now clear that the amount of dialysis necessary to sustain life is not enough to maintain a high quality of life. A challenge to current investigators is the development of techniques for analyzing and treating this "residual syndrome,"

which affects some patients more than others but reduces the quality of life despite apparently adequate dialysis. At present, several components of the syndrome can be identified, such as anemia, osteodystrophy, dialysis amyloidosis, and accelerated atherosclerosis, some of which are treatable (see Chapters 12 to 15). The proposed uremic toxins discussed previously may account, in part, for the residual syndrome, but, almost certainly, other components remain to be defined.[49,56,58,69] These components include: (1) the cause of inflammation in dialysis patients,[70-73] (2) the cause of malnutrition and accelerated atherosclerosis,[74-78] (3) the role of hyperhomocysteinemia in accelerated atherosclerosis[44,45] and graft thrombosis,[46,79] (4) the role of hyperphosphatemia in cardiovascular disease,[80-82] and (5) the interaction between malnutrition, inflammation, and atherosclerosis.[76-78] The effectiveness of increasing the frequency of dialysis to eliminate the residual syndrome remains to be proven. It is equally possible that the syndrome results from toxins that are poorly dialyzable because of protein binding in the blood or tissues or sequestration of toxins in compartments other than the blood.

Goals of Hemodialysis

The primary goal of hemodialysis is the replacement of renal excretory function. There is no doubt that hemodialysis can sustain life in patients who have no kidney function. Survival for as long as 30 years has been documented for hemodialysis alone,

a treatment that does nothing more for the patient than remove solute.[83] Moreover, the molecular weight range of effectively removed solutes was relatively low until recent years when *high-flux* dialysis membranes were introduced.[84] The earlier experience indicates that the most life-threatening toxins are easily dialyzable. Precise goals and standards of dialysis adequacy have been defined, based on outcome studies in large populations, in terms of the clearance of small-molecular-weight, easily dialyzed solutes, the marker for which is urea.[28,85,86]

A prospective interventional study of dialysis adequacy in the late 1970s, the U.S. National Cooperative Dialysis Study (NCDS), provided clear-cut evidence for a level of urea clearance that was inadequate.[87] More recent uncontrolled experience suggests that more dialysis is better for the patient[88-94] (see Chapter 3). Analysis of solute kinetics, however, suggests that the benefit of more dialysis is logarithmically related to the amount of dialysis and that a point may be reached beyond which more dialysis does nothing more than inconvenience the patient, potentially worsening the quality of life.

This theoretical construct was confirmed recently by the National Institutes of Health (NIH)–sponsored Hemodialysis (HEMO) Study, a multicenter prospective clinical trial that randomized 1846 patients to receive hemodialysis with a target equilibrated Kt/V of 1.05 (equivalent to single pool Kt/V of 1.25, the generally accepted minimal standard at the time of the study) versus 1.45 (equivalent to single pool 1.65).[95] The subjects were further randomized to receive dialysis using a high-flux membrane (β_2-microglobulin clearance >20 mL/min) versus a low-flux membrane (clearance <10 mL/min). More dialysis or the use of a high-flux membrane did not reduce mortality, reduce hospitalization rates for infection or cardiovascular disease, or maintain serum albumin levels. Although subgroup analysis showed slightly less first cardiovascular hospitalizations for patients treated with high-flux membranes[95] and slightly lower mortality for women treated with a higher urea clearance,[96] these findings were of borderline significance and must be confirmed by other studies before they can be applied clinically. As with any randomized study, the power of the study diminishes and the probability of error increases exponentially when subgroups are analyzed. For now, hemodialysis patients should receive a urea clearance (Kt/V) of at least 1.2. Whether more frequent dialysis in the form of daily short-duration hemodialysis or daily nocturnal hemodialysis will reduce further mortality or morbidity remains to be determined.

A secondary goal of hemodialysis treatment is the replacement of hormones normally produced by the kidney. Even before dialysis therapy was available, the devastating effects of vitamin D "resistance" were evident, and much was written about renal rickets in children and osteomalacia in adults, even before 1900.[97] When 1,25-dihydroxyvitamin D (calcitriol), an activated form of vitamin D, was isolated in 1969 from renal proximal tubular cells, where it is formed from the precursor 25-hydroxyvitamin D, the puzzle was solved.[98,99] The subsequent synthesis of calcitriol allowed clinical nephrologists to replace this vital hormone[100] and prevent renal osteodystrophy, one of the most devastating long-term complications of renal failure[101] (see Chapter 14). In contrast to bone disease, there was less mystery about the anemia of kidney failure, which was a recognized effect of deficient erythropoietin, a hormone uniquely synthesized by the kidney and responsible for activation of bone marrow erythroid precursors.[102-104] Even before

dialysis is necessary, hemoglobin levels begin to decline, causing a syndrome of anemia that has subtle adverse effects on multiple organ systems.[105-107] The synthesis and widespread availability of erythropoietin in the late 1980s and early 1990s removed the transfusion dependency for nearly all patients and improved the quality of life for most patients by raising the average blood hemoglobin concentration[105-107] (Chapter 15). Recent advances in the field of hormone replacement include the availability of (1) calcitriol analogues (e.g., paricalcitol and doxecalciferol that also suppress parathyroid hormone but cause less hypercalcemia) and (2) darbepoietin-α, an erythropoietin derivative with additional glycoproteins attached, conferring a longer half-life (see Chapters 14 and 15).

In addition to the need for dialysis, patients require extensive psychologic and social services support to cope with their own emotional reactions to loss of a vital organ. Nutritional counseling is also important, primarily to limit fluid gains between dialyses, to control hyperphosphatemia (phosphate is removed poorly by standard hemodialysis), to reduce the life-threatening risk of hyperkalemia, and to prevent malnutrition (a major yet potentially reversible risk for morbidity and mortality). Successful treatment and rehabilitation of the whole patient requires intensive initial emotional support and prolonged surveillance of the patient's nutrition.

DIALYSIS

As defined previously, dialysis is a process of diffusion of molecules in solution across a semipermeable membrane. Forces that govern the pattern and rate of diffusion have been defined in precise mathematical terms that include properties of the molecule, the solvent, and the membrane. The salient points of the physics of dialysis are discussed here because a detailed analysis is beyond the scope of this chapter. For detailed analysis of the physical laws that govern dialysis, the reader is referred to formal texts on kinetic modeling.[108-110]

Laws of Diffusion

Diffusion is a consequence of random molecular movements (*molecular kinetics*) that follow the laws of probability and are driven by temperature, pressure, and concentration. Since temperature and pressure are relatively constant during therapeutic dialysis and among dialysis centers (see later), the major clinical variable that affects diffusion is the solute concentration. Fick's law of diffusion, derived from mathematical laws of statistical probability, shows that the rate of diffusion is linearly dependent on the *concentration gradient* (i.e., the driving force for diffusion):

$$J = -(DA/X)\Delta C \qquad (1)$$

J is *solute flux* (mg/min), which, when applied to a membrane, can be viewed as the unidirectional rate of movement of a solute across the membrane (Figure 16–1A). ΔC is the concentration gradient across the membrane (mg/mL), A is the membrane area (cm^2), X is the membrane thickness (cm), and D is a constant, called the *coefficient of diffusion* or diffusivity (cm^2/min). The last-mentioned is a measure of the permeability of the membrane material to the measured solute, independent of solute concentration, area, and thickness. Conventionally, a minus sign is placed on the right side of

Equation 1 to indicate that solute moves away from the dialyzed compartment. Equation 1 reflects the intuitive concept that diffusion across a membrane varies directly with the membrane area and solute concentration gradient and inversely with the membrane thickness.

Dividing both sides of Equation 1 by ΔC results in an expression for *solute dialysance*:

$$J/\Delta C = -\text{ dialysance} = -DA/X \qquad (2)$$

Equation 2 shows that dialysance is always independent of concentration and is constant throughout a static dialysis despite changes in concentration on either side of the membrane. Clinicians rarely use the concept of dialysance, opting instead to describe dialysis in terms of *clearance*. This is reasonable because clearance is derived from measurements only on the blood side of the membrane, where clinical analytic techniques are readily available. The only difference between dialysance and clearance is the substitution of blood side C for ΔC in Equation 2:

$$J/C = -\text{ clearance} = -K \qquad (3)$$

When the concentration of solute on the dialysate side is 0, ΔC = C, and clearance is equal to dialysance. This condition exists at the start of a dialysis procedure and during all single-pass dialysis (see Hemodialysis). For all other conditions, ΔC is less than C, so clearance is lower than dialysance. Dialysance may also be considered the *unidirectional flux* of solute across the membrane from the blood to the dialysate compartment.

If the *volume of the dialyzed compartment* (V) is constant, dividing both sides of Equation 3 by V shows that the fractional rate of change in concentration is constant:

$$(J/V)/C = -K/V = -k \qquad (4)$$

The symbol *k* is called the *rate constant*. The constantly changing term *J/V*, when expressed at any given instant, is dC/dt and therefore (J/V)/C is (dC/C)/dt. The latter can be viewed as the fractional change in concentration over an initial short period of time (*dt*):

$$(dC/C)/dt = -K/V = -k \qquad (5)$$

Equation 5 demonstrates that concentration-dependent diffusion is a *first order process*; that is, despite the minute-to-minute changes in concentration within the dialyzed compartment, the fractional rate of change is constant when the dialysate concentration remains zero. Flux of solute across the membrane, which is the goal of dialysis, is both driven by the concentration and expressed as a change in concentration. When the rate of change is factored by the driving force [(dC/dt)/C)], the resulting fractional rate of change is constant.

The rate constant (k) has units of time^{-1} or a fraction per unit of time and is a function of both the molecular properties of size, shape, charge, and interaction with the membrane, and of the membrane itself, including its surface area, porosity, and thickness. Large molecules, those with complex shapes, and those with an electric charge diffuse less readily across the membrane. Membranes that are more porous, have larger surface, and are thinner favor passage of solutes by diffusion. Although the rate constant is useful to demonstrate the first order concept, it is of less practical value than the expression for clearance depicted in Equation 3.

The difference between the rate constant (k) in Equation 4 and the clearance (K) shown in Equation 3 is *V*, the volume of solute distribution. Equation 3 has the advantage of expressing the dialysis effect as a volume equivalent of solute diffusing across the membrane per unit of time. The volume transferred per unit of time is constant; that is, a milliliter equivalent of solute is transferred per unit of time regardless of how much solute is contained in that milliliter. The rate of diffusion is directly proportional to the membrane surface area, which is constant for any given model of dialyzer.

Effects of Temperature, Pressure, and Molecular Weight

Diffusion is a consequence of molecular motion, which is affected by pressure and heat energy and by molecular mass. The rate of diffusion is proportional to the absolute temperature, which is approximately 273°K at room temperature. Within the range of temperatures experienced in the dialysis center, the proportionate change in absolute temperature (260°K to 280°K) is so small that its influence on diffusion across the dialysis membrane is negligible. More important are the physiologic effects of temperature on blood flow and body water compartmentalization, which have significant effects on solute kinetics within the patient (see Quantifying Hemodialysis). Similarly, pressure effects have little influence on diffusion, within the range of pressures recorded in modern dialyzers.

Molecular mass plays a more significant role in determining the rate of diffusion because at a given temperature and pressure, the heavier molecules move more slowly and collide with the semipermeable membrane less frequently. Small-molecular-weight substances, such as urea and creatinine, diffuse readily across a semipermeable membrane, whereas larger substances, such as β_2-microglobulin or albumin, diffuse slowly or not at all. The larger size of the heavier molecules further impedes diffusion through small pores.

Dialysate

Preparation of the dialysate and its composition are critical to the success of dialysis. For hemodialysis, the solution must be prepared from properly treated water (see Chapter 5) and contain the solutes listed in Table 16–1 in concentrations comparable to those of plasma. Dialysate must have a low concentration of endotoxin to prevent pyrogen reactions in the patient, but, in contrast to peritoneal dialysis (see Chapter 10), sterility is not a requirement because the semipermeable membrane excludes large particles, such as bacteria and viruses. Vital electrolytes and glucose are added to the dialysate to reduce or abolish their concentration gradients, whereas bicarbonate or a bicarbonate precursor is added in higher concentrations to promote accumulation in the patient. Dialysate glucose concentrations are near those of plasma; thus, in contrast to peritoneal dialysis, osmotic forces do not play an important role in removing fluid.

In practice, solute concentrations in the dialysate are fairly standard. The most common concentrations that may be individualized are those for potassium, calcium, and bicarbonate (Table 16–1). In many dialysis centers, the bicarbonate concentration is fixed at 35 or 39 mEq/L. Potassium ranges from 0 to 4 mEq/L, depending on the patient's serum concentration before dialysis. A compelling reason must exist, however, to use dialysate potassium concentrations of 0 or 1 mEq/L because of the dangers associated with a precipitous drop in the serum concentration. In particular, patients on

digoxin must be dialyzed against at least 2 mEq/L of potassium. Calcium concentrations vary from 1 to 3.5 mEq/L. At the lower concentration, calcium is removed from the patient, whereas at the higher concentration, calcium diffuses into the patient during dialysis. The concentration of sodium is usually fixed at 140 mEq/L, which is the middle of the normal range in whole plasma. Although the concentration in plasma water is closer to 150 mEq/L, the Gibbs-Donnan effect of negatively charged plasma proteins reduces the sodium concentration in completely equilibrated dialysate closer to 140 mEq/L.[111,112]

HEMODIALYZERS

A *hemodialyzer*, synonymous with *dialyzer*, is often called an "artificial kidney." It is configured to allow blood and dialysate to flow, preferably in opposite directions, through individual compartments, separated by a semipermeable membrane. By convention, blood entering the hemodialyzer is designated *arterial*, whereas blood leaving the hemodialyzer is *venous*. The principal differences among the many available hemodialyzers are the membrane composition, membrane configuration, and membrane surface area. Hemodialyzers affect the efficiency and the quality of dialysis by virtue of their membranes, which determine their $K_O A$ value, and by the rates of blood and dialysate flow, which determine their clearance values (see later discussion of $K_O A$) (Table 16–5).

Membrane Composition, Configuration, and Surface Area

Composition of the Membrane

Two major classes of membrane material are available commercially: (1) cotton fiber, or *cellulose-based membranes,* and (2) *synthetic membranes.* Cellulose-based membranes range from unmodified cellulose to substituted cellulose membranes. Unmodified cellulose membranes have many free hydroxyl groups, which are thought to be responsible for their

bioincompatibility and propensity to activate white blood cells, platelets, and serum complement. In an effort to improve membrane biocompatibility while keeping costs down, the cellulose polymer is treated with acetate and tertiary amino compounds to form a covalent bond with the hydroxyl groups (e.g., cellulose acetate and aminated cellulose—Cellosyn or Hemophan). Further issues of biocompatibility are covered in detail in Chapter 2.

The major polymers in commercial synthetic membranes are polyacrylonitrile, polysulfone, polycarbonate, polyamide, and polymethylmethacrylate. Despite their increased thickness, these membranes can be rendered more permeable than the cellulose membranes, allowing for greater fluid and solute removal. They are also more biocompatible. Because the pore sizes in the synthetic membranes can be made wider, larger-molecular-weight substances, such as β_2-microglobulin, can be removed more efficiently.[113,114] High flux synthetic membranes also clear phosphate more efficiently, although the effect on serum phosphate levels is minimal. Despite their increased cost, synthetic hemodialyzers are increasingly preferred: 50% to 86% of new patients in 1996[115] compared with 36% in 1993 and 15% in 1990.[116]

Plate Versus Hollow Fiber Dialyzers

All current hemodialyzers are constructed with a plastic casing, usually polycarbonate. The *plate dialyzer* is made with flat membrane sheets stacked on top of each other and anchored at the two ends of the casing. Blood and dialysate flow through alternating layers of the membrane in opposite directions. The plate design has been less thrombogenic, requiring less heparin, but the tendency to thrombosis is reduced in more recent models of both plate and hollow-fiber design.[117] The main disadvantages of the plate design are the slightly higher priming volume required to fill the blood compartment (100 to 120 mL) and the expansion of the blood compartment that occurs when transmembrane pressure (TMP) increases during dialysis.

The blood compartment of the *hollow fiber dialyzer* is 60 to 120 mL and does not increase during dialysis. Several thousand of the membrane fibers, each approximately 200 μm in inside diameter, are imbedded in a *potting material*, usually polyurethane, at each end of the casing. The casing closely surrounds the fiber bundle, forcing dialysate to flow between and around each fiber in the direction usually opposite to blood flow. Blood flows to or from the open end of each fiber through a removable *header* attached to the blood tubing. In addition to a lower blood priming volume, the hollow-fiber design increases the area of contact between blood and dialysate, allowing for the most efficient exchange of solutes. Major disadvantages of the hollow-fiber design are thrombosis, and the requirement for a potting compound, which absorbs chemicals used to disinfect newly manufactured dialyzers (ethylene oxide) or reused dialyzers (formaldehyde, peracetic acid, or glutaraldehyde). These chemicals then leach slowly from the material and potentially enter the patient's blood during dialysis (see Chapter 2).

Surface Area Considerations

Most hemodialyzers have a membrane surface area of 0.8 to 2.1 m². As the area increases, the efficiency of the dialyzer

increases. To maximize membrane surface area, one can increase the length of the hollow fiber, increase the number of hollow fibers, or decrease the diameter of the hollow fiber while holding other parameters constant.[118] Each of these maneuvers, however, has undesirable effects when carried too far. Increasing the fiber length increases shear rate and magnifies the pressure drop between blood entering and exiting the dialyzer. Increased shear rate increases ultrafiltration, whereas the pressure drop decreases ultrafiltration because the TMP gradient dissipates at the venous end of the dialyzer. Any decrease in ultrafiltration decreases its contribution to solute clearance and offsets the potential advantage of the increased surface area. Increasing the number of hollow fibers increases the volume of extracorporeal blood and may eventually compromise hemodynamic stability. Finally, as the diameter of the hollow fiber decreases, the resistance to blood flow increases and clotting is enhanced. As fibers thrombose, effective surface area for diffusion decreases and solute clearances fall. Because of these adverse consequences, the minimal acceptable internal fiber diameter is 180 μm.[118] The design and geometry of the hollow-fiber dialyzer represent a delicate balance among these factors.

The composition and the thickness of the membrane are usually more important than the surface area in determining dialyzer efficiency. In general, the thinner the membrane, the more efficient the transport of solutes and fluid across the membrane. Because of the high tensile strength of cellulose fibers, cellulose membranes are thinner than synthetic membranes, partially offsetting their inherent low flux.

Effects of Flow on Clearance

Blood Flow

Dialyzer blood flow (Q_b) is driven by a roller pump and generally ranges from 200 to 500 mL/min, depending on the type of vascular access. Blood flow influences the efficiency of solute removal (see Table 16–5).

As Q_b increases, more solute is presented per unit of time to the membrane, and solute removal increases. Urea removal rises steeply as Q_b increases to 300 mL/min, and although urea removal continues to rise as Q_b approaches 400 to 500 mL/min, the slope is less steep. For larger molecular weight substances, removal is slower and more time-dependent rather than flow-dependent because diffusion across the membrane is limited as discussed previously.

Dialysate Flow

Most dialysis centers use a *single pass* of dialysate; that is, the dialysate is discarded after one passage through the dialyzer. For sorbent dialysis, however, only about 5 L of water are used and dialysate is constantly regenerated by cycling through a cartridge system to remove the undesirable solutes (e.g., urea, creatinine, and potassium). Sorbent dialysis is rare because manufacture of the Redy dialysate delivery system stopped in the mid-1990s.

Countercurrent flow maximizes the concentration gradient between blood and dialysate throughout the length of the dialyzer (see Table 16–5). When blood flow and dialysate flow are in the same direction (*co-current*), solute removal decreases by about 10%.

In addition to decreasing boundary layers and streaming effects (see later discussion), increasing Q_d minimizes the accumulation of waste products in dialysate and provides a higher solute gradient between blood and dialysate for optimal diffusion. However, even for highly diffusible solutes, the benefits progressively diminish as the dialysate flow rate is increased above the blood flow rate.

K_OA: Mass Transfer Area Coefficient

K_OA is the product of the *mass transfer coefficient*, K_O, which has units of cm/min, and the membrane area, A. K_O is specific for a particular molecule and membrane type, including the membrane's pore size and thickness, but is independent of solute concentration and membrane surface area. It can be considered the solute flux per unit of area per unit of concentration gradient and is equivalent to D/X in Equation 6. Because solute flux per unit of concentration gradient is defined as dialysance, K_O may also be expressed as the dialysance per unit of membrane area. K_OA, which is the *mass transfer area coefficient*, therefore has units of mL/min and is equivalent to the dialysance of a membrane with a fixed area during static dialysis (no flow). In addition to being independent of solute concentration, K_OA is also independent of blood and dialysate flow within certain limits (see later text). Therefore, K_OA is the most specific constant that describes the efficiency of a dialyzer for removal of a particular solute and is the best parameter for comparing dialyzers. Higher values indicate more efficient solute removal.

K_OA has the same units of measurement as clearance and, in practical terms, can be considered the maximum clearance achievable for a particular dialyzer and solute. Maximum clearance is achieved at the beginning of dialysis when blood solute concentrations along the length of the dialyzer are equal (no flow) and dialysate concentration is 0 or, at the opposite extreme, when blood and dialysate flow rates are infinite. Under these two conditions, the only factor governing a solute's clearance is the dialysis membrane.

Conversely, when Q_b and Q_d are finite, the clearance is lower than K_OA because both flow rates govern diffusion, as discussed previously and because of the way clearance is expressed, as the solute removal rate divided by the *inflow concentration*. The net driving force for removal is the *mean concentration gradient* across the membrane, which is a complex function of Q_b and Q_d (see next section). The increase in clearance caused by an increase in Q_b is the result of a flow-dependent increase in the mean concentration gradient across the membrane, driving more solute into the dialysate. Because the inflow concentration does not change with increased Q_b, the conventional measure of clearance as defined previously increases with increasing Q_b.

Relationships Between Flow, K_OA, and Solute Clearance

Because concentrations change logarithmically along the dialyzer membrane, the true mean concentration on either side of the membrane is actually the log mean concentration expressed:

$$\log \text{mean } C = (C_{in} - C_{out}) / \ln (C_{in} / C_{out}) \qquad (7)$$

where C_{in} and C_{out} represent inflow and outflow solute concentrations. Similarly, the mean gradient or concentration difference across the membrane, which is the driving force for diffusion, is actually the log mean concentration gradient. When flow is countercurrent, the log mean gradient is:

$$[(Cb_{in} - Cd_{out}) - (Cb_{out} - Cd_{in})/ \ln [(Cb_{in} - Cd_{out}) / (Cb_{out}/Cb_{in})] \qquad (8)$$

where *Cb* depicts the blood concentration and *Cd* the dialysate concentration, and the subscripts *in* and *out* represent the dialyzer inflow and outflow. A rearrangement of Equation 2 shows that J, the solute flux (removal rate, e.g., in mg/min), can be expressed as the product of K_OA and the concentration gradient:

$$J = Flux = K_O A \, (\log mean \, gradient) \qquad (9)$$

Clearance (K_d), as defined for a device with flow, is the flux measured either on the blood side $[Q_b(Cb_{in} - Cb_{out})]$ or on the dialysate side $[Q_d(Cd_{in} - Cd_{out})]$ of the membrane divided by the inflow concentration:

$$K_d = Q_b(Cb_{in} - Cb_{out})/(Cb_{in}) = - Q_d(Cd_{in} - Cd_{out})/(Cb_{in}) \qquad (10)$$

Combining Equations 3, 8, 9, and 10 yields a practical equation for calculating K_OA from an instantaneous measurement of solute clearance and both Q_b and Q_d when flow is countercurrent:

$$K_O A = \frac{Q_b \cdot Q_d}{Q_b - Q_d} \ln \left(\frac{Q_d(Q_b - K_d)}{(Q_b(Q_d - K_d)} \right) \qquad (11)$$

A rearrangement of Equation 11 gives another practical equation for calculating expected clearance from Q_b, Q_d, and K_OA. This equation eliminates the need to measure blood concentrations to predict the effect of changes in flow on clearance:

$$K_d = Q_b \left[\frac{e^{K_O A \frac{Q_d - Q_b}{Q_d Q_b}} - 1}{e^{K_O A \frac{Q_d - Q_b}{Q_d Q_b}} - \frac{Q_b}{Q_d}} \right] \qquad (12)$$

Boundary Layers and Streaming Effects

Despite a rapid flow along the membrane, the solvent tends to adhere to the membrane creating a *boundary layer*, or unstirred layer, that adds to the diffusive pathway on both sides of the membrane.[109] This layer of solvent adjacent to the membrane tends to thin out as flow is increased or as turbulence is produced at the membrane surface. In addition to forming boundary layers, dialysate tends to move along the path of least resistance or channel, leading to nonuniform flow and bypassing some of the membrane area. This s*treaming effect* is more pronounced at lower dialysate flow rates, especially in large dialyzers. Both boundary layer and streaming effects cause K_OA (the resistance to solute diffusion across the membrane) to increase as dialysate flow increases,[119] although the effect is less *in vivo* than *in vitro*.[120,121] Recent changes in the shape of hollow fibers and the insertion of inert spacer yarns have improved dialyzer performance further through reducing the effects of channeling and unstirred layers.[122,123] Both effects are less prominent on the blood side of hollow fibers because of the geometric advantages of flow within hollow fibers, the scrubbing effects of red blood cells, and less variance in Q_b.

HEMODIALYSIS

Using dialysis as a form of therapy for the patient vastly complicates this otherwise simple procedure. Factors that complicate the delivery of dialysis include the access device, the patient's compliance with the dialysis prescription and diet, and solute disequilibrium. Developing standards of adequacy requires detailed studies of large populations, with careful attention to the multiple variables that influence outcome, in addition to the dialysis itself. Achieving target solute concentrations in the patient during and between treatments requires complex mathematical models with multiple variables to account for differences among patients, including differences in size and solute generation rate. These factors add considerable complexity to the relatively simple laws of diffusion and flow discussed earlier, so that the solutions to patient problems are often approximations at best.

Types of Clearance

As noted in the discussion of dialysis and depicted in Equation 2, dialyzer clearance is the solute removal rate (flux) factored by the blood inflow concentration. During single-pass dialysis, the flux of urea is directly proportional to the inflow concentration, so that urea clearance tends to be constant despite the fall in blood concentration with time. The simplest type of clearance is the *instantaneous dialyzer clearance*, which can be measured by sampling blood on both sides of the dialyzer while recording Q_b at any instant in time. Although the dialyzer urea clearance tends to remain constant, it may fall during treatment because of loss of surface area from clotting or because of changes in Q_b or Q_d. The *effective clearance*, or *integrated dialyzer clearance*, accounts for these changes by linking the measurement of clearance to the pre-dialysis and post-dialysis blood urea nitrogen (BUN). This clearance is essentially the answer to this question: What average urea clearance would be required to drive the BUN down to the measured post-dialysis value from the measured pre-dialysis value?

The mathematical solution requires a process known as *urea modeling* (see later Quantifying Dialysis). It can be calculated using either a single-compartment or a two-compartment urea kinetic model, entering a pre-dialysis and immediate post-dialysis BUN in the former case and multiple intra-dialysis and post-dialysis BUN in the latter case. In either case, the result is a *dialyzer urea clearance* that is not affected by urea disequilibrium. The integrated dialyzer clearance is often called the *delivered clearance* to distinguish it from the *prescribed clearance*. The latter is simply the expected clearance derived from the dialyzer K_OA and flow rates (see Equation 11).

During dialysis, solutes must diffuse from within the red blood cells and tissues into the blood to reach the dialyzer. Such compartmentalization of body fluids adds complexity to the concept of clearance because different values may be chosen for the denominator of Equation 3. Even for urea, which diffuses easily across cell membranes from tissue to blood, some disequilibrium still develops among the various

body compartments during dialysis. As a result, the patient's clearance, or *whole body clearance*, is always less than the dialyzer clearance. Whole body clearance is a virtual clearance (not instantaneously measurable) derived from the pre-dialysis and *equilibrated* post-dialysis BUN. Like dialyzer clearance, it is also a mean clearance integrated over time on dialysis, but it accounts for the presence of solute disequilibrium.

Adding further complexity to the concept of clearance are the frequency and duration of dialysis. Because *residual native kidney clearance* (K_r) exerts most of its effect between dialyses when dialyzer clearance is zero, it cannot be directly added to dialyzer clearance (see Quantifying Hemodialysis). *Intermittent clearance*, as obtained with hemodialysis, is inherently less efficient than the *continuous clearance* of native kidneys or continuous peritoneal dialysis. There are two explanations for this reduced efficiency.

First, although dialyzer clearance is not compromised by an intermittent schedule, total solute removal tends to be reduced because blood solute concentration declines logarithmically and not linearly during dialysis (Figure 16–7).[110, 124, 125] Because solute levels do not change during continuous dialysis, this effect is absent, and solute removal is maximal at all times. Therefore, to reduce solute levels to a similar value, intermittent dialysis must be more intense when averaged over a week of treatment, as shown by the uppermost line in Figure 16–8. This explanation applies even in the absence of solute disequilibrium.

The second explanation applies to the more realistic situation in which solute concentration in the blood compartment is below that in other compartments as solute disequilibrium develops during dialysis. Here again, dialyzer clearance is unaffected, but solute access to the dialyzer is limited (see later further discussion of Solute Disequilibrium). For continuous replacement modalities and native kidney function, the blood solute concentration is stable, and the effect of solute disequilibrium is minimal, so clearances are easy to calculate:

$$\text{Native kidney urea clearance} = K_r = (U_{urea} \times V)/(P_{urea} \times t) \quad (13)$$
$$\text{Peritoneal urea clearance} = (D_{urea} \times V)/(P_{urea} \times t) \quad (14)$$

where U_{urea} is urinary urea concentration, P_{urea} is blood urea concentration, D_{urea} is peritoneal dialysate urea concentration, t is time, and V is 24-hour urinary volume for Equation 13 and 24-hour dialysate volume for Equation 14. Continuous clearances are easier to calculate but more difficult to measure than intermittent clearances. For hemodialysis, the clinician can take advantage of the dialysis-induced perturbations in urea concentrations to measure clearance and other patient variables that are not readily measurable by other means.

It is apparent from the previous discussion that the clearances measured during intermittent forms of dialysis are not directly comparable to native kidney clearance or clearances measured in patients undergoing continuous dialysis. These observations also help to explain the significant difference between the minimum recommended weekly dose of dialysis (Kt/V) for hemodialysis (1.2 per dialysis × 3 dialyses per week = 3.6/wk) and for peritoneal dialysis (2.0–2.2/wk). To allow a direct comparison, the following formulas adjust for intermittence by calculating the continuous equivalent of intermittent clearance (*equivalent Kt/V or EKR*). For intermittent therapy during a steady state of urea nitrogen balance[126]:

$$EKR_{mean} = \frac{\text{removal rate}}{\text{mean concentration}} = \frac{\text{generation rate}}{\text{mean concentration}} = \frac{G}{TAC} \quad (15)$$

$$EKR_{peak} = \frac{\text{generation rate}}{\text{peak concentration}} = \frac{G}{\text{Av Peak BUN}} \quad (16)$$

G and *TAC* are derived from formal urea modeling. Using Equation 15 and adjusting for time and patient volume, the quantity of hemodialysis necessary to keep a patient's time-averaged BUN constant falls from a weekly Kt/V of 3.6 for thrice-weekly treatments to an EKR of 2.8 for continuous treatment.[127] If mean peak urea is substituted for TAC in Equation 16, the EKR falls to approximately 2.0, consistent with the current clinically accepted minimum adequacy for

Figure 16–7 Changes in blood urea nitrogen (BUN) concentrations during and after dialysis. Measured BUN levels during and immediately after dialysis fit best into a two-compartment variable-volume mathematical model (*solid line*). The single-compartment variable-volume model (*dashed line*) overestimates BUN levels during the dialysis and fails to predict the rebound. The upper dotted horizontal line at 40 mg/dL is the simple arithmetic mean of the pre-dialysis and the post-dialysis BUN. The middle dotted horizontal line at 36 mg/dL represents the log mean BUN during the treatment, as predicted by the single-compartment model. The lower dotted horizontal line at 34 mg/dL is the true mean BUN, obtained from actual measurements throughout dialysis.
Figure 16–8 Urea kinetics value (Kt/V) required to maintain the same timed average urea concentration (TAC) of urea. To achieve the same mean blood urea nitrogen concentration, the dose of dialysis provided per week may be reduced as the frequency of dialysis increases. The upper solid line shows the required weekly Kt/V for urea based on an intercompartment mass transfer coefficient (K_C) of 500 mL/min. Even a simple single-compartment model with no resistance to diffusion in the patient (*dashed line* = infinite K_C) shows a dependence of weekly Kt/V on dialysis frequency. The discrepancy in weekly Kt/V between intermittent and continuous dialysis is even greater for a theoretic substance that dialyzes as well as urea but exhibits greater disequilibrium within the patient (*dotted line* = K_C of 100 mL/min). (Adapted from Depner TA: Quantifying hemodialysis and peritoneal dialysis: Examination of the peak concentration hypothesis. Semin Dial 1994; 7:315-317. Reprinted with permission of Blackwell Science, Inc.)

peritoneal dialysis[128] (see Chapter 8). Although the EKR_{peak} values calculated using the peak urea concentration (see Equation 16) better matches clinical experience, the argument that peak urea levels mediate uremic toxicity does not naturally follow since urea is relatively nontoxic.[125] Instead the relationship likely reflects a fortuitous difference between the diffusibility of urea and the true uremic toxins. One of the advantages of EKR is allowance of simple arithmetic addition of residual native kidney clearance to dialyzer clearance (see later text).

Quantifying Hemodialysis

Dialysis is a treatment born out of empiricism. Solute mass transport during dialysis was described in precise mathematical terms but only after dialysis was established as a life-sustaining treatment for patients with advanced renal failure. Much of the effort to describe the kinetics of transport has been devoted to determining how to best quantify the amount of dialysis prescribed and delivered. Because it is easy to measure and because the exact uremic toxin(s) are not known,

mathematical models of urea kinetics have been used to quantify dialysis.

Mathematical Models of Urea Kinetics

Since urea is a small, highly soluble, yet uncharged molecule with little binding to proteins, it distributes only in aqueous environments and diffuses rapidly among the various body water compartments. The rate of diffusion is so rapid that a single space of distribution (total body water) can be assumed for most approximations. Between dialyses, when urea accumulates at a slow, constant rate and there is ample time for distribution among the compartments, this assumption is reasonable, and the single-pool, or *single-compartment kinetic model*, is appropriate. During dialysis, however, when blood concentrations change rapidly, urea gradients appear. Serum concentrations fall lower than predicted by the single-compartment model during dialysis and rebound after dialysis, as shown in Figure 16–7. Because of this disequilibrium, more complicated mathematical models were developed to better explain the behavior of urea during dialysis.

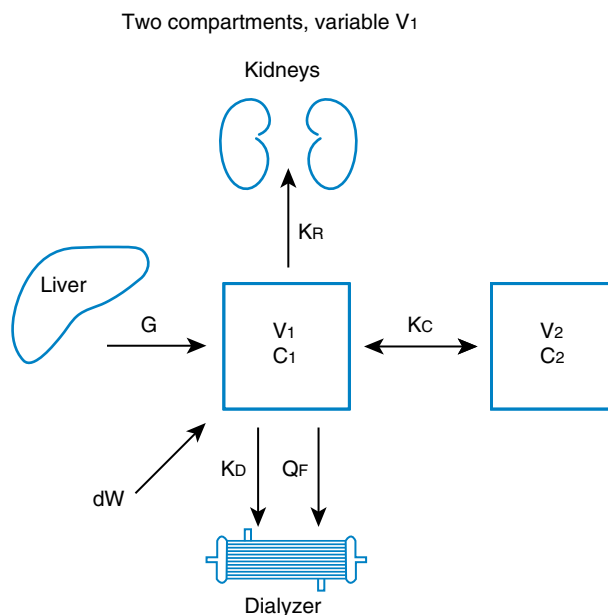
The *two-compartment model* (Figure 16–9) assumes that the body is divided into two pools of water, with a finite resistance to diffusion between them. The resistance is expressed inversely as the intercompartment mass transfer coefficient (K_C), which is a measure of the average solute conductivity among compartments for the particular solute. K_C is analogous to K_OA, is solute specific, and has units of measurement that are similar to K_OA (mL/min). The mathematical solution


Figure 16–9 Two-compartment, variable-volume urea kinetic model. This model assumes that urea is distributed in two compartments (subscripts 1 and 2). V and C are the volume and concentration of urea in each of the two compartments. *G*, urea generation rate; K_C, intercompartment mass transfer coefficient; K_R, residual native kidney clearance; K_D, dialyzer clearance; Q_F, rate of fluid removal during dialysis. (From Depner TA: Prescribing Hemodialysis: A Guide to Urea Modeling. Boston, Kluwer Academic Publishers, 1991.)

in most cases suggests that the two compartments are the intracellular and extracellular pools separated by cell membranes, but the model does not require this assumption.

For solutes of larger molecular weight, varying charge, and bulkier configuration than urea, disequilibrium among the various compartments is even more pronounced, K_C is lower, and the solute gradients are even larger. Urea is unique in its ability to diffuse across cell membranes, especially the red blood cell membrane, where urea transporters have been found.[129,130] Most other solutes, even in the same range of molecular weight as urea, probably require a more complex kinetic model.

Kt/V$_{urea}$

The greatest lesson learned from the NCDS was that patient outcome correlates best with dialyzer urea clearance (K_d). When the level of any known solute is compared to urea clearance, the latter is better able to predict morbidity and mortality in dialysis populations.[131] To allow comparisons among patients and patient populations, a standard expression of clearance must be used, normalizing variables such as the frequency and duration of dialysis and patient size. Adjustment for size is most conveniently done using the patient's volume of urea distribution (V) as the denominator instead of the patient's surface area, commonly used for native kidney clearance. Standards for adequacy are currently available for hemodialysis delivered three times weekly. If K_d/V is multiplied by the duration of each dialysis (t), the result ($K_d \times t/V$) is a normalized or fractional clearance expressed per dialysis instead of per unit of time. During dialysis, total clearance is the sum of native kidney clearance and dialyzer clearance ($K_r + K_d = K$), so the fractional clearance per dialysis is more often expressed as *Kt/V*.

Equation 5 shows that simple first-order diffusion across a dialyzer membrane can be expressed as a constant fractional removal rate, if the dialysate concentration remains zero. For hemodialysis with a constant blood flow and a constant single-pass flow of dialysate, fractional solute removal (dC/C) is also constant. Integration and log transformation of Equation 5 gives a powerful expression for the normalized clearance:

$$Kt/V = \ln(C_0/C) \qquad (17)$$

Equation 17 shows that the normalized clearance (Kt/V) can be determined simply by measuring a pre-dialysis BUN (C_0) and a post-dialysis BUN (C). This eliminates the need to measure or estimate the dialyzer clearance, the native kidney clearance, the patient's urea volume, or even the duration of each dialysis to obtain this most powerful correlate to patient survival. It also provides an effective *delivered* clearance, because it is derived from measurements of the resulting change in BUN within the patient.

Equation 17 ignores urea generation during hemodialysis (G) and the change in volume that invariably occurs due to ultrafiltration (dV). These variables have significant effects on Kt/V (changing its value by up to 30%) that can be included in the expression if formal modeling is used to calculate Kt/V:

$$d(CV)/dt = G - (K/V)C \qquad (18)$$

Equation 18 is the mathematical expression of the single pool urea kinetics described earlier. Not only does its solution for the *intra-dialysis* interval give a more accurate measure of Kt/V, but also its *inter-dialysis* solution provides a method for calculating G and V and for expressing urea concentrations (C) at any specific time during the week:

$$C = C_0\left[\frac{V - Bxt}{V}\right]^{\left(\frac{Kr + Kd + B}{B}\right)} + \frac{G}{Kr + Kd + B}\left[1 - \left[\frac{V - Bxt}{V}\right]^{\left(\frac{Kr + Kd + B}{B}\right)}\right] \qquad (19)$$

where V is the solute distribution volume after dialysis (mL), and B is the rate of change in V (mL/min), which is usually negative during dialysis and positive between dialyses.

Residual Clearance

Because native kidney function is continuous and occurs between as well as during dialysis treatments, K_r cannot be simply added to K_d. To do so would grossly underestimate the contribution of K_r to overall excretory function. Two methods have been proposed to combine the two clearances to represent overall excretory function as a single clearance. The first converts the continuous native kidney component to the equivalent of an intermittent clearance, in the form of Kt/V, before addition[108]:

$$Kt/V' = Kt/V + K_r \times 4500/V \qquad (20)$$

Kt/V′ is a new value for Kt/V and approximates the dialyzer clearance required to maintain the same solute levels and therefore the same risk to the patient. The second method is less widely used but is more exact. It essentially converts the intermittent component to an equivalent continuous clearance[126]:

$$EKR = G/TAC \qquad (21)$$

EKR is a combined clearance in mL/min that includes both the dialyzer and the residual clearance components expressed as a continuous clearance. It is calculated from the urea generation rate (G) and the mean BUN (*TAC*) obtained from formal urea kinetic modeling. Mathematical subtraction separates the two:

$$EKR_d = EKR - K_r \qquad (22)$$

where EKR_d is the dialyzer component.

Dialysate Methods

The single-pool kinetic model discussed earlier estimates mass balance of urea across the dialyzer from changes in *blood* concentration. It makes several incorrect assumptions that cause the errors shown in Figure 16–7, but the two largest errors are in opposite directions and tend to offset each other.[110] This fortuitous balancing of errors has justified continued use of the single-compartment model to monitor dialysis adequacy. The indirect measurement of urea removal on the blood side, however, has been criticized by some who favor more direct measurements on the *dialysate* side to avoid these errors. However, use of instruments that measure dialysate urea concentrations either continuously (e.g., by urea electrode) or at multiple times intermittently[132-134] is important to ensure the accuracy of the dialysate method.[135] With these instruments, the dialysate curve-fitting method can be used, which is more accurate than the dialysate/volume method.[135] Dialysate monitoring offers additional advantages, including elimination of blood removal from the patient and avoidance

of exposure to the patient's blood, eliminating this potential risk to the patients and staff.

Dialysate collection allows a more direct calculation of V from the amount of urea removed during dialysis divided by the change in concentration. Additional adjustments for ultrafiltration and urea generation yield:

$$V = \frac{Q_d C_d t_d - C_0 \Delta V - t_d (G - K_r C_{av})}{C_0 - C_e} \qquad (23)$$

where t_d is the duration of dialysis, G is the urea generation rate, ΔV is the change in volume, K_r is the residual urea clearance, C_d is the average dialysate urea concentration, C_{av} is the average serum urea concentration, C_0 is the pre-dialysis BUN, and C_e is the equilibrated post-dialysis BUN. Rearrangement of Equation 23 provides a method that avoids the delay required to measure directly the equilibrated post-dialysis urea concentration:

$$C_e = \frac{C_0 V - Q_d C_d t_d + C_0 \Delta V + t_d (G - K_r C_{av})}{V} \qquad (24)$$

eKt/V

C_e obtained from Equation 24 can be used in place of the post-dialysis urea concentration for calculating Kt/V using the single compartment model (spKt/V). This *equilibrated* value for Kt/V, or eKt/V, is always lower than spKt/V but is more realistic because it avoids the rebound error that inflates the single pool value. eKt/V has been called the patient Kt/V because it reflects the actual change in BUN and removal of urea from the patient. A recent large population study showed that eKt/V can be predicted from spKt/V as a function of time on dialysis[136]:

$$\begin{aligned} eKt/V &= spKt/V - 0.6K/V + 0.03 \qquad (25) \\ &= spKt/V \,(1 - 0.6/t) + 0.03 \end{aligned}$$

where K/V is spKt/V divided by t in hours. This estimate of eKt/V, when repeated in the same patient, had a lower variance than eKt/V measured using the dialysate method.[136,137] Although eKt/V is a more accurate measure of the dose actually received by the patient and was the target of the HEMO Study, it is not currently used as a yardstick of dialysis because there are no established standards with which to compare measured values.

Volume of Urea Distribution

The total body water volume is equal to the volume of urea distribution (V) and can be calculated using various methods, including indicator dilution,[110] bioimpedance,[138] or averaged V determined from prior kinetic modeling.[110] V is most easily estimated, however, from anthropometric formulas that use the patient's height (cm), weight (kg), sex, and age (years).[139-141] The most commonly used is the Watson formula[139]:

Males: V (liters) = 2.447-0.09516 × age + 0.1074
$$\times height + 0.3362 \times weight \qquad (26)$$

Females: V (liters) = − 2.097 + 0.1069 × height $\qquad (27)$
$$+ 0.2466 \times weight$$

Equations 26 and 27 were designed to apply to all people with widely differing anatomy, but because V can vary independently of height and weight,[141] the anthropometric estimates of V have a large coefficient of variation.[139] V can be measured more precisely by modeling urea kinetics because the model makes none of the assumptions found in the anthropometric formulas and because repeated modeling further reduces the variance. The resulting modeled V is analogous to V measured by indicator dilution methods, using urea as the indicator. The HEMO Study Group found that kinetically modeled V was consistently 13% to 19% lower than that derived from the Watson equation.[142] It is unclear whether this difference indicates a reduction in total body water or a difference in the volume of water compared to the volume of urea distribution in patients with ESRD.

Urea Generation and Protein Catabolism

In anuric patients, serum urea concentrations reflect urea generation from net protein catabolism and removal of urea by dialysis. Virtually all urea derives from breakdown of amino acids, and, conversely, protein nitrogen is catabolized mostly to urea. Under steady-state conditions, only 10% of amino acid nitrogen is converted to nonurea nitrogenous wastes.[143,144] Furthermore, the net *protein catabolic rate* (PCR) approximates protein intake during a steady state of nitrogen balance. Therefore, the measurement of the *urea generation rate* (G), provided by formal urea modeling, allows an easy estimate of PCR and protein intake. In practice, PCR is usually normalized (divided) by V (PCRn) to allow comparison among patients of different size.

Based on independent detailed studies of two separate groups of patients, one group receiving dialysis[143] and the other with chronic kidney failure not receiving dialysis,[144] the relationship between PCR (g/day) and G (mg/min) can be described with the following equation:

$$PCR = 9.35 \times G + 11 \qquad (28)$$

Equation 27 shows that the majority of nitrogen released from excess catabolism of dietary and endogenous protein is converted to urea; only 11 g of protein per day are converted to nonurea nitrogenous compounds, such as creatinine, uric acid, hippurate, and amino acids. The generation of nonurea nitrogenous compounds varies with patient size but not with daily protein intake, whereas the generation of urea depends upon protein intake. Adjusting the production of nonurea nitrogenous compounds for the average body size in these studies, using urea volume, and normalizing the entire expression to V,

$$PCRn = 5420 \,(G/V) + 0.17 \qquad (29)$$

where PCRn is normalized PCR in g/kg/day and V is the patient's urea volume (total body water) in liters.

The importance of PCR, PCRn, and G cannot be overemphasized. The NCDS showed that a consistently high BUN strongly predicted a poor outcome, but low BUN levels resulting from low urea generation rates (low PCRn) were associated with even higher morbidity and mortality.[145] A subsequent large population study[146] confirmed that patients with low PCRn, and therefore low G, had high morbidity and mortality rates, possibly as a result of severe malnutrition, although other disease states may have suppressed the patients' appetites. These studies illustrate that it is not enough to know the BUN level; one must know how it got there. A low BUN from malnutrition is bad, but a low BUN from vigorous dialysis is good. Urea kinetic modeling allows

the clinician to separate nutritional influences from the dialysis effect using urea concentrations sampled immediately before and after dialysis.

Solute Disequilibrium

Solute disequilibrium is defined as a concentration difference or gradient for dissolved solutes among body compartments. This problem develops during dialysis and slowly dissipates over several minutes to hours after the end of dialysis (Figures 16–7 and 16–10). Solute disequilibrium caused by resistance to diffusion across cell membranes is called *diffusion-dependent disequilibrium.* When disequilibrium is caused by differences in blood flow among various vascular beds, it is termed *flow-dependent disequilibrium.*

In the past, diffusion-dependent disequilibrium was thought to be more important. Mathematical models predicted that solute concentration differed among the various compartments but was uniform throughout the blood pool. More recent data suggest that the contribution of diffusion-dependent mechanisms to solute disequilibrium may be less than previously thought.[147-153] Mathematical models have been developed that fully describe urea disequilibrium using purely flow-dependent disequilibrium.[150] These models assume that solutes diffuse instantly between compartments, so the observed gradients are attributed to differences in relative blood flow/volume served by the vascular bed. The relative importance of these two types of disequilibrium remains to be determined. Both predict lower solute concentrations during dialysis than the single-pool model, thus reducing the efficiency of hemodialysis.

Vascular access recirculation may cause a decrease in effective solute clearance[147,154-156] and is a special case of flow-dependent disequilibrium. Access recirculation occurs when blood that has just been dialyzed returns immediately to the dialyzer in the reverse direction through the access device. Multiple causes have been identified, including venous outflow stenosis, central venous stenosis, close proximity of the dialysis needles, and accidental reversal of the arterial and venous needles. Although dialyzer clearance is preserved, total solute removal decreases because the recirculated venous blood dilutes the solute concentration of the incoming arterial blood, thus lowering the solute concentration gradient across the dialyzer membrane. When 100% recirculation exists, all of the dialyzed blood returns to the dialyzer, and the patient derives no benefit from dialysis. Although access recirculation is found in less than 5% of hemodialyses, when it exists, the timing of blood sampling at the end of dialysis is critical to avoid errors in measuring the delivered dialysis dose (Figure 16–10). If blood is sampled immediately at the end of dialysis (Point *A* in Figure 16–10) without slowing the blood pump, the measured urea concentration is significantly lower than the actual arterial concentration. This error leads to a falsely high Kt/V. Sampling the arterial (inflow) blood 10 to 20 seconds after slowing the blood pump at the end of dialysis eliminates dilution from access recirculation (Point *B* in Figure 16–10). Vascular access-related issues are addressed further in Chapter 4.

With a model of *multiple parallel circuits,*[152] differences in blood flowing to various parts of the body have been invoked to explain the differences in solute concentration among these vascular beds during dialysis (Figure 16–11). Blood from the rapidly flowing circuits is exposed to the dialyzer more frequently and dilutes the solute concentration of blood flowing to the dialyzer. This essentially limits the access to the dialyzer of slower-flowing circuits that have higher solute concentrations. Thus, differences in blood flow within the blood pool reduce the solute concentration entering the dialyzer and the average concentration in the patient. This reduces the efficiency of dialysis, decreases solute removal, and invalidates the use of solute concentration in peripheral venous blood for calculating vascular access recirculation.[148,149,153]

Cardiopulmonary recirculation (CPR), present in dialysis patients with AV shunts[151] (see Figure 16–11), is a specific example of one of these multiple parallel circuits. Because the vascular shunt has low resistance and routes blood directly from the arterial to the venous circulation, blood flowing through this circuit returns to the heart at a faster rate. Although the dialyzer clearance is unaffected, the concentration gradient across the dialyzer membrane is reduced by
Figure 16–10 Post-dialysis blood urea levels. The post-dialysis blood urea nitrogen (BUN) level is a moving target, so attention to sampling time is needed for consistency and accuracy when measuring both the urea kinetics value and normalized protein catabolic rate. Point A is the immediate post-dialysis sample obtained without taking precaution to prevent the dilution artifact from access recirculation. The sample at point B eliminates this artifact because it is taken from the arterial (inflow) port 10 to 20 seconds after slowing the blood pump at the end of dialysis. Sampling at point C, 2 minutes post-dialysis, eliminates the effects of cardiopulmonary recirculation. At point D, 1 hour post-dialysis, urea equilibration throughout the body is essentially complete. (From Depner TA: Assessing adequacy of hemodialysis: Urea modeling. Kidney Int 1994; 45:1522-1535. Used with permission of Kidney International.)

FLOW-RELATED DISEQUILIBRIUM
Figure 16–11 Urea disequilibrium as a consequence of differences in regional blood perfusion. Differing simultaneous concentrations of urea throughout the body can develop solely as a consequence of differences in regional blood perfusion, shown here as a parallel arrangement of tissue compartments. Although the consequences are similar to urea disequilibrium resulting from membrane-limited diffusion, the mechanism is entirely different because this model assumes an absence of diffusion barriers. Instead, the rapid changes in blood urea levels at the beginning and end of treatment are caused by the differing blood perfusion rates. Blood in the more rapidly flowing circuits comes into contact with the dialyzer more frequently, so it has a lower urea and solute concentration and essentially dilutes the solute concentration from slower-flowing blood pools. The proximal and most rapidly flowing blood pathway is the cardiopulmonary circuit through the peripheral arteriovenous (AV) access device. (From Depner TA: Approach to hemodialysis kinetic modeling. *In* Henrich WL [ed]: Principles and Practice of Dialysis, 2nd ed. Baltimore, Williams & Wilkins, 1999.)

cardiopulmonary recirculation so that solute removal is impaired. As is evident from Figure 16–10, cardiopulmonary recirculation contributes to the rebound in blood solute (urea) concentration after dialysis is completed, as the various

blood compartments equilibrate. Cardiopulmonary recirculation is not present in patients with central venous catheters for vascular access because blood drawn from the central vein is returned to the same vein, and the shunt circuit is absent.

Adequacy of Hemodialysis: Current Recommendations

Before the NCDS, absolute blood urea concentrations were used to monitor the efficacy of dialysis and to determine the frequency of dialysis. Kinetic modeling gained popularity and increasing acceptance after the NCDS reported that both high and low blood urea concentrations were associated with increased mortality,[131,145] highlighting the fact that the absolute blood urea concentration is a poor marker of uremia and dialysis dose. Using absolute blood urea levels risks setting in motion the vicious cycle of providing less dialysis to patients who are malnourished, causing a further reduction in BUN. Assessing dialysis adequacy with kinetic modeling avoids this vicious cycle because kinetic modeling determines the clearance of urea, based on the *change* in urea concentration.

The NCDS data showed that maximal benefit from dialysis was obtained above a Kt/V_{urea} of 1.0 per dialysis administered three times a week.[145] Subsequent data from uncontrolled studies suggested that further benefit may be derived from increasing Kt/V_{urea} to 1.2 or greater[88-94] (see Chapter 3). Based on the available data, the NIH, the Renal Physicians Association, and the NKF established the minimum Kt/V_{urea} at 1.2 per dialysis administered three times a week in their respective consensus conferences.[28,85,86] The HEMO Study results support this minimum Kt/V_{urea} since increasing single pool Kt/V_{urea} from an average of 1.3 to 1.7 did not reduce mortality or morbidity further.[95] The NKF additionally recommended the application of formal urea kinetic modeling (see Quantifying Hemodialysis) for routine quantification of hemodialysis.[28] If formal modeling is not available, simplified formulas should be used.

Filtration and Dialysis

Because fluid nearly always accumulates in patients between therapeutic hemodialyses, net ultrafiltration must be a part of each treatment to maintain fluid balance. In a sense, water is also a toxin that accumulates and must be removed on a regular basis. The mechanism of water removal during hemodialysis is not diffusion but pressure filtration of the blood as it passes through the dialyzer. Although filtration also removes solute, and solute removal by filtration is also a first-order process, the additional clearance from filtration is often less than expected. Conversely, one can remove solute with filtration alone (see later Hemofiltration and Hemodiafiltration Therapy). If no dialysis takes place and the sieving coefficient is close to 1.0, the clearance is simply the filtration rate (see later Quantitative Contribution of Filtration to Solute Removal). The sieving coefficient is the fractional concentration of the solute in dialysate compared to blood water.

Often patients and sometimes the technical staff equate removal of fluid to the effectiveness of a dialysis session because fluid removal is visibly measurable. Of course, if therapeutic dialysis removed only fluid, the patient would quickly die of uremia. Removal of toxic solute by diffusion, the most significant goal of dialysis, is a silent process, detectable only

by measuring solute levels in blood or dialysate samples; removal of fluid is easily displayed by modern volume-controlled dialysate delivery systems and is evident from the change in patient weight.

Dialyzer Ultrafiltration Coefficient

The same membrane properties (i.e., thinner, more porous membranes with a large surface area) that improve solute clearance also improve hydraulic fluid removal. In addition, membrane tensile strength plays a role in determining the maximum pressure that can be applied. Dialyzers are rated by their *ultrafiltration coefficient* (K_{Uf}), with units of mL/hr/mmHg. Typical K_{Uf} values for standard and high flux dialyzers are listed in Table 16–6.

Quantitative Contribution of Filtration to Solute Removal

As plasma water moves from the blood compartment to the dialysate, solutes dissolved in plasma follow passively. Convective clearance thus augments diffusive transport, and the contribution can be quantified mathematically. When ultrafiltration is present during dialysis, blood flow into the dialyzer (Q_{bi}) can be expressed as the sum of blood flow out of the dialyzer (Q_{bo}) and the ultrafiltration rate (Q_f):

$$Q_{bi} = Q_{bo} + Q_f \tag{30}$$

From the previously described definition of dialyzer clearance and considering mass balance, dialyzer clearance (K_d) can be expressed as a function of solute concentrations and blood flow rates through the dialyzer:

$$K_d = J/C_{in} = [(C_{in} \times Q_{bi}) - (C_o \times Q_{bo})]/C_{in} \tag{31}$$

where J is the solute flux, C_{in} the inlet (arterial) solute concentration, and C_o the outlet (venous) solute concentration. Combining and rearranging Equations 30 and 31 yields the following,

$$K_d = Q_{bi}(C_{in} - C_o)/C_{in} + Q_f(C_o/C_{in}) \tag{32}$$

Equation 32 shows that dialyzer clearance of a particular solute is the sum of solute clearance in the absence of ultrafiltration ($Q_{bi} = Q_{bo}$) and a fraction of the ultrafiltration rate. At

one extreme, when all the solute is removed by diffusion ($C_o = 0$), there is no contribution from ultrafiltration. At the other extreme, when no diffusion is present ($C_{in} = C_o$), the dialyzer clearance is the ultrafiltration rate. This latter case occurs in the setting of hemofiltration (to be discussed further), where all solute clearance results from filtration. During the usual hemodialysis treatment, the contribution of convective clearance to the total dialyzer clearance is small. Even at high rates of ultrafiltration (2 L/hr or 33 mL/min), the relative contribution of ultrafiltration to total urea clearance is only about 10 mL/min or 5%, assuming C_o/C_{in} for urea of 0.3 to 0.4 and dialyzer urea clearance of 200 mL/min.

In clinical practice, outlet solute concentration is rarely measured, limiting the usefulness of Equation 32. With further mathematical manipulation,[110] C_o can be eliminated, yielding:

$$K_d = K_{d0} + Q_f(1 - K_{d0}/Q_{bi}) \tag{33}$$

where K_{d0} is the dialyzer clearance without ultrafiltration and can be calculated from Q_{bi} and the dialyzer K_OA. Q_f is readily calculated from the weight loss during dialysis divided by the duration of dialysis or directly measured by volume-controlled dialysis machines.

Hemofiltration and Hemodiafiltration Therapy

Up to now, we have discussed the principles of filtration in the context of hemodialysis, using filtration mainly for removing excess fluid, while relying on diffusion for solute removal. Filtration alone can also be used to remove both solute and solvent, so-called *hemofiltration*.[157, 158] As discussed earlier and as evident from Equation 33, in the absence of diffusion, dialyzer clearance is the ultrafiltration rate. Therefore, to achieve solute clearance comparable to that of hemodialysis, large amounts of fluid must be removed, on the order of 30 to 40 L during each treatment, with simultaneous replenishment using a pyrogen-free physiologic salt solution.

The benefits of hemofiltration are improved hemodynamic stability[159,160] and improved removal of larger solutes.[158,161] Larger-molecular substances are removed more effectively by hemofiltration because convection has a greater effect of enhancing the relatively slow diffusive movement of larger molecules compared to small molecules (see earlier discussion

Table 16–6 Characteristic Values for Standard, High-Efficiency, and High-Flux Dialyzers and Hemodialysis

	Standard	High Efficiency	High Flux
Blood flow rate (mL/min)	250	≥350	≥350
Dialysate flow rate (mL/min)	500	≥700	≥700
K_OA urea	300–500	600–1000	Variable
Urea clearance (mL/min)	<200	250–400	Variable
Urea clearance/body weight (mL/min/kg)	<3	>3	Variable
Vitamin B_{12} clearance (mL/min)	30–60	Variable	>100
Ultrafiltration coefficient (mL/hr/mmHg)	3.5–5.0	<15	>15
Membrane	Cellulose	Variable	Variable

of convection and diffusion). In addition, filtration requires a highly permeable (high flux) membrane to achieve the high filtration rates (30 to 40 L per dialysis).[158,161] During filtration, peripheral vascular resistance has been observed to increase, whereas it remains unchanged or decreases during hemodialysis against a bicarbonate-containing or acetate-containing dialysate.[160,162] The reason for the increase is not entirely clear but recent studies have suggested a temperature effect.[163] The increased vascular resistance helps to support the blood pressure during hemofiltration. The primary disadvantage of hemofiltration is the large amount of sterile replacement fluid required, but equipment designed to simplify hemofiltration and produce sterile replacement fluid on-line is under development.[164]

Hemodiafiltration is the combination of hemodialysis and hemofiltration (i.e., addition of dialysate flow to the hemofiltration circuit). Solute removal is accomplished by diffusion and by filtration, but, in contrast to traditional hemodialysis, the filtration component contributes much more because of the higher magnitude of filtration relative to dialysis. Although intermittent hemofiltration and hemodiafiltration are not widely used in the United States for treating ESRD, these two modalities have been adapted for wide use in intensive care units to treat patients with acute renal failure.

Filtration Effects on Blood Pressure, Regional Blood Flow, and Solute Removal

Blood pressure falls as fluid is removed (see Chapter 11), in part, because the normal response of vasoconstriction to fluid removal is impaired in dialysis patients. The use of bioincompatible membranes and acetate as a source of bicarbonate may predispose the patient to vasodilation. To aggravate the situation further, solute removal decreases blood osmolarity, causing slight fluid shifts from the intravascular compartment into the intracellular compartment. In patients at high risk of hypotension during dialysis, separating filtration (*isolated ultrafiltration*) from dialysis may improve their hemodynamic stability.[159,160]

Although theoretically filtration may account for a significant fraction of solute removal during dialysis, in practice it can also interfere with solute removal. The development of intravascular volume depletion during dialysis causes vasoconstriction in the skin and skeletal muscle and shunts blood through other vascular circuits (such as the AV shunt), enhancing flow-related solute disequilibrium.

High-Efficiency, High-Flux Hemodialysis

Initial hemodialyses were limited by low dialyzer membrane permeability, requiring more than 6 hours for each treatment. Although treatment times were shortened to 4 hours or less three times a week as dialyzer design improved, the time spent attached to the dialysis machine was still unacceptable to many patients. The next major advancement came in the late 1980s, when the technical problems with bacteriologic contamination of bicarbonate dialysate, inadequate blood flow, imprecise ultrafiltration control, and continued low dialyzer solute clearance were solved.

The distinction between *high-efficiency* and *high-flux* dialysis is not always made clear, and sometimes these terms are

used interchangeably. In essence, both terms address improved solute and fluid clearance compared with standard hemodialysis, taking advantage of higher blood and dialysate flow rates to decrease dialysis time while maintaining an adequate dose. These two therapies are not mutually exclusive and, in fact, frequently overlap (see Table 16–6). The high-efficiency dialyzer contains either a synthetic or a modified cellulose membrane and has a higher clearance of small molecules, such as urea (Table 16–6), compared with a standard dialyzer. The high-flux dialyzer always has a highly permeable synthetic or modified cellulose membrane that removes larger molecules. By their nature, high-flux dialyzers have a higher K_{Uf} compared to high-efficiency dialyzers but not necessarily high urea clearances (see Table 16–6). Conversely, high urea clearance defines high-efficiency dialysis, but the clearance of larger molecules is variable (see Table 16–6).

The advent of substituted cellulose and synthetic membranes improved dialyzer permeability because substituted cellulose membranes can be made thinner to increase porosity and surface area, whereas synthetic membranes can be manufactured with more and larger pores. Both high-efficiency and high-flux dialysis require the use of bicarbonate dialysate and volume-controlled filtration. Standard hemodialysis uses acetate, which the liver and skeletal muscle metabolize to bicarbonate.[165] During high-efficiency and high-flux hemodialysis with acetate, the rate of acetate acquisition exceeded the metabolic ability of the liver and muscle cells, resulting in varying degrees of acidosis[165,166] and leading to peripheral vasodilation and hypotension, which prohibited continuation of the treatment. Substituting bicarbonate for acetate in the dialysate maintains hemodynamic stability, decreases nausea and vomiting, and allows dialysis to proceed. Because the high-efficiency and high-flux dialyzers have a higher K_{Uf}, precise control of ultrafiltration is also mandatory to prevent massive volume depletion (see later Mechanics of Hemodialysis).

The most significant difference is the capability of high-flux dialyzers to remove larger molecules[113,114] because of their greater porosity. Increased β_2-microglobulin removal has reduced the risk of carpal tunnel syndrome in long-term patients treated with high-flux dialysis[38,113,167-169] (see Chapters 13 and 14). Other benefits that derive possibly from removal of large molecules are an improved lipid profile,[167,170-172] a greater response to erythropoietin,[173] a higher leptin removal (leptin is thought to suppress appetite),[174] and perhaps lower mortality and hospitalization rates.[167,168,175] Potential adverse consequences from increased removal of larger molecules, however, include greater removal of drugs, such as vancomycin[176] (see Chapter 19), amino acids,[177] and albumin,[178] although the last-mentioned is disputed.[113] The presence of *back-filtration* during high-flux dialysis has been postulated to increase the risk of exposing patients to endotoxin from the dialysate, although this potential problem has not been clearly demonstrated in clinical studies.[179,180]

Despite the widespread use of these modalities since the 1980s, few comparative data are available. Most of the literature is descriptive[181]; only a few studies have evaluated its efficacy. Despite the shorter duration of dialysis, the urea clearance per dialysis is comparable to that of standard

hemodialysis, although the two-compartment model best explains solute removal during treatment with these modalities.[110,182,183] Randomized control or cross-over trials using bicarbonate dialysate found no difference in the incidence of hypotension and intra-dialytic symptoms[113,184,185] or in the control of blood pressure[186] among the three modalities. In studies of a small number of patients treated with high efficiency dialysis, neuropsychological function,[187] mortality, and morbidity[188] are comparable to those for patients treated with standard hemodialysis. The best data available come from the HEMO Study, which detected no difference in mortality or morbidity between patients treated with high-efficiency versus high-flux dialysis.[95]

Limitations to the Delivery of Hemodialysis

High-efficiency dialysis increases solute clearance, but the shorter duration of dialysis decreases efficiency because it accentuates the effects of intermittence and exacerbates solute disequilibrium (see Solute Disequilibrium and Figure 16–7). In addition, as discussed earlier, the shorter duration of high-efficiency hemodialysis may not allow sufficient time to remove larger molecules, such as β_2-microglobulin, for which removal is more time dependent.[113,114] Another potential problem with shortening time is the required increase in the filtration rate.[113,185,189] Most patients can tolerate up to 0.35 mL/min/kg of filtration (1.5 L/hr in a 70-kg person) without developing nausea, cramping, or hypotension.[189] Therefore, an average-sized patient whose weight gain exceeds 4 to 5 kg is a poor candidate for short-duration dialysis and will experience a progressive rise in end-dialysis weight, eventually leading to pulmonary edema. Finally, once patients are accustomed to the shorter time, they are devastated psychologically when their medical condition, such as large fluid gains, inadequate clearance of larger molecules, poorly functioning access, or loss of residual renal function, requires prolonging dialysis time.

Ensuring the adequacy of high-efficiency dialysis is more difficult than for standard dialysis because the myriad of confounding factors already discussed are magnified, including access recirculation, access blood flow, needle positioning, needle size, actual duration of dialysis, compromised dialyzer clearance, and errors in the assumptions made for urea diffusion. Time lost during a high-efficiency dialysis is a larger fraction of the total dialysis time. Factors that decrease actual dialysis time include failure to account for machine downtime caused by alarms, delayed achievement of target Q_b, clotting in the dialyzer requiring a second setup, patient tardiness, and patient noncompliance. Because high-flux and high-efficiency dialyzers are reused, thrombosed hollow fibers that do not reopen during reprocessing may reduce the fiber bundle volume and the surface area for diffusion critically (see Chapter 5). The higher solute removal rate of high-efficiency dialysis further magnifies the differences between the one-compartment and the two-compartment models (see Figure 16–7) by exaggerating the logarithmic decline in urea removal during dialysis and the urea rebound after dialysis.[110,183,190,191] The timing of blood sampling for the post-dialysis BUN becomes even more important (see Figure 16–10), as demonstrated by the average 20% decrease in cal-

culated Kt/V_{urea} if BUN is drawn at 30 minutes instead of immediately after dialysis.[190]

Achieving the desired Q_b is crucial to the success of high-efficiency dialysis. Longer needles and needles with a smaller diameter impede blood flow because resistance is directly proportional to length and inversely related to the fourth power of the needle's inside diameter. An excessively pliable tubing pump segment or low pre-pump pressure invalidates flows reported by the blood pump's RPM meter, as illustrated in Figure 16–12. Not only is the desired Q_b not achieved in this case; health care personnel are also unaware of this problem until urea kinetic study results return. Even if the desired Q_b is achieved, access recirculation is more likely to appear at the higher Q_b used for high-efficiency and high-flux hemodialysis. However, in recent years, the flow variance seems to have diminished due to manufacturing modifications to the tubing pump segment.

Improper needle position with the venous needle abutting the wall causes turbulence and retards the egress of blood
Figure 16–12 Blood flow variance from variable roller pump function. As the roller pump passes along the curved trace and compresses the tubing pump segment, elastic recoil in the tubing behind the roller creates a negative pressure, which refills the tubing with blood. If the pre-pump pressure is too low, the pump segment will not re-expand completely. This incomplete expansion reduces the flow despite no change in the pump speed. (From Depner TA, Rizwan S, Stasi TA: Pressure effects on roller pump blood flow during hemodialysis. ASAIO Trans 1990; 36:M456-M459.)

from the access, promoting recirculation. Placing the arterial and venous needles too closely together at a higher Q_b also creates recirculation. Other important contributors to access recirculation are venous outflow stenosis, arterial insufficiency from atherosclerotic disease in the afferent artery, or stenosis at the inflow anastomosis.

Microbiologic contamination is a risk associated with the use of bicarbonate concentrate because of its potential to support bacterial growth. Recognition of this risk and the subsequent steps taken to prevent contamination have greatly reduced the incidence of pyrogen reactions reported during the early application of high-flux dialysis. Although the risk is theoretically increased by back filtration during high-flux dialysis, few reports of this complication have appeared[179] (see later Dialysate Delivery Systems).

MECHANICS OF HEMODIALYSIS

Twenty to 30 years ago, hemodialysis equipment for a single patient occupied the greater part of an entire room. Now, hemodialysis machines are about the size of a three- to four-drawer filing cabinet and can be transported easily by one person. In addition to the reduction in size, advances have included more reliable dialysate delivery systems, monitoring devices, and automated safety mechanisms. Several on-line devices allow dynamic monitoring of the vascular access, the hematocrit, and the adequacy of the treatment.

Dialysate Delivery Systems

The most commonly used system discards the dialysate after a single passage through the dialyzer (*single-pass* delivery). Most dialysis clinics also use *single-patient delivery* systems in which a machine at each patient station continuously prepares dialysate by mixing a liquid concentrate with a proportionate volume of purified water. To dilute the concentrates safely, the dialysis machine has many built-in safety monitors. Some clinics use a central multi-patient delivery system in which either the concentrated dialysate is mixed in an area away from patient care and then piped to each dialysis station, or the concentrate is piped to each station before mixing. The advantages of these centralized systems are lower patient care costs and less staff back injuries from carrying the individual concentrate jugs, but a major disadvantage is inflexibility in modifying the dialysate concentration of electrolytes, such as calcium and potassium, to suit individual patient needs.

Mechanical and Safety Monitors

The dialysis machine draws up and warms purified water to physiologic temperatures. The heated water then undergoes *deaeration* under vacuum to prevent dissolved air from coming out of solution as negative pressure is applied during dialysis. Air bubbles in the dialysate cause the blood leak detector and the conductivity detector to malfunction. They also "lock" part of the dialysate pathway, increasing channeling and masking parts of the membrane surface area.

The heated and deaerated product water is then mixed with the concentrate to produce dialysate. To ensure proper proportioning, the *conductivity monitor* downstream from the proportioning pump continuously measures the electrical conductivity of the product solution. Because mal-proportioned dialysate may cause severe electrolyte disturbances in the patient, leading to death, the conductivity monitor has a narrow range of tolerance and is usually redundant. Dialysate conductivity may be altered by temperature, the presence of air bubbles, or malfunction of the sensor, usually an electrode. Periodically, the conductivity monitor must be calibrated using standardized solutions or by laboratory measurements of electrolytes in the dialysate.

Since the patient is exposed to 100 to 200 L of dialysate during each treatment, the dialysate must be heated to near body temperature to avoid hypothermia. If the dialysate is too hot, however, protein denaturation (>42°C) and hemolysis (>45°C) occur. In practice, the dialysate temperature is maintained at 36°C to 37°C and falls slightly in transit from the proportioning device to the patient. The *temperature monitor* within the dialysate circuit sets off an alarm if the dialysate temperature is outside of the limits of 36°C to 42°C, and dialysate is pumped directly to the drain, automatically bypassing the dialyzer.

Located after the dialyzer, the *dialysate pump* controls dialysate flow and generates negative dialysate pressure. The dialysate circuit must be able to generate both negative and positive dialysate pressures within the dialyzer because, although many dialyzers require a negative dialysate pressure for filtration, dialyzers with high K_{Uf} or conditions that increase pressure in the blood compartment require a positive dialysate pressure to limit filtration. The dialysate circuitry controls the pressure by variably constricting the dialysate outflow tubing while maintaining a constant flow rate. The dialysate delivery system also monitors the filtration rate, either indirectly by controlling the TMP (*pressure-controlled* ultrafiltration) or directly by controlling the actual filtration (*volume-controlled* ultrafiltration). Earlier dialysate delivery systems used pressure-controlled filtration, requiring dialysis personnel to calculate the TMP, enter the TMP into the machine, closely monitor the filtration rate, and recalculate and adjust the TMP as needed. To prevent excessive fluid removal when using dialyzers with K_{Uf} greater than 6 mL/hr/mmHg, dialysate delivery systems capable of performing volume-controlled filtration are mandatory. Such systems have built-in balance chambers and servomechanisms that accurately control the volume of fluid removed during dialysis once the desired goal is set.[192]

The *blood leak monitor* is situated in the dialysate outflow tubing and is designed to alarm and shut off the blood pump when blood is detected. The presence of blood in the dialysate usually indicates membrane rupture and may be caused by a TMP exceeding 500 mmHg. Although a rare complication, membrane rupture can be potentially life threatening because it allows nonsterile dialysate to come into contact with blood. In this era of dialyzer reuse, the potential for membrane rupture is increased because both bleach and heat disinfection can damage the dialyzer membrane (see Chapter 5). Intravascular hemolysis with hemoglobin in the dialysate may also trigger the blood leak alarm.

Bicarbonate Delivery

Previously, dialysate contained acetate as a source of bicarbonate. The advantages of acetate are the low incidence of bacterial

contamination and its ease of storage. Acetate is a hemodynamic stressor, however, during high-efficiency and high-flux dialysis[193-195] (see Chapter 11) because the rate of acetate diffusion into blood often exceeded the metabolic capacity of the liver and skeletal muscle. Acetate accumulation leads to acidosis, vasodilation, and hypotension. The majority of dialysis clinics now use bicarbonate-based dialysate to prevent these complications.

The major complications of bicarbonate dialysate are bacterial contamination and precipitation of calcium and magnesium salts. Gram-negative halophilic rods require sodium chloride or sodium bicarbonate to grow and thus thrive in bicarbonate dialysate.[196,197] When bicarbonate containers are disinfected, these bacteria have a latency period of 3 to 5 days, have an exponential growth phase at 5 to 8 days, and achieve maximum growth at 10 days,[196] compared with a latency of 1 day, exponential growth phase at 2 to 3 days, and maximum growth by 4 days in a contaminated container. Mixing bicarbonate and disinfecting the containers daily help prevent bacterial contamination. Alternatively, commercially available dry powder cartridges can circumvent this problem.

To prevent formation of insoluble calcium and magnesium salts with bicarbonate, the final dialysate is mixed from two separate components: the bicarbonate concentrate and the acid concentrate. The acid concentrate contains all solutes other than bicarbonate and derives its name from the inclusion of a small amount of acetic acid (4 mEq/L in the final dilution). The dialysate delivery system draws up the two components separately and mixes them proportionately with purified water to form the final dialysate. This process minimizes but does not eliminate the precipitation of calcium and magnesium salts, so the dialysate delivery system must be rinsed periodically with an acid solution to eliminate any buildup.

Water Quality

Treatment of the water used to generate dialysate is essential to avoid exposure during dialysis to harmful substances, such as aluminum, chloramine-T, endotoxin, and bacteria. Accumulation of aluminum in the body may cause dialysis dementia, microcytic anemia, and osteomalacia. Chloramine-T, a product of chlorine and organic material, causes acute hemolysis during dialysis. Endotoxin and bacteria cause febrile reactions and hypotension. Good water quality is even more imperative when dialyzers are reused because the blood compartment is exposed to unsterile water and any accompanying bacteria or endotoxin. To avoid these complications, tap water is first softened, then exposed to charcoal to remove contaminants such as chloramine, then filtered to remove particulate matter, and then filtered under high pressure (reverse osmosis) to remove other dissolved contaminants (see Chapter 5).

Blood Circuit Components

The steady flow of blood required for dialysis may be drawn from a central vein, from the ports along the sides of a double-lumen catheter (arterial lumen), and returned through the port at the distal tip (venous lumen). Alternatively, the blood may be drawn from an AV fistula or graft. The blood pump is usually a peristaltic roller pump, which sequentially compresses the pump segment of the blood tubing against a curved rigid track (see Figure 16–12), forcing blood from the tubing. After the roller has passed, the elastic tubing recoils and refills with blood, ready for the next roller. As a result, blood flow through the dialyzer is pulsatile. Most pumps have two or three rollers. The greater the number of rollers, the less pulsatile the flow, but the higher the risk of hemolysis and damage to the pump segment.

The blood pump flowmeter displays flow calculated solely from its speed of rotation (RPM), whereas the actual Q_b is the product of the RPM and the volume of blood forced from the tubing with each revolution. Therefore, the displayed Q_b may be higher than the actual Q_b. As illustrated in Figure 16–12, if the pre-pump pressure is too low, the pump segment will not re-expand completely, leading to a lower blood flow despite no change in the pump speed. This inaccuracy is magnified at higher Q_b if the vascular access is unable to support the desired blood flow.[198] However, because of changes in the manufacturing of blood tubing, the blood pump flowmeter readings may be more accurate.

When the upper or lower limits are exceeded, *pressure monitors* sound an alarm and turn off the blood pump. An arterial pressure monitor should be located proximal to the blood pump and a venous monitor located distal to the dialyzer. Accepted ranges for arterial inflow pressures are −20 to −80 mmHg, but may be as low as −200 mmHg when Q_b is high. Accepted ranges for venous pressures are +50 to +200 mmHg. Kinks in the tubing, improper arterial needle position, hypotension, or arterial inflow stenosis can cause excessively low arterial pressures. High venous pressures should prompt an investigation for blood clotting in the dialyzer, kinking, or clotting in the venous bloodlines, improperly positioned venous needles, infiltration of a venous needle, or venous outflow stenosis. Accurate measurements of both the arterial and venous pressures are essential to determining the TMP. Excessive positive pressures anywhere in the blood compartment may rupture the dialyzer membrane or cause the blood circuit to disconnect. An abrupt fall in pressure anywhere in the blood circuit may signal an accidental disconnection of the blood circuit, which can result in exsanguination if not corrected promptly.

Two other important safety devices, located in the bloodline distal to the dialyzer, are (1) the *venous air trap* and (2) the *air detector*. The venous air trap prevents any air that may have entered the blood circuit through loose connections, improper arterial needle position, or the saline infusion line from returning to the patient. If air is still detected in the venous line after the venous air trap, the machine alarms and turns off the blood pump. Excessive foaming of blood will also trigger the air detector. These safety features prevent air embolism, which carries a high mortality rate, especially when the problem is not immediately recognized.[199]

Computer Controls

As discussed earlier, solute removal during hemodialysis decreases plasma osmolarity, favors fluid shift into the cells, and makes fluid removal more difficult. Increasing the dialysate sodium concentration helps to preserve plasma osmolarity and allows continued fluid removal[200, 201] but may lead to increased thirst, excessive weight gain, and hypertension[200,202] (see Chapter 11). Computer-controlled *sodium*

modeling allows the dialysate sodium concentration to change automatically during dialysis according to a preselected profile, usually 150 to 160 mEq/L at the beginning of dialysis to 135 to 140 mEq/L near or at the end of dialysis. Theoretically, this sodium modeling offers the benefit of greater hemodynamic stability while minimizing thirst and inter-dialytic hypertension. To date, a few small studies support this theory,[202-206] but the results are not conclusive.[207,208]

Ultrafiltration modeling, like sodium modeling, provides a variable rate of fluid removal during dialysis, according to a preprogrammed profile (linear decline, stepwise changes, or exponential decline of filtration rate with time). Altering the filtration rate during dialysis theoretically allows time for the blood compartment to refill from the interstitial compartment, leading to improved hemodynamic stability and less cramping. As with sodium modeling, ultrafiltration modeling must be individualized. In fact, the effects of the two are difficult to distinguish because they are often used together.[203,206,207,209]

Anticoagulation

Blood clotting during dialysis is a source of patient blood loss and interferes with solute clearance by decreasing the dialyzer surface area.[210] To prevent clotting, a dose of heparin, the most commonly used anticoagulant in dialysis, is usually given at the start of dialysis (2000–5000 units or 50 units/kg), then continuously infused (1000–1500 units/hr) into the blood circuit before the dialyzer, until 15 to 60 minutes before the end of dialysis.[211] Alternatively, heparin boluses may be given intermittently during dialysis as needed. The bolus method increases nursing time and results in episodes of over-anticoagulation and under-anticoagulation. If the patient is at risk of bleeding, low-dose heparin (bolus of 500 to 1000 units followed by 500 to 750 units/hr)[212,213] or no heparin may be appropriate.[214-218] For heparin-free dialysis, prerinsing the blood circuit with heparinized saline and flushing the dialyzer with 100 mL of 0.9% sodium chloride every 15 to 30 minutes helps prevent clotting. Avoiding blood or platelet transfusions through the circuit is also required to minimize clotting.

Alternatives to heparin anticoagulation include regional citrate anticoagulation,[219-222] low-molecular-weight heparin,[223-230] hirudin,[231-233] prostacyclin,[234-236] dermatan sulfate,[237,238] and serine protease inhibitors.[239, 240] None is in wide use, however, because of complexity, expense, lack of sufficient clinical experience, or equivalency to heparin. Citrate anticoagulation, in particular, may cause hypocalcemia and death if calcium replacement is inadequate[241] and significant metabolic alkalosis if the dialysate bicarbonate concentration is not decreased.[242, 243] In the rare case of confirmed heparin induced thrombocytopenia, low-molecular-weight heparin, hirudin, and citrate anticoagulation have been used with varying success.[244, 245]

On-Line Monitoring of Clearance, Hematocrit, and Access Flow

Urea concentration, hematocrit, and access blood flow may be measured on-line, that is, during the dialysis. Although the equipment and effort are expensive at present, they may prove cost-effective in the long run by improving patient care.

Monitoring can minimize the amount of blood drawn and allow more sensitive and frequent assessment of adequacy, control of ultrafiltration, and detection of vascular access stenosis.

Monitoring Clearance

On-line monitoring of urea kinetics may provide the best assessment of urea removal and dialysis adequacy.[246-250] Available monitors include those that sample dialysate continuously or periodically to measure urea concentration[132-134, 251, 252] and those that monitor dialyzer sodium clearance by pulsing the dialysate sodium concentration and measuring conductivity.[253] The on-line methods for monitoring urea kinetics provide Kt/V_{urea} based on whole-body urea clearance, not just dialyzer clearance.

Monitoring Hematocrit

The hematocrit can be measured during dialysis, using either a conductivity method[254] or an optical technique.[255-257] These methods may benefit dialysis patients prone to hypotension and cramping because these symptoms are usually caused by intravascular volume depletion, which is reflected by the degree of hemoconcentration.[256] By monitoring the hematocrit on-line, the filtration rate can be varied during dialysis to minimize the magnitude of hemoconcentration and the occurrence of symptoms during dialysis.[255, 257]

Monitoring Access Flow

Vascular access failure is a major problem, costing mil-lions of health care dollars each year and diminishing the patient's quality of life,[258,259] prompting the National Kidney Foundation to issue management guidelines.[27] If impending access thrombosis can be predicted, the opportunity to intervene with angioplasty or surgery is available to prevent thrombosis and to extend access function. Many techniques have been described, including measuring venous pressures and determining access recirculation. Unfortunately, these techniques have not prevented access thrombosis[258-260] because the venous pressure technique is unable to detect inflow and mid-graft stenosis[261] and because access recirculation calculated using peripheral venous blood is actually an artifact of solute disequilibrium.[148,149,152,153,262] The indicator dilution techniques for measuring access blood flow noninvasively during hemodialysis have strong predictive power and may allow timely intervention.[263-268] Observational studies[261,269-273] suggest that an absolute vascular access blood flow of less than 600 mL/min and a 25% decrease in access flow strongly predict vascular access failure within 3 to 12 months. Angioplasty prompted by a decrease in access flow is effective in prolonging fistula survival and preventing thrombosis, but prospective studies of surveillance and angioplasty in arteriovenous grafts have shown mixed results[267, 268, 274-277] (for more details, see Chapter 4). However, because preemptive correction of a stenosis before the access clots is shorter, less expensive, and decreases the risk for a missed dialysis treatment or a temporary dialysis catheter, access surveillance and intervention is still preferred in the absence of conclusive evidence for improved graft survival.[27, 278, 279]

MANAGEMENT OF THE HEMODIALYSIS PATIENT

The general principles of managing the hemodialysis patient are highlighted briefly here because the following chapters provide greater detail on many of these important topics. A typical *hemodialysis prescription* brings together all of the principles discussed so far and includes:

- Duration and frequency of dialysis
- Type of dialyzer
- Blood flow rate
- Dialysate flow rate
- Heparin load and infusion rate
- Amount of fluid to be removed
- Location and type of vascular access
- Dialysate sodium, potassium, calcium, and bicarbonate concentrations

Medication and Diet

Once a patient begins dialysis, the *medications* should be reviewed and adjusted. In particular, the patient should receive vitamin B complex, vitamin C, folic acid supplements, and trace minerals because dialysis removes water-soluble vitamins and trace elements. The major goals are to simplify and to optimize the medication regimen to improve compliance and outcome. Therefore, patients with little urine output should discontinue diuretics, and patients who may benefit from an angiotensin converting enzyme inhibitor should start this medication once dialysis starts. Any medications that may be removed by dialysis or that accumulate in dialysis patients must be adjusted appropriately (see Chapter 19).

The dietitian should meet with the patient on a regular basis to provide feedback and teaching on the *dietary prescription*. Fluid, potassium, and phosphate restrictions are vital to the success of dialysis, given the problems with intra-dialytic hypotension and inefficient removal of phosphate, as discussed earlier. Additionally, adequate protein and calorie intake must be stressed in light of the high morbidity and mortality associated with hypoalbuminemia.[280,281]

Hormonal and Metabolic Disturbances

As management has improved and patients live longer on dialysis, the spectrum of the various *renal osteodystrophies* is changing. The incidence and severity of hyperparathyroid bone disease have decreased as the use of phosphate binders and calcitriol has become routine. Aluminum bone toxicity was an important cause of bone pain and pathologic fractures until the use of aluminum-based phosphate binders declined and water treatment improved. With the advent of high-flux dialyzers, amyloid bone disease is declining. Instead, adynamic bone disease from excessive suppression of parathyroid hormone has emerged, although its clinical significance is still debated[282,283] (see Chapters 13 and 14).

Although replacing erythropoietin in ESRD patients has corrected much of the observed *anemia*, there are still some issues to be resolved (see Chapter 15). The NKF guidelines for treating anemia in patients with ESRD[26] favor administering erythropoietin subcutaneously because of its increased efficacy, supported by the findings of a Veterans Affairs Cooperative Study.[284] The guidelines also suggest using maintenance doses of intravenous iron dextran 50 to 100 mg weekly or every other week to prevent relative iron deficiency. In patients who are anemic despite greater than 150 units/kg/dialysis of erythropoietin and intravenous maintenance iron, evidence for aluminum toxicity, hyperparathyroid bone disease, vitamin deficiency, and inflammation (activation of the acute-phase response) should be sought.[73]

As discussed earlier, *metabolic acidosis* may increase protein and muscle catabolism and is a potential cause of morbidity, but the impact in dialysis patients is debated.[43,285,286] Dialysis does not always correct acidosis completely because the effect of the dialysate on acid/base balance in the patient is complex, the net result of acetate and bicarbonate flux in opposite directions and removal of organic anions.[287] If acidosis is corrected by raising the dialysate bicarbonate concentration, anthropometric parameters improve in both hemodialysis and peritoneal dialysis patients,[288] although the effect on serum albumin is variable.[289] If acidosis cannot be corrected by increasing dialysate bicarbonate, then oral supplementation with bicarbonate should be considered.

Blood Pressure

Both *hypertension* and *hypotension* occur in dialysis patients and pose significant management problems. Blood pressures measured immediately before and during dialysis may not reflect the average pressure between dialyses. Epidemiologic data suggest that blood pressure correlates poorly with mortality in dialysis patients probably because of the confounding effects of severe malnutrition and myocardial failure, which reduce blood pressure and increase mortality risk.[290,291] This association, however, should not engender complacency about blood pressure control in light of the high cardiovascular mortality and widely prevalent left-ventricular hypertrophy in dialysis patients (see Chapter 12).

Intra-dialytic hypotension is associated with significant acute morbidity, including sudden death, and may be a cause of chronic morbidity and mortality when it is recurrent.[292] Hypotension is the result of rapid fluid removal from the blood compartment at a rate faster than refilling from the other fluid compartments, compounded by either a reduced myocardial contractile reserve or inadequate arterial vasoconstriction in response to the blood volume contraction.[293,294] Using a higher dialysate sodium concentration, dialysate sodium modeling, and ultrafiltration modeling during dialysis (see earlier Mechanics of Hemodialysis) may ameliorate the hypotension. However, these maneuvers usually result in increased thirst and greater interdialytic weight gains, thus promulgating the vicious cycle.[295] Additional maneuvers to maintain hemodynamic stability during dialysis include: (1) pharmacologic agents such as midodrine,[296-299] (2) cooling the patient,[296,298] (3) isothermic dialysis using the Fresenius Blood Temperature Monitor,[300] (4) biofeedback devices that prevent excessive blood volume contraction (not yet available in the United States),[301,302] and (5) increasing dialysis frequency, especially nocturnal hemodialysis.[303-306]

Dialysis-Related Complications

Given the excellent predictive value of low blood flows in fistulas and grafts as a signal for impending occlusion and the availability of surveillance techniques, each dialysis clinic should have a vascular access surveillance program in place to decrease the morbidity associated with graft thrombosis[27,307] (see earlier discussion). Ensuring a properly functioning AV graft or fistula minimizes the need for inserting a temporary or permanent dialysis catheter and therefore the risk of catheter-related sepsis. Should a catheter be required, a cuffed and tunneled catheter or a subcutaneous catheter[308-310] is preferable because it lasts longer and has a lower risk of infection compared with a temporary, non-cuffed catheter.

Vaccinations against hepatitis B as well as the influenza virus and pneumococcus are important for health care maintenance in dialysis patients because of the increased risk of exposure to hepatitis B and the patients' compromised immune status. Because dialysis patients carrying hepatitis B have a high incidence of hepatitis B e antigenemia,[311] making the disease more contagious, all hepatitis B-naive patients initiating dialysis should receive recombinant hepatitis vaccine. Only 60% to 70% of patients, however, seroconvert on completing the series.[312] Strategies for revaccination, increasing the dose of the vaccine, or changing to the intradermal route of administration[313,314] may enhance seroconversion[313,314] (see Chapter 18).

Although hemodialysis is much safer now than Kolff's[5] first hemodialysis attempts, the many technical advances have not completely eliminated complications resulting from the dialysis procedure itself (see Chapter 11). Some patients experience anaphylactoid and allergic reactions during the first few minutes of hemodialysis from exposure to the sterilant ethylene oxide, the plasticizers present in the dialyzers, or the less biocompatible dialyzers (see Chapters 2 and 5). Bioincompatible dialyzers activate complement, leukocytes, and platelets and cause chest pain, shortness of breath, and sludging of leukocytes and platelets in the pulmonary vasculature.

Fever during dialysis may be caused by bacterial contamination or endotoxin in the source water or dialysate and by access infection. Rapid removal of solutes may cause symptoms of disequilibrium, including fatigue, light-headedness, and decreased ability to concentrate when mild; and altered mental status, seizures, and death when severe (see Chapter 11). Although many advances have been made during the past three decades of life support with hemodialysis, much remains to be done to improve patients' quality of life.

FUTURE CONSIDERATIONS

More than 30 years of experience have demonstrated that thrice-weekly hemodialysis is not completely successful in reversing the syndrome of uremia. Reasons for this are not entirely clear, but they almost certainly include the residual syndrome (see earlier discussion). Failure to eliminate the residual syndrome may be related to inadequate dialysis, failure of dialysis to reproduce one or more functions of the native kidney, or complications derived from the dialysis treatment itself.

The discovery of dialysis-related amyloidosis and the subsequent identification of β_2-microglobulin as the amyloid precursor represent a major advance in the battle to sustain and maintain a reasonable quality of life over an extended number of years on hemodialysis.[38] Because β_2-microglobulin is a relatively large molecule that is not removed by cellulose membranes, its discovery prompted an investigation into the more permeable high-flux dialysis membranes. Accumulated evidence shows increasingly strong support for the use of synthetic high-flux membranes to prevent clinical progression of dialysis-related amyloidosis.[38]

The ever-changing landscape of the residual syndrome now encompasses adynamic bone disease, uncovered during efforts to improve the understanding and treatment of hyperparathyroid bone disease. Other battle fronts in the effort to improve the quality of life include studies of nutrition; the cause of the acute-phase response in dialysis patients; the complex interaction between the acute-phase response, nutrition, and atherosclerosis[77,78]; and methods to prevent both protein and calorie malnutrition.[75,280] Understanding the mechanisms responsible for accelerated atherosclerosis in dialysis patients may be a key to improving the high mortality from cardiovascular disease.

The HEMO Study suggests that increasing the urea clearance (Kt/V) above 1.3 during three times a week dialysis and enhancing clearance of larger molecular molecules do not correct further the residual syndrome.[95] Instead, preliminary data from daily home hemodialysis show promise in normalizing blood pressure and further correcting the residual syndrome.[304,305] Because goals for future deployment of hemodialysis include reducing the need for travel to and from the dialysis center and shortening the time required for preparation and administration of hemodialysis, home hemodialysis, especially at night or during sleep, has obvious advantages in this regard. Maintaining or improving work conditions for staff managing hemodialysis patients is justifiable in itself but is especially important in dialysis centers where a positive attitude in the staff promotes better tolerance of dialysis by the patient.
