Infection in Renal Transplant Recipients

Jay A. Fishman, M.D. • Emilio Ramos, M.D.

Successful management of infections in the immunocompromised renal transplant recipient is complicated by a variety of factors.[1] These include increased susceptibility to a broad spectrum of infectious pathogens and the difficulty in making a diagnosis of infection in the face of diminished signs and symptoms of infection, an array of noninfectious etiologies of fever (e.g., graft rejection, drug toxicity), and the possibility that multiple processes are present simultaneously. Further, because immunocompromised patients tolerate invasive and established infection poorly with high morbidity and mortality, the urgency for an early and specific diagnosis to guide antimicrobial therapy is increased. Given the primacy of T-lymphocyte dysfunction in transplantation, viral infections in particular are increased and contribute to graft dysfunction, systemic illness, graft rejection, and enhancing the risk for other opportunistic infections (e.g., *Pneumocystis* and *Aspergillus* species) and for virally-mediated cancers.

RISK OF INFECTION

The risk of infection in the renal transplant recipient is determined by the interaction of two factors:

1. The epidemiologic exposures of the patient, including those unrecognized by the patient or distant in time (Table 37–1).
2. The patient's net state of immunosuppression, including all of the factors contributing to the risk for infection in the transplant recipient (Table 37–2).

Epidemiologic Exposures

The prevention and treatment of infection is central to the optimal management of transplant recipients, given the adverse impact of infections on quality of life. Consideration of the epidemiology of infection allows the clinician to establish a differential diagnosis for a given "infectious" presentation and to design the optimal preventive strategy for each patient. Donor and recipient screening are critical components to the post-transplant health maintenance of the patient (Table 37–3). Of these, consideration should be given to empiric therapy for purified protein derivative (PPD) positive patients, for *Strongyloides stercoralis* in patients from endemic regions, and for patients known to have received organs from donors with acute bacterial and fungal infections. Specific antiviral strategies stratified according to individual risk should be considered for all kidney recipients.

Exposures of importance can be divided into four overlapping categories: donor- or recipient-derived infections, and community- or nosocomial-acquired exposures.

Donor-Derived Infections

Infections that are derived from the donor tissues and activated in the recipient are among the most important exposures in transplantation. Some of these are latent while others are the result of bad timing—active infection transmitted at the time of transplantation. All of the known types of infections have been recognized in transplant recipients. The activation of these infections may reflect the intensity of immune suppression or result from the allogeneic response (graft rejection), which activates latent viral pathogens. Three types of infection merit special attention. First, in donors who are bacteremic or fungemic at the time of donation, these infections—staphylococci, pneumococcus, *Candida* species, *Salmonella, E. coli*—tend to "stick" to anastamotic sites (vascular, urinary) and may produce leaks or mycotic aneurysms. Second, viral infections, including cytomegalovirus (CMV) and Epstein-Barr virus (EBV), are associated with particular syndromes and morbidity in the immunocompromised population (discussed later in text). The greatest risk of such infections is in recipients who are seronegative (immunologically naïve) and receive infected grafts from seropositive donors (latent viral infection). Third, late, latent infections, including tuberculosis, may activate many years after the initial exposure. Disseminated mycobacterial infection is often difficult to treat once established due largely to interactions between the antimicrobial agents used to treat infection (e.g., rifampin, streptomycin, isoniazid) and the agents used in immune suppressive therapy.

Given the risk of transmission of infection from the organ donor to the recipient, certain infections should be considered relative contraindications to organ donation. Given that renal transplantation is, in general, elective surgery, it is reasonable to avoid donation from individuals with unexplained fever, rash, or infectious syndromes. Some of the common criteria for exclusion of organ donors are listed in Table 37–4.

Recipient-Derived Exposures

Infections in this category are generally latent infections activated in the setting of immune suppression. It is necessary to obtain a careful history of travel and exposures to guide preventive strategies and empiric therapies. Notable among these infections are tuberculosis, strongyloidiasis, viral infections (herpes simplex and Varicella zoster or shingles), histoplasmosis, coccidioidomycosis, hepatitis B or C, and human immunodeficiency virus (HIV). Vaccination status should be evaluated (tetanus, hepatitis B, childhood vaccines, influenza, pneumococcal vaccine). Dietary habits should also be considered, including the use of well water (*Cryptosporidia*), uncooked meats (*Salmonella, Listeria*), and unpasteurized dairy products (*Listeria*).

Table 37–1 Significant Epidemiologic Exposures Relevant to Transplantation

Donor-Derived
Viral
- Herpes group (cytomegalovirus, Epstein-Barr virus, human herpes viruses 6, 7, 8, herpes simplex)
- Hepatitis viruses (notably B and C)
- Retroviruses (HIV, HTLV-1 and -2)
- Others

Bacteria
- Gram-positive and gram-negative bacteria (*Staphylococcus* species, *Pseudomonas spp.*, Enterobacteriaceae)
- Mycobacteria (tuberculosis and nontuberculous)
- Nocardia asteroides

Fungi
- *Candida* species
- *Aspergillus* species
- Endemic fungi (*Cryptococcus neoformans*)
- Geographic fungi (histoplasma capsulatum, *Coccidioides immitis*, blastomyces)

Parasites
- *Toxoplasma gondii*
- *Trypanosoma cruzi*

Nosocomial Exposures
Methicillin-resistant staphylococci
Vancomycin-resistant enterococci (also linezolid and quinupristin-dalfopristin resistance)
Aspergillus species
Candida non-albicans strains

Community Exposures
Food and water-borne (*Listeria monocytogenes*, *Salmonella spp.*, *Cryptosporidium spp.*, hepatitis A, *Campylobacter spp.*)
Respiratory viruses (RSV, Influenza, parainfluenza, adenovirus, metapneumovirus)
Common viruses: often with exposure to children (Coxsackie, parvovirus, polyomavirus, papilloma virus)
Atypical respiratory pathogens (*Legionella spp.*, *Mycoplasma spp.*, Chlamydia)
Geographic fungi and *Cryptococcus*, *Pneumocystis jiroveci*
Parasites (often distant)
- *Strongyloides stercoralis*
- *Leishmania* species
- *Toxoplasma gondii*
- *Trypanosoma cruzi*
- *Naeglaeria spp.*

Table 37–2 Factors Contributing to the "Net State of Immunosuppression"

Immunosuppressive Therapy: Type, Temporal Sequence, Intensity
Prior therapies (chemotherapy or antimicrobials)
Mucocutaneous barrier integrity (catheters, lines, drains)
Neutropenia, lymphopenia (often drug-induced)
Underlying immune deficiency
- Hypogammaglobulinemia from proteinuria
- Systemic lupus, complement deficiencies

Metabolic Conditions: Uremia, Malnutrition, Diabetes, Alcoholism/Cirrhosis
Viral infection (CMV, hepatitis B and C, RSV)
Immune suppression
Graft rejection
Cancer/cellular proliferation

Community Exposures

Common exposures in the community are often related to contaminated food and water ingestion, exposure to infected children or coworkers, or exposures due to hobbies (gardening), travel, or work. Respiratory virus infection due to influenza, respiratory syncytial virus, and adenoviruses and more atypical pathogens (Herpes simplex virus, Herpes zoster virus) carries the risk for viral pneumonia but increased risk for bacterial superinfection. Community (social or transfusion-associated) exposure to CMV and EBV may produce severe primary infection in the nonimmune host. Recent and remote exposures to endemic, geographically restricted systemic mycoses (*Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum*) and *Mycobacterium tuberculosis* can result in localized pulmonary, systemic, or metastatic infection. Asymptomatic *strongyloides stercoralis* infection may activate more than 30 years after initial exposure due to the effects of immunosuppressive therapy. Such reactivation can result in either a diarrheal illness and parasite migration with hyperinfestation syndrome (characterized by hemorrhagic enterocolitis, hemorrhagic pneumonia, or both) or disseminated infection with accompanying (usually) gram-negative bacteremia or meningitis. Gastroenteritis due to *Salmonella* species, *campylobacter jejuni*, and a variety of enteric viruses can result in persistent infection, more severe and prolonged diarrheal disease as well as an increased risk of bloodstream invasion and metastatic infection.

Nosocomial Exposures

Nosocomial infections are of increasing importance because organisms with significant antimicrobial resistance predominate in many centers. These include vancomycin, linezolid and quinupristin/dalfopristin-resistant enterococci, methicillin-resistant staphylococci, and fluconazole-resistant *Candida* species. A single case of nosocomial *Aspergillus* infection in a compromised host should be seen as an indication of the failure of infection control practices. Antimicrobial abuse has resulted in increased rates of *C. difficile* colitis. Outbreaks of infections due to *Legionella* species have been associated with hospital plumbing and contaminated water supplies or ventilation systems. Each nosocomial infection should be investigated to ascertain the source and prevent subsequent infections. Nosocomial spread of *P. jiroveci* between immunocompromised patients has also been suggested by a variety of case series. Respiratory viral infections may be acquired from medical staff and should be considered among the causes of fever and respiratory decompensation among hospitalized or institutionalized, immunocompromised individuals.

Table 37–3 The Pre-Transplant Evaluation of the Donor and Recipient (Consider the Following)

Laboratory Test	All Patients	Patients with Exposure to Endemic Area	Quantitative Viral Studies Available (PCR)
Serologies			
CMV	√		√

Table 37–4 Common Infectious Exclusion Criteria for Organ Donors*

Active Infectious Disease
Unknown infection of central nervous system (encephalitis, meningitis)
Herpes simplex encephalitis or other encephalitis
H/o JC virus infection
West Nile virus infection
Cryptococcal infection of any site
Rabies
Creutzfelt-Jacob disease
Other fungal or viral encephalitis
Untreated bacterial meningitis (proof of cure)
Infection with HIV (serologic or molecular)
Active viremia: herpes, acute EBV (mononucleosis)
    Serologic or molecular evidence of HTLV-I/II
Active hepatitis A, B
Infection by: *Trypanosoma cruzi, Leishmania, Strongyloides, Toxoplasmosis*
Active tuberculosis
SARS
Untreated pneumonia
Untreated bacterial or fungal sepsis (e.g., candidemia)
Untreated syphilis
Multisystem organ failure due to overwhelming sepsis, gangrenous bowel

*Must be considered in the context of the individual donor and recipient.

Net State of Immunosuppression

The net state of immunosuppression is a measure of all of the factors contributing to the patient's risk for infection (Table 37–2). Among these are:

1. The specific immunosuppressive therapy, including dose, duration, and sequence of agents.
2. Technical problems from the transplant procedure, resulting in leaks (blood, lymph, urine) and fluid collections, devitalized tissue, poor wound healing, and surgical drainage catheters for prolonged periods.
3. Prolonged airway intubation
4. Prolonged use of broad-spectrum antibiotics
5. Renal and/or hepatic dysfunction
6. Prolonged use of vascular access or dialysis catheters

Presence of infection with one of the immunomodulating viruses, including CMV, EBV, hepatitis B (HBV) or C (HCV), or HIV.

Specific immunosuppressive agents are associated with increased risk for certain infections (Table 37–5). Combinations of these agents may enhance this risk or cause toxicity (e.g., nephrotoxicity) and may further enhance risk.

TIMETABLE OF INFECTION

As immunosuppressive regimens have become more standardized, the specific infections that occur most often will vary in a predictable pattern depending on the time elapsed

Table 37–5 Specific Immunosuppressive Drugs and Infection

- Antilymphocyte globulins (lytic) and alloimmune response: Activation of latent (herpes)virus, fever, cytokine release
- Plasmapheresis: Encapsulated bacteria
- Co-stimulatory blockade: Unknown so far
- Corticosteroids: Bacteria, PCP, hepatitis B, C
- Azathioprine: Neutropenia, papilloma virus?
- Mycophenylate mofetil (MMF): Early bacterial infection, B-cells, late CMV?
- Calcineurin inhibitors (cyclosporine/tacrolimus): Enhanced viral replication (absence of immunity), gingival infection, intracellular pathogens
- Sirolimus: Excess infections in combination with current agents, idiosyncratic pneumonitis?

since transplantation (Figure 37–1). This is a reflection of the changing risk factors (surgery/hospitalization, immune suppression, acute and chronic rejection, emergence of latent infections, and exposures to novel community infections.[1] The pattern of infections will be changed with alterations in the immunosuppressive regimen (pulse dose steroids or intensification for graft rejection), intercurrent viral infection, neutropenia (drug toxicity), graft dysfunction, or significant epidemiologic exposures (travel or food).

The time line reflects three overlapping periods of risk for infection: (1) the perioperative period to approximately 4 weeks after transplantation; (2) the period 1 to 6 months after transplantation (depending on the rapidity of taper of immune suppression and the type and dosing of antilympho-cyte "induction" that may persist); and (3) the period beyond the first year after transplantation. These periods reflect the changing major risk factors associated with infection: (1) surgery and technical complications; (2) intensive immune suppression with viral activation; and (3) community-acquired exposures with the return of normal activities.

The time line may be used in a variety of ways: (1) to establish a differential diagnosis for the transplant patient suspected of having infection; (2) as a clue to the presence of an excessive environmental hazard for the individual, either within the hospital or in the community; and (3) as a guide to the design of preventive antimicrobial strategies. Infections occurring outside the usual period or of unusual severity suggest either excessive epidemiologic hazard or excessive immunosuppression. The prevention of infection must be linked to the risk for infection at various times after transplantation. Routine preventive strategies from the Massachusetts General Hospital are outlined in Table 37–6. It should be noted that such strategies serve only to delay the onset of infection in the face of epidemiologic pressure. The use of antibiotic prophylaxis, vaccines, and behavioral modifications (e.g., routine hand washing or advice against digging in gardens without masks) may only result in a "shift to the

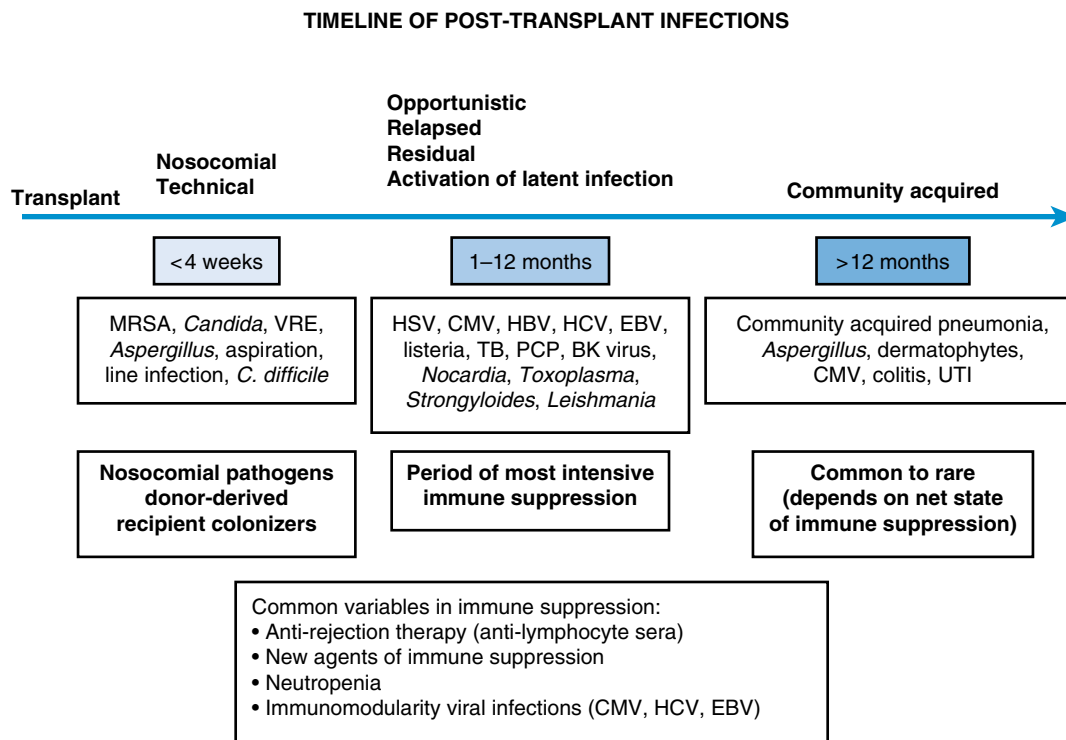
TIMELINE OF POST-TRANSPLANT INFECTIONS


Figure 37–1 The timeline of post-transplant infections.

Table 37-6 Renal Transplantation Antimicrobial Protocols at the Massachusetts General Hospital, Boston, Massachusetts

A. Anti-*Pneumocystis* jiroveci Pneumonia (PCP) and General Antibacterial Prophylaxis

Background: Low dose trimethoprim-sulfamethoxazole prophylaxis (in adults: 1 single strength per day orally) is well tolerated and essentially eradicates *Pneumocystis* infection from this patient population. Lower doses (3 days per week) prevent PCP but may not prevent other infections such as urinary tract infection, nocardiosis and listeriosis, toxoplasmosis, and a variety of gastrointestinal and pulmonary infections.

Regimen: One single strength trimethoprim-sulfamethoxazole tablet (containing 80 mg trimethoprim, 400 mg sulfamethoxazole) po qhs for a minimum of 4–6 months post-transplant. Patients infected with CMV, with chronic rejection, or recurrent infections are maintained on lifelong prophylaxis.

Alternative Regimen: For those patients proven to not tolerate trimethoprim-sulfamethoxazole, alternative regimens include: (1) a combination of atovaquone 1500 mg po with meals once daily plus levofloxacin (or equivalent fluoroquinolone without anti-anaerobic spectrum) 250 mg once daily; (2) pentamidine (300 mg iv or inhaled q 3–4 weeks); and (3) Dapsone (100 mg po qd to biweekly) +/− pyrimethamine. Each of these agents has toxicities that must be considered, including hemolysis in G6PD-deficient hosts with dapsone. None of these alternative programs offer the same broad protection of TMP-SMX.

B. Herpes Group Virus Prevention

Background: The human herpes viruses (cytomegalovirus, CMV; herpes simplex viruses 1 and 2, HSV-1 and HSV-2; Epstein-Barr virus, EBV; varicella-zoster virus, VZV; human herpes virus-6, HHV-6; human herpes virus-7, HHV-7; and human herpes virus-8, HHV-8/Kaposi's sarcoma-associated herpes virus) are among the most important causes of infectious disease morbidity and mortality in the transplant recipient. Different regimens are determined by the clinical risk, the major determinants of which are the past experience of donor and recipient with the virus (as defined by the presence or absence of circulating antibody prior to transplant) and the nature of the immunosuppressive therapy.

1. Treatment of Symptomatic CMV Disease

  a. Reduce immune suppression, if possible
  b. Consider CMV hyperimmune globulin
  c. The standard of care for treating symptomatic CMV disease is a minimum of 2 to 3 weeks of intravenous ganciclovir at a dose of 5 mg/kg twice daily (with dosage adjustment for renal dysfunction). It is not yet clear whether oral valganciclovir may be substituted for intravenous therapy. Regardless of the type of therapy, microbiologic and clinical responses must be demonstrated. The main side effect of ganciclovir is hematopoietic toxicity (some renal toxicity). Alternative agents (cidofovir with renal toxicity, foscarnet with renal, CNS and hepatic and hematopoietic toxicity) are also available and may be preferred in individual patients. The end point of intravenous therapy is the documented clearance of virus from the blood as demonstrated by a negative CMV antigenemia assay or quantitative PCR assay. In seropositive individuals, the risk of subsequent relapse can be essentially eliminated by following intravenous therapy with oral valganciclovir 450 mg PO qd (not FDA approved dose—check creatinine clearance) in renal transplant recipients (see following table) for 3 additional months. Such follow-up oral therapy is obligatory for individuals with primary CMV disease (donor seropositive, recipient seronegative [D+R−]), in whom the risk of relapse without oral therapy is high.
  d. Dosing Nomogram for Ganciclovir Treatment of CMV Infections

Serum Creatinine (mg/dL)	Intravenous Dose (mg/kg)	Frequency
<2.0	5	Q12h
2–3	5	Daily
3–5	1.25*	Daily
>5.0	1.25*	QOD
Hemodialysis	5	Post-dialysis
Peritoneal dialysis	2.5*	Daily

*After loading dose of 5 mg/kg. All patients (prophylaxis or therapeutic) received: leukocyte or CMV-negative blood; CMV-hyperimmune globulin 150 mg/kg IV for first dose and 100 mg/kg × 4 at the discretion of the physician.
Data from Fishman JA, Doran MT, Volpicelli SA, et al: Dosing of intravenous ganciclovir for the prophylaxis and treatment of cytomegalovirus infection in solid organ transplant recipients. Transplantation 2000; 69:389-393.

Valganciclovir Conversions: With the availability of oral valganciclovir (full dose therapy as 900 mg po bid), many patients can be converted to oral therapy. It may be preferable to load intravenously and to document a clinical response before conversion. Gastrointestinal CMV requires prolonged therapy.

Valganciclovir Dose Modifications for Patients with Impaired Renal Function*			
Serum Cr	CrCl (mL/min)	Treatment dose	Prophylaxis dose
≤ 1.5	≥ 60	900 mg bid	450 renal; 900 mg qd other
1.6–2.5	40–59	450 mg bid	450 mg qd
2.6–4.0	25–39	450 mg qd	450 mg qod
> 4.0	10–24	450 mg qod	450 mg twice weekly

*Formal measurement of creatinine clearance is preferred because measurements of serum creatinine may be misleading. Hemodialysis patients: There are no data on dosing for HD patients at present.

Table 37–6 Renal Transplantation Antimicrobial Protocols at the Massachusetts General Hospital, Boston, Massachusetts—cont'd

2. Guidelines for Prevention of Cytomegalovirus Infection

Prophylaxis of High-Risk Patients: Prophylaxis is achieved with 50% of the therapeutic dose of ganciclovir or valganciclovir (corrected for renal function). In some patients, intravenous immune globulin (IvIG or hyperimmune globulin) is used as an adjunctive therapy for prophylaxis.

Certain subgroups merit routine prophylaxis. These include:

- Solid organ transplant recipients who are naïve (seronegative) and receive an organ from a seropositive donor (D+/R–)
- Solid organ transplant recipients who are seropositive (R+) and receive antilymphocyte antibodies or other intensive immune suppression (e.g., for graft rejection)

Antiviral Prophylaxis Made Simple*

CMV Serologic Status +/– Antilymphocyte Antibody Therapy	Therapy	Screening (Antigenemia)
D+/R-	Intravenous ganciclovir 5mg/kg iv for loading dose then per renal function to discharge; then po valganciclovir (450 mg/d for renal transplants) × 3 mo	Monthly for 6 months after D/C of therapy+
D+ or R+ with antilymphocyte antibody therapy	Intravenous ganciclovir 5mg/kg iv for first dose then per renal function to discharge; D/C on po valganciclovir (450 mg/d renal) × 6 months	Monthly for 6 months after D/C of therapy+
D–/R+ (no antilymphocyte antibody therapy)	Oral valganciclovir (450 mg/d renal) × 3 months	Symptoms only
D–/R–	Oral famciclovir (Famvir) 500 mg po qd × 3–4 mo (or valacyclovir 500 bid or acyclovir 400 tid) Use of CMV-negative or leukocyte-filtered blood	Symptoms, fever/neutropenia
Status unknown with ALS	Intravenous ganciclovir 5mg/kg iv for first dose and QD (corrected for renal function) until sero-status determined.	

Neutropenia: The dose of antiviral and antibacterial therapies ARE NOT, in general, reduced for neutropenia. Consider other options first!

\+ ALS: Antilymphocyte antibodies include any of the lytic, lymphocyte-depleting antisera

*Note: Not FDA approved at these doses

3. Anti-*Candida* Prophylaxis:

Prevention of mucocutaneous infection can be accomplished with oral clotrimazole (may increase CyA levels) or nystatin 2 to 3 times per day at times of steroid therapy or in the face of antibacterial therapy. Fluconazole, at a dose of 200–400 mg/day for 10–14 days is utilized in the treatment of prophylaxis failures. Routine prophylaxis with fluconazole is used for pancreas transplants.

right" of the infection time line, unless the intensity of immune suppression is reduced or immunity develops.

Phase One: 1 to 4 Weeks After Transplantation

During the first month after transplantation, three types of infection occur.

The first type of infection is that present in the recipient prior to transplantation, was inadequately treated, and now has emerged in the setting of surgery, anesthesia, and immunosuppression. Pre-transplantation pneumonia and vascular access infections are common examples of this type of infection. Colonization of the recipient with resistant organisms is also common (e.g., MRSA). The first rule of successful transplant infectious disease is the eradication of all infection possible prior to transplantation.

The second type of early infection was present in the donor before transplantation. This is often a nosocomial-acquired organism (resistant gram-negative bacilli and *S. aureus* or *Candida* species) due to (1) systemic infection in the donor (e.g., line infection) or (2) contamination during the organ procurement process. The end result is a high risk of infection of vascular suture lines with resultant mycotic aneurysm. Uncommonly, infections have been transmitted from donor to recipient, including tuberculosis or fungal (e.g., histoplasmosis) infection that may emerge earlier in the time line than would be predicted (i.e., in the first month).

The third type and the most common source of infections in this period are related to the complex surgical procedure of transplantation. These include surgical wound infections, pneumonia (aspiration), bacteremia due to vascular access or surgical drainage catheters, urinary tract infections, or infections of fluid collections—leaks of vascular or urinary

anastamoses or of lymphoceles. These are nosocomial infections and, as such, are due to the same bacteria and *Candida* infections observed in nonimmunosuppressed patients undergoing comparable surgery. However, given the immune suppression, the signs of infection may be subtle and the severity or duration may be greater. The technical skill of the surgeons and meticulous postoperative care (i.e., wound care, endotracheal tubes, vascular access devices, and drainage catheters) are the determinants of risk for these infections. Also among the common infections is *C. difficile* colitis. Limited perioperative antibiotic prophylaxis (i.e., from a single dose to 24 hours of an antibiotic such as cefazolin) is usually adequate with additional coverage only for known risk factors (e.g., prior colonization with MRSA). For pancreas transplantation, perioperative prophylaxis against yeasts with fluconazole is used in addition, bearing in mind the interactions between azole antifungal agents and calcineurin inhibitors and sirolimus (levels may be increased significantly).

Notable by their absence in the 1st month after transplantation are opportunistic infections, even though the daily doses of immunosuppressive drugs are at their highest during this time. The implications of this observation are important: The net state of immunosuppression is not great enough to support the occurrence of opportunistic infections unless an exposure has been excessive; this observation suggests that it is not the daily dose of immunosuppressive drugs that is of importance but rather the sustained administration of these drugs, the "area under the curve," in determining the net state of immunosuppression. Thus, the occurrence of a single case of opportunistic infection in this period should trigger an epidemiologic investigation for an environmental hazard.

Phase Two: 1 to 6 Months After Transplantation

Infection in the transplant recipient 1 to 6 months after transplantation has one of three causes:

1. Lingering infection from the peri-surgical period, including relapsed *C. difficile* colitis, inadequately treated pneumonia, or infection related to a technical problem (e.g., urine leak, lymphocele, hematoma). Fluid collections require drainage.
2. Viral infections, including CMV, HSV, shingles (VZV), human herpesvirus 6 or 7, EBV, relapsed hepatitis (HBV, HCV), and HIV. This group of viruses is unique: lifelong infection; tissue-associated (often transmitted with the allograft from seropositive donors); immunomodulating—systemically immune suppressive and, potentially, predisposing to graft rejection. It is also notable that the herpesviruses are prominent due to the attenuated ability of T cells to control these infections. Among the other viral pathogens of this period must be included BK polyomavirus in association with allograft dysfunction and community-acquired respiratory viruses (adenovirus, influenza, parainfluenza, respiratory syncytial virus, metapneumovirus). The suppression of antibody production (e.g., using tacrolimus and mycophenylate mofetil or with lymphopenia) may predispose to other infections.
3. Opportunistic infection due to *P. jiroveci*, *Listeria monocytogenes*, *T. gondii*, *Nocardia* species, *Aspergillus* species, and other agents.

In this period, the stage is also set for the emergence of a subgroup of patients, the "chronic ne'er-do-wells"—individuals who require higher than average immune suppression to maintain graft function or who have prolonged untreated viral infections and other opportunistic infections, predicting long-term susceptibility to many other infections (third phase, discussed later). Such individuals may merit prolonged (lifelong) prophylaxis (antibacterial and/or antiviral) to prevent life-threatening infection.

The specific opportunistic infections that occur, reflect the specific immunosuppressive regimen used and the presence or absence of immunomodulating viral infection. Viral pathogens (and rejection) are responsible for the majority of febrile episodes that occur in this period. During this period, anti-CMV strategies and trimethoprim-sulfamethoxazole prophylaxis are effective in decreasing the risk of infection. Trimethoprim-sulfamethoxazole prophylaxis eliminates *P. jiroveci* pneumonia (PCP) and reduces the incidence of urinary tract infection and urosepsis, *L. monocytogenes* meningitis, *Nocardia* species infection, and *Toxoplasma gondii*.

Phase Three: More Than 6 to 12 Months After Transplantation

Transplant recipients who are more than 6 months past the procedure can be divided into three groups in terms of infection risk.

The first group consists of the majority of transplant recipients (70%–80%) who had a technically good procedure with satisfactory allograft function, reduced and maintenance immunosuppression, and absence of chronic viral infection. These patients resemble the general community in terms of infection risk, with community-acquired respiratory viruses constituting their major risk. Occasionally, such patients will develop primary CMV infection (socially acquired) or infections related to underlying diseases (e.g., skin infections in diabetes).

The second group (~10% of patients) suffers chronic viral infection, which, in the absence of effective therapy, will lead inexorably to one of three results:

- End organ damage (e.g., BK polyomavirus nephropathy, cryoglobulinemia, or cirrhosis from HCV—HBV being relatively well managed at present)
- Malignancy (post-transplantation lymphoproliferative disease [PTLD] due to EBV, skin, or anogenital cancer due to papilloma viruses)
- Acquired immunodeficiency syndrome (HIV/AIDS)

The third group of patients (~10% of all recipients) has less than satisfactory allograft function and requires excessive amounts of immunosuppressive therapy for recurrent graft rejection. This may be associated with chronic viral infection. This is the subgroup of transplant recipients, often termed the "chronic ne'er-do-wells," who are at highest risk for opportunistic infection with such pathogens as *P. jiroveci*, *L. monocytogenes*, *N. asteroides*, and *Cryptococcus neoformans*. It is our practice to give these patients lifetime maintenance trimethoprim-sulfamethoxazole prophylaxis and to consider the use of fluconazole prophylaxis. Also, this group is susceptible to organisms more often associated with immune dysfunction of AIDS (Bartonella, Rhodococcus, Cryptosporidium, and Microsporidium species) and invasive fungal pathogens

(*Aspergillus, Zygomycetes,* and the *Dematiaceae,* or pigmented, molds). Minimal signs or symptoms merit careful evaluation in this group of "high-risk" individuals.

ASSESSMENT OF INFECTIOUS DISEASE IN RECIPIENT AND POTENTIAL DONOR BEFORE TRANSPLANTATION

Guidelines for pre-transplant screening have been the subject of several recent publications including a consensus conference of the Immunocompromised Host Society (ICHS), the American Society for Transplantation (AST) Clinical Practice Guidelines on the evaluation of renal transplant candidates, and the ASTP Clinical Practice Guidelines on the evaluation of living renal transplant donors.[2–9]

The Transplant Donor

Deceased Donor Evaluation

The critical feature of screening for deceased donors is time limitation. A useful organ must be procured and implanted before some microbiologic assessments have been completed. Thus, major infections must be excluded and appropriate cultures and stored samples obtained for future reference. As a result, bacteremia or fungemia may not be detected until after the transplant has occurred. Such infections have not generally resulted in transmission of infection as long as the infection has been adequately treated, both in terms of use of antimicrobial agents to which the organism is susceptible and time. In recipients of tissues from 95 bacteremic donors, a mean of 3.8 days of effective therapy post-transplantation appeared adequate to prevent transmission; longer courses of therapy in the recipient are preferred, targeting known potential pathogens from the donor.[10] Bacterial meningitis must also be treated with antibiotics that penetrate the CSF before procurement. Similarly, due to the limited time for testing, certain acute infections (CMV, EBV, HIV, HBV, or HCV) may be undetected in the period prior to antibody formation, and viral DNA detection is preferred. As a result, the donor's clinical, social, and medical histories are essential to reducing the risk of such infections. However, in the presence of known infection, such infections must be treated prior to procurement, if possible. Major exclusion criteria are outlined in Table 37–4.

Living Donor Evaluation

The differences in screening of the living donor and the cadaver donor are largely based on the different time frames during which this screening takes place. The living donor procedure should be considered elective—and, thus, evaluation completed and infections treated prior to such procedures. An interim history must be taken at the time of surgery to assess the presence of new infections since the initial donor evaluation. Intercurrent infections (flu-like illness, headache, confusion, myalgia, cough) might be the harbinger of important infection (West Nile Virus, SARS, rabies, *Trypanosoma cruzi*). Live donors undergo a battery of serologic tests (Table 37–3) as well as PPD skin test and, if indicated, chest radiograph.

The testing must be individualized based on unique risk factors (e.g., travel). Of particular importance to the renal transplant recipient is the exclusion of urinary tract infection. Whether focal infections in the donor outside the procured organs merit therapy remains unresolved.

Special Considerations in Procurement

Mycobacterium tuberculosis. This bacterium from the donor represented approximately 4% of reported post-transplant TB cases in a review of 511 patients by Singh and colleagues.[11] Active disease should be excluded in PPD positive donors, including chest radiograph, sputum cultures, and chest CT, if the chest radiograph is abnormal. Urine AFB cultures may be useful in the PPD-positive kidney donor. Isoniazid prophylaxis of the recipient should be considered for untreated, PPD-positive donors.[12] Factors mitigating towards prophylaxis include donor from endemic region, use of high-dose steroid regimen, or high-risk social environment.

Chagas' disease (T. cruzi). This parasitic disease has been transmitted by transplantation in endemic areas and recently in the United States. Schistosomiasis and infection by *Strongyloides stercoralis* are generally recipient-derived problems.

Viral Infections other than CMV

Epstein-Barr virus. The risk for post-transplant lymphoproliferative disease (PTLD) is greatest in the EBV seronegative recipient of an EBV seropositive allograft (i.e., D+/R−). This is most common in pediatric transplant recipients and in adults coinfected with CMV or on higher levels of immune suppression. Monitoring should be considered for at-risk individuals using a quantitative, molecular assay (e.g., PCR) for EBV.[13,14] EBV is also a cofactor for other lymphoid malignancies.

Varicella screening should be used to identify seronegative individuals (no history of chicken pox or shingles) for vaccination prior to transplantation. HSV screening is performed by most centers despite the use of antiviral prophylaxis during the post-transplant period. VZV serologic status is particularly important in children who may be exposed at school (for antiviral or varicella immune globulin prophylaxis) and in adults with atypical presentations of infection (pneumonia or GI disease). Other herpesviruses may reactivate with HHV-6 and HHV-7 serving as cofactors for CMV and fungal infections and in endemic regions, Kaposi's sarcoma-associated herpesvirus (HHV-8/KSHV) causing malignancies.

Hepatitis B virus (HBV). HBsAg and HBV core antibody (HBcAb) are used for screening purposes with HBsAb positivity indicating either vaccination or prior infection. HBcAb-IgM positivity suggests active HBV infection, whereas IgG positivity suggests a more remote or persistent infection. The HBsAg negative, HBcAb-IgG positive donor may have viral DNA in the liver but may be appropriate as a donor for HBV-infected renal recipients. Quantitative assays for HBV should be obtained to guide further therapy. The presence of HBsAg negative, HBcAb-IgG positive assays may be a false-positive or reflect true, latent HBV infection.

Hepatitis C virus (HCV) infection will generally progress more rapidly with immune suppression and with CMV coinfection. HCV seropositive renal transplant candidates are more likely to develop cirrhosis and complications of liver

failure. There is no good therapy for HCV infection; management is by quantitative molecular viral assays.

HIV-infected donors have not been utilized. The progression of disease is rapid and outweighs the benefits of transplantation. Donors may be excluded based on historic evidence of "high-risk" behavior for HIV infection. Western blot testing and molecular assays (PCR) should be obtained prior to the use of tissues from any HIV-seropositive donor.

Human T-lymphotropic virus I (HTLV-I) is endemic in the Caribbean and parts of Asia (Japan) and can progress to HTLV-I-associated myelopathy/tropical spastic paraparesis (HAM/TSP) or to adult T cell leukemia/lymphoma (ATL). HTLV-II is similar to HTLV-I serologically but is less clearly associated with disease. Use of organs from such donors is generally avoided.[15,16]

West Nile virus (WNV) is a flavivirus associated with viral syndromes and meningoencephalitis and may be transmitted by blood transfusion and organ transplantation.[17,18] Routine screening of donors is not advocated other than in areas with endemic infection of the blood supply. Donors with unexplained changes in mental status or recent viral illness with neurologic signs should be avoided.

SARS (Severe Acute Respiratory Syndrome) is a recently described coronavirus, thought to be associated with exposure to civets or other animals common to the diet of certain regions of China. Tissue persistence is prolonged and infection of transplant recipients appears to be severe and often symptomatic. Organ procurement should exclude patients with recent acute illnesses meeting SARS criteria.

Recipient Screening

The pre-transplant period is useful for a thorough travel, animal, and environmental and exposure history; updating immunizations; and counseling of the recipient regarding travel, food, and other infection risks. Ongoing infection must be eradicated prior to transplantation. Two forms of infection pose a special risk:

1. Bloodstream infection: This is related to vascular access, including that for dialysis and pneumonia, which puts the patient at high risk for subsequent lung infection with nosocomial organisms. Infected ascites or peritoneal dialysis fluid must also be cleared prior to surgery. Urinary tract infection (UTI) must be eliminated prior to transplantation with antibiotics with or without nephrectomy. Similarly, skin disease that threatens the integrity of this primary defense against infection should be corrected before transplantation, even if doing so requires the initiation of immunosuppression prior to transplantation (e.g., the initiation of immune suppression to treat psoriasis or eczema). Finally, the history of more than one episode of diverticulitis should initiate an evaluation to determine whether sigmoid colectomy should be carried out prior to transplantation.
2. Tuberculosis: Both the incidence of active disease and the occurrence of disseminated infection due to *M. tuberculosis* are far higher in the transplant recipient than in the general population. Active tuberculous disease must be eradicated prior to transplantation. The major antituberculous drugs are potentially hepatotoxic, and significant

drug interactions are common between the anti-TB agents and the agents of immune suppression. In patients with active infection, from endemic regions or with high risk exposures, TB therapy should be initiated in all PPD positive individuals prior to transplantation. Some judgment may be used as to the optimal timing of treatment in individuals without evidence of active or pleuropulmonary disease. Greater risk may include:

- Previously active tuberculosis or significant signs of old tuberculosis on chest radiograph
- Recent tuberculin reaction conversion
- Known exposure to active disease
- Protein-calorie malnutrition, cirrhosis, or other immune deficiency
- Living in a shelter or other group housing

AIDS

For those benefiting from HAART, AIDS has been converted from a progressively fatal disease to a chronic infection controlled by complex regimens of antiviral agents. HAART has been associated with reduced viral loads, improved CD4 lymphocyte counts, and reduced susceptibility to opportunistic infections. In the pre-HAART era, organ transplantation was generally associated with a rapid progression of AIDS. As a result, HIV-infected individuals have been excluded at most transplantation centers. However, prolonged disease-free survival with HAART has lead to a reconsideration of this policy. Renal transplantation in HIV has been associated with good outcomes in individuals with controlled HIV infection and in the absence of HCV co-infection.[19] Management requires some sophistication regarding both the immune suppressive agents and the various HAART regimens.

SELECTED INFECTIONS OF IMPORTANCE

General Considerations

The spectrum of infection in the immunocompromised host is quite broad. Given the toxicity of antimicrobial agents and the need for rapid interruption of infection, early, specific diagnosis is essential in this population. Advances in diagnostic modalities (CT or MRI scanning, molecular microbiologic techniques) may greatly assist in this process. However, the need for invasive diagnostic tools cannot be overemphasized. Given the diminished immune responses of the host and the frequency of multiple simultaneous processes, invasive diagnosis is often the only method for optimal care. The initial therapy will, by necessity, be broad with a rapid narrowing of the antimicrobial spectrum as data become available. *The first choice of therapy is to reduce the intensity of immune suppression.* The risk of such an approach is that of graft rejection. The selection of the specific reduction may depend upon the organisms isolated. Similarly, reversal of some immune deficits (neutropenia, hypogammaglobulinemia) may be possible with adjunctive therapies (colony stimulating factors or IgG). Co-infection with virus (CMV) is common and merits additional therapy.

Viral Pathogens

Cytomegalovirus (CMV)

CMV is the single most important pathogen in transplant recipients, having a variety of direct and indirect effects.[1,27] The direct effects include:

- Fever and neutropenia syndrome with features of infectious mononucleosis, including hepatitis, nephritis, leukopenia, and/or thrombocytopenia
- Pneumonia
- Gastrointestinal invasion with colitis, esophagitis, gastritis, ulcers, bleeding, or perforation
- Hepatitis, pancreatitis, chorioretinitis

With the exception of chorioretinitis, the direct clinical manifestations of CMV infection usually occur 1 to 4 months after transplantation; chorioretinitis usually does not begin until later in the transplant course.

Although CMV is the most common cause of clinical infectious disease syndromes, its "indirect effects" are often more important. CMV infection produces a profound suppression of a variety of host defenses, predisposing to secondary invasion by such pathogens as *P. jiroveci*, *Candida* and *Aspergillus* species, and some bacterial infections. CMV also contributes to the risk for graft rejection, PTLD, HHV6, and HHV7 infections. The mechanisms for this effect are complex, including altered T-cell subsets and MHC synthesis, and the elaboration of an array of pro-inflammatory cytokines, chemokines, and growth factors.

Patterns of Transmission

Transmission of CMV in the transplant recipient occurs in one of three patterns: primary infection, reactivation infection, and superinfection.[1]

Primary CMV infection

Primary infection occurs when seronegative individuals receive grafts from latently infected, seropositive donors (donor seropositive, recipient seronegative [D+R−]), with subsequent reactivation of the virus and systemic dissemination after transplantation. Between 40% and 50% of these patients experience direct infectious disease manifestations of CMV while the majority are viremic, often without symptoms. Primary CMV infection may also occur in seronegative individuals after transfusion or sexual contacts in the community. This disease may be severe.

Reactivation CMV infection

In reactivation infection, seropositive individuals reactivate endogenous virus after transplantation (donor seropositive or seronegative, recipient seropositive [D+R+ or D−R+]). When conventional immunosuppressive therapy is used (e.g., no antilymphocyte antibody treatment), approximately 10% to 15% experience direct infectious disease syndromes with a higher rate with the use of induction antilymphocyte therapy. Up to 50% of these individuals are viremic, often without symptoms.

CMV superinfection

Virus may be reactivated in the setting of an allograft from a seropositive donor transplanted into a seropositive recipient (D+R+).

Pathogenesis

Control of CMV infection is via MHC-restricted, virus-specific, cytotoxic T lymphocyte response (CD8+ cells) controlled by CD4+ lymphocytes. Seroconversion is a marker for the development of host immunity. Thus, the major effector for activation of virus is the nature of the immunosuppressive therapy being administered. The lytic antilymphocyte antibodies, both polyclonal and monoclonal, are direct activators of viral infection (mimicking the alloimmune response) and also provoke the elaboration of TNF and the other pro-inflammatory cytokines that enhance viral replication. Cyclosporine, tacrolimus, sirolimus, and prednisone (other than pulse doses) have limited ability to reactivate latent CMV while azathioprine, mycophenolate, and cyclophosphamide are moderately potent in terms of promoting viral reactivation. These agents perpetuate infection once established.

Allograft rejection is a major stimulus for CMV activation and vice versa. Thus, the CMV infection has been linked to a diminished outcome of renal and other allografts. As a result, Reinke and colleagues[27] showed that 17 of 21 patients for whom biopsy revealed evidence of "late acute rejection" demonstrated a response to antiviral therapy. Further, Lowance and colleagues[28] demonstrated that the prevention of CMV infection also resulted in a lower incidence of graft rejection.

Diagnosis

Clinical management of CMV, both prevention and treatment, is of great importance for the transplant recipient. It is based on a clear understanding of the causes of CMV activation and the variety of diagnostic techniques available. CMV cultures are generally too slow and insensitive for clinical utility. Further, a positive CMV culture (or shell vial culture) derived from respiratory secretions or urine is of little diagnostic value—many patients secrete CMV in the absence of invasive disease. Serologic tests are useful prior to transplantation to predict risk but are of little value after transplantation in defining clinical disease (this statement includes measurements of anti-CMV immunoglobulin M [IgM] levels). Should a patient seroconvert to CMV, this is evidence that the patient has been exposed to CMV and has developed some degree of immunity. However, seroconversion in transplantation is generally delayed and, thus, not useful for clinical diagnosis. The demonstration of CMV inclusions in tissues in the setting of a compatible clinical presentation is the "gold standard" for diagnosis.

Quantitation of the intensity of CMV infection has been linked to the risk for infection in transplant recipients.[29–33] Two types of quantitative assays have been developed: the molecular assays and the antigen detection assays. The antigenemia assay is a semiquantitative fluorescent assay in which circulating neutrophils are stained for CMV early antigen (pp65), which is taken up nonspecifically as a measure of the total viral burden in the body. The molecular assays (direct DNA PCR, hybrid capture, amplification assays) are highly specific and sensitive for the detection of viremia. Most commonly used assays include plasma-based PCR testing and the whole-blood hybrid capture assay, noting that whole blood and plasma-based assays cannot be directly compared. The highest viral loads are often associated with tissue-invasive

disease with the lowest in asymptomatic CMV infection. Viral loads in the CMV syndrome are variable. Either assay can be used in management.

The advent of quantitative assays for the diagnosis and management of CMV infection has allowed noninvasive diagnosis in many patients with two important exceptions:

1. Neurologic disease, including chorioretinitis
2. Gastrointestinal disease, including invasive colitis and gastritis.

In these syndromes, the CMV assays are often *negative* and invasive (biopsy) diagnosis may be needed.

The central role of assays is illustrated by the approach to prevention and treatment of CMV (Table 37–6). The schedule for screening is linked to the risk for infection. Thus, in the high risk patient (D+/R− or R+ with antilymphocyte globulin) after the completion of prophylaxis, monthly screening is performed to assure the absence of infection for 3 to 6 months. In the patient being treated for CMV infection, the assays provide an end point (zero positivity) for therapy and the initiation of prophylaxis.

CMV Prevention

Prevention of CMV infection must be individualized for immunosuppressive regimens and the patient. Two strategies are commonly used for CMV prevention: (1) universal prophylaxis and (2) preemptive therapy. Universal prophylaxis involves giving antiviral therapy to all "at-risk" patients beginning at or immediately post-transplant for a defined time period. In preemptive therapy, quantitative assays are used to monitor patients at predefined intervals to detect early disease. Positive assays result in therapy. Preemptive therapy incurs extra costs for monitoring and coordination of outpatient care while reducing the cost of drugs and the inherent toxicities. Prophylaxis has the possible advantage of preventing not only CMV infection during the period of greatest risk, but also diminishing infections due to HHV6, HHV7, and EBV. Further, the indirect effects of CMV (i.e., graft rejection, opportunistic infection) may also be reduced by routine prophylaxis. In practice neither strategy is perfect. Both breakthrough disease and ganciclovir resistance have been observed in both approaches.

Given the risk for invasive infection, patients at risk for primary infection (CMV D+/R−) are generally given prophylaxis for 3 to 6 months after transplantation. We utilize 6 months of prophylaxis in patients receiving lytic antilymphocyte antibodies. Other groups are candidates for preemptive therapy *if* an appropriate monitoring system is in place and patient compliance is good.

Treatment

The standard of care for treating CMV disease is 2 to 3 weeks of intravenous ganciclovir (5 mg/kg twice daily, with dosage adjustments for renal dysfunction). In patients slow to respond to therapy and who are seronegative, the addition of 3 months of CMV hyperimmune globulin in seronegative individuals (150 mg/kg/dose iv) may be useful. Relapse does occur, primarily in those not treated beyond the achievement of a negative quantitative assay. Therefore, we treat intravenously until viremia has been cleared and following it with

prophylaxis with 2 to 4 months of oral ganciclovir (1 g two or three times daily) or valganciclovir (based on creatinine clearance). This approach has resulted in rare symptomatic relapses and appears to prevent the emergence of antiviral resistance.

A number of issues remain. First, the role of oral valganciclovir in treatment has not been well studied. This agent provides good bioavailability but is not approved for this indication. Further, some relapses occur in GI disease because the assays used to follow disease are not reliable in this setting. Thus, repeat endoscopy should be considered to assure the clearance of infection. The optimum dosing of valganciclovir for prophylaxis in renal transplant recipients is also unclear. Many centers use 450 mg/day po (given reduced creatinine clearance) although the FDA approved dosing 900 mg/day. It is worth measuring the creatinine clearance to ensure appropriate dosing.

Alternative therapies are available in intravenous form only. These include foscarnet and cidofovir. Foscarnet has been used extensively for therapy of CMV in AIDS patients. It is active against most ganciclovir-resistant strains of CMV, although we prefer combination therapy (ganciclovir and foscarnet) for such individuals, given the toxicities of each agent and the antiviral synergy demonstrated. Cidofovir has been used in renal transplant recipients, often with nephrotoxicity. Both foscarnet and cidofovir may exhibit synergistic nephrotoxicity with calcineurin inhibitors. A newer class of agents (leflunamide) has been approved for immune suppression and treatment of rheumatologic diseases but also appears to have useful activity against CMV (and possibly BK polyomavirus).

Epstein-Barr Virus

EBV is a ubiquitous herpesvirus (the majority of adults are infected) that has B-lymphocytes as a primary target for infection. In immunosuppressed transplant recipients, primary EBV infection (and relapses in the absence of antiviral immunity) causes a mononucleosis-type syndrome, generally presenting as a lymphocytosis (B-cells) with or without lymphadenopathy or pharyngitis. Meningitis, hepatitis, and pancreatitis may also be observed. Remitting-relapsing EBV infection is common in children and may reflect the interplay between evolving antiviral immunity and immune suppression. This syndrome should suggest relative over-immune suppression.

EBV also plays a central role in the pathogenesis of post-transplant lymphoproliferative disorder or PTLD.[34–37] The most clearly defined risk factor for PTLD is primary EBV infection that increases the risk for PTLD by 10- to 76-fold. PTLD may occur, however, in the absence of EBV infection or in seropositive patients. Post-transplant non-Hodgkin's lymphoma (NHL) is a common complication of solid organ transplantation. Lymphomas comprise up to 15% of tumors among adult transplant recipients (51% in children) with mortality of 40% to 60%. Many deaths are associated with allograft failure after withdrawal of immune suppression during treatment of malignancy. Compared with the general population, PTLD has increased extranodal involvement, poor response to conventional therapies, and poor outcomes. The spectrum of disease ranges from benign polyclonal, B-cell infectious mononucleosis-like disease to malignant, monoclonal

lymphoma.[38] The majority is of B-cell origin, although T-cell, NK-cell and null cell tumors are described. It should be noted that EBV-negative PTLD has been described and that T-cell PTLD has been demonstrated in allografts, confused with graft rejection or other viral infection. PTLD late (more than 1–2 years) after transplantation is more often EBV-negative in adults.

The clinical presentations of EBV-associated PTLD vary:

1. Unexplained fever (fever of unknown origin)
2. A mononucleosis-type syndrome, with fever, malaise, with or without pharyngitis or tonsillitis (often diagnosed incidentally in tonsillectomy specimens); often no lymphadenopathy is observed.
3. Gastrointestinal bleeding, obstruction, perforation
4. Abdominal mass lesions
5. Infiltrative disease of the allograft
6. Hepatocellular or pancreatic dysfunction
7. Central nervous system disease

Diagnosis

Serologic testing is not useful for the diagnosis of acute EBV infection or PTLD in transplantation. Thus, quantitative EBV viral load testing is required for the diagnosis and management of PTLD.[39–42] Serial assays are more useful in an individual patient than specific viral load measurements. These assays are not standardized and cannot be directly compared between centers. There are some data to suggest that assays using unfractionated whole blood are preferable to plasma samples for EBV viral load surveillance.

Management

Clinical management depends on the stage of disease. In the polyclonal form, particularly in children, reestablishment of immune function may suffice to cause PTLD to regress. At this stage, it is possible that antiviral therapy might have some utility given the viremia and role of EBV as an immune suppressive agent. With the progression of disease to extra-nodal and monoclonal malignant forms, reduction in immune suppression may be useful, but alternate therapies are often required. In renal transplantation, the failure to regress with significant reductions in immune suppression may suggest the need to sacrifice the allograft for patient survival. Combinations of anti-B-cell therapy (anti-CD20 rituximab), chemotherapy (CHOP), and/or adoptive immunotherapy with stimulated T cells have been utilized.[43–46]

Polyomaviruses

Polyomaviruses have been identified in transplant recipients in association with nephropathy and ureteral obstruction (BK virus) and in association with demyelinating disease of the brain (JC virus) similar to that in AIDS. Polyomaviruses are small nonenveloped viruses with covalently closed, circular, double-stranded DNA genomes. Adult levels of seroprevalence are 65% to 90%. BK virus appears to achieve latency in renal tubular epithelial cells. JC virus has also been isolated from renal tissues but appears to have preferred tropism for neural tissues. Reactivation occurs with immune deficiency and suppression and tissue injury (e.g., ischemia-reperfusion).

BK Polyomavirus Infection

BK virus is associated with a range of clinical syndromes in immunocompromised hosts: viruria and viremia, ureteral ulceration and stenosis, and hemorrhagic cystitis.[47–54] Active infection of renal allografts has been associated with progressive loss of graft function (BK nephropathy) in some individuals. This may be referred to as polyomavirus-associated nephropathy or PVAN. BK nephropathy is rarely recognized in recipients of nonrenal organs. The clinical presentation of disease is usually as sterile pyuria, reflecting shedding of infected tubular and ureteric epithelial cells. These cells contain sheets of virus and are detected by urine cytology as "decoy cells." In most cases, such cells are not detected and the patient presents with diminished renal allograft function or with ureteric stenosis and obstruction. In such patients, the etiologies of decreased renal function must be carefully evaluated (e.g., mechanical obstruction, drug toxicity, pyelonephritis, rejection, thrombosis, recurrent disease), and choices must be made between *increasing immune suppression* to treat suspected graft rejection and *reducing immune suppression* to allow the immune system to control infection. Patients with BK nephropathy treated with increased immune suppression have a high incidence of graft loss. Reduced immune suppression may stabilize renal allograft function but risks graft rejection. Polyoma-associated nephropathy manifested by characteristic histologic features and renal dysfunction is found in about 1% to 8% of renal transplant patients.

Risk factors for nephropathy are poorly defined. Nickeleit and colleagues[51,52] found that cellular rejection occurred more commonly in patients with BK nephropathy than in controls. Other studies have implicated high dose immunosuppression (particularly tacrolimus and mycophenolate mofetil), pulse dose steroids, severe ischemia-reperfusion injury, exposure to antilymphocyte antibody therapy, increased number of HLA mismatches between donor and recipient, cadaver renal transplants, and presence and degree of viremia in the pathogenesis of disease. The role of specific immunosuppressive agents has not been confirmed.

Diagnosis

The use of urine cytology to detect the presence of infected decoy cells in the urine has approximately 100% sensitivity for BK virus infection but a low (29%) predictive value.[53,54] It is, therefore, a useful screening tool but cannot establish a firm diagnosis. The use of molecular techniques to screen blood or urine has also been advocated but is more useful in management of established cases (viral clearance with therapy) than in specific diagnosis.[55–60] Hirsch and colleagues[53] showed that patients with BK nephropathy have a plasma viral load statistically significantly higher (>7700 BK virus copies per mL of plasma, $p<.001$, 50% positive predictive value, 100% negative predictive value) when compared to patients without such disease.[53]

Given the presence of viremia in renal allograft recipients, it is critical to reduce immune suppression when possible. However, the possible coexistence of rejection with BK infection makes renal biopsy essential for the management of such patients. Renal biopsies will demonstrate cytopathic changes in renal epithelial cells without cellular infiltration with the gradual evolution of cellular infiltration consistent

with the diagnosis of interstitial nephritis. Fibrosis is often prominent occasionally with calcification. Immunostaining for cross reacting SV40 virus demonstrates patchy staining of viral particles within tubular cells.

Treatment

There is no accepted treatment for PVAN other than a marked reduction in the intensity of immune suppression. It is possible to monitor the response to such maneuvers using urine cytology (decoy cells) and viral load measures in blood and/or urine. The greatest incidence of BK nephropathy is at centers with the most intensive immune suppressive regimens. Thus, it is unclear whether reduction of calcineurin inhibitors or antimetabolites should be considered first. Given the toxicity of calcineurin inhibitors for tubular cells and the role of injury in the activation of BK virus, as well as the need for anti-BK T-cell activity, we have generally reduced these agents first. Other centers have selected reduction of the antimetabolite first. Regardless of the approach, renal function, drug levels, and viral loads must be monitored carefully.

Some centers advocate the use of cidofovir for BK nephropathy in low doses (0.25–1 mg/kg every 2 weeks).[61–64] Significant renal toxicity may be observed with this agent, especially in combination with the calcineurin inhibitors. Retransplantation has been achieved in such patients with failed allografts, possibly as a reflection of immunity developing subsequent to reduction in immune suppression.[65]

JC Virus

Infection of the central nervous system by JC polyomavirus has been observed uncommonly in renal allograft recipients as progressive multifocal encephalopathy. This infection generally presents with focal neurologic deficits or seizures and may progress to death following extensive demyelination. PML may be confused with calcineurin neurotoxicity; both may respond to a reduction in drug levels. It is thought that these are distinct entities, but further studies are underway.

Fungal Infections

In addition to the endemic mycoses, transplant recipients are at risk for opportunistic infection with a variety of fungal agents, the most important of which are *Candida* species, *Aspergillus* species, and *C. neoformans*.

Candida Species

The most common fungal pathogen in these patients is *Candida*, with *C. albicans* and *C. tropicalis* accounting for 90% of the infections and *C. glabrata* for most of the rest. Mucocutaneous candidal infection (e.g., oral thrush, esophageal infection, cutaneous infection at intertriginous sites, candidal vaginitis) occurs particularly when candidal overgrowth is promoted by the presence of high levels of glucose and glycogen in tissues and fluids (e.g., with poorly controlled diabetes, high-dose steroid therapy) and by broad-spectrum antibacterial therapy). These infections are usually treatable through correction of the underlying metabolic abnormality and topical therapy with clotrimazole or nystatin.

More difficult to manage is candidal infection occurring in association with the presence of foreign bodies that violate the mucocutaneous surfaces of the body (e.g., vascular access catheters, surgical drains, and bladder catheters). Optimal management of these infections requires removal of the foreign body and systemic antifungal therapy with either fluconazole or amphotericin.

A special problem in renal transplant recipients is candiduria, even if the patient is asymptomatic. Particularly in individuals with poor bladder function, obstructing fungal balls can develop at the ureteropelvic junction, resulting in obstructive uropathy, ascending pyelonephritis, and the possibility of systemic dissemination. A single positive culture result for *Candida* species from a blood specimen necessitates systemic antifungal therapy, because this finding carries a risk of visceral invasion of more than 50% in this population. Fluconazole (400-600 mg/day, with adjustment for renal dysfunction), because of its better safety profile, is usually used as initial therapy, unless the patient is critically ill or a fluconazole-resistant species (e.g., *C. glabrata* or *C. krusei*) is present. In these instances, therapy is with caspofungin or amphotericin B, usually in a lipid preparation. Flucytosine may be useful as an adjunctive therapy in resistant infections but must be guided by drug levels and attention to hematopoietic toxicity.

Aspergillus Species

Invasive aspergillosis is a medical emergency in the transplant recipient, with the portal of entry being the lungs and sinuses in more than 90% of patients and the skin in most of those remaining. Two species, *A. fumigatus* and *A. flavum*, account for most of these infections, although amphotericin-resistant isolates (*A. terreus*) are occasionally recognized. The pathologic hallmark of invasive aspergillosis is blood vessel invasion, which accounts for the three clinical characteristics of this infection: tissue infarction, hemorrhage, systemic dissemination with metastatic invasion. Early in the course of transplantation, central nervous system involment with fungal infection is most often due to *Aspergillus* species; more than 1 year after transplantation, other fungi (zygomycetes, dematiaceous fungi) are increasingly prominent.

The drug of choice for this infection is probably voriconazole, noting the intense interactions between this agent and the calcineurin inhibitors and sirolimus. Liposomal amphotericin is a reasonable alternative, and combination therapies are under study. Of note, surgical debridement is often essential for the successful clearance of such invasive infections.

Central Nervous System Infection and *Cryptococcus neoformans*

Central nervous system (CNS) infection in the transplant recipient is an important differential for the clinician. The spectrum of causative organisms is broad and must be considered in terms of the timeline for infection in this population. Many infections are metastatic to the CNS, often from the lungs. Thus, a "metastatic workup" is a component of evaluation of CNS lesions, including those due to *Aspergillus, Cryptococcus, Nocardia,* or *Strongyloides stercoralis*. Viral

infections include cytomegalovirus (nodular angiitis), herpes simplex meningoencephalitis, JC virus (PML), and varicella zoster virus. Common bacterial infections include *Listeria monocytogenes*, mycobacteria, *Nocardia*, and occasionally *Salmonella* species. Brain abscess and epidural abscess may be observed with methicillin-resistant staphylococcus, penicillin resistant pneumococcus and quinolone-resistant streptococci problematic. Metastatic fungi include *Aspergillus* and *Cryptococcus* but also spread from sinuses (*Mucoraceae*), skin (*Dematiaceae*), and bloodstream (*Histoplasma* and *Pseudoallescheria/Scedosporium, Fusarium* species). Parasites include *Toxoplasma gondii* and *Strongyloides*. Given the spectrum of etiologies, precise diagnosis is essential. In particular, empiric therapy must "cover" *Listeria* (ampicillin), *Cryptococcus* (fluconazole or amphotericin), and herpes simplex virus (acyclovir) while awaiting data from lumbar puncture, blood cultures, and radiographic studies. Included in the differential diagnosis are noninfectious etiologies, including calcineurin inhibitor toxicity and lymphoma, as well as metastatic cancer. Biopsy is often needed for a firm diagnosis.

Cryptococcus neoformans

Cryptococcal infection is rarely seen in the transplant recipient until more than 6 months after transplantation. In the relatively intact transplant recipient, the most common presentation of cryptococcal infection is that of an asymptomatic pulmonary nodule, often with active organisms present. In the "chronic ne'er-do-well" patient, pneumonia and meningitis are common with skin involvement at sites of tissue injury (catheters) also being observed.

Cryptococcosis should be suspected in transplant recipients present with unexplained headaches (especially when accompanied by fevers), decreased state of consciousness, failure to thrive, or unexplained focal skin disease (which requires biopsy for culture and pathologic evaluation) more than 6 months after transplantation. Diagnosis is often achieved by serum cryptococcal antigen detection, but all such patients should have lumbar puncture for cell counts and cryptococcal antigen studies. Initial treatment is probably best with amphotericin and 5-flucytosine followed by high dose fluconazole until the cryptococcal antigen is cleared from blood and cerebrospinal fluid. Scarring and hydrocephalus may be observed.

Fever and Pneumonitis and *Pneumocystis* Infection

The spectrum of potential pathogens of the lungs in transplantation is too broad for this discussion. However, some general concepts are worth mentioning. As for all infections in transplantation, invasive diagnostic techniques are often necessary in these hosts. The depressed inflammatory response of the immunocompromised transplant patient may greatly modify or delay the appearance of a pulmonary lesion on radiograph. Focal or multifocal consolidation of acute onset will quite likely be caused by bacterial infection. Similar multifocal lesions with subacute to chronic progression are more likely secondary to fungi, tuberculosis, or nocardial infections. Large nodules are usually a sign of fungal or nocardial infection, particularly if they are subacute to chronic in onset. Subacute disease with diffuse abnormalities, either of the peri-

bronchovascular type or miliary micronodules, are usually caused by viruses (especially CMV) or *Pneumocystis jiroveci*.[66,67] Additional clues can be found by examining pulmonary lesions for cavitation; cavitation suggests such necrotizing infections as those caused by fungi (*Aspergillus* or *Mucoraceae*), *Nocardia*, *Staphylococcus*, certain gram-negative bacilli, most commonly with *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*.[68–70] CT of the chest is useful when the chest radiograph is negative or when the radiographic findings are subtle or nonspecific. CT is also essential to the definition of the extent of the disease process, the possibility of multiple simultaneous processes (superinfection), and to the selection of the optimal invasive technique to achieve microbiologic diagnosis.

Pneumocystis jiroveci Pneumonia

The risk of infection with *Pneumocystis* is greatest in the first 6 months after transplantation and during periods of increased immune suppression.[1,66,67] The natural reservoir of infection remains unknown. Aerosol transmission of infection has been demonstrated by a number of investigators in animal models, and clusters of infections have developed in clinical settings, including between HIV-infected persons and renal transplant recipients. Activation of latent infection remains a significant factor in the incidence of disease in immunocompromised hosts. In the solid organ transplant recipient, chronic immune suppression that includes corticosteroids is most often associated with pneumocystosis. Bolus corticosteroids, cyclosporine, or co-infection with CMV may also contribute to the risk for *Pneumocystis* pneumonia.

In patients not receiving trimethoprim-sulfamethoxazole (or alternative drugs) as prophylaxis, most transplant centers report an incidence of *Pneumocystis jiroveci* pneumonia of approximately 10% in the first 6 months post-transplant. There is a continued risk of infection in three overlapping groups of transplant recipients: (1) those who require higher than normal levels of immune suppression for prolonged periods of time due to poor allograft function or chronic rejection; (2) those with chronic cytomegalovirus infection; and (3) those undergoing treatments that increase the level of immune deficiency, such as cancer chemotherapy or neutropenia due to drug toxicity. The expected mortality due to *Pneumocystis* pneumonia is increased in patients on cyclosporine when compared to other immunocompromised hosts. The hallmark of infection due to *P. jiroveci* is the presence of marked hypoxemia, dyspnea, and cough with a paucity of physical or radiologic findings. In the transplant recipient, *Pneumocystis* pneumonia is generally acute to subacute in development. Atypical *Pneumocystis* infection (radiographically or clinically) may be seen in patients who have coexisting pulmonary infections or who develop disease while receiving prophylaxis with second choice agents (e.g., pentamidine or atovaquone). Patients outside the usual period of greatest risk for PCP may present with indolent disease confused with heart failure. In such patients, diagnosis often has to be made by invasive procedures. The role of sirolimus therapy in the clinical presentation is unknown. A number of patients have been identified with interstitial pneumonitis while receiving sirolimus; it is not known whether this syndrome is directly attributable to sirolimus or reflects concomitant infection.

Diagnosis

The characteristic hypoxemia of *Pneumocystis* pneumonia produces a broad alveolar-arterial PO_2 gradient. The level of serum lactic dehydrogenase (LDH) is elevated in most patients with *Pneumocystis* pneumonia (>300 international units [IU]/mL). However, many other diffuse pulmonary processes also raise serum LDH levels.

Like many of the "atypical" pneumonias (pulmonary infection without sputum production), no diagnostic pattern exists for *Pneumocystis* pneumonia on routine chest radiograph. The chest radiograph may be entirely normal or develop the classical pattern of perihilar and interstitial "ground glass" infiltrates. Microabscesses, nodules, small effusions, lymphadenopathy, asymmetry, and linear bands are common. Chest computerized tomography (CT-scans) will be more sensitive to the diffuse interstitial and nodular pattern than routine radiographs. The clinical and radiologic manifestations of *P. jiroveci* pneumonia are virtually identical to those of CMV. Indeed, the clinical challenge is to determine whether both pathogens are present. Significant extrapulmonary disease is uncommon in the transplant recipient.

Identification of *P. jiroveci* as a specific etiologic agent of pneumonia in an immunocompromised patient should lead to successful treatment. A distinction should be made between the diagnosis of *Pneumocystis* infection in AIDS and in non-AIDS patients. The burden of organisms in infected AIDS patients is generally greater than that of other immunocompromised hosts and noninvasive diagnosis (sputum induction) more often achieved. In general, noninvasive testing should be attempted to make the initial diagnosis, but invasive techniques should be used when clinically feasible. The diagnosis of *P. jiroveci* infection has been improved by the use of induced sputum samples and of immunofluorescent monoclonal antibodies to detect the organism in clinical specimens. These antibodies bind both cysts and trophozoites. The cyst wall can be displayed by a variety of staining techniques; of these, the Gomori's methenamine-silver nitrate method (which stains organisms brown or black) is most reliable, even though it is susceptible to artifacts. Sporozoites and trophozoites are stained by polychrome stains, particularly the Giemsa stain.

Therapy

Early therapy, preferably with trimethoprim-sulfamethoxazole (TMP-SMZ) is preferred; few renal transplant patients will tolerate full-dose TMP-SMZ for prolonged periods of time. This reflects both the elevation of creatinine due to trimethoprim (competing for secretion in the kidney) and the toxicity of sulfa agents for the renal allograft. Hydration and the gradual initiation of therapy may help. Alternate therapies are less desirable but have been used with success, including: intravenous pentamidine, atovaquone, clindamycin with primaquine or pyrimethamine, and trimetrexate. Although a reduction in the intensity of immune suppression is generally considered a part of anti-infective therapy in transplantation, the use of short courses of adjunctive steroids with a gradual taper is sometimes used in transplant recipients (as in AIDS patients) with severe respiratory distress associated with PCP.

The importance of preventing *Pneumocystis* infection cannot be overemphasized. Low dose trimethoprim-sulfamethoxazole

Table 37–7 Vaccinations to Consider Prior to Transplantation

Measles/mumps/rubella (MMR)
Diphtheria/tetanus/pertussis (DTP)
Poliovirus
Haemophilus influenzae type b
Hepatitis B
Pneumococcus
Influenza
Varicella

is well tolerated and should be used in the absence of concrete data demonstrating true allergy. Alternative prophylactic strategies including dapsone, atovaquone, inhaled or intravenous pentamidine, are less effective than trimethoprim-sulfamethoxazole but useful in the patient with significant allergy to sulfa drugs. TMP-SMX is the most effective agent for prevention of infection due to *P. jiroveci*. The advantages of TMP-SMX include increased efficacy, lower cost, the availability of oral preparations, and possible protection against other organisms, including *Toxoplasma gondii*, *Isospora belli*, *Cyclospora cayetanensis*, *Nocardia asteroides*, and common urinary, respiratory, and gastrointestinal bacterial pathogens. It should be noted that alternative agents lack this spectrum of activity.

Vaccination

Due to concerns about the efficacy of vaccines following transplantation, patients should complete vaccinations at least 4 weeks beforehand to allow time for an optimal immune response and resolution of subclinical infection from live vaccines. Vaccinations should include pneumococcal vaccine (if not vaccinated in last 3–5 years), documentation of tetanus and MMR (measles, mumps, rubella) and polio status, as well as vaccines for hepatitis B and Varicella zoster (if no history of chickenpox or shingles) (see also Table 37–7). After transplant, influenza vaccination should be performed yearly or as per local guidelines. Recommended schedules and doses for routine vaccinations can be obtained from the United States Centers for Disease Control and Prevention (CDC) at www.immunize.org or the CDC Immunization Information Hotline, (800) 232-2522.

Noninfectious Complications in Renal Transplant Recipients

Anil Chandraker, M.D. • Colm C. Magee, M.D.

The survival of cadaveric and living donor renal allografts continues to improve. This reflects many factors, including lower rates of acute rejection (mainly due to better immunosuppressive regimens), better antimicrobial prophylaxis, and probably improvements in general medical and surgical care. With recipients and allografts surviving longer, more attention is being focused on ways to reduce the relatively high burden of morbidity and mortality in renal transplant recipients. Patient death is actually the leading cause of allograft loss beyond the first post-transplant year, with cardiovascular disease, infection, and malignancy being the main causes of death. The management of these and other problems is reviewed in this chapter.

CARDIOVASCULAR DISEASE

Death from cardiovascular disease is the leading cause of late mortality in renal transplant recipients.[1,2] Data from USRDS suggest that death from cardiovascular disease in the first year post-transplant accounts for 40% of deaths with graft function. Other estimates place the figure anywhere between 17% and 51%.[2] Post-transplant heart disease can take the form of either coronary heart disease (CHD) or cardiomyopathy (left ventricular hypertrophy or congestive heart failure).[2] This division may be somewhat arbitrary because some degree of CHD and cardiomyopathy is usually present in patients with cardiovascular disease, and either condition can exacerbate the other. A high prevalence of cardiomyopathy (presenting clinically as congestive heart failure or as left ventricular enlargement on echocardiography) has been noted.[2,3] One retrospective analysis found that the development of congestive heart failure after transplant was as common as the development of coronary heart disease; furthermore, it was associated with the same risk of death.[3] The authors thus proposed the interesting concept that transplantation is a state of "accelerated heart failure." The effects of treating anemia and hypertension (which are very prevalent after transplant—see later text) on rates of development of cardiomyopathy require study.

Although there is no reason to believe that the cardiac risk factors present in patients with chronic kidney disease or ESRD are different in renal transplant recipients, studies of causes of cardiovascular disease in the renal transplant population are limited.[4] Kasike and associates[5] reported that risk factors associated with cardiovascular disease in the general population, namely hypertension, hyperlipidemia, and cigarette smoking, were also predictive of cardiac disease in renal transplant recipients. Two or more episodes of acute rejection within the first year of transplant were also associated with a greater risk.

PREEXISTING CARDIOVASCULAR DISEASE

The majority of renal transplant recipients have risk factors for cardiovascular disease prior to transplant. Patients with chronic and end-stage kidney disease have a very adverse cardiovascular risk profile with a 10- to 20-fold increased risk of cardiovascular disease compared with the general population.[4] Hypertension, hypervolemia, anemia, diabetes, hyperlipidemia, and physical inactivity are all more common than in the general population.[6]

Given the high incidence of preexisting disease in the ESRD population, screening for cardiac disease is an important part of renal transplant evaluation. This is discussed in Chapter 33. Any patient with symptomatic coronary artery disease or positive stress testing should receive intensified medical therapy and be considered for coronary angiography and pre-transplant; this has been shown to decrease cardiovascular events after transplantation when compared to medical treatment alone.[7] Following transplantation, risk factors for development of CHD and cardiomyopathy should be aggressively controlled, and patients at risk for CHD should be placed on standard prophylaxis, including aspirin.[5,8]

Hypertension

Hypertension is common in renal transplant recipients and can have many causes. These include: high renin output state from diseased native kidneys, immunosuppressive drugs, chronic allograft nephropathy, obesity, hypercalcemia, transplant renal artery stenosis, and donor kidney with a family history of hypertension.[9]

Cyclosporine is well known to cause hypertension, although the mechanisms responsible are not fully understood.[10] Cyclosporine causes vasoconstriction of the renal vasculature (perhaps mediated by endothelin) and sodium retention (and thus a volume dependent form of hypertension).[11] Evidence to support the latter comes from observations of cyclosporine-treated diabetic patients transplanted with simultaneous kidney and bladder draining pancreas grafts; these patients do not develop the same degree of hypertension when compared to kidney only transplant recipients, probably because of sodium wastage in the exocrine pancreatic excretion.[12] High plasma renin does not appear to be an important mechanism in the development of cyclosporine-induced hypertension because patients treated with the drug are less responsive to ACE-inhibitors than are those treated with azathioprine.

Data on whether tacrolimus has the same adverse effects on hypertension are mixed, but overall it is probably less hypertension-inducing. Long-term studies in liver allograft

recipients suggest that cyclosporine and tacrolimus have similar effects on blood pressure (BP), and another study directly comparing the two calcineurin inhibitors showed no difference in mean blood pressures or incidence of hypertension.[13,14] However, by 5 years fewer patients treated with tacrolimus needed antihypertensive medications compared with cyclosporine treated patients.[15] Hypertension has also been shown to resolve when patients were switched from cyclosporine to tacrolimus and to increase again when switched to cyclosporine treatment.[16] In addition, normal subjects without renal disease are more likely to develop hypertension, if given cyclosporine rather than tacrolimus.[17]

It has been suggested that because of their vasodilatory action, calcium channel blockers should be more effective in counteracting calcineurin inhibitor-induced hypertension. However, studies have not resolved this issue.[18,19] Caution should be exercised when prescribing calcium channel blockers because of their potential adverse cardiovascular effects or because several calcium channel blockers can interfere with the metabolism of calcineurin inhibitors and raise their plasma concentrations.

Steroids also elevate blood pressure. The effects are dose related and the relatively low doses of steroids used after the first 6 to 12 months are thought to have a minimal effect on blood pressure, although patients with preexisting hypertension appear to be susceptible to this adverse effect of chronic steroid use.[20] Obesity is exacerbated by use of steroids, which is discussed later.

Chronic allograft nephropathy (CAN) is also associated with hypertension. Multiple immunologic and nonimmunologic factors are associated with development of this condition (see Chapter 37). Hypertension itself is also thought to accelerate development of CAN. Treatment is directed at preventing progression of CAN, including reduction/elimination of calcineurin inhibitors.

Transplant renal artery stenosis is a less common but important cause (in that it is potentially treatable) of hypertension in transplant recipients. It is thought to be more common in recipients of living kidneys where an end-to-side anastomosis of donor renal artery to iliac artery is made compared to recipients of cadaveric grafts, where an aortic cuff protecting the orifice of the renal artery can be harvested.[21] The true incidence of this condition is difficult to define; one recent study found significant lesions in 5.4% of renal transplant recipients with at least 1 year of follow-up.[22] Development of the lesion was associated with weight at time of transplant, male gender, discharge serum creatinine greater than 2 mg/dL, and donor age. The presence of significant transplant renal artery stenosis is suggested by a reversible rise in plasma creatinine after administration of an ACE-inhibitor or angiotensin receptor blocker.[23] Unlike native renal artery stenosis, Doppler studies can be highly sensitive but are operator dependent. MR imaging is a useful screening test, but arteriography remains the gold standard diagnostic test. If multiple lesions or kinking of the artery is not present, percutaneous balloon angioplasty is successful about 80% of the time in previously untreated stenoses, however, lesions recur in about 20% of patients, who should then be considered for placement of a stent.[21,24–26] It is likely that primary placement of stents will be increasingly used.

Finally, studies have shown that donor and recipient family histories of hypertension are important in determining the need for blood pressure medications post-transplant.[27,28] For example, kidneys from a donor with a family history of hypertension transplanted into a recipient without a family history of hypertension lead to an increased need for antihypertensive medications post-transplant.

With the lack of good studies to confirm specific treatments, the Ad Hoc Group for the Prevention of Post-Transplant Cardiovascular Disease defers to the recommendations of the National Kidney Foundation Task Force on Cardiovascular Disease, setting a blood pressure control of less than 135/85 mmHg.[8] For patients with any of the following: diabetes, proteinuria greater than 500 mg/24 hr, greater than normal risk factors for CVD, or evidence of end organ damage, the goal blood pressure target should be less than or equal to 125/75 mmHg. Guidelines for treatment of BP post-transplant should generally follow the recommendations set by the Joint National Committee on prevention, detection, evaluation, and treatment of high blood pressure.[8,29] Depending on the cause, more specific treatment for elevated blood pressure is possible, such as reversing renal artery stenosis. The minimization/elimination of cyclosporine (and probably tacrolimus) has been shown to be effective in reducing the need for blood pressure medications.[30,31] Table 38–1 summarizes drugs commonly used to treat post-transplant hypertension; in practice, more than one agent is often needed to achieve adequate control of hypertension.

Smoking

There is accumulating evidence that continued smoking after transplant is associated with poorer renal allograft survival, even after censoring for death.[32] The mechanisms by which this might occur are unknown but could include exacerbation of transplant renovascular disease or of chronic rejection. Smoking, of course, also increases the risk of many squamous cell cancers, which are more common in transplant recipients. Thus, all recipients should be strongly encouraged to stop smoking, both to prolong recipient and allograft survival.

Dyslipidemia

The prevalence of hypercholesterolemia and hypertriglyceridemia after transplantation has been estimated as 60% and 35%, respectively.[33] Dyslipidemia very likely contributes to the high risk of cardiovascular disease. A major contributor to the development of post-transplant dyslipidemia is the use of immunosuppressive drugs. Sirolimus, corticosteroids, and the calcineurin inhibitors are all known to cause elevated plasma lipids with sirolimus probably having the greatest effect.[34] One study found around 80% of patients treated with this drug had serum cholesterol levels greater than 240 mg/dL or serum triglyceride levels greater than 200 mg/dL at some point after transplantation.[35] In this study, high-dose sirolimus was used; others have shown that dose reduction appears to reduce the degree of lipid abnormality, as does the withdrawal of steroids.[20]

Tacrolimus appears to have a less adverse effect on the lipid profile than does cyclosporine, which, in turn, is better than sirolimus.[36] Interestingly, sirolimus-coated stents reduce rates of re-stenosis in coronary arteries, but whether sirolimus has any such effect when given orally is not known. Both animal

Table 38–1 Antihypertensive Drugs Commonly Used in Renal Transplant Recipients

Drug	Potential Advantages	Potential Disadvantages	Comment
Thiazides	Well proven to reduce the complications of hypertension in the general population; inexpensive	Increase plasma creatinine; exacerbate gout and glucose intolerance	Avoid in first 2–3 months because of effect on plasma creatinine; probably underused in RTRs
Loop diuretics	Effectively treat volume component of hypertension	Increase plasma creatinine	Avoid in first 2–3 months, if possible
β-Blockers	Cardioprotective effects useful in many recipients because of high prevalence of coronary heart disease	As for non-transplant patients	Indications are the same as those for non-transplant patients
Calcium channel blockers	May ameliorate toxicity of calcineurin inhibitors; some evidence that they improve graft outcomes	Verapamil and diltiazem inhibit metabolism of calcineurin inhibitors; nifedipine exacerbates gum enlargement	Often used in the early post-transplant period because no effect on plasma creatinine
ACE-inhibitors, angiotensin receptor blockers	Postulated to slow progression of allograft failure, as in native kidney disease	Increase plasma creatinine; exacerbate anemia	Avoid in first 2–3 months because of effect on creatinine; useful in treating plasma post-transplant erythrocytosis
α-Blockers	Usually well tolerated	Allhat study showed inferior outcomes with α-blockers	Use for resistant hypertension only

and clinical studies have suggested an association between hyperlipidemia and progression of chronic allograft nephropathy.[37] Although this does not prove causality, cardiac disease in the general population is accelerated by occurrence of the so-called dysmetabolic state known as syndrome X, consisting of atherogenic lipid profile, hypertension, diabetes mellitus, and a chronic prothrombotic state.[38] These factors are known to contribute to the progression of renal failure, which would include chronic allograft nephropathy.[4]

Because cardiovascular disease is so prevalent in renal transplant recipients, it is reasonable to consider the renal transplant state a "coronary heart disease risk equivalent" when applying guidelines.[8,39] This implies targeting plasma LDL cholesterol less than 100mg/dL (newer guidelines are now suggesting < 70 mg/dL in high-risk patients) via a combination of therapeutic lifestyle changes and drug therapy. Reduction in steroid dose and switching cyclosporine to tacrolimus will also aid treatment of dyslipidemia.

Statins are the cholesterol-lowering drug of choice in transplant recipients. A recently published trial of statin use in renal transplant recipients showed them to be safe and effective in lowering plasma LDL cholesterol concentrations.[40] Cardiac deaths and nonfatal myocardial infarcts—although not overall mortality—were reduced. Because metabolism of many statins is partly inhibited by the calcineurin inhibitors, blood and tissue concentrations of statins may be increased in transplant recipients, thereby increasing the risk of adverse effects, such as rhabdomyolysis. This interaction is further enhanced, if additional inhibitors of cytochrome P450, such as diltiazem, are administered. Measures to minimize the risk of statin toxicity include the following: (1) starting with low statin doses, (2) use of pravastatin or fluvastatin (which appear to have the least interaction with CNIs), (3) avoidance of other inhibitors of the cytochrome P450 system, (4) avoidance of fibrates, and

(5) periodic checking of plasma creatine kinase and liver function tests.[41] Rarely, nonstatin drugs are used to lower plasma lipids in transplant patients. Bile acid sequestrants, if used, should be taken separately from calcineurin inhibitors as they impair absorption of these drugs. Fibrates should be prescribed with extreme caution to patients on statins and calcineurin inhibitors.

HYPERHOMOCYSTEINEMIA

As in the general population, hyperhomocysteinemia has been recognized as an independent risk factor for the development of cardiovascular disease.[42] The use of cyclosporine has also been associated with higher plasma levels of homocysteine.[43] Even though administration of folate and vitamins B_6 and B_{12} effectively lowers homocysteine levels in transplant patients, no effect on outcome of cardiovascular disease has yet been shown.[8]

Post-Transplant Diabetes Mellitus

A recent study examined the economic impact of developing new onset diabetes mellitus post-transplant.[44] The cost to Medicare 2 years post-transplant was estimated as $21,500 per incident case. The "cost" in terms of morbidity and mortality is obviously much greater. There is no reason to believe that the effects of post-transplant diabetes mellitus (PTDM) are any different from those encountered by other diabetic patients. As in other diabetics, development of PTDM is associated with an adverse cardiovascular profile, including higher cholesterol and triglyceride levels as well as increased systolic blood pressure.[45]

Although the incidence of PTDM was exceptionally high (40%–60%) in the early days of renal transplantation, this

was associated with use of very large doses of steroids. The incidence had declined but appears to be increasing again. The incidence of PTDM varies widely in different centers and in different studies. This is partially due to a varying definition of PTDM/impaired glucose tolerance. One study of USRDS patients who received their first renal allograft between 1996 and 2000 estimated the incidence of PTDM at 36 months post-transplant to be as high as 24%.[46] Risk factors for development of PTDM included age, black or Hispanic ethnicity, male donor, increasing HLA mismatches, hepatitis C infection, body mass index greater than or equal to 30 kg/m^2, and the use of tacrolimus as initial maintenance immunosuppression. Not surprisingly PTDM was associated with a poorer outcome in terms of increased graft failure, death-censored graft failure, and mortality. Other studies have found that PTDM is associated with not just the use, but also the dose of calcineurin inhibitor, use of intravenous methylprednisolone for treatment of acute rejection, cadaveric allograft donor, family history of diabetes as well as older recipient age, CMV infection, and use of furosemide.[47–50]

The mechanisms responsible for the development of PTDM appear to be mixed. In early studies where development of PTDM was related to high doses of steroids and weight gain, the major mechanisms appeared to be related to insulin resistance, that is, decreased activity of glycogen synthase, decreased number and binding affinity of insulin receptors, malabsorption of glucose in peripheral organs, or activation of the glucose/fatty acid pathway. This appears still to be important in some patients, especially those who gain significant amounts of weight post-transplant.[51] The introduction of calcineurin inhibitors appears to have exacerbated the situation, however, through decreased insulin secretion.[52] Most studies indicate that tacrolimus has a greater effect than cyclosporine. Even though animal models have shown that both cyclosporine and tacrolimus inhibit the ability of cells to secrete insulin, the precise mechanisms by which these drugs exert their diabetogenic effects in humans may differ.

Although both insulin resistance and impaired insulin secretion appear to be responsible for the development of PTDM, recent data suggest that abnormal insulin secretion is the dominant mechanism responsible.[51,53] Patients on high dose tacrolimus or methylprednisone who are also hepatitis C positive have a higher likelihood of developing PTDM. This appears to be related to active viral replication because treatment with antiviral medication brought the glycemia under control.[54,55]

PTDM is a potentially treatable condition. Some studies have indicated that one third of patients initially diagnosed with PTDM can return to normal glucose tolerance.[49] This figure may well be higher, if patients with PTDM are aggressively treated with reduction of steroids and lowering of calcineurin inhibitor levels.[56] Once PTDM has developed, treatment should be aggressive and take into account the primary cause of PTDM in that individual, for example, emphasizing weight reduction in an overweight patient with insulin resistance. Most patients, however, will require a multi-pronged approach with lifestyle modification, reduction in steroids and calcineurin inhibitors (if safe), and use of oral hypoglycemics and/or insulin. Metformin has the advantages of causing weight loss and not causing hypoglycemia but should be used with caution in those with renal impairment. Tight control of blood sugar has been shown to slow the progression of end-organ damage in diabetes; similar benefits are likely in renal transplant patients.

Obesity

Transplantation can exacerbate obesity, probably because of the effects of steroids. Dietary intervention after transplant can limit weight gain and hyperlipidemia.[57,58] It is likely that pharmacologic treatment of obesity will be increasingly prescribed to transplant recipients. This subject has recently been reviewed.[59] Orlistat and similar compounds can reduce absorption of cyclosporine (and probably other immunosuppressives) and should be administered at least 2 hours separately; concentrations of cyclosporine and tacrolimus should be closely monitored.[59]

Post-Transplant Anemia

Post-transplant anemia (PTA) is common; causes are shown in Table 38–2. A drop in hematocrit is associated with the perioperative period, and one study reported that 76% of patients had a hematocrit of less than 36 at the time of transplantation; this figure decreased to 21% at 1 year and rose again to 36% at 4 years.[60] Lorenz and associates[61] found a 40% prevalence of anemia and a 20% prevalence of iron deficiency (as measured by ≥2.5% hypochromic peripheral red blood cells) in renal transplant recipients. A similar retrospective study found that 30% of patients were anemic at some point during the post-transplant period.[62] The cause of anemia in the early post-transplant period is likely to be related to blood loss at the time of transplant and the sudden loss of exogenous erythropoietin supplementation. Surprisingly, given its prevalence, anemia is often not corrected in the transplant recipients, and the causes and effects of anemia in this population have not been well studied.[60] The association of anemia with the new development of left ventricular hypertrophy has been discussed earlier.[2,3,63]

Although there is a correlation between anemia and renal function in transplant patients, the degree of anemia is more severe than one would expect from renal dysfunction alone. Medication is an important cause. Mycophenolate mofetil, azathioprine, sirolimus, (val)gancyclovir, and SMX-TMP are all associated with bone marrow suppression. ACE-inhibitors and angiotensin receptor blockers are used to treat post-transplant erythrocytosis and were long suspected to be a potential cause of post-transplant anemia; this effect has recently been confirmed in the TRESAM study.[64] The benefits of ACE-inhibitor therapy in patients with progressive renal dysfunction probably outweigh the small associated drop in hematocrit. Gastrointestinal bleeding—perhaps related to steroids—can also contribute to post-transplant anemia. Other causes are shown in Table 38–2.

A common finding in the previously mentioned studies is that the causes of anemia are not aggressively investigated. A "standard" anemia workup should be performed (e.g., careful history and examination, fecal occult blood testing, iron studies, plasma LDH). As with anemia in general, treatment should be directed at the cause. Adequate treatment of anemia often requires use of erythropoietin, however.

Studies looking at the use of erythropoietin in transplant patients have found a low use of this medication.[60,64] It is not clear why this is so. The majority of anemic renal transplant

Table 38–2 Causes of Anemia in Renal Transplant Recipients

Cause	Mediated By	Ultimate Effect
Allograft dysfunction	Impaired production of erythropoietin	Decreased bone marrow production of RBCs
Azathioprine, MMF, sirolimus, SMX-TMP, (val)ganciclovir	Direct suppression of bone marrow turnover (all cell lines)	Decreased bone marrow production of RBCs
Acute inflammatory state, hyperparathyroidism	Impaired production of, or resistance to, erythropoietin	Decreased bone marrow production of RBCs
ACE-inhibitors, angiotensin receptor blockers	Impaired production of, or resistance to, erythropoietin	Decreased bone marrow production of RBCs
Iron deficiency	Impaired synthesis of hemoglobin	Decreased bone marrow production of RBCs
Minor ABO incompatibility	Donor antibodies	RBC hemolysis
Post-transplant hemolytic uremic syndrome	Multiple factors, including genetic defects, viral infection, calcineurin inhibitors, antiphospholipid antibodies	RBC hemolysis
Gastrointestinal or other bleeding		RBC losses exceed production

RBC, red blood cell.
This table shows only the more common causes of anemia post-transplant. Frequently, more than one is present in the individual recipient.

patients may not have as profound a drop in their glomerular filtration rate as what occurs in non-transplanted patients because of the additive effect of marrow suppressing medications. Because the recommendations for treatment for anemia with chronic kidney disease is based on GFRs from non-transplanted patients, there may be difficulty prescribing or getting reimbursement for use of erythropoietin in some transplant patients. Regardless, erythropoietin appears to work well in this population, and, although there are no prospective studies showing that correction of anemia slows progression of left ventricular hypertrophy in renal transplant patients, it would appear reasonable that the findings from treatment of anemia in the chronic kidney disease population could be extrapolated to the renal transplant population.

Peripheral and Cerebrovascular Disease

Data on the prevalence and risk factors for the development of peripheral vascular and cerebrovascular disease in renal transplant recipients are scarce. Kasiske and associates[33] reported a 15% prevalence of peripheral vascular disease at 15 years post-transplant. Sung and associates[65] retrospectively studied 664 adult recipients and found a cumulative 5- and 10-year incidence of 4.2% and 5.9%, respectively; the presence of peripheral vascular disease was independently associated with poorer recipient survival. There is also some evidence from registry data that peripheral vascular disease is a risk factor for poorer graft outcome.[66] It therefore seems reasonable to aggressively treat patients with this condition with measures, such as aspirin, statins, cessation of smoking, and revascularization where appropriate.

The 15-year cumulative incidence of cerebrovascular disease has been estimated as 15%.[33] As with the non-transplant population the benefits of carotid endarterectomy in patients with asymptomatic disease have not been proven. Management should be similar to that recommended by expert groups for the general population.[67,68] Control of hypertension is, of course, vital to prevent stroke.

Cancer

Data from many tumor registries clearly demonstrate that the overall incidence of cancer in renal transplant recipients is greater than in dialysis patients and the general population.[69–71] This increase in incidence applies to many cancers but particularly to those of the skin, lymphoid tissue, or urogenital tract. Table 38–3 shows data from one of the most comprehensive registries. Note that cancers common in the general population (those of the breast, lung, large bowel, and prostate) are only slightly increased in incidence. Exposure to excess ultraviolet light is particularly common in Australia; the cumulative risk of nonmelanotic skin cancers 20 years post-transplant in Australia is greater than 50%.[70]

Table 38–3 Relative Risk of Cancer Following Primary Cadaveric Kidney Transplantation (n = 8881), Compared to an Age-Matched Australian Population, 1963–2002*

Cancer	RR	95% CI
Carcinoma or vulva or vagina	35.5	25.7–49.1
In situ carcinoma of uterine cervix	17.2	13.5–21.9
Non-Hodgkin's lymphoma	8.7	7.3–10.3
Liver	7.8	4.8–12.9
Kidney	6.7	5.3–8.4
Malignant melanoma	3.6	3.0–4.2
Invasive carcinoma of uterine cervix	3.0	1.8–5.0
Colon	2.6	2.1–3.2
Lung, trachea	2.1	1.7–2.6
Breast	1.2	0.9–1.5
Prostate	0.7	0.5–0.9
Total (includes others not shown)	3.0	2.9–3.2

*Nonmelanotic skin cancers are not included. (Adapted from Chapman J, Webster A: 2002 Report of the ANZDATA Registry. Chapter 10: Cancer report: Australia and New Zealand Dialysis and Transplant Registry [ANZDATA], 2002.)

The reported incidence of cancers in transplant recipients is increased for several reasons. First, immunosuppression allows relatively uncontrolled proliferation of oncogenic viruses and probably inhibits normal tumor surveillance mechanisms. There is also experimental evidence that calcineurin inhibitors may promote tumor growth via their effects on TGFβ production.[72] Second, recipient factors associated with the primary renal disease may also be associated with neoplasia. Thus, viral hepatitis can cause both kidney disease and liver cancer. Finally, ascertainment bias may occur due to more complete reporting of cancers in RTRs compared to the general population; this is not a major factor, however.

It is believed that the cumulative amount of immunosuppression is the most important factor increasing the cancer risk. Aggressive immunosuppression with any one drug, such as tacrolimus, cyclosporine, or OKT3, can suffice. For example, renal transplant recipients were randomized in one study at 1 year post-transplant to either a standard or low-dose cyclosporine regimen. After 66 months follow-up, rates of rejection were higher in the low-dose group, but allograft survival was similar.[73] The cumulative incidence of cancers in the low-dose group was 20%; in the high-dose group, it was significantly increased to 32% (the majority being skin cancers).

The single most important measure to prevent cancers is, therefore, to minimize excess immunosuppression. Of course, achieving the optimum balance between excess and inadequate immunosuppression is a matter of subjective clinical judgement with an individual patient. Current guidelines are to employ primary and secondary preventive strategies for breast, lung, bowel, and urogenital cancers similar to those recommended for the general population (i.e., mammography, smoking cessation, endoscopy, pelvic examination in females). Because of the particularly high prevalence of skin cancers in transplant recipients, preventive measures for these cancers should be more rigorous.[74] Thus, patients should be specifically counseled to minimize exposure to ultraviolet light, to wear protective clothing, and to apply sunscreen to exposed areas. Premalignant skin lesions should be treated with cryotherapy or surgical excision.[74]

In general, when cancer occurs, immunosuppression should be decreased. Obviously, this increases the risk of graft rejection and loss. Fortunately, loss of the renal allograft is not fatal (unlike the situation in cardiac and lung transplantation), because dialysis is an option. There is experimental evidence that sirolimus has antineoplastic effects,[75,76] but long-term data are not yet available as to whether this new immunosuppressive drug can reduce the incidence of post-transplant cancers. The long-term effects of newer, more intensive immunosuppression regimens (using drugs such as tacrolimus and MMF) on the risk of developing post-transplant cancers are unknown. Certainly, the recent rise in reported cases of polyoma virus infections is a warning that some of our patients are being over-immunosuppressed.

Post-Transplant Lymphoproliferative Disease

Post-transplant lymphoproliferative disease (PTLD) is one of the most serious complications of transplantation because of its high associated morbidity and mortality. The cumulative incidence in renal transplant recipients overall is 1% to 5%, with most cases arising in the first 24 months after transplant.[33]

The majority are non-Hodgkin's lymphomas and of recipient B cell origin.[77] Risk factors include: (1) the combination of an EBV+ donor and EBV– recipient, (2) the combination of a CMV+ donor and CMV– recipient, (3) pediatric recipient (in part because children are more likely to be EBV–), and (4) more intensive immunosuppression.[78] In many cases of PTLD, the pathogenesis involves infection and transformation of B cells by EBV; transformed B cells then undergo proliferation, which is initially polyclonal, but a malignant clone may evolve. The clinical and pathologic spectrum and treatment of PTLD are quite variable, and readers are referred to recent reviews for more information.[79,80]

Treatment involves drastic reduction in immunosuppression (e.g., to low-dose steroids alone) and variable combinations of antiviral therapy, radiotherapy, chemotherapy, and surgery. The prognosis of severe forms of PTLD is poor but there is optimism it will improve. Techniques for monitoring EBV viral load after transplantation are being developed. These may allow earlier identification of transplant recipients who are at high risk of developing PTLD or who have early disease, thus allowing preemptive or early therapy of such patients. In addition, nontoxic immunotherapies have been developed or are already in clinical use. These include biologic immune-modifiers, such as interferon-α and IL-6, adoptive immunotherapy with virus-specific T cells, and, most promisingly to date, elimination of B cells by the anti-CD20 monoclonal antibody, rituximab.[80]

Electrolyte Disorders

Electrolyte disorders are common after kidney transplant but rarely severe. Hyperkalemia can be caused by poor graft function, calcineurin inhibitors, and other drugs, such as ACE-I or β-blockers. Treatment is similar to that of hyperkalemia in chronic (native) kidney disease: reduction in potassium intake, adjustment in medications, and so forth. Posttransplant hypercalcemia can be caused by tertiary hyperparathyroidism and by administration of calcium or vitamin D (these drugs are used to prevent loss of bone density) or by both. Severe tertiary hyperparathyroidism requires parathyroidectomy (see later text). Many patients have hypophosphatemia in the first 6 months after transplant. This is due to increased urinary excretion of phosphate (mainly secondary to persistence of hyperparathyroidism) and probably decreased intestinal absorption secondary to steroids. Posttransplant hypophosphatemia is usually asymptomatic but can rarely cause severe muscle weakness, including weakness of respiratory muscles. The benefits of phosphate supplementation in the setting of mild or moderate post-transplant hypophosphatemia have not been well studied. Phosphate supplementation should be prescribed for severe (e.g., plasma phosphate <1.2 mg/dL) or symptomatic cases.

Bone Disorders after Renal Transplantation

Bone disease in the dialysis patient is multifactorial, involving varying degrees of hyperparathyroidism, vitamin D deficiency, adynamic bone disease, aluminum intoxication, and amyloidosis. Successful renal transplantation can reverse or at least prevent further progression of these conditions. Unfortunately, bone disease continues to be a major problem

after renal transplantation due to persistence of the previously mentioned conditions, suboptimal kidney function, and the superimposed effects of steroids on bone.

Osteoporosis

Reduction in bone mineral density is a common complication of all forms of solid organ transplantation; one recent review estimated an incidence of up to 60% in the first 18 months after renal transplant.[33] The main cause of post-transplant osteoporosis is steroids through multiple effects, including direct inhibition of osteoblastogenesis, induction of apoptosis in bone cells, inhibition of sex hormone production (in both men and women), decreased gut calcium absorption, and increased urinary calcium excretion.[81] Other factors that may contribute to post-transplant osteoporosis include persistent hyperparathyroidism, presence of type 1 diabetes, postmenopausal state, vitamin D deficiency/resistance, and phosphate depletion. Thus, the pathophysiology of osteoporosis often differs from that seen in the non-transplant population (see Table 38–4).

Whether low bone mineral density (as identified by dual energy X-ray absorptiometry [DEXA] correlates with risk of fracture in RTRs remains unclear.[82,83] Certainly, pathologic fractures are common after renal transplantation. The estimated total fracture rate in nondiabetics renal transplant recipients is 2% to 3% per year; in type I diabetics 5% per year; and in pancreas–kidney recipients up to 12% per year.[82,84]

Measures to minimize post-transplant bone loss are summarized in Table 38–4. It is important that these measures are instituted immediately post-transplant, because most bone loss occurs in the first 6 months, when steroid doses are highest. All transplant recipients should receive calcium (at least 1000 mg elemental calcium per day) and vitamin D (at least 800 IU/day; more if serum 25-vitamin D3 concentrations are low or low-normal) and should be encouraged to perform weight-bearing exercises, stop smoking, and avoid excess alcohol consumption. Several trials have shown a benefit with the post-transplant use of vitamin D analogues and calcium.[85,86]

The role of DEXA and bisphosphonates in the prevention and treatment of post-transplant bone disease requires further prospective study. There is evidence that bisphosphonates prevent post-transplant bone loss, but trials reported to date have not been adequately powered to detect reductions in post-transplant fracture rates.[87] There is still concern that these agents, by suppressing bone remodeling, could worsen the mechanical integrity of bone in conditions, such as osteomalacia or adynamic bone.[84,87] A reasonable approach is to obtain DEXA from three bone sites (lumbar spine, forearm, hip) at the time of transplant in all patients. In those considered to be at high risk of osteoporosis related fracture based on their clinical features and DEXA results, post-transplant administration of bisphosphonates and the use of minimal dose steroid protocols should be considered.

Hyperparathyroidism

Incomplete resolution of hyperparathyroidism is common after renal transplantation. This probably reflects multiple factors: inherent slow involution of parathyroid cells, suboptimal renal function, suboptimal production of 1,25 vitamin D3, and steroid-induced reduction in intestinal calcium absorption.[83] Two clinical characteristics identify those at risk of post-transplant hyperparathyroidism: duration of dialysis and degree of pre-transplant hyperparathyroidism.[83] Patients scheduled for transplant who have persistent elevated PTH greater than 300 pg/mL, despite medical therapy should be considered for pretransplant parathyroidectomy. The most important complications of post-transplant

Table 38–4 Comparison of Postmenopausal and Postrenal Transplant Osteoporosis

	Postmenopausal Osteoporosis	Post-Transplant Osteoporosis
Pathophysiology		
Deficiency of sex hormones	Yes	Sometimes
Increased activity of osteoclasts; accelerated breakdown of bone	Yes	Sometimes
Decreased activity of osteoblasts; reduced bone sythesis	No	Yes
Background of renal osteodystrophy	No	Yes
Associated renal dysfunction	No	Frequent
Clinical		
Fracture sites	Mainly axial skeleton	Mainly appendicular skeleton
Diagnosis		
DEXA predicts fracture risk	Yes	Unclear
Recommended prevention/treatment measures		
Weight-bearing exercise	Yes	Yes
Calcium	Yes	Yes
Vitamin D	Yes	Yes; use calcitriol if GFR< 50 mL/min
Hormone replacement therapy	Only if other indications	Only if other indications
Bisphosphonates	Yes	Unclear

hyperparathyroidism are hypercalcemia and exacerbation of bone loss. If hypercalcemia is severe and associated with complications, early parathyroidectomy is indicated. Less severe cases can be managed conservatively in the hope that overactivity of the gland resolves; late parathyroidectomy may ultimately be required, however.

Osteonecrosis

Osteonecrosis, or avascular necrosis of bone, has been reported to occur in 3% to 16% of renal transplant recipients.[82] Hip, knee, ankle, shoulder, or elbow joints can be involved. If severe, significant joint damage can occur. The principal cause is steroids. Fortunately, the incidence has declined because RTRs are now receiving lower cumulative doses of steroids (maintenance doses are lower, and fewer "pulses" are required because acute rejection is less common). The presenting symptom is joint pain. MRI, radionuclide bone scan, and plain films (in order of decreasing sensitivity) are used to confirm the diagnosis. Severe cases require surgery.

CONCLUSION

Although acute rejection and early graft loss have become relatively uncommon, late graft loss and premature death (mainly from cardiovascular disease) remain major problems. Morbidity from diabetes mellitus and bone disease is also substantial. More attention is therefore being paid toward preventing and treating these "medical complications" of transplantation. In many ways, renal transplant recipients need to be managed similarly to those with chronic kidney disease. More effective intervention at the pre-dialysis or dialysis stage is also needed to reduce the burden of morbidity in transplant patients. Finally, reduction in long-term immunosuppression should be strongly considered in all patients.

Recurrent and De Novo Renal Disease in Kidney Transplantation

Denise Sadlier, M.B., M.R.C.P.I. • Yvonne M. O'Meara, M.D., F.R.C.P.I.

Recurrence of original disease following renal transplantation affects 10% to 20% of patients in most series and accounts for up to 8% of graft failures at 10 years post-transplant.[1–7] There is, however, wide variation in the reported rates of recurrence of different diseases and the ensuing rates of graft loss (Tables 39–1 and 39–2). Accurate estimation of the incidence of recurrence is difficult for a number of reasons. First, definitive diagnosis of recurrence requires histologic confirmation of the primary disease in the native kidney by renal biopsy. The latter is often omitted in patients presenting with renal dysfunction and small kidneys, and many patients are classified clinically with "chronic glomerulonephritis." Second, biopsy of the allograft is undertaken in many centers only upon occurrence of a clinical indication, such as deterioration in renal function or the development of proteinuria. Thus, asymptomatic histologic recurrence will be missed without a policy of routine renal biopsy. Third, a variety of pathologic processes, such as ischemia, nephrotoxicity, hypertension, and acute and chronic rejection, can induce morphologic changes that mimic primary glomerulopathies and that may be difficult to distinguish from true recurrence.[8] Fourth, glomerular lesions can occur de novo in the transplanted kidney. In the absence of histologic confirmation of the patient's original disease, these lesions may also be misclassified.

Multiple factors influence the likelihood of recurrence. These include the type and severity of the original disease, the age at onset of the disease, the source of the donor kidney, and the immunosuppressive regimen used to prevent allograft rejection. In general, disease recurrence in an allograft implies persistence of an extrarenal pathogenetic stimulus. In certain diseases, modification of the pathogenetic stimulus can prevent or delay recurrence of the disease in the allograft. For example, in Goodpasture's syndrome, the presence of circulating anti-GBM antibodies in high titer at the time of transplantation increases the risk of recurrence in the allograft.[4,10] Conversely, clinical recurrence is extremely rare, if the antibody is undetectable over a 6- to 12-month period prior to transplantation.[10] Diabetic nephropathy invariably recurs in the allograft. However, this process can be delayed or prevented by improved glycemic control achieved by simultaneous pancreatic transplantation.[11,12] Similarly, in primary hyperoxaluria, another disease that invariably recurs, the use of simultaneous liver transplantation to provide a source of the absent hepatic peroxisomal alanine glyoxylate aminotransferase prevents disease recurrence in the renal allograft.[13–15]

The severity of disease in the native kidney influences the incidence of recurrence of certain diseases. Focal and segmental glomerulosclerosis (FSGS) illustrates this point. A culminant presentation with a short interval (<3 years) between diagnosis and development of end-stage renal disease (ESRD) increases the risk of disease recurrence in the allograft.[1,16] With regard to age of onset, recurrence of FSGS is greatest in younger patients whose primary disease presents before the age of 16 years.[17] Conversely, in Henoch-Schönlein purpura (HSP) recurrence is greatest in patients who develop their disease after the age of 14 years.[18]

With respect to the source of the renal allograft, some studies have demonstrated higher rates of recurrent glomerulonephritis in living related donor allografts compared with cadaveric grafts.[4,6] This observation suggests that phenotypic characteristics shared by related donor-recipient pairs may render the kidney more susceptible to humoral pathogens. It should be emphasized, however, that many studies fail to demonstrate an increased tendency to disease recurrence in recipients of living related grafts.[7,19]

Turning finally to the immunosuppressive regimen, cyclosporine A (CsA) is a potent immunosuppressive agent that induces remission of nephrotic syndrome associated with minimal change disease, FSGS, and membranous nephropathy, among other glomerulopathies.[20] It was anticipated that the introduction of CsA would reduce the incidence of recurrent glomerulonephritis. However, studies involving large numbers of transplant patients have failed to confirm this prediction.[21] CsA has been reported, however, to modify the course of recurrent glomerulonephritis and slow the rate of graft loss in some patients.[21]

The most recent and comprehensive data on graft loss, as a result of recurrent glomerulonephritis, derive from an Australian study involving 1505 patients with biopsy-proven glomerulonephritis as a primary cause of ESRD.[5] Post-transplantation patients were followed over a period of 10 years when the incidence of graft loss from recurrent glomerulonephritis was 8%. The diseases with the highest rates of graft loss were focal segmental glomerulosclerosis (31%) and type I membranoproliferative glomerulonephritis (17%). Both male gender and high pre-transplant panel-reactive antibody levels were noted to be independent risk factors for graft loss from recurrent disease. Recurrent glomerulonephritis was the third most common cause of graft loss at 10 years post-transplant, and, as previously reported, the relative importance of recurrence as a cause of graft loss increases with time post-transplant.[5]

Table 39–1 Estimated Rates of Recurrence of Primary Glomerulopathies and Consequent Graft Loss

	Recurrence Rate	Graft Loss in Patients with Recurrent Disease
FSGS	~30%	~50%
MGN	3%–10%	~30%
IgA nephropathy	30%–60%	10%–30%
MPGN I	15%–30%	~33%
MPGN II	~80%	10%–20%
Anti-GBM disease	~10%	<5%

FSGS, focal segmental glomerulosclerosis; *MGN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis. See text for further details.

Table 39–2 Estimated Rates of Recurrence of Secondary Glomerulopathies and Consequent Graft Loss

	Recurrence Rate	Graft Loss in Patients with Recurrent Disease
Diabetic nephropathy	~100%	<5%
SLE	<3%	<5%
ANCA-associated vasculitis	~25%	<5%
HSP	~50%	~10%
HUS	10%–41%	10%–40%
Scleroderma	20%–30%	?
Amyloidosis	8%–26%	~40%
LCCD	~50%	?
EMC	~50%	?
Multiple myeloma	~27%	<5%
Fibrillary GN	~50%	~50%

SLE, systemic lupus erythematosus; *ANCA,* anti-neutrophil cytoplasmic antibody; *HSP,* Henoch-Schönlein purpura; *HUS,* hemolytic uremic syndrome; *LCCD,* light chain deposition disease; *EMC,* essential mixed cryoglobulinemia. See text for further details.

PRIMARY GLOMERULOPATHIES

Focal Segmental Glomerulosclerosis

Recurrent Disease

Primary or idiopathic FSGS accounts for approximately 10% and 20% of cases of idiopathic nephrotic syndrome in children and adults, respectively, and the lesion progresses to ESRD in about 60% of patients.[22] Since the first description of recurrent FSGS in renal transplantation,[23] the reported rates of recurrence have ranged from 15% to 50%.[10,16,24] Most authors report a recurrence rate of approximately 30% for first allografts[6,10,19,24,25] and a higher incidence in children.[24,26] The rate of recurrence may be as high as 80% in patients who have previously lost a graft to recurrent FSGS.[1,2,27] Collapsing glomerulopathy, an aggressive subtype of FSGS characterized by severe visceral epithelial cell injury, can also recur following transplantation and trigger rapid loss of GFR in the face of massive proteinuria.[28,29] It must be stressed that secondary FSGS can complicate a plethora of renal insults rendering the diagnosis of true recurrence difficult in many instances.

Recurrent FSGS presents clinically with heavy proteinuria, often with full-blown nephrotic syndrome and its attendant risk of thromboembolic complications.[25] Recurrence may be evident within days of transplantation, particularly in children.[26,30] Most patients display evidence of recurrent disease at the end of the first month post-transplantation. Graft failure occurs in as many as 50% of adult patients and is more likely in the presence of nephrotic syndrome.[2,16,27,31,32] Graft loss may be even higher in children, as exemplified in a series by Muller and colleagues[33] in which five of six grafts with recurrent FSGS were lost. A history of accelerated primary graft loss from recurrence significantly increases the risk of loss of subsequent grafts.[19] Conversely, patients who have had prolonged function of their primary graft, despite recurrent FSGS, may expect a similar, more slowly progressive course in subsequent grafts.[33]

A number of risk factors for recurrence of FSGS have been identified: (1) diffuse mesangial proliferation in the native kidney[1,9,16,17,19]; (2) rapid deterioration of renal function in the native kidney (i.e., renal failure <3 years after diagnosis)[10,16,17,27]; and (3) younger age at diagnosis.[9,16,17,19] Other less well-established predictors of recurrence are acute tubular necrosis in the immediate post-transplant period[33] and racial background, a few studies indicating a lower incidence of recurrence in blacks than in whites.[9,27,30–32] The routine use of CsA has not reduced the incidence of recurrent FSGS,[19,21,27,33,34] although some authorities claim that high doses ameliorate the clinical course.[27,35] Whereas some studies have found an increased incidence of graft loss due to recurrence in recipients of living related kidneys, no such statistically significant difference was found in the large series by Briganti and colleagues.[5]

It has long been postulated that a circulating factor(s), possibly of T lymphocyte origin is responsible for the induction of glomerular damage in FSGS.[36] A number of observations on recurrent disease in the renal allograft support this theory.[37–40] Savin and colleagues[37] recently isolated a "factor" from sera of patients with FSGS, which increases glomerular permeability to albumin *in vitro*. In 33 patients who had recurrent FSGS post-transplantation, there was a direct correlation between the level of this factor and the tendency to disease recurrence. Plasmapheresis in six patients reduced the level of this factor and decreased urinary protein excretion from 8.2 to 0.9 g/24hr. Subsequent work by the same group has shown the permeability factor to be a protein of molecular weight between 30 and 50 kDa.[39] Dantal and colleagues[40] showed that immunoadsorption of sera from patients with recurrent FSGS on a protein A column transiently reduced proteinuria by an average of 82%. Furthermore, elute from the protein A column enhanced urinary albumin excretion when injected into rats. In aggregate, these observations suggest a central role for a circulating humoral mediator in the pathogenesis of FSGS.

Current treatment strategies for recurrent FSGS are designed to inhibit secretion of the putative lymphocyte-derived "factor" (CsA or FK506) and enhance removal by plasmapheresis. As noted above, CsA has been reported to reduce proteinuria by some but not all investigators.[27,35] Similarly, variable success has been reported for plasmapheresis.* The latter appears most

---

*References 2,16,19,27,38,39,41,42.

useful if instituted early in the course of disease before glomerulosclerosis has become established.[38,41] For example, in a study by Artero and colleagues,[38] six of nine patients with recurrent FSGS had a rapid reduction in proteinuria when plasmapheresis was instituted within 2 weeks after documentation of recurrent proteinuria, at which time only one of these patients displayed evidence of glomerular hyalinosis on renal biopsy. Post-plasmapheresis biopsies showed evidence of restoration of foot processes in four of these patients. In one study, the use of prophylactic plasma exchange in the week prior to transplantation led to a significant reduction in the rate of recurrence from 66% to 37%.[43] However, it is not clear from this report whether benefit was sustained in the long-term. Dall'Amico and colleagues[42] reported a benefit with plasmapheresis combined with cyclophosphamide in a study of 15 patients with recurrence in 18 grafts. Reversal of proteinuria occurred in 9 of 11 treated patients, and a persistent remission was obtained in 7 patients.[42]

Angiotensin-converting enzyme inhibitors (ACEIs) also reduce proteinuria in patients with recurrent FSGS. It is not established as yet whether they prolong allograft survival. In a representative study, administration of ACEIs to nine patients with recurrent disease reduced average proteinuria from 11.1 to 4.22 g/24 hr.[27] Remission or amelioration of nephrotic syndrome has been described in occasional patients with recurrent FSGS treated with nonsteroidal anti-inflammatory agents (NSAIDs).[44] Potential benefits of NSAIDs must be weighed against the risk of exacerbating CsA toxicity.

De Novo Disease

Whereas de novo FSGS may be a direct consequence of immune attack, emerging evidence suggests that the disease is, at least in part, triggered by hemodynamic stress in remnant nephrons following injury to the kidney by rejection, ischemia, and CsA.[45] In many instances de novo FSGS is felt to be a manifestation of chronic rejection.[25] Histologically, this lesion is characterized by occlusive vascular changes typical of chronic rejection, which primarily involve the glomeruli in the outer cortical region. This observation contrasts with recurrent FSGS, where the mild obliterative arteriopathy preferentially involves the juxtamedullary glomeruli. Clinically de novo FSGS presents with proteinuria and a less aggressive course than recurrent FSGS, but it is nonetheless a negative independent predictor of graft survival.[46] Collapsing GN, the aggressive subtype of FSGS, has also been described as a de novo lesion in the renal allograft.[28]

Membranous Nephropathy

Recurrent Disease

Membranous nephropathy is the most common cause of idiopathic nephrotic syndrome in adults and progresses to ESRD in 20% of cases.[22] Membranous nephropathy may recur in allografts or develop as a de novo lesion, 75% being in the latter category.[1,10] Most studies quote a recurrence rate of 3% to 10%,[1,2,47,48] though figures as high as 25% to 57% have been reported.[4,9,10]

Recurrent membranous nephropathy occurs earlier post-transplantation than de novo disease and runs a more aggressive course. The average time from transplantation to recurrence is 10 months,[47] though appearance as early as one week[49] and as late as 7 years post-transplantation has been reported.[4] Patients typically present with nephrotic-range proteinuria, and graft loss is in the order of 30%.[10,47,48,50] However, many grafts lost to recurrent membranous nephropathy have displayed evidence of other pathologic processes, such as rejection, and the relative contribution of each process to graft failure is not often clear.[48]

Some studies suggest that a high degree of HLA matching between donor–recipient pairs and the use of living related kidneys also increases the risk of recurrence.[47] Furthermore, recurrent disease may manifest earlier (in the first 3 months post-transplantation) in living-related than in cadaveric grafts.[47] The routine use of CsA has not reduced the rate of recurrence.[21,48,50] High-dose steroids have not been successful in reducing proteinuria,[47,51] and no effective therapeutic regimen has been identified. Re-transplantation should be considered in patients who lose their initial graft, although consecutive recurrent membranous glomerulonephritis has been described.[48]

De Novo Disease

De novo membranous nephropathy is the most frequent cause of post-transplant nephrotic syndrome after rejection-induced transplant glomerulopathy (vide infra).[47,51] The reported incidence varies from 0.3% to 6.7%[51,52] with a higher frequency reported in centers with a policy of routine renal biopsy for assessment of non–nephrotic-range proteinuria. In one study, de novo membranous nephropathy recurred in four of seven patients in a second transplant.[53] The incidence of de novo membranous nephropathy increases with time, and, as overall graft survival rates improve, it is being increasingly recognized as a late complication in otherwise functional grafts.[51] De novo disease presents later than recurrent disease and manifests with gradual development of proteinuria. However, almost one third of patients remain asymptomatic with low-grade proteinuria.[51] Graft loss may occur in as many as 50% of patients with persistent nephrotic-range proteinuria.[54,55] However, because membranous nephropathy and chronic rejection often coexist, it may be difficult to determine the relative contribution of each to graft failure, and, indeed, graft loss has been attributed to chronic rejection rather than to membranous nephropathy in many cases.[51,52] For example, 14 of 21 grafts with de novo membranous nephropathy in one series failed, but chronic rejection was felt to be responsible for 13 of these graft losses.[51]

De novo membranous nephropathy is often associated with some degree of vascular rejection[51,52] and cyclosporine-induced vasculopathy.[51] An association with chronic viral infection, most commonly, hepatitis C, has been demonstrated in up to a third of patients with de novo membranous nephropathy, suggesting a potential viral trigger for immune complex formation.[51,55] Cyclosporin A is not effective in preventing development of the lesion.[21] Similarly, pulse steroid therapy was not effective in reducing proteinuria in larger series,[74] although occasional successes have been claimed.[56]

IgA Nephropathy

Immunoglobulin A (IgA) nephropathy is the most common primary glomerular disease worldwide.[57] Histologic evidence

of recurrence is reported in 30% to 60% of allografts.[4,10,58–62] IgA deposition alone is not clinically significant unless accompanied by the development of mesangioproliferative changes. A recent retrospective study of 106 patients with biopsy proven IgA nephropathy demonstrated a similar 10-year graft survival in patients with IgA nephropathy when compared to 212 patients without IgA nephropathy who were transplanted during the same period.[60] Occasionally, recurrent IgA nephropathy presents as aggressive crescentic disease.[63,64] Recurrent IgA nephropathy has generally been considered a benign condition that causes graft loss in less than 10% of cases.[1,2,60] Interestingly, recent data suggest that recurrent IgA nephropathy may carry a more adverse prognosis and become an increasingly important cause of graft loss as overall allograft survival improves.[59–61] In one study, 9 of 13 patients with histologically confirmed recurrent IgA deposition had evidence of mesangioproliferative glomerulonephritis.[59] Although 5-year allograft survival was similar in the presence or absence of recurrent IgA nephropathy, four of these nine patients subsequently lost their grafts to recurrent disease from 60 to 119 months post-transplantation. Similarly, Frohnert and colleagues[61] reported that recurrent IgA nephropathy led to significant loss of graft function in 10 of 14 patients with prolonged follow-up and was responsible for 3 of 4 late graft losses.[61]

A recent report described recurrence of crescentic IgA nephropathy in a patient who had both IgA and IgG anti-neutrophil cytoplasmic antibodies (ANCA), with specificity for myeloperoxidase (MPO), prior to onset of ESRD.[65] The patient developed acute nephrotic syndrome with rapidly progressive renal failure due to recurrent crescentic IgA nephropathy associated with a rise in titer of IgA anti-MPO antibodies. The authors proposed the existence of a subgroup of patients who have an overlap syndrome of IgA nephropathy and microscopic polyangiitis in which IgA and IgG ANCA coexist and who are at increased risk of developing recurrent crescentic glomerulonephritis.[65] It is suggested that the titer of IgA anti-MPO antibodies but not IgG anti-MPO antibodies correlates with disease activity and tendency to recur. Further studies will be necessary to confirm the prognostic value of detection of IgA ANCA prior to renal transplantation.

Some studies suggest that recurrent IgA nephropathy is more frequent in living related than in cadaveric grafts,[58,64] though this is not a universal finding.[5,60,61] For example, in one study the recurrence rate was 83% in living related transplants compared with 14% in cadaveric grafts.[58] It is possible that inherited susceptibility factors, such as HLA DR4 in the case of IgA nephropathy, confer an increased risk of recurrence in living related transplants when shared by donor and recipient.[66] Alternatively, recurrence in this setting may reflect the presence of subclinical IgA nephropathy in the donor, with resultant inadvertent transmission of IgA deposits in the donor allograft to the recipient.[64] Instances of transplantation of kidneys containing mesangial IgA deposits have been described, and the glomerular mesangial deposits have been documented to disappear with time.[67] It has been suggested that when considering living related transplantation for patients with IgA nephropathy, the donor family should be evaluated for subtle evidence of nephritis and that pre-transplant donor biopsy or cadaveric transplantation should be considered if familial clustering is demonstrated.[64] In the study by Ponticelli and colleagues,[60] younger age was found to be a risk factor for recurrence with patients under 30 years having a relative risk of 2.6.

Several therapeutic strategies have been proposed for patients with recurrent IgA nephropathy, including combinations of steroids, cyclophosphamide, azathioprine, CsA, or plasma exchange, but without compelling evidence to support their use. Although the incidence of mesangial deposition of IgA is not altered by CsA, the latter agent has been reported by some[19] to ameliorate the clinical course and to reduce the rate of graft loss. Consistent with the known renoprotective effects of ACEI in native kidney disease, these agents have recently been reported to have a beneficial effect in patients with proteinuria secondary to recurrent IgA nephropathy.[68,69]

Membranoproliferative Glomerulonephritis Type I

Recurrent Disease

MPGN type I is an immune-complex-mediated glomerulonephritis that frequently follows an indolent clinical course and progresses to ESRD in approximately 20% of patients.[22] It recurs in 15% to 30% of renal allografts and causes graft loss in one-third of these patients.[2,4,5,9,70,71] Accurate estimation of disease recurrence has proved difficult in the past because of the similarities between this lesion and transplant glomerulopathy (vide infra) on light microscopy.[72] Routine examination of biopsy specimens by immunofluorescence and electron microscopy usually distinguishes between the two entities—subendothelial Ig-containing deposits being characteristic of MPGN but absent in transplant glomerulopathy.[10,73]

Recurrent MPGN type I may be a renal-limited disease or present in association with systemic signs of cryoglobulinemia. However, the prevalence of cryoglobulins, hypocomplementemia, and rheumatoid factor positivity is less in transplant MPGN, perhaps due to concomitant pharmacologic immunosuppression.[74,75] Recurrent renal disease presents clinically with heavy proteinuria and microscopic hematuria and may be evident within 3 weeks of transplantation.[75] No definite predictors of disease recurrence have been established. Crescentic disease with a rapidly progressive course in the native kidneys has been associated by some authors with an increased tendency to recurrence.[70] The use of living related kidneys and loss of a previous graft to recurrent disease may also favor recurrence.[71] Hypocomplementemia persisting after renal transplantation does not appear to be associated with higher recurrence rates.[70]

There are isolated reports in the literature of successful treatment of recurrent disease with increased immunosuppression. One group used long-term plasmapheresis over a 16-month period to maintain renal function along with the administration of monthly pulsed intravenous cyclophosphamide.[76] Cahen and colleagues[75] successfully induced remission of recurrent disease with a combination of prednisolone, cyclophosphamide, and dipyridamole. Aspirin and dipyridamole have also been shown to stabilize renal function.[70]

---

*References 2,4,5,9,70,71.

De Novo Disease

MPGN accounts for about 33% of cases of de novo glomerulonephritis in renal allografts.[21,74,77,78] The most important etiologic factor appears to be chronic hepatitis C infection, which is present in up to 30% of patients with ESRD.[77,79] In a study of a cohort of 94 hepatitis C–positive transplant recipients, de novo MPGN was demonstrated in 6 of 9 patients undergoing renal biopsy for investigation of proteinuria of greater than 1.5 g/day.[78] Type II cryoglobulinemia, circulating immune complexes, and classic pathway complement activation were observed in all patients. In another study of 98 hepatitis C–positive recipients, de novo MPGN was demonstrated in 5 of 8 patients who underwent biopsy for the investigation of proteinuria of greater than 1 g/day.[74] Interestingly, cryoglobulinemia was not a prerequisite for the development of MPGN as has also been noted with primary glomerulonephritis in the native kidney.

Hepatitis C infection is associated with development of a variety of glomerular lesions in native kidneys including MPGN. A similar spectrum has been observed in renal transplant recipients. Hepatitis C–positive transplant recipients have an increased incidence of both de novo glomerulonephritis and transplant glomerulopathy compared to hepatitis C negative patients (13.7% in hepatitis C–positive recipients versus 4.2% in hepatitis C–negative patients).[80] Intriguingly, Gallay and colleagues[77] described two hepatitis C–positive transplant recipients who developed a hybrid lesion with ultrastructural features of both MPGN and transplant glomerulopathy, namely electron-dense immune complex deposits typical of MPGN along with subendothelial accumulation of electron-lucent material, typical of transplant glomerulopathy (vide infra). It is not clear why only some transplant recipients with chronic hepatitis C infection develop glomerular lesions and what dictates the morphology of the glomerular lesion. Differences in viral strains, viral titers, and individual T cell–mediated responses may account for some of the variation. The occurrence of hybrid lesions as described by Gallay and colleagues[77] may simply reflect the coexistence of hepatitis C induced glomerulonephritis and allograft rejection, or, alternatively, it may reflect modification of the morphology of hepatitis C–associated glomerulonephritis by immunosuppressive therapy.

The role of interferon-α in treatment of hepatitis C–associated MPGN in renal transplant recipients is controversial because of the risk of precipitating acute cellular rejection. Whereas successful treatment of viral infection and stabilization of renal function has been reported in occasional patients,[77] interferon-α has been observed to trigger acute rejection when used as prophylaxis for CMV[81] and as treatment for hepatitis C–associated liver disease.[82,83]

Membranoproliferative GN Type II

Recurrent Disease

MPGN type II, which is characterized pathologically by accumulation of dense deposits within the glomerular basement membrane, is less common than MPGN type I and accounts for half as many cases of ESRD.[22] Recurrence of MPGN type II is very common affecting up to 80% of allografts.[1,4,10,84] The

rate of graft loss from recurrence is in the order of 10% to 20%,[1,10] although a 50% graft failure rate was reported in one series of 10 transplant recipients with recurrent disease.[84] Recurrence of disease in a second graft after loss of the first allograft to recurrence has been described.[1]

Recurrence is usually clinically evident or ascertained by examination of renal biopsy specimens within the first year post-transplantation. Despite the high rate of histologic recurrence, clinical manifestations are absent in 40% of patients. The remainder present with proteinuria and slow, progressive deterioration of renal function. It appears that graft loss is more likely in male patients who present with nephrotic-range proteinuria and rapidly progressive glomerulonephritis.[84]

Unlike patients with native disease, most patients with recurrence do not have circulating C3 nephritic factor, probably reflecting the presence of chronic immunosuppression.[1] The use of CsA has generally not been found to influence the rate of recurrent MPGN, apart from one study, which suggested a reduced incidence.[34] Treatment of recurrent dense deposit disease has generally been ineffective, as in native disease. One isolated report described clinical and pathologic improvement with the use of plasma exchange.[85]

Anti-glomerular Basement Membrane Disease

Anti-GBM nephritis accounts for less than 2% of glomerulonephritis causing ESRD.[22] Recurrence, as defined by the reappearance of linear IgG deposition along the glomerular capillary walls, has been reported to occur in up to 55% of patients.[1] However, only 25% of these patients have clinical manifestations of recurrent disease, and graft loss is rare.[1,2] A more recent report by Pirson and colleagues[86] noted recurrence of IgG deposition in only 1 of 10 patients. Even in this patient, serum creatinine was normal after 15 months of follow-up. Of note, this patient had been on dialysis for 28 months prior to transplantation and had no detectable circulating antibodies at the time of transplantation.[86] Given the compelling evidence that anti-GBM antibodies are pathogenic in this disease, it is standard practice to delay transplantation for a 6- to 12-month period after this serum marker is undetectable.[87]

De Novo Crescentic Glomerulonephritis

De novo crescentic glomerulonephritis is rare in renal allografts, the most common setting being anti-GBM nephritis developing in allografts of patients with Alport's syndrome. The autoantigen in anti-GBM nephritis is a 28 kDa component of the α3 chain of type IV collagen.[88] In X-linked Alport's syndrome, a mutation in the gene encoding the α5 chain of type IV collagen is associated with abnormal assembly of the α3 chain of type IV collagen.[89] Anti-GBM antibodies may develop when the immune system of Alport patients encounters the Goodpasture antigen in the allograft for the first time. Whereas asymptomatic linear deposition of anti-GBM antibody is most common, full-blown rapidly progressive glomerulonephritis and graft loss can occur, albeit rarely.[90–93]

In a review of renal transplantation in a series of 30 patients with Alport's syndrome, patient and graft survival rates were similar to those of an age-matched control group.[94] Five of 15 grafts examined histologically were positive for linear IgG

deposition; however, crescentic nephritis was not seen. Two patients underwent repeat biopsies. Linear IgG deposition had disappeared in one after 12 months but persisted in the second patient 5 years later.[94] The survival of the IgG positive and negative grafts was similar, as was the level of renal function. A single case of recurrent crescentic glomerulonephritis in a second allograft in an Alport's patient who had already lost the first graft to anti-GBM disease has been described.[93] In this patient renal function stabilized following plasmapheresis and an increase in the dose of CsA.

Development of de novo crescentic glomerulonephritis is very rare in patients with ESRD due to diseases other than Alport's syndrome.[95,96] In one report, de novo crescentic glomerulonephritis developed early in association with glomerular basement membrane deposition of IgG.[95] The author proposed that exposure of the allograft to a circulating antibody, perhaps contained in antilymphocyte globulin may have contributed to the development of this lesion. Treatment of de novo crescentic glomerulonephritis is similar to that for disease in the native kidney. Success has been claimed with early use of cyclophosphamide, plasmapheresis, steroids, and dipyridamole[93,95,96]; however, others dispute the long-term effectiveness of treatment.[91]

SECONDARY GLOMERULOPATHIES

Diabetes Mellitus

Diabetic nephropathy is the leading cause of ESRD and accounts for approximately 20% of renal transplants performed annually in North America. Diabetic nephropathy invariably recurs in the renal allograft and progresses at a similar rate to disease in the native kidney.[1,97,98] Recurrent disease typically presents with proteinuria and slow deterioration of renal function over a period of 15 to 20 years. Renal biopsy may reveal glomerular basement membrane deposition of IgG as the sole abnormality in the early post-transplant period. However, the classic histologic changes of diabetic nephropathy, such as glomerular basement membrane thickening, mesangial expansion, and arteriolar hyaline deposition, are seen within 2 to 4 years.[11,97,98] Graft loss from recurrent disease is seen in less than 5% of cases, largely because grafts fail from chronic rejection or patients die from extrarenal complications before diabetic nephropathy reaches end-stage.[12]

As with primary disease, the degree of glycemic control is a critical determinant of the rate of progression of recurrent diabetic nephropathy. It is also advisable to treat recurrent disease with ACEI, given the compelling evidence that they slow progression of primary disease in experimental animals and humans.[99] In selected patients, normalization of glucose levels with combined pancreatic and renal transplantation cures diabetes and prevents the development of diabetic renal disease in the transplanted kidney.[11,97,100]

Systemic Lupus Erythematosus

Lupus nephritis accounts for about 1% of cases of ESRD. In the majority of patients, disease activity declines upon institution of maintenance dialysis and declines further after renal transplantation.[101,102] It is not clear whether this response represents the natural history of SLE or the immunomodulatory effects of uremia and immunosuppression. In general, lupus nephritis recurs in less than 3% of patients following transplantation and is rarely responsible for graft loss.[1,2,10,103–107] In series by Nossent and colleagues[103] and Goss and colleagues,[105] only 1 of 28 patients and 1 of 14 patients, respectively, suffered recurrence. In another series of 80 patients with ESRD due to lupus nephritis, two patients (2.5%) suffered recurrence, one of whom lost their allograft.[106] More recent studies have documented a higher rate of recurrence.[108,109] For example, Stone and colleagues[108] documented a recurrence rate of 10% in a group of 97 transplant recipients with SLE; however, recurrence was felt to contribute to graft loss in only 4 patients. In most cases the recurrent lesion is of the same histologic class, as observed in the native kidney,[104,110] with occasional exceptions.[111] Overall, mean patient and graft survival following renal transplantation for lupus nephritis compare favorably with transplantation for other causes of ESRD.[104,110]

Several authorities recommend a 3- to 6-month waiting period between initiation of dialysis and transplantation in patients with lupus nephritis.[102,109] This approach allows time for recovery of any reversible component of renal failure and facilitates disease quiescence prior to transplantation. Some authors advocate delay of transplantation until patients are seronegative on the basis that active serology at the time of transplantation is associated with a worse outcome.[105,110] This view is not universally supported, however.[112]

Index case studies report a 1.5% rate of occurrence of lupus in first degree relatives.[102] Accordingly, it is of paramount importance to screen prospective living donors for hematuria and proteinuria prior to transplantation. A small increased risk of recurrent lupus nephritis in recipients of living related kidneys was suggested by the review of Mojcik and colleagues[104] but was not confirmed in other reports.[108] Furthermore, the results with living related kidneys are better than with cadaveric in patients with lupus nephritis, presumably because of shorter ischemic times and better HLA matching.[106] As mentioned above, disease recurrence rarely produces significant renal dysfunction and usually responds to increased immunosuppression.[109,111] Success has been reported with higher dose corticosteroids,[107] chlorambucil,[111] and cyclophosphamide.[110,112]

ANCA-Associated Vasculitis

The ANCA-associated renal diseases comprise Wegener's granulomatosis, Churg-Strauss syndrome, microscopic polyangiitis, and renal-limited crescentic glomerulonephritis.[113] ESRD requiring dialysis or transplantation occurs in approximately 10% of cases.[113] The data on renal transplantation derive mostly from small series of patients with Wegener's granulomatosis. In this setting, vasculitis–glomerulonephritis recurs in approximately 25%, but ensuing graft loss is rare.[114–119] A lower incidence of recurrence of 9% was reported by Allen and colleagues, possibly reflecting their policy of a longer duration of immunosuppressive therapy for patients once they commence maintenance dialysis.[115] In a series of 20 patients reported by Schmitt and colleagues[120] (6 of whom had active disease at the time of transplantation), 5 patients had clinical relapses during a 4-year follow-up, all of which were extrarenal. Graft survival in these patients was

similar to that in the group as a whole. In a small series, the outcome of transplantation for microscopic polyangiitis and Wegener's granulomatosis seems to be similar.[117,121] In a pooled analysis of 127 patients the relapse rates of microscopic polyangiitis or renal limited crescentic GN (n = 51) was similar to Wegener's granulomatosis (n = 54).[114] Renal recurrence of Wegener's has been documented as early as 5 days after transplantation,[122] and typically presents with hematuria and deteriorating renal function. An interesting report described a patient with recurrent Wegener's granulomatosis who presented with obstructive uropathy secondary to ureteric stenosis caused by the vasculitic process.[119]

The preoperative ANCA titer does not appear to correlate with the risk of recurrence, and ANCA positivity is not a contraindication to transplantation.[114] Of eight patients described by Rostaing and colleagues,[117] seven had positive ANCA titers at the time of transplantation. Positive titers persisted in five patients after transplantation, and only one patient developed recurrent disease. Similarly, the reappearance of ANCA or a rising ANCA titer following transplantation does not accurately predict disease recurrence.[117,120] There are no data that suggest different risks of recurrence in patients with proteinase-3-specific c-ANCA or MPO-specific p-ANCA.[114]

The optimal immunosuppressive regimen post-transplantation in patients with ANCA-associated renal diseases has not been determined. Control of systemic disease as well as recurrent renal disease has to be considered. Some centers include cyclophosphamide in the immunosuppressive regimen for these patients, on the basis that it reduces the risk of recurrent disease. For example, Clarke and colleagues[118] noted a higher recurrence rate of Wegener's granulomatosis in patients receiving CsA without azathioprine or cyclophosphamide. Recurrences involved the lungs or ear, nose and throat more frequently than the kidney. In agreement with these data, Schmitt and colleagues reported a lower recurrence rate with triple therapy combining CsA and steroids with either azathioprine or cyclophosphamide than with CsA and steroids alone.[120] In the pooled analysis by Nachman and colleagues there was no difference in the rates of recurrence in patients receiving CsA compared to those not receiving CsA.[114] Recurrent disease usually remits following treatment with pulsed intravenous methylprednisolone and cyclophosphamide.[114,115,117,118] This overall favorable response to cyclophosphamide has led some authors to conclude that cyclophosphamide be reserved for those with recurrent disease, rather than used prophylactically.[123]

Henoch-Schönlein Purpura

HSP is an immune-complex disorder characterized by skin, joint, abdominal, and renal involvement. The pathologic hallmark of the disease is deposition of IgA in the glomerular mesangium and blood vessels of the dermis and intestine. The incidence of histologic recurrence following renal transplantation is approximately 50%.[10,18,58] This incidence is similar to IgA nephropathy, a disease that may be a renal-limited form of HSP.[58] Recurrent HSP is usually benign, but active proliferative nephritis with or without extrarenal manifestations has been noted in up to 20% of patients.[18] Purpura is noted in up to 10%. Although graft loss is reported to occur in 9% of cases of recurrence,[3] it may approach 50% in a subgroup of patients with renal involvement accompanied by recurrent

purpura.[10,124] The actuarial risk of recurrence and resultant graft loss in two of the larger series was estimated at 35% and 11%, respectively, 5 years after transplantation.[18]

Severe systemic activity, especially purpura, in the year prior to transplantation[1, 2] and rapid progression of the primary disease to renal failure[18] are risk factors for recurrence. For these reasons, a waiting period of 6 to 12 months after resolution of purpura is generally advised before proceeding with transplantation.[1,2,124] Recurrence may be observed even with these precautions, however, as illustrated in a series by Meulders and colleagues, where two patients with recurrence had been on dialysis for 22 and 37 months prior to transplantation.[18] Age of onset of original disease of greater than 14 years may also predict recurrence.[18] Some but not all investigators have noted an increased incidence of recurrence in recipients of living-related kidneys.[18] In general, CsA does not appear to alter the incidence of recurrent HSP,[18,59] and no effective therapeutic regimen has been described.

Hemolytic Uremic Syndrome–Thrombotic Thrombocytopenic Purpura (HUS-TTP)

Recurrent Disease

HUS-TTP is a spectrum of disease characterized by microangiopathic hemolytic anemia, thrombocytopenia, intravascular coagulation, and acute renal failure, which may culminate in ESRD. The reported recurrence rates of HUS after renal transplantation vary widely from as low as 9% to as high as 56%.* Graft loss attributable to HUS occurs in 10% to 40% of these patients.[10,125,127–130] In a meta-analysis of 10 studies comprising 159 grafts in 127 patients, 1-year graft survival in patients with recurrence was as low as 33.3%.[128] Recurrence is less likely in diarrhea-associated HUS than in non-diarrhea–associated HUS, which might explain the lower incidence of recurrence in children, where the disorder is more frequently Shiga toxin–associated.[127] For example, Broyer and colleagues,[7] in an analysis of EDTA registry data, reported that of 71 failures of 170 first grafts in children with HUS only 1 was due to recurrent disease. In a series of 18 children in Argentina there was no documented case or recurrent HUS.[131]

Acute vascular rejection or CsA alone induces endothelial cell injury, which can trigger a de novo thrombotic microangiopathy with features similar to classic HUS and may predispose patients with ESRD due to primary HUS to development of recurrent disease.[132,133] Indeed, higher recurrence rates in some series have been related to more frequent use of CsA,[128,134] albeit with dissenting views.[21,129] In a recent review of 114 patients with recurrent HUS, Agarwal[126] found that about two thirds were exposed to CsA, whereas one third did not receive CsA. Other immunosuppressive agents that may predispose to recurrence are antilymphocyte globulin (ALG)[125] or OKT3.[135] In the meta-analysis by Duclox and colleagues,[128] additional risk factors for recurrence were a shorter mean interval between HUS and transplantation, older age at onset of HUS, a shorter mean interval between HUS and ESRD, and the use of living related donors. In one report a much lower rate of recurrence was found in patients who had

---

*References 1,2,10,24,125–130.

undergone pre-transplant bilateral nephrectomies than in those whose native kidneys were in situ.[130]

With these observations in mind, a number of strategies are advocated to reduce the risk of recurrence. Transplantation should not be undertaken until the clinical features (anemia, thrombocytopenia, abnormal smear) of HUS have subsided. OKT3, ALG, and the oral contraceptive pill (all risk factors for primary HUS) should be avoided.[135] Some authors urge avoidance of CsA if a previous graft was lost to recurrent HUS while on CsA.[126] Low-dose salicylates and dipyridamole have been recommended to prevent recurrence,[125] although without compelling evidence to support their use.

Treatment of recurrent HUS is essentially the same as for primary disease and centers around plasma exchange and plasma infusions. Although controlled trials are lacking in this area, anecdotal reports describe successful outcomes with plasmapheresis.[128,133] In patients on CsA, it is prudent to reduce the dose by 50% or withdraw CsA and replace it with FK506 or other agent, if additional immunosuppression is deemed necessary.[136]

De Novo Disease

De novo HUS has been reported more frequently since the incorporation of CsA into immunosuppressive regimens.[128] There are also a growing number of reports implicating tacrolimus in the causation of de novo HUS.[137–139] A more recent review by Schwimmer and colleagues[139] documented de novo HUS in 21 of 742 transplant recipients. The causative agent was deemed to be tacrolimus in 10 patients and CsA in 9 patients. Thirteen patients had systemic features, whereas 8 had localized renal disease. Graft loss was higher in patients with systemic manifestations (38% vs. 0%), and renal function improved in the group with localized disease on reduction, conversion, or temporary discontinuation of calcineurin inhibitor.[139] A number of prothrombotic mechanisms whereby CsA may perturb endothelial function *in vitro* and *in vivo* and trigger thrombotic microangiopathy have been postulated.[140] Viral infections have also been implicated as triggers for de novo HUS, as exemplified by a recent case report of HUS-TTP in association with HIV infection.[141] Recent reports suggest an association between sirolimus and de novo and recurrent thrombotic microangiopathy.[143,144] In a recent review of USRDS data additional risk factors identified for de novo TMA included younger age of recipient, older donor age, female recipients, and use of sirolimus.[144] De novo HUS in patients on CsA carries a poor prognosis with a high incidence of graft loss, even after withdrawal of the drug.[142] Again, treatment of de novo HUS is based on regimens for disease in native kidneys.

Systemic Sclerosis

The literature on renal transplantation in systemic sclerosis is rather limited. Patient and graft survival is poorer in this condition than in other causes of ESRD.[146,147] It is estimated that renal disease recurs in 20% to 30% of patients; this may be an overestimate given the rarity of the condition and the similarity of the pathologic lesion of renal scleroderma to vascular rejection. The risk of recurrence appears greatest in patients with a history of aggressive primary disease, particularly where the time interval from onset of systemic sclerosis to transplantation is less than 1 year.[3]

Graft survival can be maximized by ensuring that the patient is free of active disease at the time of transplantation and by aggressive control of hypertension post-transplantation. Early reports suggested that bilateral nephrectomy at the time of transplantation improved outcome; however, with improvement in antihypertensive therapy, this procedure should no longer be deemed necessary.[3] Cyclosporine does not appear to influence the incidence of recurrence.[205]

GLOMERULAR DEPOSITION DISEASES

Amyloidosis

Amyloid deposits recur in 8% to 26% of allografts in patients with primary (AL) and secondary (AA) amyloidosis, who survive longer than 1 year.[2,3,148–150] In the two largest single-center series, recurrent amyloidosis was documented in 4 of 45 patients by Pasternak and colleagues[148] and in 6 of 54 patients by Hartmann and colleagues.[150] In a review by Harrison and colleagues,[149] recurrent renal amyloidosis was documented in 21% of patients with familial Mediterranean fever, 15% of patients with AA amyloidosis secondary to rheumatic and chronic infectious disease, and 27% of patients with AL amyloidosis. The rate of loss of grafts with recurrent amyloidosis appears to be about 40%.[148,150] In general, survival of patients with amyloidosis has been found to be significantly less than for patients with other causes of ESRD, as a result of the high incidence of cardiovascular and other extrarenal complications, and death of the patient with a functioning graft accounts for as many as 60% of graft failures.[148,150] However, much better patient and graft survival were reported with living-donor renal transplantation in 23 patients with amyloidosis (16 with familial Mediterranean fever and 7 with primary amyloidosis) when compared to 47 nonamyloidotic controls.[151] In this report, both the 5- and 10-year patient and graft survival rates were similar to the control group, and recurrence was documented in only one case.[151]

Recurrent amyloidosis presents clinically with proteinuria or nephrotic syndrome, however, histologic recurrence is not invariably accompanied by clinical manifestations. The deterioration in renal function is often more gradual than in native kidneys. Controlling the activity of the underlying inflammatory focus may reduce the risk of recurrence of AA-amyloidosis.[152] No specific therapeutic strategies have been identified. Despite the risk of recurrence and the relatively high mortality rate, patients with amyloidosis should nonetheless be considered for transplantation, as survival appears superior with renal transplantation than with maintenance dialysis.

Essential Mixed Cryoglobulinemia

The clinical and serologic activity of essential mixed cryoglobulinemia decreases after the onset of ESRD. Data on the outcome of this disease following renal transplantation are sparse. Reactivation has been estimated to occur in as many as 50% of renal allograft recipients.[153] In two cases described by Hiesse and colleagues,[153] renal recurrence was accompanied by extrarenal disease and by the reappearance of rheumatoid factor positivity, the presence of serum cryoglobulins, and depressed levels of C3 and C4 components of complement. Recurrent renal disease can be seen as early as 30 days after

engraftment, is often aggressive, and may ultimately result in graft loss. The high risk of significant recurrent disease has led some investigators to suggest that cadaveric grafts should be used in preference to living related grafts for these patients.[153]

Monoclonal Gammopathies

Lymphoplasmacytic disorders may cause renal insufficiency via a variety of pathologic mechanisms. Chief among these are AL amyloidosis (vide supra), light chain deposition disease (LCDD), myeloma cast nephropathy, and fibrillary-immuno-tactoid GN (vide infra).[154] Rarer manifestations include Fanconi's syndrome and heavy chain deposition disease. It is difficult to make strong inferences about the outcome of transplantation in these disorders because the available information is limited to case reports.[155–160]

LCDD recurs in approximately 50% of allo-grafts.[155–157,159,161] Recurrent LCDD can cause severe impairment and loss of graft function,[156,157] although renal function may be well maintained in some patients despite histologic evidence of recurrence.[155,161] De novo LCDD without evidence of malignancy has been reported in a renal allograft 16 years after successful renal transplantation.[163]

Of seven reported patients with myeloma cast nephropathy who underwent renal transplantation, recurrence was observed in two patients without adversely affecting graft function.[158,160,162,164,165] However, a number of patients died from recurrent extrarenal disease or sepsis illustrating the poor prognosis in this disease. A few case reports have also described the occurrence of de novo multiple myeloma in renal allograft recipients following transplantation.[166,167] In one of these patients the myeloma was associated with LCDD in the allograft.[167]

Fibrillary-Immunotactoid Glomerulopathy

Fibrillary-immunotactoid glomerulopathy is characterized by extracellular deposition of congo-red–negative, nonbranching microfibrils or microtubules within the glomerular mesangium and capillary walls in the absence of light chains or cryoglobulins.[168] Patients with fibrillary immunotactoid glomerulopathy frequently progress to ESRD (50% after 5 years). Experience with transplantation in these patients is limited. From the small number of cases reported, it appears that fibril deposition recurs in at least 50% of patients.[168–172] Despite the high recurrence rate, the decline in renal function in allografts is usually slower than in native kidneys, and many patients maintain satisfactory function for over 5 years. Indeed, three patients with recurrent disease reported by Pronovost and colleagues[169] continued to have functioning grafts between 6 and 11 years post-transplantation. Whether the slower rate of progression in allografts reflects a beneficial effect of immunosuppressive therapy or spontaneous attenuation of disease activity is unclear.

NONGLOMERULAR DISEASES

Oxalosis

Oxalosis, or primary hyperoxaluria type I, is an autosomal recessive disease, which results from deficiency of hepatic peroxisomal alanine glyoxylate aminotransferase. Absence of this enzyme causes oxalate overproduction and recurrent calcium oxalate nephrolithiasis and nephrocalcinosis. Oxalosis was originally considered a contraindication to transplantation because of universal recurrence of renal disease and graft loss.[1,171] More recently, combined liver and kidney transplantation has produced encouraging results.[13–15,173,174] In one report, 17 of 24 patients had functioning grafts 1 to 6 years post-transplantation.[13] Some authors advocate liver transplantation simultaneously with the first kidney transplant,[13] whereas others suggest it be deferred until the first allograft fails from disease recurrence.[175] Several measures have been recommended to maximize successful engraftment.[176] First, renal replacement therapy should be instituted early (once the GFR approaches 20 mL/min) to limit tissue oxalate deposition, which will be released into the circulation and deposited in the allograft post-transplant.[124,174,175] Aggressive preoperative dialysis is recommended to deplete the extrarenal tissue oxalate pool. It is essential to establish a brisk postoperative diuresis, because deposition of oxalate in the allograft seems to be accelerated during periods of primary nonfunction.[176] The use of a large living related allograft and avoidance of the immediate use of CsA can accomplish this goal. Administration of pyridoxine, a coenzyme that functions in the conversion of glyoxylate to glycine and thereby decreases the glyoxylate pool, has also been recommended to maintain graft function.[177,178]

Cystinosis

Cystinosis is an autosomal recessive disorder that results from defective transport of cystine from lysosome to cytosol. Lysosomal accumulation of cystine in the renal interstitium ultimately causes interstitial fibrosis, glomerular sclerosis, and renal failure. Renal transplantation is very successful and is the preferred mode of treatment for children with this condition.[171,179] Cystinosis and cystine-induced tubular cell dysfunction per se do not recur.[124] However, cystine-laden cells, probably host macrophages, can be found in the transplanted kidney.[180] Despite successful renal transplantation, the systemic effects of pre-transplantation cystine accumulation in other organs persists and accounts for ongoing morbidity.

Fabry's Disease

Fabry's disease is an X-linked recessive disorder due to deficiency of the enzyme α-galactosidase, which results in the accumulation of glycosphingolipids in most tissues of the body, including the kidneys. Early reports of renal transplantation in Fabry's disease suggested a very poor outcome, and many patients died of pulmonary hemorrhage, thrombosis, and sepsis.[171,181] More recent reports indicate a better outcome, with 3 years graft survival rates of up to 80%.[124,182]

Initial hopes that kidney transplantation would provide an adequate source of the missing enzyme have not been realized[183] and recurrence has been described.[184] Recurrence does not result in clinical sequelae, however, and patient survival of up to 11 years has been reported.[184] Consequently, renal transplantation is now considered a reasonable option in this condition.

Sickle Cell Disease

Approximately 4% of patients with sickle cell disease progress to ESRD.[185] Experience with transplantation is rather limited.[254–257] Despite reasonable graft survival in some reports,[186–188] allograft failure in the first year was reported in six of eight patients in a series by Barber and colleagues.[188] Four of these grafts were deemed lost to recurrent sickling.[188] Graft loss may result from an acute vaso-occlusive crisis or from the more indolent effect of recurrent sickling episodes. Secondary focal sclerosis has been described in transplanted kidneys presumably a consequence of nephron loss due to intrarenal sickling.[187] An increased incidence of sickling crises has been described following renal transplantation, possibly due to the increased hematocrit and blood viscosity that follow successful engraftment.[186,188] Crises appear to be more common following transplantation in homozygotes than in heterozygotes.[186] There is a suspicion that OKT3 induces sickling crises in some patients, and this agent should be used with caution in this setting.

TRANSPLANT GLOMERULOPATHY

The term *transplant glomerulopathy* has been used to define a constellation of histologic, ultrastructural, and immunofluorescence findings in the renal allograft.[72,189,190] It is characterized pathologically by diffuse endothelial cell swelling, mesangial cell proliferation, and glomerular basement membrane reduplication with mesangial cell interposition. Immunofluorescence studies are usually negative but may show scant deposition of IgM and fibrin. Electron microscopy reveals reduplication of the basement membrane and widening of the subendothelial space by a layer of electrolucent flocculent material. This lesion resembles membranoproliferative glomerulonephritis (MPGN) by light microscopy; however, electron microscopy reveals absence of electron dense deposits in the capillary walls, which are typical of MPGN.[70,190]

The usual clinical presentation is with nephrotic syndrome and progressive impairment of renal function,[72,73] but a significant number of patients remain asymptomatic.[190] A diagnosis of transplant glomerulopathy was made in 4.3% of patients in a large series of long-term transplant recipients.[72] In a study by Habib and colleagues,[190] transplant glomerulopathy was demonstrated in 38 of 540 allografts (7%) in whom adequate tissue was available for pathologic examination. Although, typically considered a late occurrence, in the latter study it was noted as early as 4 months post-transplantation. Heavy proteinuria occurred in 29 patients, 10 of whom developed nephrotic syndrome, but, of note, 9 patients had absent or minimal proteinuria even on prolonged follow-up. Graft loss ultimately occurred in 60% of these patients, but 35% still had functioning grafts at a mean follow-up of 11 years.[190]

Nankivell and colleagues[189] recently studied the natural history of transplant glomerulopathy by performing serial renal biopsies in 120 patients with ESRD from diabetes mellitus who received a combined kidney and pancreas transplant (n = 119) or kidney transplant alone (n = 1). The natural history consisted of two distinct phases: an initial phase of early tubulointerstitial damage, due to ischemic injury, prior severe rejection, and subclinical rejection; and a later phase characterized by microvascular and glomerular injury. Calcineurin inhibitors were associated with increasing glomerulosclerosis and further tubulointerstitial damage. Severe chronic allograft glomerulopathy was present in 58% of patients at 10 years.[189]

Although no effective treatment has been identified for transplant glomerulopathy,[73,190] current treatment strategies include reduction or withdrawal of calcineurin inhibitors and the substitution of mycophenolate mofetil (MMF). In a series of 118 patients with biopsy proven transplant glomerulopathy reduction or withdrawal of either CsA or FK506, combined with the introduction or continuation of MMF, was found to be safe, well tolerated, and to either slow the rate of progression or stabilize renal function.[191] Future directions may include the combination of MMF and rapamycin, which has shown to be promising in experimental models.[192]

Pediatric Renal Transplantation

William E. Harmon, M.D.

ROLE OF TRANSPLANTATION

Chronic dialysis and renal transplantation are both excellent treatments for end-stage renal disease (ESRD). The majority of adults with ESRD are receiving dialysis rather than undergoing renal transplantation, although the number seeking renal transplantation is continuing to rise substantially.[1] There is a survival advantage of transplantation for virtually all candidates. Unfortunately, the lack of suitable donors has limited the number of people who can receive transplants. Renal transplantation was recognized as the better form of treatment for children with ESRD two decades ago.[2] Both peritoneal dialysis, delivered as CAPD or CCPD, and hemodialysis lead to a deceleration of growth. Data from the dialysis component of the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) registry[3] show that the overall height deficit of −1.8 S.D. became more negative reaching a value of −2.16 S.D. at 24 months after initiation of dialysis. Additionally, children do not tolerate being "dependent" on any modality and maintenance dialysis induces loss of self-esteem and emotional maladjustment in them.[4] Cognitive achievement testing may diminish with prolonged time on dialysis.[5] In contrast, the mobility and freedom from dietary restrictions afforded by a functioning renal transplant enable children to live nearly normal lives. Although renal transplantation has not lived up to the promise of normal growth for all children, dramatic short-term improvements in height can be seen in many, and final adult height is improving after transplantation.[6–9] Most important, successful transplantation permits the child to attend school and to develop normally. School function testing improves dramatically following transplantation.[10,11] Also important is that young children now have the best long-term outcomes of all ages of transplant recipients, verifying the utility of transplantation in this age group.[12] For all of these reasons, successful renal transplantation remains the primary goal of programs that care for children with ESRD.

Incidence and Frequency of Transplantation

NAPRTCS has registered about 500 pediatric kidney transplants each year since its inception in 1987, accounting for 75% of all those performed in North America, and that number has remained relatively constant. In 2002 there were about 14,700 kidney transplants performed in the United States, suggesting that pediatric patients comprise about 5% of all transplant recipients. Although the number of pediatric transplants performed each year has varied by no more then 10%, the donor origin has undergone substantial changes. The Scientific Registry of Transplant Recipients (SRTR) data show that living kidney donation has expanded substantially, and

the number of living donors (LD) exceeded the number of cadaver donors (CAD) for the first time in 2001.[1] Living donation now accounts for 43% of all kidney transplants in the United States. In 1987 only 40% of all transplants performed in children were from an LD source; by 1991 the figure had risen to 53%, and, for the last 5 years LDs accounted for over 60% of all pediatric renal transplants (Table 40–1).[13] Parents comprise 82% of LDs. Mothers comprise the majority of parent donors; fathers account for 46%. Since there are more boys than girls who receive kidney transplants, it should not be surprising that fathers donate to sons 64% of the time and mothers to sons 60%. There is no outcome advantage to either parent, with the possible exception that infants less than 1 year of age seem to have fewer rejections if the mother is the donor.[14,15] Because children most often have siblings who are too young to donate (less than 18 years), the NAPRTCS registry has recorded only 305 transplants between siblings. Of these, 150 grafts were from donors less than 21 years of age. A review of the NAPRTCS registry identified only 12 living donors under 18 years of age, of which 11 were transplants between siblings and 1 was from parent to child. It is quite clear that most programs are very reluctant to use minor donors.[16,17] However, a review of UNOS data revealed that from approximately 40,000 LDs in the United States between 1987 and 2000, 60 were from donors less than 18 years of age.[18] Twenty-four of the recipients were children and 36 were adults; only 7 of the transplants were between identical twins. In recent years there has been a substantial interest in living-unrelated donation in adult transplant literature because the outcome of the grafts has been shown to be better than that of cadaver source kidneys.[19] NAPRTCS identified 123 instances of living-unrelated donation between 1987 and 2001. In a preliminary analysis of the first 38 living-unrelated recipients, 23 (61%) were male, 30 (79%) were Caucasian, 8 were younger than 6 years old, and 20 were older than 12 years.[20] This was the primary transplant for 29 of the 38 recipients. Of the 38 donors, 22 were nonbiologic parents, and a family friend was the donor in 10 of the cases.

Thus, the majority of cadaver kidneys for children are recovered from adult donors. In the 1980s there was a tendency to preferentially place kidneys recovered from infants into infant recipients, with disastrous consequences for patient and graft survival.[21] As a result of widespread dissemination of these data,[22,23] there has been a marked change in the practice (Table 40–1). From 1987 through 1990, the percentage of cadaver donors older than 10 years ranged from 59% to 68%. From 1991 through 1994, these percentages ranged from 78% to 88%. Prior to 1991, children younger than 2 years of age comprised 3.2% of cadaver donors. In 1991 no pediatric recipient received a kidney from a cadaver donor less than 2 years of age; and in 1995 and 1996, there were no such kidneys utilized in children.[24] Between 1991

and 2002, less than 1% (23/2464) of cadaver donors for children were less than 2 years of age.[13] This change in allocation of kidneys from young donors led to improvement in graft survival.[21] Some specialized pediatric programs have reported good results with young donors,[25] but many programs reserve grafts from very young donors for en bloc transplantation into older recipients.[26]

Primary Diagnosis

Because of the large database of the NAPRTCS, it is now possible to determine the percentages of each disease category leading to ESRD by age at transplantation as well as by gender and race. ESRD in children is generally due to congenital or inherited diseases. In reviewing 7651 transplants, the most common congenital diagnoses are obstructive uropathy and aplastic/hypoplastic/dysplastic kidneys, each representing about 16% of the patients[13] (Table 40–2). Among glomerular disorders, focal segmental glomerulosclerosis (FSGS) is the most common; 873 children received a renal transplant for FSGS between 1987 and 2002. The primary diagnosis also varies with the race of the recipient. Overall in the NAPRTCS registry, Caucasian children account for 62% of all recipients; however, Caucasian children account for less than 50% of the children transplanted for FSGS. The data regarding the role of FSGS in leading to ESRD can be better appreciated by observations from the dialysis section of the registry, in which the two most common diagnoses are FSGS and aplastic/dysplastic kidneys at 14% each. Of 733 children with FSGS on dialysis, Caucasian children account for only 34%, with African-American and Hispanic children accounting for 62% of the patients. Twenty-four percent of African-American children on dialysis and 30% of those greater than 12 years old have FSGS. Table 40–2 shows the primary diagnoses by gender and race of 7651 children who have received a transplant as recorded by NAPRTCS since 1987, as well as the percentage of biopsy proven diagnoses. It is important to observe that the biopsy confirmation of the primary diagnosis was made in 94% of FSGS, in 93% of systemic immunologic diseases and in 90% of congenital nephrotic syndrome patients. The information regarding primary diagnosis is critical in predicting graft survival as well as recurrence of the original disease, as discussed later.

Age at Transplantation

Kidney transplantation prior to 6 months of age, or in a recipient who weighs less than 6 kg is exceptional. From 1987 to 2002, NAPRTCS recorded 81 transplants performed in children younger than 12 months.[13] Of these, 5 transplants were performed in children between 3 and 5 months, 21 were performed in children between 6 and 8 months, and 55 were performed in children between 9 and 11 months of age. Only 12 infants have been reported since 1996. In general, the number of kidney transplants performed in infants and young children seems to be declining (Table 40–1). Since infants and adolescents have different risk factors for both patient and graft survival, children frequently have been grouped into five age categories: 0 to 1 year; 2 to 5 years; 6 to 12 years; 13 to 17 years; and 18 to 21 years of age. In 1987, 25% of all pediatric transplants were performed in children 0 to 5 years of age,[27] whereas in 1995, the same age group accounted for 15%,[24] and it is currently 17%.[13] Whether the decreased number of transplants in this group is due to a perception of their vulnerability or to the development of more optimum dialysis has not been established. It is important to note that excellent results have been obtained in very young patients in some individual centers.[28,29] The concept of a heightened immune response in young recipients is currently controversial.[30–32] Thus, the unique problems associated with transplantation in young recipients may be related to infections, technical issues, and differences in pharmacokinetics[14,33–36] rather than their immune response. Recent reports of outstanding long-term graft survival rates for these young children seem to indicate that their specific problems can be overcome successfully.[12]

Indications for Transplantation

Because of the shortage of donors for kidney transplantation, the evaluation of potential recipients and the indications for transplantation have recently been reviewed.[37,38] Virtually all children reaching ESRD are considered to be candidates for a renal transplant. In some settings, the definition of ESRD is related to the need for chronic dialysis to sustain life. Currently in the United States, dialysis is rarely indicated in adults until the serum creatinine has exceeded 8 mg/dL. The definition of dialysis dependency is inadequate in pediatrics, however, because a significant number of children receive a preemptive kidney transplant without ever having been on dialysis.[39] In a review of 7053 primary kidney transplants in children transplanted from 1987 through 2002, the NAPRTCS noted that 1713 (24%) of the patients had never received maintenance dialysis.[13] In the past, growth failure was considered one indication for transplantation, but the success of recombinant human growth hormone in overcoming this complication of chronic kidney disease (CKD) in children[8,40] has virtually eliminated growth failure as an absolute indication. A very disturbing result from an analysis of UNOS data demonstrated that African-Americans in the United States are less likely to be waitlisted for transplantation at any time after their first dialysis treatment than Caucasians.[41] The point at

which a child with chronic renal insufficiency (CRI) should be considered for renal transplantation remains controversial.

PREEMPTIVE TRANSPLANTATION

Since preemptive transplantation is an important modality for children, NAPRTCS conducted a special study to determine the frequency and outcome of this approach[39] and has updated it in the annual reports.[13] From 1987 through 1992, 26% of the patients were registered as having had preemptive transplantation. The study compared data of those recipients who had been on maintenance dialysis versus patients who had no previous dialysis. Of 2213 primary grafts during that time period, 1150 (52%) were from an LD source, whereas for the preemptive group 70% were recipients of an LD kidney. More recently, of 7053 primary transplants, 1713 (24%) were preemptive. Preemptive transplantation was more common in LD (33%) than in CAD (13%) and in males (27%) than in females (20%). The rate varies among age groups with 20%, 24%, 28%, 27%, and 20% for the 0 to 1, 2 to 5, 6 to 12, 13 to 17, and 18 to 20 age groups, respectively. It also varies across races with Caucasians, African-Americans, Hispanics, and other races, having rates of 30%, 14%, 16%, and 16%, respectively. As noted above, African-Americans were also less likely to be waitlisted than Caucasians following initiation of dialysis.[41] A proposed objection against preemptive transplants has been that without the rigors of prior dialysis, compliance with immunosuppression might be poor. To determine whether this hypothesis might be correct, graft survival was compared between the two groups and was determined to not be different at 1 or 4 years.[39] When causes for graft loss were analyzed, the preemptive group did not have a higher incidence due to noncompliance. The NAPRTCS also surveyed the motive for preemptive transplantation and determined that the primary reasons were parents' desire to avoid dialysis (34%) and the nephrologists' recommendation (18%). Desire for improved growth was considered a contributory factor in 50% of the patients.[39]

CONTRAINDICATIONS TO TRANSPLANTATION

There are few absolute contraindications to transplantation. The concern of further immunosuppressing an already

compromised host made transplantation of HIV-positive children a perceived relative contraindication. Many children who developed HIV nephropathy succumb to the systemic ravages of the virus, either before or very shortly after reaching ESRD status.[42] However, marked advances of treatment of HIV-positive patients, especially with protease inhibitors and other antiretroviral therapies, makes consideration of kidney transplantation more likely.[43,44] Ironically, initial results from a few centers suggest that HIV-positive patients with reasonable CD4 cell counts may have more problems with rejection rather than infection post-transplantation.

Another relative contraindication is a preexisting malignancy. The NAPRTCS dialysis registry contains 70 children with Wilms' tumor or Drash syndrome.[45] Thirteen of these did not receive a transplant because of metastatic disease and all 13 died. The transplant registry contains 86 children who have these diagnoses and who have received a kidney transplant, and no recurrences have been reported in any of them. The outcome of those who received transplants was similar to non-Wilms'/Drash recipients. However, children with already existing metastatic disease are generally not considered transplant candidates. Also, children with devastating neurologic dysfunction may not be suitable transplant candidates, but the wishes of the parents, as well as the potential for long-term rehabilitation, must be considered in these circumstances. Potential for recurrence of the original renal disease is of major concern but has not generally precluded at least an initial transplant. Oxalosis, which once was considered an absolute contraindication due to a high incidence of recurrence, can be treated successfully with combined liver and kidney transplantation,[46,47] although the complication rate remains high.[29,48,49]

PRE-TRANSPLANT PREPARATION

Recipient Preparation

Before a child can undergo transplantation, the problems caused by CKD must be addressed and repaired, if possible. In those cases where ESRD is due to urologic abnormalities, corrective reconstructive surgery should be undertaken, especially to the lower urinary tract, prior to transplantation. Two of the major consequences of CKD are anemia and growth retardation, both of which should be addressed prior to transplantation. A recent report of final adult height in pediatric renal transplant recipients suggests that the current improvement in final adult height post-transplantation is more related to improving height deficits prior to transplant than to any net gains achieved after transplantation.[8,9] Uremia also leads to wasting and malnutrition in the child, and this can compromise the success of the procedure. For example, prophylactic native nephrectomy and reversal of protein wasting and malnutrition improves the outcome of transplantation in children with congenital nephrotic syndrome.[50–52] Careful preparation is particularly important in children undergoing preemptive transplants. Although there exist guidelines for the evaluation of the adult transplant recipient,[37,38] there are no similar published reports for pediatric patients. Nonetheless, Table 40–3 details typical preparation utilized prior to surgery for pediatric recipients.

UROLOGIC EVALUATION

Children with the diagnoses described in Table 40–4 require a thorough urologic evaluation prior to transplantation. In the NAPRTCS report 1878 of 7651 (25%) pediatric transplant recipients were identified as having lower urinary tract abnormalities.[13] For all such patients, a history of voiding pattern prior to development of renal failure is most helpful. Preliminary investigations consist of measurement of urinary flow rate and ultrasound estimation of the post micturition urine volume. Urinary flow rate should be at least 15 mL/sec,[53] and the residual volume should be less than 30 mL. Further investigations would consist of urethrocystoscopy in patients suspected of a urethral stricture, and a voiding cystometrogram is essential for complete assessment of bladder function.[54] This provides information about bladder capacity, pressure rise, and the efficiency of voiding. Still more information can be obtained by combining urodynamic studies with radioisotope imaging. Routine voiding cystourethrogram is not indicated in older patients with no symptoms related to the urinary tract.[55]

A bladder with a very small capacity may not be adequate for a functioning transplant. Occasionally, the small capacity bladder may develop in patients with prolonged oligoanuria. However, if the bladder is distensible and the bladder wall compliant, such a bladder may be used safely for kidney transplantation. Other criteria for a usable bladder are an end-filling pressure less than 30 cm of H_2O and a good flow rate. In patients with a poor flow rate, if urethral and bladder outlet obstructions are ruled out, the problem may be due to detrusor malfunction.[53] When a bladder fails to empty completely, infection and obstruction are potential complications that may shorten graft survival. Intermittent, clean, self-catheterization, which is widely used in urologic practice, can be safely used post-transplantation in patients where the primary abnormality is inefficient and uncoordinated detrusor function.

Table 40–4 Possible Lower Urinary Tract Abnormalities of Pediatric Renal Transplant Recipients

Bladder exstrophy
Neuropathic bladder (meningomyelocele, spinal cord trauma, neurological disease)
Posterior urethral valves
Prune belly syndrome
Vesicoureteral reflux

Most pediatric patients have a urinary bladder that will adapt to the new kidney. Although the bladder may not appear to have the capacity, especially in patients on long-term dialysis prior to transplantation, it will most often distend with usage.[46] However, in patients with a truly low capacity or high pressure, bladder augmentation may be necessary prior to transplantation.[56–58] Augmentation cystoplasty consists of adding bowel or gastric wall to the bladder, whereas substitution cystoplasty is performed when most of the bladder is excised and replaced with bowel. Gastric remnants have been popular for augmentation, however, they do tend to cause excessive loss of acid in the urine, leading to discomfort and metabolic alkalosis. Early attempts to reconstruct bladders with bioengineered material are ongoing. There are promising reports of "bioengineered" bladder material, although these have not yet been tried in transplant recipients.[59,60] In those patients in whom augmentation has been performed prior to transplantation, long-term antibiotic therapy and intermittent catheterization may have to be carried out to prevent urine stasis and infection. In a very small subset of patients, whose bladder is unusable and augmentation unsuccessful, some form of urinary diversion may be necessary.[46]

PRETRANSPLANT BLOOD TRANSFUSIONS

In the precyclosporine era blood transfusions were shown to have a beneficial effect on graft outcome,[61] but their effect subsequently diminished,[62] and they are currently rarely utilized. The early beneficial effect of pre-transplant transfusions in children was similar to what was seen in adults. In the past, donor-specific transfusions were also given to children. Early results from such studies suggested better graft survival; however, more prolonged follow-up with improved immunosuppression showed diminished benefit,[63] and the practice of donor-specific transfusions has now been largely abandoned in pediatric renal transplantation. The theoretic advantages of pre-transplant tolerance induction by antigen presentation remain intriguing.[64] Two recent reports of the beneficial effects of deliberate pre-transplant transfusions have reinstated interest in their use.[65,66]

The role of random pre-transplant transfusions in improving graft survival remains unclear. In 1992, the NAPRTCS, in a study of 1667 transplants of which 57% were of CAD origin, did not observe any beneficial or detrimental effect of pre-transplant blood transfusions.[27] However, subsequently, a deleterious effect associated with pre-transplant transfusion became apparent. For LD source transplants the use of five or more prior transfusions was associated with graft loss with a relative risk (RR) of 1.8.[22] By 1995, the use of prior transfusions

was a risk factor for CAD source transplants as well, and the use of five or more transfusions was associated with graft loss with a relative risk of 1.3.[3] The 1996 NAPRTCS report, which analyzed 4714 transplants, shows that greater than five transfusions are associated with graft loss with a relative risk of 1.7 for LD and 1.3 for CAD graft failure.[24] A NAPRTCS special analysis indicated that multiple transfusions have a deleterious effect on graft survival, but fewer then five transfusions may be associated with a decreased incidence of acute rejection episodes.[67] Sixty-five percent of pediatric living donor renal transplant recipients and 56% of cadaver donor recipients now have no random transfusions prior to transplantation, and donor-specific transfusion is rarely performed.[13] Pre-transplant blood transfusions would be of only historical interest except for a renewed interest related to tolerance induction and the recent reports mentioned above.[65,66] Whether they will be utilized in the future for this indication is unknown.

Effect of the Age of the Cadaver Donor

For many years there was a tendency to use kidneys recovered from infants and young children for transplantation into young recipients.[21] Early studies showed that 25% of all cadaver transplants performed in children were recovered from children under 10 years.[27] A special study of the NAPRTCS[68] demonstrated that the preferential placement of small kidneys into infants and very young children had disastrous consequences for graft survival, and this was subsequently confirmed by a larger study.[69] As a result, CAD allocation policies for pediatric recipients were changed resulting in improved outcome.[21] More recent information shows that this practice has now undergone substantial change.[13] Since 1991, less than 1% of cadaver kidneys for pediatric recipients have come from donors younger than 2 years. And, during the same time, the percentage of kidneys recovered from donors over the age of 10 years increased from 78% to 88%. Importantly, the kidneys from young donors have not been discarded but have been utilized for transplantation via the en bloc technique into adult recipients.[26,69,70] Also, single centers have reported better success with young donors, utilizing carefully controlled protocols.[25] Advanced donor age is also associated with diminished long-term graft survival[71,72] and should likely be avoided for young recipients.[68,73,74]

HLA Matching Results in Children

For CAD transplants the NAPRTCS registry indicates that a 2-DR mismatched graft has a relative hazard (RH) of first rejection of 1.27 compared to a 0-DR mismatch, and an RH of graft failure of 1.21 ($p = .002$).[13] These outcomes are consistent with the relationship between histocompatibility matching and graft outcome in adults.[75,76] Unfortunately, since children have waiting-time preference on the CAD waiting list in the United States, HLA-matching for them is generally poorer than for adults.[12] Because most living donors of renal transplants for children are parents, these transplants are mismatched at one haplotype.

ABO BLOOD TYPE IN CHILDREN

NAPRTCS has recorded 27 confirmed kidney transplants across ABO blood group compatibility barriers. Of these, most are

O recipients of A donors. A NAPRTCS special study of 11 of these patients concluded that the procedure could be successful if done under carefully controlled conditions.[77] Evaluation of recipient isohemagglutinin levels may be helpful to identify suitable donor-recipient pairs. A more recent strategy for ABO mismatching entails "donor-swaps," either with a complementary donor-recipient pair or with a CAD waiting list.[78,79]

THE TRANSPLANT PROCEDURE

Technical Issues in Transplantation

The operative technique differs based on the weight of the child. For small children less than 15 kg, the transplant is frequently done through a midline incision and the larger vessels are utilized for anastomosis with the donor kidney (Figure 40–1).[46] After reflection of the cecum and the right colon, the anterior wall of the aorta and the inferior vena cava are exposed and dissected.[80] The aorta is mobilized from above the inferior mesenteric artery to the external iliac artery on the right side. After ligating and dividing the lumbar branches, the iliac arteries and the inferior mesenteric are encircled. Next, the inferior vena cava is mobilized from the left renal vein to the iliac veins. After ligating the lumber veins the iliac veins are encircled. The donor renal vein is anastomosed to the recipient vena cava in an end-to-side technique.[81] The donor renal artery is then anastomosed to the recipient aorta in an end-to-side fashion. Careful attention needs to be paid to the recipient hemodynamic response upon clamping and unclamping of the major vessels, and it is desirable to maintain a central venous pressure of 15 to 18 cm H_2O prior to unclamping.[46,80] The filling of the transplanted kidney may be slow because a large adult kidney will take up
Figure 40–1 ^{99M}Tc-MAG3 radionuclide renal scan in a 9-month-old infant who received an LD renal transplant from his father. The graft is intraperitoneal and occupies most of the right side of the peritoneal space. Note the relative sizes of the graft and the heart.

a significant portion of the normal pediatric blood volume. Recent hemodynamic studies suggest that the cardiac output of infants must double to perfuse the adult donor kidney adequately.[82] Thus, volume replacement is critical. The ureteral anastomosis is done by implanting the donor's ureter into the recipient's bladder using either a Leadbetter-Politano procedure or a modification of it. Many surgeons now prefer a nonrefluxing extravesical rather than transvesical approach for ureteroneocystostomy because it is faster, a separate cystotomy is not required, and less ureteral length is necessary, thus assuring a distal ureteral blood supply.[83–85]

The transplantation technique utilized in children with a body weight greater than 15 kg is similar to that employed in adults. Unlike the transperitoneal approach necessary in younger children, this transplant is extraperitoneal, with the renal vein anastomosed to the common iliac or to the external iliac vein.[80] The arterial anastomosis can be to either the common iliac or to the internal iliac artery. The ureterovesicular anastomosis is done using the techniques described earlier.

Evaluation of Graft Dysfunction

At the completion of the vascular anastomosis and release of the vascular clamps, immediate function of the transplanted kidney is demonstrated by the production of urine. Various causes, however, may prevent initial function, and evaluation of immediate nonfunction and the differential diagnosis of this condition is a critical component of the transplant physician's role.

ACUTE TUBULAR NECROSIS (ATN)

ATN represents the most frequent cause of immediate graft nonfunction. Data from the NAPRTCS 1996 Annual Report showed that ATN was observed in 5% of LD and 19% of CAD transplants.[24] Since the NAPRTCS definition for ATN is stringent, requiring dialysis in the first post-transplant week, these figures probably underrepresent the actual incidence of ATN. The risk of early ATN in LD kidneys is related to factors such as prior transplants and more than five transfusions. Similarly, the risk factors of ATN in CAD kidneys include prolonged cold ischemia, absence of prophylactic antibody therapy, and the use of more than five blood transfusions. The diagnosis is confirmed in most cases by the use of radionuclide scan (Figure 40–2). If recovery of graft function is delayed, however, a transplant biopsy may be necessary because other diagnostic tests cannot distinguish between ATN and rejection.[86,87] Importantly, early acute rejection can mimic ATN or coexist with it. The presence of ATN does not auger well for the transplant, particularly for those of cadaver source because graft failure and death are more common among patients with ATN.[48] The NAPRTCS data show that 71% of CAD grafts without ATN were functioning at 4 years compared to only 51% of those with ATN.[88]

GRAFT THROMBOSIS

Graft thrombosis is an important complication of pediatric transplantation. Although usually a major cause of immedi-
Figure 40–2 99MTc-MAG3 radionuclide renal scan of a CAD renal transplant in a 15-year-old boy performed on the first post-op day. The cold ischemia time exceeded 24 hours, and the recipient experienced oliguric ATN. Note the good perfusion, followed by little excretion and "wash out" of the tracer from the graft.
Figure 40–3 99MTc-MAG3 radionuclide renal scan in a 6-year-old girl with FSGS who received an LD renal transplant, performed 16 hours post-operatively. Note the photopenic area in the right abdomen, indicating thrombosis of the graft with no perfusion.

ate graft nonfunction, it can be seen later in the course and has been recorded to occur as late as 15 days post-transplant following initial engraftment and function. Graft thrombosis has been the third most common cause of graft failure in pediatric renal transplantation[13] and may rise to second if acute rejection rates continue to fall.[89] The critical nature of this complication can be appreciated because it accounts for 11% of graft failure in index transplantation and 13% in repeat transplants in the NAPRTCS registry. A dreaded event, this condition is irreversible in most cases and necessitates removal of the graft. Graft thrombosis should be suspected in cases where there has been immediate function followed by the development of oligoanuria. The diagnosis is established by a radionuclide scan using diethylenetriamine pentaacetic acid (DTPA) or MAG3,[90] which reveals a photopenic defect with no uptake by the transplant kidney (Figure 40–3).

Because the outcome of graft thrombosis is uniformly dismal, numerous studies have been conducted in an attempt to understand and anticipate this complication. The etiology of graft thrombosis is multifactorial, but it is more commonly seen in young recipients.[91] In a special study of 2060 LD and 2334 CAD kidneys,[92] the NAPRTCS has shown that a history of prior transplantation increases the risk, whereas increasing recipient age has a protective effect for LD kidneys. The prophylactic use of antilymphocyte antibody also decreases the risk, and this may be particularly true for the monoclonal IL2r antibodies.[89] For cadaver source kidneys, a cold ischemia time longer than 24 hours increases the risk of thrombosis. The use of antibody induction therapy, the use of donors greater than 5 years of age, and increasing recipient age were factors that decreased the risk of thrombosis. A heightened thrombotic state has also been implicated.[90,93,94] One study showed that centers that performed fewer infant transplants had higher rates of graft thrombosis,[95] and another suggested that pre-transplant use of peritoneal dial-

ysis increased the risk of thrombosis.[96,97] Some centers routinely administer anticoagulants to pediatric recipients at high risk of graft thrombosis, but no clinical studies of their effectiveness have been performed, and its use is not without complications.[98] This incidence of graft thrombosis has not changed over the past 15 years[13]; however, a preliminary report suggests that a new approach to induction therapy may have been associated with a decrease.[89]

OBSTRUCTION AND URINARY LEAK

An uncommon but correctable cause of immediate graft dysfunction is obstruction of the urinary flow, which presents as decreasing urine output and the development of hydronephrosis. An ultrasound or radionuclide scan with a furosemide washout enables the clinician to establish this diagnosis. Obstruction can be due to kinking of the ureter, to edema or blockage of the implantation site of the ureter, or to development of a lymphocele. A more ominous cause of immediate nonfunction is the rare case of urinary leak due to disintegration of the distal ureter or rupture of the bladder. This condition can be painful due to the extravasation of urine into the pelvis or peritoneal cavity and is established by radionuclide scan (Figure 40–4). The appearance of the tracer in the peritoneal cavity or in the scrotal, vulval, or inguinal area clinches the diagnosis and immediate surgical correction is necessary.

Induction Therapy
IL-2 Receptor Antibodies

There are two two high-affinity chimeric or humanized antibodies that act on the inducible α-chain of the interleukin-2
Figure 40–4 ^{99M}Tc-MAG3 radionuclide renal scan in an 8-year-old girl who received a CAD renal transplant, performed 12 hours post-operatively. Note the good perfusion of the graft and the rapid concentration and excretion from the kidney. Tracer, however, rapidly accumulates in the right lower quadrant, outside of the bladder. Investigation demonstrated a traumatic bladder rupture.

receptor (IL-2r) on the surface of the activated lymphocyte, basiliximab (Simulect, Novartis) and daclizumab (Zenapax, Roche). Basiliximab is generally given as two-dose regimen (generally 10 mg for children <40 kg and 20 mg for those >40 kg) on days 0 and 4 post-transplantation.[99] A pharmacologic study showed that basiliximab clearance in children is reduced by approximately half compared with adults and was independent of age, weight, or body surface area.[100] One study has noted that pediatric recipients receiving basiliximab may have significantly elevated levels of cyclosporine and may require reduced doses to avoid toxicity.[101] Daclizumab is generally given in a dose of 1 mg/kg intravenously on the day of transplantation and every 14 days thereafter for a total of five doses.[102] Higher doses may be required for saturation of IL-2 receptors in younger children.[6] Both antibodies are generally well tolerated without substantial side effects. Both antibodies have been studied extensively in children and have been shown to be safe and effective.[6,99,101,103–105] The precise mechanism of the antibodies is not known but is presumed to be saturation of the IL-2 receptor and subsequent competitive antagonism of IL-2-dependent proliferation. A novel 6-month dosing schedule of daclizumab has been reported as part of a steroid-avoidance pilot study and appears to be well tolerated.[6] There are no comparative studies between the two antibodies. Up to 65% of pediatric renal transplant recipients are now receiving an IL-2 receptor antibody as induction therapy.[13]

T-CELL ANTIBODIES

Retrospective data from the NAPRTCS do show a beneficial effect of prophylactic anti–T-cell antibody. In a review of LD transplants, 5-year graft survival was 81% in 1041 patients who received T-cell antibody therapy compared with 75% in 1399 patients who did not. Similar figures for CAD kidneys were 66% in 1423 T-cell antibody treated patients, compared to 56% in 1034 patients who did not receive T-cell antibody.[24]

A major problem of these analyses is that several different types of T-cell antibody were used. In the early years a polyclonal antibody was used, the most common of which was prepared from horse serum and designated as MALG (Minnesota antilymphocyte globulin).[106] A monoclonal antibody directed at subsets of T cells, called OKT3, was subsequently employed.[107]

Two polyclonal antibodies currently available are Atgam (Upjohn), and Thymoglobulin (Sangstat). Atgam, because of the sclerosing nature of the preparation, is given intravenously through a central catheter for 10 to 15 days. The dose used is 15 mg/kg, and calcineurin inhibitors are generally withheld during the administration of the antibody. Thymoglobulin is provided through a peripheral vein at a dose of 1.5 to 2 mg/kg/dose. A recent report suggests daily monitoring of CD3+ subsets to guide therapy: the daily dose is given only when the CD3+ count exceeds 20 cells/mm^3.[108] Thymoglobulin has been studied in small groups of pediatric renal transplant recipients and was found to be effective.[109] Comparison of efficacy of removal of circulating T cells suggested that thymoglobulin may have some benefit over Atgam,[110] but no comparisons of clinical outcomes have been performed. The monoclonal antibody, OKT3, is administered as a bolus injection into a peripheral vein daily for 10 to 14 days at a dose of 5 mg for older children and 2.5 mg for children weighing less than 30 kg. Calcineurin inhibitors are also withheld during the use of OKT3. The major problem with these induction therapies include the "first-dose reaction"[111,112]; neurologic problems,[113] and the potential for the development of superimposed infections, such as cytomegalovirus (CMV) or Epstein-Barr virus (EBV) disease. Although retrospective analysis of pediatric kidney transplantation continues to show a clear benefit to the use of prophylactic induction antibody,[13] a recent prospective randomized trial of OKT3 induction showed no clear advantage.[114] Currently, less than 10% of pediatric renal transplant recipients receive an anti–T-cell antibody for induction therapy.[13] Depleting T-cell antibodies, such as Campath, have not yet been evaluated systematically in children.

OTHER INDUCTION

If T-cell antibody is not chosen for induction therapy, one of the calcineurin inhibitors may instead be used. Currently, there are two such drugs, cyclosporine and tacrolimus, which have similar mechanisms but act at different sites to inhibit calcineurin. A possible complication of this type of induction, particularly if it is given intravenously, is delayed graft function.[115,116] The most recent NAPRTCS data show that about 35% of children receive no induction antibody.[13]

Maintenance Immunosuppression

Cyclosporine

Cyclosporine was first used in renal transplantation by Calne[117] in 1978. The initial experience was followed by controlled trials in the United States, Canada, and Europe, all of which showed a significant improvement in graft survival over existing therapies. The drug was licensed in the United States in 1983 and has been used in all types of solid organ transplantation for over 20 years. There have been no controlled trials in children, but over the years of use a large body of information regarding its dosing and side effects has accumulated.[13]

Induction Dose

For induction purposes cyclosporine is given intravenously in a dose of 165 mg/m^2 daily for children under 6 years of age and 4.5 mg/kg daily in children over 6 years. The dose for younger children is calculated in square meter format because they metabolize the drug differently. The drug is preferably given in a continuous infusion over a 24-hour period starting intraoperatively. If practicality precludes a continuous infusion, the drug should be administered in three divided doses daily but over as long an interval as possible. If possible, induction therapy using cyclosporine should be continued for 48 hours only and then converted to oral cyclosporine. The recommended starting oral dose for children under the age of 6 years is 500 mg/m^2 daily, administered in three divided doses; for children over the age of 6 years, it is 15 mg/kg daily, administered in two divided doses. These doses are higher than those prescribed for adults because experience over the last 10 years has determined that the drug is metabolized more rapidly in children.[118] A calcium channel blocker is typically given with cyclosporine to reduce toxicity.[119]

Maintenance Dose

Because of its irregular absorption and inherent nephrotoxicity, dose adjustments of cyclosporine are constantly necessary.[120] Data from the NAPRTCS show that at 1 year post-transplant the mean cyclosporine dose can vary from 5.6 mg/kg to 8 mg/kg.[24] It has also been demonstrated that higher maintenance doses are associated with diminished chronic graft rejection.[118] Among cadaver kidney recipients the rate of rejection was 16% in those receiving doses higher than 8 mg/kg at 1 year post-transplant, compared to 24% in those receiving less than 6 mg/kg daily.[121] The difficulty of maintaining constant dosing has led to several methods of measuring cyclosporine blood levels.[116] Either high-pressure liquid chromatography (HPLC) or fluorescence polarization immunoassay (FPIA) techniques are used. Drug adequacy is considered to be a range of 100 to 200 ng/mL HPLC whole blood trough level or 200 to 450 ng/mL TDX whole blood levels for patients more than 3 months post-transplant. Higher levels are necessary in the first 3 months. Newer data suggest that measuring the level 2 hours after receiving the dose may lead to more accurate dosing, assessing the true area under the curve, and avoiding toxicity.[122–124]

Side Effects

Treatment with cyclosporine is associated with nephrotoxicity, hypertension, and hepatotoxicity. A major concern in children is the hypertrichosis and the facial dysmorphism.[125] Hyperkalemia is common in patients on cyclosporine[126] and also responds to dose reduction. The mechanism is possibly due to diminished tubular excretion. Renal handling of uric acid is also altered, leading to hyperuricemia.[127] Hypomagnesemia is also observed as a result of altered tubular function.[128] Tremors, convulsions, and parasthesias have been recorded in patients on cyclosporine.[129] These side effects may be multidrug induced rather than from cyclosporine alone; however, they are often seen with high blood levels. Both hypertension and hyperlipidemia are observed in patients on cyclosporine. A worrisome side effect in children is gingival hypertrophy,[130] seen more often with higher doses and in the presence of poor dental hygiene.[131] The most recent data from the NAPRTCS registry show that slightly less that 50% of renal transplant recipients are currently receiving cyclosporine as initial immunosuppression.[13]

Tacrolimus

Tacrolimus (Prograft, Fujisawa) was introduced as an immunosuppressant for kidney transplantation in the mid-1990s.[132–134] Recent data from the NAPRTCS show that slightly less than 50% of children are being maintained on tacrolimus at 31 days post-transplantation.[13]

Dosage

One method of initiation of tacrolimus is to provide 0.1 mg/kg/24 hr as a continuous infusion, with a switch to oral therapy within 2 to 3 days. However, because of the good absorption of the oral preparation and the concern about nephrotoxicity, many programs begin treatment via oral or NG tube very early post-transplant. Initial oral doses should not exceed 0.15 mg/kg twice daily and should be reduced to 0.1 mg/kg as maintenance dose. Blood monitoring is necessary as with cyclosporine, and target whole blood trough levels, measured by an enzyme linked immunosorbent assay (ELISA), should be maintained between 5 to 20 µGm/L. Diarrhea, which is common, particularly in infants, may lead to increased tacrolimus levels.[135]

Side Effects

Because of the similar mechanism of action, virtually all of the side effects of cyclosporine therapy are also seen with tacrolimus.[133] The nephrotoxic effect is similar.[136] The hypertrichosis and the dysmorphic features noted with cyclosporine are not seen with tacrolimus.[137] Neurologic side effects are common and may be seen more frequently than with cyclosporine.[138,139] A concern for the use of tacrolimus in pediatric renal transplantation was the development of post-transplant diabetes mellitus (PTDM), because in an early

Japanese renal study a third of the patients developed hyperglycemia requiring insulin therapy,[140] which has also been reported from other single center reports.[141,142] The mechanism may be related to a diminished insulin secretion in association with the insulin resistance related to steroid use.[143] The incidence of post-transplant lymphoproliferative disorder (PTLD) was much higher with the use of tacrolimus than with other immunosuppressants during early experience.[134,144] However, a more recent retrospective analysis showed that the use of tacrolimus was not a risk factor for development of PTLD, likely due to the lower doses currently utilized.[145]

Choice of Calcineurin Inhibitor

Calcineurin inhibitors have been mainstays of immunosuppression for pediatric transplantation for the past decade and likely account for the continuing improvement in graft survival rates.[12,146,147] The choice between the drugs has often been based on a center preference. An open-label randomized trial of the two drugs with steroids and azathioprine was recently completed.[148] Tacrolimus-treated patients had a lower rate of acute rejection (37%) than cyclosporine-treated patients (59%), although both rates were higher than current standards,[13] and not all episodes were biopsy-proven. One-year graft survival rates were similar, although the glomerular filtration rate (GFR) was higher in the tacrolimus group. Hypomagnesemia, diarrhea, and PTDM were higher in the tacrolimus group, and hypertrichosis and gum hyperplasia were higher in the cyclosporine group. In a retrospective analysis of NAPRTCS data of the two drugs given with MMF and steroids,[137] there was no difference in early rejection rate (29%), risk of rejection, or risk of graft loss. At 2 years, graft survival was not different (tacrolimus 91%, cyclosporine 95%). Tacrolimus-treated patients were less likely to require antihypertensives and had higher GFR at 2 years.

Azathioprine

For pediatric patients azathioprine is given in the dose of 1 to 2 mg/kg/day. Higher doses should be closely monitored for myelosuppression. In the early years of transplantation azathioprine was routinely used in all transplant recipients; when cyclosporine became available it was still widely used as an adjunct drug. In 1989 and 1990, 80% of pediatric patients in the NAPRTCS registry were receiving azathioprine, but as more familiarity is established with mycophenylate mofetil (MMF) the use of azathioprine has diminished substantially and is currently in less than 10% of patients.[13]

Mycophenylate Mofetil (MMF)

As of 1996 the NAPRTCS registry noted that only 6.5% of patients were being maintained on MMF,[24] but the most recent figures show that it is used in about two thirds of pediatric kidney transplant recipients.[13] There are mixed results concerning its advantages over azathioprine.[149–152] A well-controlled study, however, concluded that it was safe and effective for use in pediatric renal transplantation.[153] A major difficulty in widespread use of the drug in children has been the gastrointestinal disturbance, especially in young children.[154] Both nausea and vomiting are common, but in some patients the drug has to be withdrawn due to intolerable diarrhea. Current recommended dose of MMF for pediatric patients is 1200 mg/m^2/day, divided into two, three, or four doses.[155] It is likely that therapeutic monitoring should be employed, but clear standards are not yet available to guide treatment.[156–161]

Corticosteroids

The NAPRTCS reports show that 96% of children with a functioning graft are maintained on prednisone.[24] The numerous mechanisms of action of steroids lead to side effects and toxicities. The important concern in children is growth retardation. Studies have shown that doses in excess of 8.5 mg/day will impair normal growth.[162] Other side effects include increased susceptibility to infection, impaired wound healing, aseptic necrosis of the bone, cataracts, glucose intolerance, hypertension, cushingoid facies, and acne.[163] The preparations commonly used are prednisolone, its 11-keto metabolite prednisone, and methylprednisone. Although the half-lives of these preparations are very short, they can be administered once daily because their effect on inhibition of lymphocyte production persists for 24 hours.[164] The dosage is usually high in the immediate post-transplant period, about 2 mg/kg/day, with a gradual reduction to approximately 0.2 to 0.3 mg/kg/day within a 6-month to 1-year period. Because of the multiple side effects of maintenance steroid therapy, attempts have been made to withdraw steroids altogether, reported both in adult and pediatric kidney transplantation.[165] Unfortunately, the majority of these attempts have failed because of the development of acute rejection episodes.[166–168] The use of alternate-day steroid therapy, which appears to reduce the growth inhibiting effect without unduly increasing rejection episodes,[169,170] seems reasonable, but only a minority of pediatric renal transplant recipients is receiving steroids in that manner.[13] Several ongoing studies are investigating the use of steroid avoidance or steroid withdrawal protocols, and it is likely that steroids will not be used for immunosuppression in the future.

Sirolimus

Sirolimus (Sirolimus, Rapamune [Wyeth]) is the newest immunosuppressive agent used for kidney transplantation. It is the product of a fungus that was discovered on Easter Island (Rapa Nui) in 1969. It was first investigated for antifungal properties, and its immunosuppressant properties were first discovered in 1988. It was approved by the FDA in 1999. A similar compound that may be an analogue, SDZ-RAD, is currently undergoing clinical trials. Rapamycin is classified as a TOR inhibitor. TOR is a cytosolic enzyme that regulates differentiation and proliferation of lymphocytes. Then TOR is activated as a result of the cascade of reactions in lymphocytes by the proliferation of cytokines, and it initiates production of messenger RNAs that trigger cell-cycle progression from G_1 to S phase. The TOR inhibitors bind to the immunophilin FKBP12 and inhibit the actions of TOR.[171–176] The TOR inhibitors may be particularly important in long-term immunosuppression because they stimulate T-cell apoptosis. TOR-inhibitors also inhibit mesenchymal proliferation, which may prove to be important in graft vascular

disease.[177,178] Also, since the mechanism of action of sirolimus is different from other currently available immunosuppressants, it can be used in combination with all of them. Sirolimus has been found to be effective in combination with calcineurin inhibitors,[179–183] in a calcineurin-inhibitor sparing protocol,[184] and in a steroid-free protocol.[185] The role of sirolimus or SDZ-RAD in pediatric transplantation is undergoing study.[34,186,187]

Dosage

Sirolimus is available as an oral preparation, either as a solid or liquid. Sirolimus was shown to have a prolonged half-life in adults that allowed a single daily dose in adults.[181–183] However, pharmacokinetic studies in children have demonstrated a much shorter half-life, as short as 12 hours.[34,188] Thus, children may require twice-per-day schedules to maintain therapeutic levels. Retrospective analysis of early trials of sirolimus have suggested a relationship between blood levels and risk of rejection.[189] Current suggestions for therapeutic levels remain speculative and range between 25 ng/mL in the early posttransplant period without calcineurin inhibitors[34,184] and 5 to 10 ng/mL later in the course of transplantation.

Side Effects

Sirolimus's major side effects are hyperlipidemia, thrombocytopenia, leucopenia, and possibly delayed wound healing.[181] The former complications can respond to lipid lowering drugs or dose reduction. The latter complication may require suspension of the drug until the wound heals completely.

Maintenance Immunosuppression Combinations

Most pediatric renal transplant recipients are treated with triple immunosuppression.[13] When the number of drugs was limited, the number of possible combinations was small. However, there are at least 20 possible combinations of the 6 available drugs, and when the induction antibodies are added, there are over 60 possible reported protocols.[190] No "best" protocol for children has been established, although most clinical trials are currently directed at eliminating either steroids or calcineurin inhibitors, or both. Currently, most children are receiving prednisone, MMF, and cyclosporine or tacrolinus after kidney transplantation.[13]

There are many possible targets for immunosuppression strategies for children.[191] One promising new protocol of steroid avoidance has been recently reported.[6] This approach consists of 6 months of anti-IL2r antibody, tacrolimus, and MMF. Short-term patient and graft survival rates have been excellent, and growth rates have been very good. Major complications have included bone-marrow suppression and nephrotoxicity. Other protocols currently under investigation include calcineurin inhibitor avoidance or withdrawal and costimulation blockade with the eventual goal of avoiding both corticosteroids and calcineurin inhibitors.

ALLOGRAFT REJECTION

In the absence of tolerance the renal allograft is destined for loss by some form of rejection. Rejections are classified as hyperacute (occurring immediately upon grafting), accelerated acute (occurring within the first week after transplantation), acute (generally occurring within the first year of transplantation), late acute (occurring after the first year), and chronic, for which the time sequence is difficult to establish because it may occur as early as 3 months but generally occurs years later in the course of the transplant.

Hyperacute Rejection

Hyperacute rejection is the result of specific recurrent antidonor antibodies against HLA, ABO, or other antigens.[192] Irreversible rapid destruction of the graft occurs. Histologically there is glomerular thrombosis, fibrinoid necrosis, and polymorphonuclear leukocyte infiltration. In the early years of transplantation, when the HLA matching techniques were not well developed, hyperacute rejection was more common. In most centers, it occurs very rarely. The latest data from the NAPRTCS show the incidence of hyperacute rejection to be less than 0.25% (17 cases) over the last 15 years. The only treatment is surgical removal of the allograft.

Acute Rejection

Information regarding the incidence and outcome of acute rejection in pediatric renal transplantation is available from the NAPRTCS data. Because NAPRTCS receives data from multiple sites that utilize many different diagnostic and treatment protocols, the definition of a rejection episode is based upon the circumstance of a patient having been treated with anti-rejection therapy, although biopsy confirmation is becoming more common. In a review of 8777 rejection episodes over a 15-year study, there were, on average, 0.89 rejection episodes for each LD transplant and 1.23 for each CAD transplant. A remarkable decrease in the incidence of acute rejection has occurred over the past 15 years (Table 40–5). In a study of two cohorts of pediatric renal transplant recipient (1469 in 1987–1989; 1189 in 1997–1999), the rejection ratios dropped from 1.6 to 0.7 per patient.[193] Sixty percent of the latter group were rejection-free compared to 29% of the former, and 1-year graft survival was 94% compared to 80%. Historically, over half of the patients experienced a rejection in the first post-transplant weeks, now the majority experiences a rejection-free first year. Risk factors for cadaver source transplants include the absence of prophylactic T-cell antibody therapy, donor age less than 5 years, black race, and no DR matches. Risk factors for living-related source transplants are the absence of T-cell antibody and one or two DR mismatches, black race, and ATN. In an earlier study the NAPRTCS noted that when reviewed by age groupings, rejection

Table 40–5 12-Month Probability (%) of First Rejection, by Transplant Year

Transplant Year	Living Donor		Cadaver Donor	
	%	SE	%	SE
1987-1990	54.2	1.7	69.2	1.4
1991-1994	45.2	1.5	60.8	1.6
1995-1998	34.0	1.4	41.0	1.7

ratios, time to first rejection, and the mean number of rejection episodes were not different; however, for the initial rejection episode, recipients less than 6 years of age had significantly increased irreversible rejections leading to graft loss.[23] There are conflicting data about whether infants and small children have a "heightened" immune response and an increased incidence of acute rejection episodes. Indirect evidence suggested a more vigorous immune response, especially in infants.[194] Also, data from the UNOS registry demonstrated a higher rate of acute rejections in young children after both living donor and cadaver donor transplantation, although adolescents were noted to have a higher rate of late acute rejections.[14] On the other hand, data from surveillance transplant biopsies suggest equivalent rejection responses in all groups.[31] Data from one large pediatric transplant program demonstrated that infants have a lower rate of acute rejection than older children.[33] A recent SRTR report demonstrated that infants and young children now have the best outcomes of all age groups.[12] Thus, either the proposed heightened immune response has been overcome by improved immunosuppression or the cause of previously poor outcome was related to other factors.

Diagnosis of Acute Rejection

Rejection is suspected when there is decreasing urinary outflow and a rising serum creatinine. In the past, classic signs of acute rejection included fever and graft tenderness. Under calcineurin inhibitors and prophylactic antibody therapy, however, these signs are rarely seen; thus, early evidence of graft dysfunction even without other signs, should initiate concern. The differential diagnosis consists of ureteral obstruction, renal artery stenosis, urinary leak, and an infectious process. When rejection is suspected, a urinalysis and urine culture should be performed to assess the possibility of infection. The urinalysis is also helpful if it suggests intragraft inflammation or an acute immune response as evidenced by proteinuria and the presence of leukocytes and other cells in the sediment. Blood or urinary cytokine analysis may also be useful for diagnosing rejection,[195,196] and examination of the sediment may be useful in detecting other reasons for graft dysfunction. An ultrasound is performed to rule out anatomic obstruction. Obstruction can be the result of perirenal fluid collection, a large lymphocele, hematoma, or rarely, an abscess. The ultrasound can also provide information about intragraft blood flow and pressure.[86] A radionuclide renal scan, using a tracer such as MAG 3, is a very helpful tool in establishing some diagnoses (Figures 40–2 to 40–4).[197] Rejection is suggested by rapid uptake of the tracer by the kidney but a delayed excretion. Unfortunately, radionuclide scans cannot distinguish among various causes of intragraft dysfunction, such as rejection, cyclosporine toxicity, and ATN. Thus, a definitive diagnosis of rejection requires a transplant biopsy.

Renal Transplant Biopsy

The renal transplant biopsy procedure is very easy and safe when conscious sedation and ultrasound guidance are utilized. Recent data evaluating over 150 pediatric renal transplant biopsies, including some in intraperitoneal kidneys and many perfomed during the first week post-transplantation, have demonstrated a very low risk.[87] One factor in reducing post-biopsy bleeding is the use of an automated biopsy "guns" using a small (18-gauge) rather than the standard (15-gauge) needle. Biopsies should be performed in pediatric renal transplant recipients whenever the diagnosis of rejection is in doubt.

Treatment of Acute Rejection

Standard treatment of an episode of acute rejection is intravenous methylprednisolone in a single daily dose of 20 to 25 mg/kg (maximum dose: 0.5 to 1 g), for 3 consecutive days. Most grades I and II rejections will respond to steroid therapy. Steroid resistant rejection episodes are treated with T-cell antibody, either the monoclonal OKT3 or the polyclonal antithymocyte globulin (Atgam or Thymoglobulin). OKT3 is administered in the dose of 2.5 mg for children with a body weight of 30 kg and 5 mg for children over 30 kg for 10 to 14 days. Atgam is given in the dose of 15 mg/kg, through a central venous catheter, for 10 to 14 days, depending upon the white cell and platelet count, because it will frequently deplete all formed elements in the blood system. It is advisable to maintain the white blood cell count above $2000/mm^3$ and the platelet count above $20,000/mm^3$. Thymoglobulin is given in a dose of 1.5 to 2 mg/kg/dose for a total of 10 to 14 days. It may be advisable to monitor CD3+ cells during treatment and restrict the frequency of dosing to days only when the count is greater than 20 cells/mm^3.[108] All antibodies have several side effects. Of concern are the first dose symptoms of OKT3 due to cytokine release.[111,112] This is clinically observed as fever with chills and, rarely, as pulmonary edema. Antipyretics, such as acetaminophen, should be given every 4 hours, and the administration of the antibody should be preceded by a bolus dose of 500 mg of methylprednisolone 1 hour prior to administration. Respiratory compromise, in the form of fluid extravasating into the pulmonary capillary bed, is seen only in patients with fluid overload. Fluid removal by dialysis should be considered prior to the administration of OKT3 in patients whose body weight exceeds 5% of their baseline. Precaution against the potential anaphylactic reaction related to polyclonal antibodies consists of using 500 mg of methylprednisone with the infusion of the antibody and administration of an antihistamine, such as diphenhydramine (Benadryl), 30 minutes prior to drug administration.

Reversibility of Acute Rejection

NAPRTCS data observe that among LD kidneys, 55% of rejection episodes are completely reversed, 40% are partially reversed, and 5% end in graft failure. Similar figures for CAD kidneys are 48%, 45%, and 7%, respectively.[24] When stratified by age, young transplant recipients have irreversible rejection episodes more frequently. Ten percent of acute rejections among infants receiving a LD kidney end in graft failure, compared to 4% for older children. For CAD kidneys the rate of graft failure in infants is 15%, compared to 7% for older children. Despite decreasing rejection frequency, complete reversal for pediatric living donor recipients seems to be improving in later cohort years. Molecular or genomic characterization of rejection biopsies may be helpful in describing different types of acute rejection.[195,196,198–200]

Rescue Therapy

In those patients in whom neither steroids nor antibody therapy have successfully reversed a rejection episode conversion to an alternative calcineurin inhibitor or to other immunosuppressants would appear to be warranted. There have been

no controlled studies to document reversal of rejection with conversion to tacrolimus; however, anecdotal reports do suggest that in some cases conversion does help to stabilize graft function.[133,134,168]

Chronic Rejection

The gradation from acute to chronic rejection is gradual; however, many biopsies may show features of both, and some characteristic vascular changes of chronic rejection may be seen as early as 10 days post-transplant.[201] The clinical picture is that of gradually declining renal function together with varying degrees of proteinuria and hypertension. The clinical condition may also be referred to as *transplant glomerulopathy*. An ongoing controversy exists as to whether the changes seen in chronic rejection are immune mediated, ischemic in nature, or nonimmunologic injury due to hyperfiltration.[202,203] Data in children have shown clearly that acute rejection is a predictor of chronic rejection.[146] In a study of 1699 LD and 1795 CAD patients, the NAPRTCS noted that acute rejection was a relative risk (RR) factor for chronic rejection (RR = 3.1), and multiple acute rejections increased the RR to 4.3. Late acute rejections are also clinical correlates of chronic rejection.[204] Even if acute rejection is the most critical element in the genesis of chronic rejection, other immune mechanisms may mediate its progression. One possible explanation would be that in patients who go on to develop chronic rejection, the immune mediators of acute rejection, such as granzyme B, perforin and Fas ligand, are expressed in a more robust fashion and are quantitatively different from the responses of an acute rejection that does not lead to chronic rejection. Alternatively, the immune mediators of chronic rejection may be qualitatively different from those associated with an acute episode. For example, the multifunctional cytokine TGF-β1, which has fibrogenic properties, is present in biopsy tissue of patients with chronic rejection.[205] Identification of the mechanism of initiation or progression of chronic rejection will be vital to any attempts to control it.

Management of Chronic Rejection

Symptomatic therapy is currently the only available method of dealing with chronic rejection. Hypertension should be controlled, and the proteinuria may occasionally respond to ACE inhibitors; however, renal function will continue to decline. In children, chronic rejection produces an additional burden because decreased renal function will result in deceleration of growth.[206,207] It is in this context that prevention of chronic rejection by early aggressive therapy in patients who have had an episode of acute rejection may be rewarding. Because currently available immunosuppressive medications have been unsuccessful in preventing or slowing the progression of chronic rejection, the use of immunosuppressives, other than those currently approved, may be reasonable.

GRAFT SURVIVAL

Pediatric renal centers reporting graft survival show varying results. Because the number of patients at any one center is small, such data cannot represent the pediatric transplant population at large. Furthermore, multiple factors affect graft survival, such as donor and recipient age, histocompatibility matching, recipient race, and so forth. Thus, there cannot be accurate descriptions of graft survival rates without classification of the important variables. To obtain a proper population mix representing gender, age, and racial diversity, the NAPRTCS annual reports have been used.[13]

A total of 2201 graft failures occurred from 8399 (26%) transplants. Of index transplants 1924 of 7651 (23%) failed, whereas 277 of 748 (37%) subsequent transplants had graft failure. Of the failures, 1648 (75%) were returned to dialysis, and 132 (6%) were retransplanted at the time of failure. Table 40–6

provides the distribution of causes of graft failure. With increased length of follow-up, chronic rejection continues to increase in importance. It is now the most common cause of graft failure. Overall, 47% of graft failures are caused by rejection with chronic rejection accounting for 33% and acute rejection accounting for 14%. Recurrence of original disease as a cause of graft failure was observed 146 times (focal segmental glomerulosclerosis, 66; membranoproliferative glomerulonephritis type II, 13; oxalosis, 10; hemolytic uremic syndrome, 16; chronic glomerulonephritis, 6; and others, 35). Vascular thrombosis remains a major cause of failure, and 204 graft failures were attributed to primary nonfunction, vascular thrombosis, or miscellaneous technical causes. These data show that such problems occur in 3.8% of pediatric transplants.[91–93,95–97,208]

Overall 5-year graft survival curves by donor source are shown in Figure 40–5. Current graft survival for index transplants at 1, 3, and 5 years for LD kidneys is 95%, 90%, and 83%, respectively, and for CAD kidneys it is 91%, 82%, and 73%, which are substantially better than previous results (Table 40–7). Table 40–8 shows relative hazards for graft failure for selected transplant characteristics for both LD and CAD kidneys. Five-year graft survival rates by selected variables for LD grafts are shown in Figure 40–6, and for CAD grafts survival rates are shown in Figure 40–7. An important trend in improved graft survival in pediatric LD and CAD renal transplant outcome has been reported,[12,121] and the most recent data are shown in Figures 40–8 and 40–9.

Registry based graft survival data can be used to establish risk factors. Relative risks of graft failure are derived using Cox proportional hazards regression models. For LD kidneys the

risk factors for graft failure include blacks (RH = 1.88), more than five prior transfusions (RH = 1.41), and absence of HLA-B matches (RH = 1.39) (Table 40–8). No induction antibody is also a risk factor (1.13), as is transplant era (0.95).[13] A similar risk factor analysis for CAD kidneys has been reported,[13,24,209] and the most recent data are presented in Table 40–8. The risk factors are similar to those seen with LD grafts with additional hazards, such as young recipient age (RH = 1.80), young donor age, and prolonged cold ischemia time (RH = 1.20). Some factors that increase the relative risk of cadaver graft failure in children, such as recipient age, are integral to pediatrics. Other factors, such as recipient race, the degree of HLA matching, and prior transplantation, cannot be easily altered. Improvement in cadaver allograft survival rates, however, can be achieved by judicious choice of donors, pre-transplant management, changes of induction therapy, and optimal immunosuppressive therapy.[23]

Another measure of long-term graft function is the calculation of graft half-life. A recent analysis of 8922 pediatric and 78,418 adult renal transplants demonstrated superior long-term graft function in young pediatric recipients.[14] Infants (ages 0–2) had the worst 1-year graft survival rates (71%) compared to children (ages 3–12) (83%), adolescents (ages 13–21) (85%), and adults (86%). However, for all grafts that survived at least 1 year, infants had the longest projected half-life (18 years), compared to children (11 years), adolescents (7 years), and adults (11 years). A similar analysis of UNOS data showed that young recipients who received adult donor kidneys and had immediate graft function had projected half-lives greater than 25 years, better than even HLA-identical adult donor-recipient pairs.[210]

The primary disease causing ESRD can have an effect on graft survival. Children with oxalosis used to have very bad outcomes, to the extent that the diagnosis was considered a contraindication to transplantation. However, improvements in outcome related to combined liver-kidney transplantation have been encouraging.[29,47–49] Similarly, infants with congenital nephrotic syndrome often had very poor outcomes,[48,211] but strategies designed to reduce the risk of thrombosis and to improve nutrition pre-transplantation have led to marked improvements.[50–52,94] Focal segmental glomerulosclerosis (FSGS) can be a devastating disease that recurs very quickly following renal transplantation, sometimes as early as the first post-transplant day.[211–215] Although recurrence is no more frequent in LD transplants, the graft survival advantage of LD transplantation is lost for children with FSGS.[216] Little is known about the pathophysiology of the disorder or the cause for recurrence.[217,218] There are sev-

eral proposed approaches to preventing or treating recurrence, mostly involving enhanced immunosuppression with plasmapheresis.[215,219–224] Lupus nephritis surprisingly does not recur following renal transplantation to any great extent. Patients with lupus have similar outcomes compared to other patients,[225,226] except for a slight increase in mortality,[226] an increase in incidence of recurrent rejections, and a slight tendency to graft failure in those patients receiving CAD grafts following peritoneal dialysis.[225] Children with sickle cell disease and ESRD can receive kidney transplants successfully,[227] as can those with Down syndrome.[228,229] Hemolytic uremic syndrome (HUS) has been variably described as likely to recur or not.[211,230] After distinguishing the etiologic factors, epidemic shiga toxin-associated hemolytic syndrome is unlikely to recur following renal transplantation,[231,232] whereas atypical or familial HUS may recur with devastating and irreversible consequences.[232]

GROWTH FOLLOWING TRANSPLANTATION

A major distinguishing feature of pediatric from adult recipients is the need for children to grow. The growth failure commonly observed in children at the time of transplantation is multifactorial; however, the most important cause is the reduced response to endogenous growth hormone,[40] related to several mechanisms. Growth failure often begins insidiously early in the course of chronic renal insufficiency. In a NAPRTCS analysis of 1768 children with CKD (glomerular

Am J Transplant 2003; 3[suppl 4]:53-63, with permission.)

filtration rate <75/mL/min/m^2), over one third had a height deficit of more than 2 SDS. It has been amply demonstrated that chronic renal insufficiency beginning in infancy leads to permanent reduction in growth potential.[233] Growth retardation continues in children on a dialysis regime, whether the mode of dialysis is peritoneal or hemodialysis. For several years it has been suggested that a functioning transplant would enable the child to achieve catch-up growth.[7] Unfortunately, long-term data from registry studies have shown a more disappointing outcome.

NAPRTCS data show that the mean height deficit at the time of transplantation is −1.88. Males (−1.92) and younger recipients have greater height deficits at the time of trans-

plantation.[13] Younger children can show catch-up growth with complete inversion of Z-score up to 0.60 at 2 years for those less than 5 years of age at transplant. Older children may grow at a normal rate but rarely show catch-up growth. The Z-score for 19-year-olds is −1.5. Final adult height for children with ESRD is improving, but all of the improvements seem to be related to the gains achieved during treatment for CKD rather than after transplantation.[8]

These studies on long-term growth post-transplantation are disappointing; however, they do focus on mechanisms that prevent growth, despite a milieu with normal renal function. Individual center studies have adopted a variety of techniques, such as discontinuation of prednisone,[234,235] alternate-day steroid therapy,[169,170,236] steroid avoidance,[6] or the use of recombinant human growth hormone.[237] It has been known for several years that steroids used for immunosuppressive therapy will inhibit growth.[165] It has also been demonstrated that steroids affect growth hormone secretion.[206,238–240] Measurements of pulsatile and pharmacologically stimulated hormone release reveal that steroids play an inhibitory role.[165,241] Conversion of children to alternate-day steroid therapy has shown improvement in growth[169,170]; however, the best catch-up growth is seen in patients completely withdrawn from steroids.[6,134,166] Numerous uncontrolled studies have shown that steroids can be withdrawn from children post-transplantation[6,134,242]; however, acute rejection tends to occur shortly afterwards in many of these patients,[167] with marked detrimental long-term effects. An alternative method of attaining catch-up growth post-transplantation would be the use of growth hormone. Recombinant human growth hormone is not approved for use in children post-transplantation; however, numerous

uncontrolled studies have shown its ability to accelerate growth in this setting.[243] Several complications of the use of rhGH post-transplantation have been suggested,[243–246] but a controlled trial demonstrated that it could be used safely and effectively.[247]

MORBIDITY

Hospitalization

The median duration of hospitalization at the time of transplantation in the most recent NAPRTCS report was 13 days, with longer stays required for young patients and for recipients of CAD transplants.[13] The mean hospital stay has fallen by about 8 days between 1987 and 2001. Most children require rehospitalization at least once after the initial discharge after renal transplantation. Fifty percent of LD recipients and 62% of CAD recipients are hospitalized during the first 6 post-transplant months. The hospitalization rate falls with increasing time after transplantation, but 16% require at least one hospital stay in the fourth post-transplant year.[24] The most common reason for hospitalization used to be for treatment of rejection. However, a recent analysis supports that treatment of viral and bacterial infections are the next most common reasons for hospitalization.[248] The most common bacterial infection in children less than or equal to 5 years of age is *Clostridium difficile* diarrhea and urinary tract infection for those greater than 5 years of age.[33] CMV appears to be the most common viral infection in older children. Treatment for hypertension is the cause for hospitalization in the first 6 months in 5% to 8% of recipients and falls to approximately 1% at 5 years after transplantation.[24]

Post-Transplant Lymphoproliferative Disease and Malignancy (PTLD)

Although PTLD has been reported as a complication of pediatric organ transplantation for many years,[249] the number of published reports seem to be increasing.[250] It is not clear whether this indicates that the incidence of this potentially lethal complication of immunosuppression is increasing or if it is just more readily recognized. If the incidence is increasing, it may be the unfortunate consequence of "improved" immunosuppression.[144] In a review of UNOS data, the most incidence of PTLD following pediatric renal transplantation is clearly increasing, and those who are less than 18 years of age, Caucasian, and male gender are significant risk factors.[251] Current incidence appears to be 1% to 2% of all pediatric renal transplants.

PTLD often presents within lymph nodes, but it can be extra-nodal, frequently occurring within the gastrointestinal tract,[252] proximate to or within the graft,[253] or distant from it.[254] Presentation of PTLD within the central nervous system is often devastating and rapidly fatal. PTLD is generally thought to emanate from EBV infection.[252,255,256] Thus, the pre-transplant EBV status of the donor and recipient may be an important determinant of the disease and may explain why the disease is more common in children than in adults.[257,258] In several reports, the incidence rate of PTLD for EBV-seronegative recipients was many times higher than that for EBV-seropositive recipients[259,260] and, in others, the source was the donor in most of the cases.[261] Concomitant primary infection with CMV may increase the risk of PTLD

fivefold.[259] The intensity of immunosuppression may also predispose the child to PTLD.[262] Treatment with antilymphocyte antibodies, such as OKT3, as either induction or antirejection therapy, may increase the risk of developing PTLD substantially.[259,260,263] Although it has been reported following both cyclosporine and tacrolimus treatment, programs that have used both drugs have suggested that the incidence was higher in tacrolimus-treated recipients.[144,257,264] However, a recent registry report suggests that neither MMF nor tacrolimus were independent risk factors for PTLD; rather, the intensity of immunosuppression was most important.[145]

The diagnosis of PTLD has generally been made on the basis of characteristic pathologic findings, and the diagnosis cannot be made without biopsy material. Advances in detection of EBV DNA[265–269] and in the outgrowth of transformed lymphocytes[270,271] have permitted early detection of patients at high risk to develop PTLD. Surveillance of blood and prospective adjustment of immunosuppression has been proposed, but there are no universally-accepted standards in this area.[272] Similar tests have been used also to guide treatment,[265] but their absolute value for this function is not established.

The mainstay of treatment of PTLD is the reduction or discontinuation of immunosuppression.[261,273,274] Of interest, in many of these cases, the graft is not rejected despite the marked lowering or discontinuation of immunosuppressive medications. Interferon-α and intravenous γ-globulin,[275,276] ganciclovir,[277] and even chemotherapy have been suggested, but their efficacy has been variable. Prophylaxis of high-risk patients may be useful.[278] Recently, treatment with the monoclonal antibody rituximab has shown promising results.[279–283]

Other Infections

Immunosuppression renders the recipient susceptible to numerous viral and bacterial infections. Infections account for the majority of complications post-transplantation in children and are the principle cause of morbidity. Prophylactic therapy against the more common infections seen in the context of a renal transplantation is employed by most centers.

Cytomegalovirus (CMV)

CMV is an extremely important cause of infectious complications affecting transplant recipients. Unlike the situation seen in nonimmunocompromised individuals, cytomegalovirus infection in renal allograft recipients more often causes serious symptoms. CMV presents as a primary infection in seronegative patients; in seropositive patients the infection is secondary due to reactivation of the patient's own latent virus. Clinically, the two types cannot be distinguished although the former is generally more severe. Because of the high risk to the patient and renal allograft, prophylactic therapy is indicated for all seronegative patients who receive a seropositive kidney and for all patients who receive induction with a T-cell antibody. Prophylaxis can be carried out using either specific antiviral therapy or with high-titer CMV immunoglobulin, or both. The incidence of virologically confirmed CMV-associated syndromes was reduced from 60% in controls to 21% in recipients of CMV immune globulin. CMV immunoglobulin is generally given in the first 4 months post-transplantation. Both acyclovir[284] and ganciclovir[285] have been shown to be

effective as prophylactic therapy; however, the latter should replace the former since the introduction of an oral preparation has been shown to be highly efficacious.[286,287] The dose of oral ganciclovir is 500 to 700 mg/m^2 every 8 hours.[288] There have been no controlled trials of CMV immunoglobulin versus ganciclovir, so the relative merits and indications of the two preparations are unknown, although the former seems to ameliorate the severity of CMV disease, whereas the latter decreases the frequency.

Pneumocystis Carinii Pneumonia (PCP)

Because of their defective cellular immunity, transplant patients are susceptible to respiratory infections by opportunistic organisms that are not of concern to normal children. Pneumonia is a common cause of morbidity in children with a renal allograft, and *Pneumocystis carinii* is the most important cause, occurring in about 3% of all renal transplant recipients.[289] Pneumocystis produces a diffuse pneumonia in which shortness of breath and hypoxemia are salient features. If diagnosed quickly it can be treated effectively; however, delay can be fatal and hence prophylaxis is standard therapy in most centers. The risk is highest in the first month and treatment with SMX-TMP in the dose of 10 mg/kg (trimethoprim component) three times per week should be given during the period of highest risk.

Varicella

Chickenpox is one of the constant worries of both the transplant physician and the patient's family, since exposure in the pediatric age range is extremely high.[33] The rash in an immunocompromised patient may become confluent, bullous, and hemorrhagic. If the disease becomes systemic, the fatality rate can be high.[290] Treatment of varicella in immunocompromised children generally consists of intravenous acyclovir at least until all lesions are crusted.[289,291] Prophylaxis, consisting of the administration of varicella zoster immunoglobulin (VZIG), is carried out routinely in all transplanted seronegative children upon exposure.[289] The administration of varicella vaccine (Varivax) prior to transplantation substantially reduces the frequency and severity of the disease post-transplant.[292] The use of varicella vaccine post-transplantation has been reported in only a small series,[293] but it is likely safe, although not uniformly successful.

Urinary Tract Infection (UTI)

UTI are extremely common during the first 3 months post-transplant and may be seen in as many as 50% of patients.[33,294] It appears that beyond the first 3 months episodes of asymptomatic bacteruria are more common. However, during the first 3 months UTI may be a common source of bacteremia.[295] Chemoprophylaxis, by the administration of SMX-TMP as described for *P. carinii*, should be provided in the first month in all patients and may be continued up to 1 year in patients whose original disease was urologic in origin.

Polyoma Virus

Polyoma BK virus infection may be an increasingly important cause of graft dysfunction and graft loss following renal transplantation,[296] but there has been little information about its frequency or severity in children. In one retrospective analysis of 100 pediatric renal transplants, 26 had BK virus detected in urine and 5 in blood.[297] Those with viremia had elevated serum creatinines and evidence of interstitial nephritis on graft biopsies. Screening of susceptible patients by urine analysis for BK messenger RNA has been proposed,[298] but proper therapeutic treatments in response to rising titers have not been identified.

Hypertension

The incidence of hypertension post-transplant is demonstrated in a NAPRTCS study wherein 70% of patients required antihypertensive medications at 1 month post-transplant; the incidence decreased to 59% at 24 months.[299] Hypertension may be detected more common if ambulatory blood pressure monitoring methods are used.[300,301] Hypertension post-transplant is primarily related to the side effects of drug therapy. The two most widely used immunosuppressives: calcineurin inhibitors and prednisone both exacerbate preexisting hypertension. Hypertension has been correlated with multiple complications of transplantation, including reduced graft survival and cardiovascular complications.[302–305]

Antihypertensive Therapy

With dose reduction of prednisone and calcineurin inhibitors almost all hypertensive patients can be managed, though multiple drug regimens may be necessary in some patients. An effective and safe drug to use is a calcium channel blocker, such as nifedipine, which also reduces cyclosporine toxicity (nifedipine may exacerbate gum enlargement, however).[119,306] Another drug particularly favored in adolescent patients due to concerns of noncompliance is clonidine, which is available in a transdermal patch. Clonidine may induce drowsiness, and sudden withdrawal tends to produce rebound hypertension. In patients who complain of palpitations due to drug-induced reflux tachycardia, prazosin is more effective because it induces the least amount of tachycardia. Minoxidil, an acute vasodilator, should only be used with severe hypertension and for only a limited duration because it causes hirsutism. ACE inhibitors should be used with caution because converting enzyme inhibition in a single kidney model leads to reduction in the glomerular filtration.[307,308]

Hyperlipidemia

Steroids, calcineurin inhibitors, and sirolimus induce hyperlipidemia. A fall in serum cholesterol levels on conversion from cyclosporine to azathioprine has been demonstrated.[309] The mechanism by which calcineurin inhibitors might increase plasma cholesterol is unclarified. The drugs are highly lipophylic and up to 80% is transported in plasma by binding to lipoproteins, particularly LDL. It is conceivable that the binding to LDL cholesterol results in impaired clearance of LDL from the circulation via cell-surface receptors.[310] Post-transplant hyperlipidemia in adults has an adverse effect on cardiovascular morbidity.[311,312] NAPRTCS reviewed post-transplant patients maintained under a rigid common protocol of immunosuppression and observed that at 1 year post-transplant they did exhibit significantly elevated levels of plasma cholesterol and VLDL cholesterol compared to normal

controls; however, the elevated cholesterol levels (mean 213 mg/dL) were not high enough to require lipid lowering agents.[313] In cases with higher serum lipid levels (cholesterol 250 mg/dL or greater), 3-hydroxy-3 methylglutaryl (HMG) co-enzyme (CoA) reductase inhibitors are particularly effective in reducing total cholesterol levels.[314,315] The use of sirolimus may increase the need for lipid-lowering agents in the future.

Post-Transplant Diabetes Mellitus

Hyperglycemia and post-transplant diabetes mellitus (PTDM) in children may be increasing in frequency.[142] Corticosteroids use leads to peripheral insulin insensitivity and hyperglycemia that is relatively insensitive to exogenous insulin. Steroid withdrawal has led to improvements in this condition.[316] A NAPRTCS study described an overall incidence of less than 3% of pediatric renal transplant recipients, with African-Americans at highest risk.[317] Tacrolimus use was identified as a significant risk factor, a finding confirmed by reports, some with incidence rates exceeding 50%.[133,140–142,318] Tacrolimus may diminish insulin secretion.[143] Treatment may be aided by reducing or eliminating corticosteroid or calcineurin inhibitor doses.[316,319]

Noncompliance

Noncompliance or nonadherence is often cited as a cause of long-term graft loss in pediatric renal transplant recipients, especially in adolescents. A major reason for noncompliance is thought to be the alteration in appearance that accompanies immunosuppressive medications, including the cushingoid facies and growth retardation related to long-term daily corticosteroid administration and the hirsutism and gingival hypertrophy associated with cyclosporine. However, the true incidence of noncompliance is unknown. Noncompliance rates of 22%,[320] 43%,[321] and as high as 64% in adolescents[322] have been reported. Some factors, such as young age, adolescence, poor socioeconomic status, and family stress have been associated with increased levels of noncompliance.[320,322–324] Importantly, however, health care workers are not able to identify a significant proportion of noncompliant patients.[325] Treatments, such as educational programs[321] and family-based therapy,[326] have been proposed, but these types of programs have not been universally succesful in changing motivation.

LONG-TERM OUTCOME

Rehabilitation

Organ transplantation typically results in dramatic improvement of all aspects of physical, emotional, and social functioning. Importantly, cognitive skills improve after successful renal transplantation,[11] suggesting stabilization of neurophysiologic functioning. Health related quality of life measures are generally good, especially in older children and adolescents, although all ages report some problems with usual activities.[327] Interestingly, the perceived emotional status of the children was actually better than controls, especially during and after adolescence.[327]

Long-term survival is generally excellent,[328] and measures of quality of life have demonstrated excellent rehabilitation in long-term survivors.[329,330] Over 90% have rated health as good or excellent, and most did not feel that health interfered with normal functioning. Most of them were full-time students or employed. The majority were below normal height, and up to a third were dissatisfied with their body appearance. In one report, only a small minority of long-term survivors were married,[331] but, in another, 50% were married and half of those had children.[330]

Mortality

Infection is generally the major cause of death, particularly in the first post-transplant years.[13] Other major causes include cancer/malignancy and cardiopulmonary causes. The best patient survival results are found in older pediatric recipients and in recipients of LD transplants.[48] Risk factors for excess mortality include young recipient age, graft dysfunction (ATN) at day 30 following transplant, and certain underlying renal diseases (oxalosis, congenital nephrotic syndrome, Drash syndrome).[48] Mortality after 10 years post-transplant seems to be related primarily to cardiovascular causes,[328] which may be linked to the hyperlipidemia and hypertension associated with chronic immunosuppression. The mortality rate of children, except for the very youngest, is very low and is generally better than what is found in adults.

Emerging Strategies in Kidney Transplantation

Marilia Cascalho, M.D., Ph.D. • Brenda M. Ogle, Ph.D. • Jeffrey L. Platt, M.D.

No area of medicine has provoked so much excitement and so much frustration as transplantation. The excitement stems from the possibility that transplanting an organ such as a kidney into a desperately ill individual can change that individual's condition almost immediately to one of good health. The frustration stems from the fact that organs, such as the kidney, are not available for transplantation into all of those who need them[1] and from the fact that those who are fortunate enough to receive an organ transplant must also be treated for life with toxic immunosuppressive therapies to avoid rejection of the graft. New developments in medicine and biotechnology may add substantially to the excitement and frustration.

One new development that may change the demand for transplantation is molecular and genomic diagnosis. Advances in molecular diagnostics, genomics, and possibly proteomics may soon make it possible to predict the onset of disease long before the symptoms are manifest and to predict the course once disease has become apparent. With this information, the clinician may be tempted even more than before to carry out "preemptive" transplantation to spare the patient from adding the risks of organ failure or other diseases to the risks of transplantation.[2] For example, molecular diagnostics and genomics are approaching the levels of specificity and sensitivity that may make it possible to diagnose cancer before it can be localized by imaging. If new diagnostic tools make it possible to say with reasonable certainty that an individual has renal-cell or bladder cancer but that the cancer is too small to be localized by imaging, then it may be tempting to consider removing the kidneys or the bladder and replacing them with suitable substitutes. This type of preemptive transplant is sometimes carried out when an infant with ambiguous genitalia is found to have the Denys-Drash syndrome.[3,4] Extending preemptive transplantation to adults with high likelihood of tumor formation could add as many as 89,000 potential recipients per year to those awaiting kidney transplants. The circumstances are worse for the lung; preemptive transplantation would increase the demand for transplantation by 100-fold.

Another advance that could vastly increase the demand for kidney transplantation or renal cell transplantation comes from recent studies on the epidemiology of cardiovascular disease. Mann and associates[5] found that small decreases in glomerular filtration and the presence of microalbuminuria correlate with heightened risk of atherosclerosis, ischemic heart disease, and death.[6] Of course, this association between minor renal abnormalities and cardiovascular disease may simply mean that the kidney is a sentinel for diseases of the blood vessels and the heart. However, a more intriguing explanation for these findings is that the kidney may support cardiovascular health and that a small loss of renal function may cause a disproportionate amount of cardiovascular damage. For example, the kidney may clear insulin, metabolize vitamin D, or remove a toxin from the blood. Such a function might explain why atherosclerosis and ischemic heart disease are observed so often in those who receive a kidney transplant (and thus are uni-nephric) and in those on dialysis. If the kidney does contribute to cardiovascular health, then one might argue that transplants should contain a larger renal mass, that is, transplants should be of two kidneys, or that the transplants need to include a larger number of a specific cell type. This concept suggests the possibility that transplantation of the kidneys or of a type of renal cell might someday be undertaken to prevent vascular disease in those with minimal decreases in renal function, and that scenario could clearly increase the demand for renal transplantation by yet another order of magnitude.

Clearly, the number of kidneys available for transplantation today is by any measure too small. Hence, one can anticipate a growing interest in seeking alternatives to the use of human organs for renal replacement. This chapter will consider various technologies that might be used to augment renal function and some strategies through which those technologies may some day be applied.

XENOTRANSPLANTATION

The most obvious alternative to the use of human organs and cells for transplantation is xenotransplantation, the transplantation of animal organs, tissues, or cells into humans. Xenotransplantation has been advocated and tried at various times during the past century for replacement of renal function. The experience with clinical xenotransplantation of the kidney is summarized in Table 41–1. The sections that follow will consider the biologic barriers that prevent clinical application of xenotransplantation. The reader is referred to a collection of recent reviews for more detailed consideration.[7] Although kidneys from nonhuman primates have been used in some trials of xenotransplantation,[8–10] and the results in one were quite good,[11] we shall focus on the use of lower animals as a source of kidneys, because among other problems nonhuman primates, such as baboons, are too small and not sufficiently numerous to address the need. Larger mammals, particularly the pig, are suitable in size, available in large numbers, and these animals can be genetically engineered and bred.

Barriers to Xenotransplantation

Three factors pose barriers to clinical xenotransplantation. These factors are the immune response of the recipient against

Table 41–1   Experience with Clinical Xenotransplantation

the graft, the physiologic limitations of the transplant in the foreign host, and the possibility of transferring infectious agents from the graft to the recipient and potentially to others in society. Because xenotransplantation has been attempted on a number of occasions over the past 100 years, much more is known about these barriers than the barriers to other technologies, such as stem cells and tissue engineering. Because we believe that the immune response to xenotransplantation is the most difficult barrier to overcome, we shall focus especially on this subject.

The immune responses to xenotransplantation are much more severe than the immune responses to allotransplantation.[12] One reason why immune responses to xenografts are severe is that all normal individuals have innate immune reactants—including xenoreactive natural antibodies, complement, and natural killer cells—against xenogeneic cells. Not only can innate immunity destroy a xenograft, but it also amplifies adaptive immune responses. Another reason why immune responses to xenografts are severe is that xenografts carry a diverse set of foreign antigens against which cellular and humoral immune responses can be elicited (in allotransplants, the main foreign antigens are MHC antigens).[13] Finally, immune responses to xenografts may be severe because immune-regulation, which might partially control responses to allografts, may fail to do so in responses to xenografts.

The Barrier to Xenotransplantation of Cells and Tissues

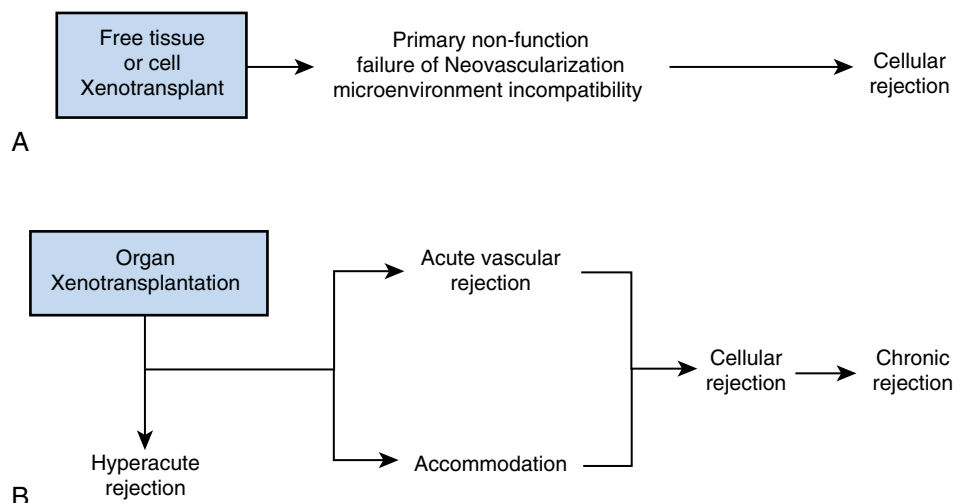
As the preceding discussion suggested, one might seek to replace or amplify some aspect of renal function by a cellular transplant. The main barrier to transplanting xenogeneic cells and tissues is cellular rejection (Figure 41–1). Cell-mediated


Figure 41–1 Biologic hurdles for xenotransplantation. A, Tissue or cell xenotransplants are subject to failure caused by primary nonfunction that may reflect failure of engraftment or a very rapid immune response. If primary nonfunction is bypassed and the tissue or cells engraft, they are then subject to cellular rejection. Humoral rejection is not usually observed because the blood vessels are of recipient origin. **B**, Organ transplantation between disparate species can lead to hyperacute rejection. If hyperacute rejection is averted by depletion of xenoreactive natural antibodies or inhibition of the complement system, the xenograft is subject to acute vascular rejection, or "accommodation." If acute vascular rejection is prevented, the graft will be subject to cellular rejection or chronic rejection.

immune responses to xenotransplantation are thought to be especially severe[13–15] and may, in our view, be further amplified by the humoral immune reactions and by failure of immune regulation between species.[12,16] Some fundamental aspects of the cellular immune response to xenotransplantation have been reviewed by us[12,17] and others.[18,19] What is pertinent to mention here is that, despite the severity of cell-mediated rejection of cell and tissue transplants between disparate species, it appears to be subject to control by immunosuppressive agents currently available.[20–23] In fact, under some conditions, xenogeneic cellular grafts survive and function without immunosuppression.[23] Thus, if one were to identify or engineer a xenogeneic cell or cell line that could replace critical metabolic functions of the kidney, that xenograft might be undertaken today without new methods of immune modulation.

The Barriers to Xenotransplantation of Vascularized Organs

The barriers to transplantation of whole organs, such as the kidney, are much higher than the barriers to transplantation of cells or tissues. In kidney transplants, the donor blood vessels are directly exposed to components of the immune system of the recipient, and this interaction gives rise to severe vascular disease in various forms, which has, to this point, prevented clinical xenotransplantation (Figure 41–1). The types of vascular disease observed in xenografted organs are the same as those observed in allografted organs; however, the incidence, severity, and resistance to therapy are greater in xenografts.

Renal xenografts are quite susceptible to hyperacute rejection, which can destroy the graft within minutes to a few hours.[17,20,24] Hyperacute rejection of porcine organs transplanted into primates is triggered by xenoreactive natural antibodies, which are found in all immunocompetent people and higher primates and are specific for Galα1-3Gal, a saccharide expressed by pigs and other lower mammals.[25] The binding of these antibodies activates complement, and complement activation in blood vessels of the graft causes hyperacute rejection.

How complement activation triggers hyperacute rejection has been elucidated largely through the study of experimental xenografts. Hyperacute rejection is caused by the rapid insertion of terminal complement complexes into the cell membranes of the endothelial lining of blood vessels in the donor organ.[20,26] What makes hyperacute rejection of xenografts especially severe is that activation of complement in the graft is poorly controlled by endogenous complement regulators, such as decay accelerating factor, membrane cofactor protein, and CD59.[27,28] These proteins function poorly across species, and, consequently, the complement regulators in a porcine organ would provide only a low level of protection against human complement.[17] Consistent with this concept, organs from transgenic pigs expressing human complement regulatory proteins are protected from hyperacute rejection.[29–32] Today, pigs expressing these proteins have been widely used in experimental studies, and hyperacute rejection is no longer viewed as a substantial barrier to xenotransplantation.

If hyperacute rejection is prevented, a renal xenograft becomes susceptible to a condition we have called acute vascular rejection.[33,34] Acute vascular rejection, sometimes called acute humoral rejection or delayed xenograft rejection, may well be the main hurdle to clinical application of xenotransplantation.[35–37] Acute vascular rejection appears to be caused by xenoreactive antibodies that bind to the xenograft, causing "activation" of endothelium in the graft.[33,38,39] Whereas the endothelium of normal blood vessels promotes blood flow and inhibits thrombosis and inflammation, activated endothelium promotes vasoconstriction, thrombosis and inflammation, giving rise to the picture of ischemia and thrombosis characteristic of acute vascular rejection of xenografts.[34,35,40] These pathophysiologic changes in endothelium are due, at least in part, to coordinated elaboration of tissue factor, plasminogen activator inhibitor type I, E-selectin and thromboxane A2, and other products of genes induced by the action of xenoreactive antibodies, small amounts of complement, or platelets.[17,36,38,40–42] Because acute vascular rejection is thought to be the main biologic obstacle to xenotransplantation of organs, much effort is now directed at developing the means to prevent or treat this disorder. Here we summarize the main approaches.

One way to prevent acute vascular rejection may be to suppress the production of xenoreactive antibodies by drug therapy or through induction of tolerance. However, various regimens of immunosuppressive agents have failed to control the humoral response to xenotransplantation. Another way to prevent acute vascular rejection is to induce immunologic tolerance to xenografts. Various approaches to tolerance have been tried[43]; however, most approaches effective in rodents have not proven applicable in humans. One approach that might be sufficiently effective is the engraftment of hematopoietic cells.[44,45] Unfortunately, the biologic hurdles to engraftment of xenogeneic bone marrow cells, which include the action of antibodies and complement on the cells, the incompatibility of host growth factors,[46,47] and induction of thrombosis,[48,49] have precluded application of this method to the present.

Another way to prevent acute vascular rejection might be to eliminate the antigens targeted by xenoreactive antibodies. Although porcine cells express many antigens potentially recognized by the human immune system, the main antigen target by the earliest observed types of acute vascular rejection is Galα1-3Gal.[50] Recent progress in the cloning of pigs[51–53] and in gene targeting[54] makes it possible to knock out the gene encoding the enzyme (α1,3-galactosyltransferase) responsible for synthesis of this saccharide.[55–57] Pigs lacking this enzyme have been recently produced and are under study. As of this date, it is not clear that this manipulation has solved the problem. Indeed, some have questioned whether knocking out this enzyme would eradicate the sugar.[58] And, even if it is possible to eliminate this antigen, it may not be possible to eliminate many other xenogeneic potential antigens present in the xenogeneic kidney.[59–61]

Still another approach to preventing acute vascular rejection may be the inducing of "accommodation." First described in organs transplanted across ABO-blood group barriers,[62,63] accommodation is an acquired resistance of an organ to immune-mediated injury.[17] Accommodation has been used to prevent acute vascular rejection in rodents and, arguably, in pig-to-primate xenografts.[41,50,64]

How can accommodation be reliably induced and what mechanisms underlie it? Accommodation might reflect a change in xenoreactive antibodies or a change in the antigens in the graft[65]; however, experimental work in xenograft

models suggest accommodation results at least in part from an acquired resistance of the graft to humoral injury.[64] Consistent with the later possibility are experiments showing that endothelial cells exposed to xenoreactive antibodies acquire resistance to complement mediated injury, owing to increased expression of CD59[66] and other inhibitors of injury.[67] Studies in rodents have shown that accommodation is associated with expression of genes, such as Bcl-2 that inhibit apoptosis and hemoxygenase-1 (HO-1) that confer protection against toxic injury.[68] Organ grafts deficient in HO-1 or in functional complement-regulatory proteins appear to be subject to severe vascular injury,[69] and current study suggests that the regulatory function of HO-1 is related to carbon monoxides generated by HO-1.[70] However, efforts to prevent vascular injury by expression of these genes may not be sufficient to induce a state of accommodation, because grafts with increased expression of HO-1 and/or CD59 may still undergo acute vascular rejection.[71,72] (unpublished observations). This suggests that accommodation is multifactorial.

When acute vascular rejection is prevented, xenografts are susceptible to cellular rejection, as discussed previously, and presumably to chronic rejection.[73] If chronic rejection is caused by an immune response to the graft, as some experimental evidence suggests,[74] then it should be common and severe in xenotransplants. If chronic rejection is caused by qualities of the graft, such as preservation time, ischemia, and donor age, then it should not be much of a problem. In any case, since xenotransplantation offers an unlimited supply of organs, the impact of chronic rejection may be less serious, because the chronically-rejected organ can be replaced.

Physiologic Hurdles to Xenotransplantation

Studies in which porcine kidneys have been transplanted into nonhuman primates suggest that they function sufficiently in a human to sustain life.[75] In fact, the main functional impairment of these xenogeneic organ grafts is from rejection. However, porcine erythropoietin appears to work poorly on human cells, so supplementation with the human hormone would probably be needed. While other defects might still be discovered, these defects are probably no worse than abnormalities imposed by dialysis.

Infectious Agents

Another barrier to xenotransplantation is infection.[76,77] Infection should be less severe a risk in xenotransplantation than in allotransplantation because the animal source can be raised in an environment free of known pathogens, and the organisms associated with the animal can be fully characterized. However, attention has been focused on endogenous retroviruses of the pig, which cannot be eliminated by breeding or special handling.[78] The porcine endogenous retrovirus or PERV can infect human cells in culture and in *in vivo* model systems,[79] hence there is concern it might be transmitted to a xenograft recipient and possibly more widely in the population. However, studies of human subjects who received experimental xenografts or treatment with porcine cells have failed to reveal even a single instance in which PERV has been transmitted to a human subject.[80] Moreover, a recent study suggests that those viruses known at present could be eradicated from pig herds being bred for xenotransplantation.[81]

Although the question of relevance of PERV to public health cannot be entirely dismissed, the question may now be viewed as one that could be resolved by careful attention to the recipients of xenografts, rather than as a reason for abandoning xenotransplantation.[77,82]

Of all the barriers to xenotransplantation, immune responses against the graft appears to be the most difficult to surmount. Nevertheless, it is reasonable to assume that these responses, or their consequences, will be addressed in the coming years. The main question then will not be whether xenotransplantation is feasible, but rather whether the physiologic "cost" of immunosuppression and immune modulation needed to allow the prolonged survival and function of a xenograft justifies this approach to renal replacement. For the patient with renal failure, this biologic cost may well be justified, and xenotransplantation might be welcomed. On the other hand, the biologic costs of xenotransplantation might not justify application as a preemptive procedure, and, for this purpose, other technologies will probably be needed. One type of xenograft that could achieve widespread use is a cellular xenograft. Recent studies have shown that xenogeneic cells can be successfully engrafted with little[22] or no[23] immunosuppression. If the xenotransplantation of a renal cell or another cell suitably engineered could overcome the vascular disease putatively caused by small decrements in renal function or microalbuminuria, such grafts might be found useful at some point in the future.

Stem Cells for Augmentation and Replacement of Organ Function

Stem cells are cells capable of self-renewal and of generating at least one, and often more than one, differentiated line of cells. Stem cells obtained from the inner cell mass of the blastocysts are called *embryonic* stem cells. Stem cells may also be isolated from mature individuals or generated by transfer of nuclei from mature cells to immature cell bodies, that is, cloning (Figure 41–2). Stem cells are thought to be capable of regenerating diseased or damaged tissues[83] and of being coaxed to generate tissues and organs de novo.[84,85] However, depending

Transfer of nucleus from patient's cells to enucleated oocyte or equivalent (generates histocompatible stem cells)

Transplantation of stem cells into fetal pig kidney (generates nephrogenic mesenchyme)

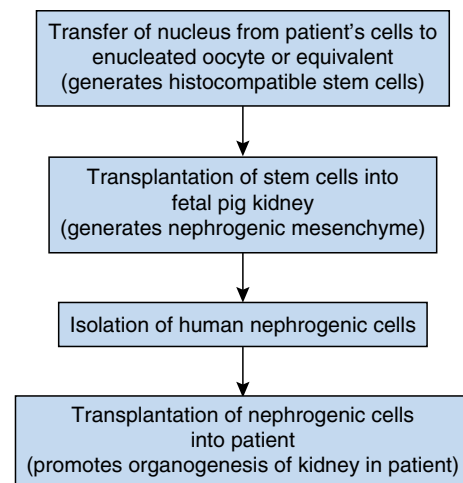
Transplantation of nephrogenic cells into patient (promotes organogenesis of kidney in patient)


Figure 41–2 A potential approach to replacement of the kidney, using multiple technologies—cloning, stem cells, and organogenesis.

on the type of stem cells used, application may be limited by (1) the proliferative senescence of the cells; (2) constraints on the ability of the cells to differentiate into mature, functional tissues; (3) the possibility that the cells might transform in culture, and (4) immune response against foreign antigens expressed by the cells. A full consideration of these limitations is beyond the scope of this chapter, but some potential applications and limitations will be discussed.

Embryonic stem cells have the capacity to proliferate indefinitely and generate all tissues and organs, including kidney-like tissue.[86] In principle, then, embryonic stem cells might be grown into a kidney. How exactly to coax organ formation, rather than kidney-like tissue, is not known. As discussed later, isolated fetal cells and organ rudiments do have the capacity to form an entire organ, a process known as *organogenesis*, but making less differentiated, less committed cells behave in this way would appear to be a challenge. One application of embryonic stem cells that might be considered is providing whatever metabolic functions are lacking in those with mild renal insufficiency. Given progress in devising methods for coaxing embryonic stem cells to serve endocrine functions,[84] it is reasonable to think the means could be devised to make the cells secrete erythropoietin or carry out needed metabolic functions. Because embryonic stem cells express allogeneic histocompatibility antigens, use of the cells might require immunosuppression. However, some recent work in rodents suggests that embryonic stem cells may not be immunogenic or may even help induce tolerance.[87]

Stem cells can be isolated from adults, and these cells do have the capacity to differentiate into complex structures.[88] The advantage of using "adult" stem cells are that the cells might be isolated from the patient themselves, thus avoiding immune reactions and ethical problems associated with use of totipotent embryonic cells. Adult stem cells can migrate through the blood and take up residence in injured tissues.[82,89] Thus, stem cells regenerate diseased tissues. However, effective application of stem cells for regeneration may require overcoming barriers still unknown that prevented the natural stem cells of the patient from regenerating the diseased kidney in the first place. The generating of a whole organ, such as the kidney, by adult stem cells is less feasible than doing so with embryonic stem cells, because adult stem cells appear to have less ability to proliferate and differentiate. However, adult stem cells might someday be used to provide metabolic functions, as discussed previously.

One approach to overcoming some of the limitations to use of embryonic and adult stem cells is through cloning. Cloning is accomplished by harvesting nuclei from the cells of one individual and implanting the nuclei in primitive cells, such as oocytes or zygotes, that have the capacity to "reprogram" the nuclei. Reprogramming involves removal of covalent modifications of DNA, restoration of the ends of chromosomes, and expression of appropriate transcription elements that allow the new cell to function as totipotent stem cells. Cloning by nuclear transfer can generate an entire individual, a process called *reproductive* cloning, or a tissue or organ, a process called *therapeutic* cloning. One advantage of therapeutic cloning is that it generates cells with the same histocompatibility antigens as the individual from whom the nucleus is obtained (except for mitochondrial antigens, which derive from the oocyte). Another advantage is that the cells, like embryonic stem cells, can develop into any tissue. However, like

embryonic stem cells, it is still unknown how to make the cells form an organ ex vivo. However, cloning might be used as a source of cells for bioengineering of tissues and organs. Indeed, one recent report claims to have generated kidney-like devices using cloned cells of cattle.[90] However, the method described used cells actually harvested from a fetus, and thus reproductive rather than therapeutic cloning was performed.

The application of cloning faces ethical hurdles. Use of a zygote or even an oocyte as a "recipient" for the donor nucleus has provoked opposition because it is seen by some as creating life. Similarly, reproductive cloning has been widely seen as unethical to undertake. However, new insights into the mechanisms of nuclear reprogramming may allow reprogramming to be directly undertaken without the use of a primitive human cell. Further, if the cloned cells can be engineered to be of limited potential, it may avert the concern about disrupting human life.

Tissue Engineering

Although embryonic stem cells or cloned cells have the capacity to differentiate any type of cell and contribute to formation of mature tissues and organs, they may not be able to form intact organs, as discussed previously. Organogenesis, as such, requires cues from complex cell–cell and cell–matrix interactions that may not be easily recapitulated outside the embryo. One way to deliver some of these cues is through tissue engineering, the use of scaffolds consisting of synthetic or biologic polymers, to coax growth and development.[91] Tissue engineering has been used to generate blood vessels,[92–95] heart valves,[96–98] cardiac muscle,[99–101] bone,[102] liver,[103–105] nerve,[106] and islets.[107] The most successful applications have been engineered cartilage[108,109] and skin.[110–113] Tissue engineering is not generally thought to be applicable for organ replacement because the matrices in current use do not permit the growth of cells into a sufficient mass or anatomic complexity to yield a whole organ.

Organogenesis

What may be needed to meet the needs for kidneys and to overcome some of the limitations mentioned earlier is a method to grow organs de novo, that is, organogenesis. The growing of organs has been carried out for experimental purposes for many years. Nephrogenic mesenchyme cultured under suitable conditions has been shown to develop into kidney-like structures in vitro.[114] Since human fetal nephrogenic mesenchyme will not be available, what is needed is a way either to use xenogeneic nephrogenic mesenchyme or to drive stem cells to become nephrogenic mesenchyme. Both will be discussed.

Fetal kidney tissues from various sources have been found to mature after implantation into adult animals.[115–118] Organs grown in this way are vascularized by ingrowth of blood vessels of the "recipient." Recently, Rogers[119] showed that fetal porcine kidney tissue can mature in an adult rat and that the tissue exhibits some renal function. Aside from the question of whether full function could be achieved by this approach, there is the concern that the xenogeneic organs would be destroyed by the immune response of the treated individual,[120,121] as described earlier. Although immune-injury is an important concern, the immune response is not as severe

a hurdle as it might seem. Since the blood vessels in the organ would derive from the animal host,[115] that is, the treated individual, the graft would not be subject to the various types of vascular rejection described previously, but rather in principle, it would be subject only to cellular rejection. Still, preventing cellular rejection would require treatment with immunosuppressive agents,[119,120] and hence this application would be less appealing for preemptive therapy.

An alternative approach to organogenesis would be to use stem cells originating from the affected individual, perhaps derived by nuclear transfer. As already indicated, these stem cells may lack the ability to grow into an intact organ, but, in a natural environment, the cells are clearly capable of forming nephrogenic mesenchyme.[90] We have proposed that stem cells might be implanted into a fetal animal and there acquire the capacity to form the kidney.[122,123] The human cells might then be harvested and placed into the subject from which they originated, and in that subject organogenesis could proceed further. Under these conditions, the parenchymal cells would be from the clones and thus might express foreign mitochondrial antigens, but blood vessels in the organ would be derived from the human host,[115] and hence severe immune reactions might be avoided. An important limitation to this approach and indeed to application of tissue engineering in general is that it might be too expensive or complex to allow routine application.

Approaches to Augmentation and Replacement of Renal Function: A Synthesis

Given the various technologies that might be applied to replacement or augmentation of renal function, what strategies can be envisioned for application in the future? To address that question, we envision certain strategies to match certain clinical needs.

Those with severe chronic renal failure require immediate replacement of function. They might receive renal allografts as a permanent therapy, as currently practiced. Such individuals might be candidates for an "engineered" organ, as discussed later; however, in this case, temporary renal replacement would be needed, and an allograft, or even a xenograft, might serve that purpose.

For preemptive treatment (e.g., the patient with early diagnosis of renal cancer), the ideal therapy would involve removing the patient's kidneys and replacing them with organs engineered to be genetically similar or identical to the patient. This approach would avoid use of immunosuppression. The sequence of steps that might generate such an organ is shown in Figure 41–2. The steps include therapeutic cloning to generate stem cells that are nearly identical to the patient genetically (only proteins encoded by mitochondrial DNA would differ). The stem cells might be used to fashion a device[90]; however, we believe the better solution might be to generate nephrogenic mesenchyme in a xenogeneic host as described previously and then use it for organogenesis in the patient.[123] Applying this approach of the "engineered kidney" is labor intensive and undoubtedly quite expensive, but it would finally address the hurdle of immune compatibility between the graft and the host.

Another potential solution for full renal replacement would involve the use of a fully implantable device, which might be envisioned in the coming years, together with a cellular implant that would provide the metabolic functions deficient in the device. The cells used to replace renal metabolic functions would ideally be generated by therapeutic cloning to make them nearly compatible or nearly so with the patient.

For those who need a renal metabolic function to forestall vascular disease, one can envision use of cellular transplants. Such transplants might consist of xenogeneic cells, embryonic stem cells, or cells cloned by nuclear transfer. Clearly, the stem cells are preferable to the extent that their use obviates need for immunosuppression. However, if effective treatment were to be widely applied and were to require extensive genetic engineering to confer metabolic function, then xenogeneic cells might be preferred because the engineering could be carried out through germline modifications, yielding a well-characterized line of engineered animals.

CONCLUSION

Any discussion of future therapies, particularly complex therapies that might be applied for the augmentation or replacement of renal function, is fraught with hazard. Some technologies may be blocked by unforeseen barriers, or new technologies may eclipse the usefulness of those discussed earlier. New treatments may eradicate diabetes, hypertension, and glomerulonephritis, which underlie most cases of renal failure in the United States (although, these diseases may soon be replaced by aging). Also, improvements in existing technologies, such as implantable devices, may reduce the need for more complex therapies. However, we believe there is much to be gained by considering what approaches might be applied at a remote time. This consideration helps to determine which technologies need to be improved and which new technologies may be needed. Certainly, there must be an advantage to anticipating such needs well in advance of potential application.

Chronic Kidney Disease and the Kidney Transplant Recipient

John S. Gill, M.D., M.S.

The premature death of kidney transplant recipients is an important factor that limits the long-term success of kidney transplantation. Early recognition, prevention, and treatment of chronic kidney disease (CKD) related complications prior to transplantation and during the period of allograft function may improve the survival of kidney transplant recipients. Recent investigations indicate that there are important differences in the clinical presentation of CKD between transplant recipients and patients with native kidney disease. This chapter will review how aggressive management of CKD may decrease the incidence of premature death with graft function (DWGF) and thus lead to improvements in long-term graft survival. In addition, the unique aspects of CKD management in kidney transplant recipients will be reviewed. The medical complications of kidney transplantation are also discussed in Chapter 38.

THE IMPACT OF DEATH WITH GRAFT FUNCTION

The two major causes of graft loss after the first year of transplantation are chronic allograft nephropathy and DWGF. Although the risk of DWGF decreased by 67% between 1988 and 1997, patient death still accounted for 43% of all graft loss.[1] The perception that DWGF is an indicator of the success of kidney transplantation is dispelled because most cases of DWGF are premature; the median time to DWGF is only 23 months, and the projected survival of transplant recipients is between 5 and 15 years, lower than that of age-matched individuals in the general population.[1,2]

The impact of DWGF on long-term graft survival is illustrated by the fact that transplant recipients die with a considerable degree of residual transplant kidney function; in an analysis of data from the United States Renal Data System (USRDS), the most recent serum creatinine prior to death was 1.9 ± 0.8 mg/dL, and 60% of patients had serum creatinine less than 2.0 mg/dL.[1] Therefore, when a patient dies with graft function, a significant amount of "potential graft function" is lost. The amount of "potential graft function" that is lost can be estimated by the difference in graft survival when death is both included and excluded as a cause of graft loss. Between 1985 and 1996, the half-life for cadaveric transplant recipients increased by 5.9 years; however, the half-life would have increased by 8.5 years, if death was excluded as a cause of graft loss.[3] Similarly, projected graft half-lives in the absence of DWGF would be 19.5 and 35.9 years for cadaveric and live donor recipients, respectively.[3] Therefore, although some

transplant recipients attain a full life, premature death with graft function is an important reason why more marked improvements in long-term graft survival have not been recognized.

PREVALENCE OF CHRONIC KIDNEY DISEASE IN TRANSPLANT RECIPIENTS

Like dialysis, transplantation falls short of replacing normal kidney function. Figure 42–1 shows the prevalence of CKD in 69,394 adults, first kidney transplant recipients between 1987 and 1997 with graft survival of at least 1 year in the United States Renal Data System (USRDS).[4] Glomerular filtration rate (GFR) was estimated at 1, 3, and 5 years after the time of transplantation with an equation derived from the Modification of Diet in Renal Disease (MDRD) Study,[5] and patients were classified by K/DOQI CKD stage.[6] At each time point, the mean GFR was approximately 50 mL/min/1.73 m^2, and the prevalence of K/DOQI CKD Stages 3, 4, or 5 was greater than 70%. This information demonstrates that kidney transplant recipients are rarely cured of their kidney disease and remain at risk for CKD-related complications.

PRESENTATION OF CHRONIC KIDNEY DISEASE IN TRANSPLANT RECIPIENTS

Prior to Transplantation

The clinical manifestations of CKD in a given transplant recipient will primarily depend on the duration and burden of CKD prior to transplantation and the level of kidney function achieved after transplantation. In addition, exposure to immunosuppressive medications after transplantation may exacerbate CKD-related complications, such as hypertension, diabetes, dyslipidemia, and anemia. Early recognition and treatment of CKD-related complications, maximization of allograft function, and minimization of immunosuppressive-related side effects should decrease the impact of CKD in transplant recipients.

Aggressive CKD care should begin prior to transplantation because the preexisting burden of CKD present at the time of transplantation will not be undone by the provision of a functional allograft. In contrast, many of the complications of CKD, such as hypertension, dyslipidemia, anemia, and malnutrition, may be prevented or delayed by early detection and treatment prior to transplantation.[7] Prolonged exposure to
Figure 42–1 Mean ± standard deviation (*SD*) of estimated glomerular filtration rate (GFR) (mL/min/1.73 m^2) and prevalence of K/DOQI chronic kidney disease stages among adult first transplant recipients in the United States between 1987 and 1997 at 1, 3, and 5 years after transplantation.

dialysis prior to transplantation has been associated with reduced allograft survival,[8,9] and preemptive transplant recipients have an allograft survival advantage.[10,11] The reasons underlying these associations are somewhat uncertain; however, a lower burden of CKD in patients with no or limited dialysis exposure is a likely explanation.[12] Reducing dialysis exposure through live donor transplantation and preemptive transplantation should be encouraged.

For patients without the possibility of a live donor transplant, aggressive CKD management prior to transplantation will become increasingly important due to longer transplant waiting times. The United Network of Organ Sharing waiting list for cadaveric kidney transplantation is increasing at a rate of 20% per year and will include an estimated 95,000 patients by 2010.[13] Under current conditions, waiting times of a decade or more are anticipated,[14] and CKD management of wait-listed individuals will be more difficult. Of particular concern is the increased risk of perioperative morbidity and mortality.[15] A detailed perioperative risk assessment and implementation of preventive measures shown to reduce operative risk in non-transplant patient populations should be considered as part of the CKD management of transplant candidates. Appropriate pre-transplant management of CKD-related complications, such as anemia, that are associated with an increased risk of perioperative mortality in non-CKD populations,[16,17] should also be prioritized. In this regard, implementation of an organ allocation strategy that facilitates the optimization of pre-transplant preventive measures may be desirable.

The Peri-Transplant Period

Transplant recipients have an increased risk of mortality in the peri-transplant period compared to wait-listed patients who remain on dialysis. Recently, data from the USRDS and

Medicare claims were used to describe the incidence of cardiovascular morbidity and mortality in the peri-transplant period.[18] There was a marked increase in the rate of all cardiovascular events (death, myocardial infarction, congestive heart failure, coronary revascularization, and stroke) during the peri-transplant period. The estimated probability of myocardial infarction, cardiac arrest, and congestive heart failure in cadaveric transplant recipients in the first post-transplant month was 1.2%, 1.1%, and 5.2%, respectively. Approximately 5% of first kidney transplant recipients will die within the first post-transplant year.[19] The majority of deaths are due to cardiac causes, and patients with comorbid disease (diabetes, peripheral vascular disease, angina) and a longer duration of CKD are at increased risk for mortality. These deaths should be regarded as failures of CKD management rather than failures of transplantation because they result from the accumulated burden of CKD prior to transplantation that may have been prevented by the provision of aggressive pre-transplant CKD care. Post-transplant complications, such as acute rejection and delayed graft function, may contribute to the development of acute coronary syndromes in the peri-transplant period. Delayed graft function may be associated with increase cardiac work due to volume expansion. Because delayed graft function is often predictable, it may be preferable to avoid the allocation of organs at high risk for delayed graft function to patients with a high burden of cardiovascular disease.

The Post-Transplant Period

Cardiovascular disease is the most important threat to long-term patient survival after transplantation. The management of cardiovascular disease in transplant recipients will continue to be an important component of post-transplant CKD care because of the increasing age and burden of CKD in these patients. Between 1995 and 2001, the percentage of cadaveric donor transplant recipients older than 50 years increased from 40% to 51%, whereas the percentage of live donor recipients over 50 years increased from 28% to 45%.[18] During this time, the percentage of cadaveric donor recipients with atherosclerotic heart disease or congestive heart failure increased from 40% to 50%, whereas the percentage of live donor recipients with these comorbid conditions increased from 33% to 40%. Comprehensive reviews of post-transplant cardiovascular disease as well as treatment guidelines for cardiovascular risk reduction are available, and therefore a detailed discussion of these issues is not provided here.[20–22]

There is increasing interest in the effect of different immunosuppressive agents on the development and progression of cardiovascular disease. With the increased choice of available maintenance immunosuppressive agents, individualization of immunosuppression, based not only on patient immunologic risk but also on cardiovascular risk, will become more important. Such strategies should be viewed as adjuncts to the early diagnosis and treatment of well-established cardiovascular risk factors. Direct evidence regarding the efficacy of cardiovascular risk reduction in transplant recipients is lacking, and it is unlikely that randomized trials, such as the recently published ALERT study,[23] will become available for all cardiovascular risk factors in the transplant population. Therefore, transplant clinicians must rely on extrapolation of information from non-transplant

populations. Currently, it would appear that there is considerable room for improvement in post-transplant cardiovascular disease management. For example, fewer than one-third of transplant recipients have lipid testing performed in the first post-transplant year.[18]

The level of kidney function achieved after transplantation has been associated with both patient and allograft survival and, more recently, with the development of hospitalized heart disease.[24,25] Because of these associations, it is important that an accurate assessment of allograft function be made. A key component of CKD care in transplant recipients is recognition that patients who are typically thought of as having "good graft function" actually have significantly impaired kidney transplant function and are at risk for the complications of CKD. Serum creatinine alone is not an accurate index of kidney function, and an estimate of the GFR is the preferred measure of kidney function. A number of widely used formulas to estimate GFR are available that perform well in the non-transplant population with CKD. Although these prediction equations have not been validated in large samples of transplant recipients, they are still preferred over the use of serum creatinine alone. The K/DOQI work group has recommended equations derived from MDRD study for use in all adult patients with CKD.[6] The most simple of these formulas includes only four variables:

$$\begin{aligned} \text{Estimated GFR} \quad &= 186 \times \text{Serum Creatinine}^{-1.154} \\ (\text{mL/min/1.73m}^2) \quad &\times \text{Age}^{-0.203} \times 0.742 \text{ if female} \\ &\times 1.210 \text{ if African American}^5 \end{aligned}$$

The level of kidney function achieved after transplantation is largely determined by donor and immunologic factors. Because the mean level of kidney function established after transplantation is only 50 mL/min/1.73 m^2,[26] preservation of kidney function is an important aspect of CKD management in transplant recipients. Recent studies of administrative data sets and from the experience in single centers have described the change in kidney function after transplantation.[26–28] Of importance is the observation that transplant recipients have a mean rate of kidney function decline that is slower than that in patients with native kidney disease with similar levels of kidney function. Further, many transplant recipients have improvement in kidney function over time. These observations highlight the need for further studies to identify the determinants of the change in kidney function after transplantation and suggest that efforts to maximize the baseline level of kidney function may be more important than efforts to slow the progression of kidney decline after transplantation.

Information regarding the determinants of the change in kidney function after transplantation is emerging. It would appear that there are only relatively small differences in the rate of kidney function decline between the most commonly used maintenance immunosuppressive agents.[29] There is preliminary evidence suggesting that kidney function may be optimized with the use of non-nephrotoxic immunosuppressive agents and reduced calcineurin inhibitor exposure.[30] Surprisingly, little direct information about the role of hypertension and proteinuria in kidney function decline in transplant recipients is available. These factors are known to accelerate the progression of kidney function decline in patients with native kidney disease. Evidence regarding the role of anemia in the progression of kidney function decline

is emerging.[31] Further studies to determine the optimal blood pressure, the role of proteinuria, and other modifiable CKD factors, such as anemia, on the rate of kidney function decline after transplantation are needed. In the absence of direct evidence in the transplant population, it is reasonable to advocate aggressive treatment of these factors based on their established role in the progression in native kidney disease and because many of these factors also increase the risk of cardiovascular disease.

PATIENTS WITH ALLOGRAFT FAILURE

Despite the improvements in allografts survival, one-third of cadaveric transplant recipients will suffer graft failure within the first 5 years of transplantation.[2] Moreover, many patients will require more than one transplant in their lifetime. As such, it is appropriate for transplant physicians to consider the survival of patients after transplant failure as part of transplant-related outcomes.

A recent study described the prevalence and treatment of CKD-related complications among 4643 patients returning to dialysis after transplant failure in the United States between 1995 and 1998.[32] Despite being known to physicians with knowledge of CKD, failed transplant recipients initiated dialysis with levels of hematocrit, albumin, erythropoietin use, and residual renal function that were suboptimal and similar to those in the general incident dialysis population (Figure 42–2). These findings demonstrate that there are many opportunities to improve the CKD management of transplant recipients and that there is a need for increased awareness of CKD among the medical professionals involved in the care of these patients.
Figure 42–2 Hematocrit (Hct), erythropoietin (EPO) use, albumin, and glomerular filtration rate (GFR) at time of dialysis initiation among failed transplant recipients and general incident dialysis patients.

The survival of patients with transplant failure is known to be poor.[33–35] Between 1995 and 1998, 25% of patients in the United States that remained on dialysis after transplant failure died within 2 years of their return to dialysis date.[33] In a multivariate analysis, the presence of comorbid disease (congestive heart failure, peripheral vascular disease, diabetes) predicted mortality. However, unlike patients with transplant function, immunologic and transplant-related factors (acute rejection, antibody induction, donor source, duration of graft survival, and the maximum attained GFR during transplantation) did not predict mortality.

CONTINUITY OF CARE

Transplant recipients will have multiple care providers before, during, and after transplantation. The overall management of CKD care should be directed by the physician most familiar with CKD. Because aggressive CKD care should begin prior to transplantation and continue after allograft failure, it may be appropriate in some cases for a nontransplant physician to direct the CKD care of transplant recipients. A more realistic and appropriate alternative is that all transplant nephrologists learn and apply the highest standards of CKD care to their transplant patients. Irrespective of who assumes the responsibility for CKD care, communication between the multiple responsible care providers is essential to ensure continuity of care. The inclusion of transplant recipients in the general NKF-K/DOQI classification of CKD should facilitate this process by providing a simple classification system and treatment action plan based on the level of allograft function.[6]

SUMMARY

Most kidney transplant recipients achieve only a modest degree of kidney function and, therefore, are never free of the burden of CKD. Aggressive management of CKD prior to transplantation may attenuate the development of complications after transplantation. Ongoing prevention, diagnosis, and treatment of CKD-related complications and comorbid conditions as patients move from the transplant waiting list through transplantation and back to dialysis after graft failure may be the key to improving long-term outcomes in transplant recipients.

Acute Renal Failure

Chapter 43

Acute Renal Failure: Bench to Bedside

Jeremy S. Duffield, M.R.C.P., Ph.D. • Joseph V. Bonventre, M.D., Ph.D.

Acute renal failure (ARF) is a common condition, which carries a high morbidity and mortality.[1] Although many advances have been made over the last 50 years, the management of ARF remains largely supportive. Basic animal and cellular research and human studies have provided limited insight into common disease mechanisms influencing the diverse etiologies of ARF.[2] By pursuing common disease mechanisms at the bench, new insights will hopefully result that will lead to new preventive therapies that could be used in high-risk patients to prevent renal injury or to modify the course of established ARF. In addition, however, fundamental observations will be made at the bedside, which then will be clarified in the laboratory. These clinical insights deriving from the patient will be facilitated by new technologies to probe the disease and by new biomarkers, which will provide better insight into the time-resolved nature of the injury to the kidney. This chapter presents an overview of ARF, including its definition, epidemiology, risk factors and clinical consequences, as well as the complex pathophysiology of this syndrome. To the extent that we have improved our understanding of many of the pathological processes that occur in the injured kidney, these insights have been derived from basic studies *in vitro* using isolated cell systems as well as from animal and human studies *in vivo*. The chapter attempts to summarize how observations at bench have led to modifications of therapeutic approach to humans and may lead to new therapeutic agents in the future.

Definition and Epidemiology

To study ARF, it is necessary to a have clear definition of the disease, for which there is still no clear consensus or standardized approach. Qualitatively, ARF is a clinical syndrome characterized by an acute deterioration of renal function over hours to days, resulting in failure of the kidney to excrete nitrogenous waste and to maintain fluid and electrolyte homeostasis. ARF is a heterogeneous condition with a wide range of etiologies. Unfortunately, there is no unified quantitative definition of the syndrome. There are many different published definitions, ranging from an abrupt (hours or days) rise in serum creatinine of ≥ 0.5 mg/dL (~ 50 μmol/L)[3,4] to an abrupt decline in renal function sufficient for introduction of dialysis.

Recent large epidemiological studies have used definitions that vary from a rise in serum creatinine of ≥ 0.5 mg/dL to a rise of normal range serum creatinine to > 2.0 mg/dL.[1] These differences in definition yield markedly different outcomes. In a single-center study of hospital acquired ARF, only 1% of patients had a rise in serum creatinine of ≥ 2.0 mg/dL, whereas 13% had a rise of ≥ 0.5 mg/dL.[5] Depending on the cohort of patients studied, the etiologic spread will be quite different. In a large multicenter study of community- and hospital-acquired ARF, obstructive causes of ARF represented more than 10% of all cases,[6] whereas in a recent hospital-based study, this amounted to only 3% of cases.[5] Thus it is necessary to evaluate studies with full knowledge of the variations in definition of ARF used, the patient population studied, and the breadth of etiologies under investigation.

The necessity for clear definitions of ARF has resulted in the development of new criteria endorsed by the Acute Dialysis Quality Initiative (ADQI). These guidelines recognize definitions based on change in glomerular filtration rate (GFR) from baseline, change in urine output, and duration of these changes. A proposed stratified definition of ARF denoted by the term "RIFLE" divides this syndrome into five groups (Figure 43–1): (1) renal *R*isk (RIFLE-R), (2) renal *I*njury (RIFLE-I), (3) renal *F*ailure (RIFLE-F), (4) renal *L*oss (RIFLE-L), (5) *E*nd stage renal disease (RIFLE-E). This classification incorporates patients with pre-renal ARF who will rapidly restore renal function to baseline if the etiology of the impaired renal parenchymal perfusion is corrected, and such patients will fall into the milder categories. GFR criteria or urine output (oliguria) criteria can also be used in this formulation. When the category is defined by oliguria, a suffix would be used to make the distinction (e.g., RIFLE-Ro). Those patients with chronic kidney disease (CKD) would be distinguished by a suffix (e.g., RIFLE-Fc). The criteria assume patients to be well hydrated and not treated aggressively with diuretic agents. These new criteria have not yet been used in any systematic study of patients with ARF, but offer a standardized approach to acute renal disease both clinically and during investigation. The rationale for the different strata is based on outcome. This new classification has been proposed to allow more consistency across studies and hence greater ability to compare results.[7,8] Future prospective studies validating this new classification and comparing it with more

Figure 43-1 RIFLE classification of acute renal failure according to decrease in GFR, urine output and duration of disease. The ARF class (R, I, F, L, or E) is based on the worst criteria following patient assessment. The shape of the figure reflects patient numbers, high for RIFLE-R and low for RIFLE-E. (Taken from ADQI at www.adqi.net.)

traditional definitions of ARF will need to be conducted prior to its more widely accepted use.

Incidence

In the absence of established standardized criteria for ARF, the incidence will vary depending on the definitions used and the patient population studied. In large community-based studies from Europe, the incidence of ARF has been reported as 260 cases per million (0.026%) of total population per year when ARF is defined as a rise of serum creatinine = 2.0 mg/dL,[6] and 140 per million per year (0.014%) when ARF is defined as a rise in serum creatinine > 4.5 mg/dL (>~ 500μmole/L).[9] In the former study from Madrid, more than half of the patients developed ARF in the hospital setting and represented < 0.5% of hospitalized patients. By comparison, a 6-month, U.S. single-center study of in-hospital ARF found an incidence of 13% when defining ARF as a rise of serum creatinine ≥ 0.5mg/dL but only 1% using a rise of serum creatinine ≥ 2.0 mg/dL.[5] These latter data are in broad agreement with large hospital-based studies from the 1980s and 1990s where the incidence of ARF among medical and surgical patients was 5%–8%.[10,11] Thus the in-hospital incidence of ARF is at least 0.5% but may be as high as 13% depending on the definitions used. There are specialized settings in which the incidence of ARF has been reported to be high. For example in the large Madrid study, 7% of patients admitted to the ICU had ARF, and this was replicated in France.[12] The reported incidence of ARF in the ICU varies from 4%-25%.[13,14] ARF has been reported to occur in approximately 7% of patients undergoing cardiac surgery, and more specifically between 15% and 42% of patients undergo-ing coronary artery bypass graft (CABG) surgery; one small study reported as many as 53% of those requiring cardiac valve replacement developed a 25% rise in serum creatinine.[12,15–19]

The development of ARF is associated with increased hospital length of stay, which further correlates with the severity of the disease. For example, among patients who develop a rise in serum creatinine ≥ 2.0 mg/dL and survive, the length of hospitalization is 9 days longer than patients who do not develop ARF.[5] Development of ARF is associated with more than doubling of the cost of hospital care when compared with patients without the diagnosis of ARF.

Mortality

Many patients with ARF will recover; however, acquisition of the disease is associated with increased mortality. In general, the severity of ARF is correlated with higher mortality. In particular, the requirement for an intensive care facility or renal replacement therapy is associated with increased mortality. Recent data indicate that even small increases in serum creatinine are associated with increased mortality. Using a rise in serum creatinine ≥ 0.5 mg/dL, patients with ARF in the hospital setting are 5.7 times more likely to die than equally sick patients without a rise in creatinine when co-morbidities are accounted for. Mortality increases exponentially with increases in serum creatinine.[5] By comparison, patients admitted with cancer have a 3-fold increased mortality and cardiovascular disease a 1.5-fold increased mortality. Subgroup analysis indicated that even a rise in serum creatinine of 0.3-0.4 mg/dL is associated with a 1.7-fold increase in mortality, although this has not been identified in other studies. Following radiocon-

trast administration, a 5.5-fold increase in mortality has been reported in those developing ARF when compared with patients without ARF.[20] Of those developing ARF during Amphotericin B administration, a 6.3-fold increase in mortality has been reported.[21] Many studies have looked at mortality and ARF in specific clinical settings (Table 43–1). In summary, ARF is associated strongly with mortality.[12,19,22–25] Patients with ARF who require ICU management have a higher risk of death (e.g., 71% ICU vs. 32% non-ICU)[6] and sepsis is associated with increased mortality in patients with ARF (e.g., 75% sepsis vs. 45% no sepsis).[26]

In many reports it is not possible to dissociate whether the mortality was due to or was simply associated with ARF. However, the study by Liano and colleagues[6] indicates that although 45% of patients with ARF died, only 26% were attributable to ARF as the primary etiology. From a study of 42,000 patients who had cardiac surgery, ARF (defined by a serum creatinine >3 mg/dL) was found to be an independent risk factor for death (7.9 fold), after adjusting for surgical complications and co-morbid conditions.[27] Together with the increased mortality observed after only small rises in serum creatinine,[5] it is fair to conclude that any degree of ARF is an independent risk factor for increased mortality, even if ARF is defined as an increase in serum creatinine of only 0.5 mg/dL.

Etiology

The clinical etiologies of ARF vary widely according to the setting of the study and the cohort of patients. In particular, community-based studies include more patients with pre-renal ARF and obstructive ARF than do hospital-based studies. Prostate-related obstructive uropathy accounted for 25% of cases of ARF in one community-based series, and 10% in

Table 43–1 Mortality of Patients with ARF in Different Clinical Settings*

Author (yr)	Clinical setting	% mortality
Smith (1955)[236]	Trauma patients	68
Kennedy (1973)[22]	Surgical patients	58
Iaina (1975)[237]	Trauma patients	64

Nash (2002)[11]	All hospital pts. Cr >3 mg/dL	38

*Note high mortality in all groups, but particularly in ICU and cardiac surgery settings.

another.[9] It is likely that many patients with acute obstruction and pre-renal ARF patients are managed in the community without the necessity for hospital admission (Table 43–2). The hospital setting leaves patients at particular risk from low perfusion states; drug toxicities such as aminoglycosides, amphotericin B, and cisplatin; radiocontrast-induced injury; and hemodynamic and septic disturbances associated with major surgery. In one study of all hospital–acquired ARF, these four etiologies accounted for nearly 80% of all cases of ARF.[10]

Within the context of hospital-acquired ARF, certain high-risk groups have been identified. The post-operative period represents greatest risk with 27% of postsurgical patients developing ARF in one study.[6] In addition patients with neoplasia (16%), cardiovascular (30%), respiratory (9%), and gastrointestinal disease (9%), as well as injury/poisoning (14%) and musculoskeletal (5%) disorders, have been shown to be at greater risk of developing ARF in the hospital.[5] In the ICU setting, ARF has been reported to be due to intrinsic renal causes (mainly acute tubular necrosis [ATN]) in 78%, pre-renal in 17%, and post-renal in 5%.[12] In more than 70% of ICU patients with ATN, a combination of hemodynamic instability, nephrotoxins and sepsis can be found reinforcing the view that in most cases of ARF in the ICU there are multiple contributing factors to the etiology (see Table 43–2).[12]

Prerenal causes of ARF

When considering the etiologies of ARF, it is useful to categorize according to whether it is due to pre-renal, post-renal or intrinsic renal parenchymal causes (Figure 43–2). Pre-renal kidney dysfunction can return to normal rapidly with correction of the causative insult. It is more common in the community setting, where it is often related to extracellular fluid (ECF) volume losses, associated with gastrointestinal fluid losses. Less often, excessive renal fluid losses or skin losses are implicated (Figure 43–2). In the hospital setting ineffective perfusion of the kidney is often the result of common conditions such as cardiac failure, hemorrhage, sepsis, and liver cirrhosis. In surgical patients—in addition to vasodilatation caused by anesthetic agents, sepsis, or intravascular fluid losses from the surgery—after surgery there are frequently large shifts of intravascular fluid to the extravascular fluid compartment, resulting in effective intravascular fluid depletion. Elderly patients and those with hypertension or diabetes are particularly susceptible to changes in renal perfusion because of pre-existing, covert renal vascular disease. Noncompliant intra-renal vasculature from arteriosclerosis disables hemodynamic mechanisms designed to maintain glomerular filtration during variations in renal blood flow.[28,29]

Most cases of ARF are multifactorial in their etiology. In addition to predisposing renal vascular disease, many widely used pharmacological agents alter the response of the vasculature and are frequently implicated in the pathogenesis. Nonsteroidal anti-inflammatory drugs prevent pre-glomerular arteriolar vasodilatation, whereas angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor antagonists prevent post-glomerular arteriolar vasoconstriction.[30,31] Thus in patients at risk for acute deterioration in renal function, these drugs should be temporarily withdrawn or given with caution. There are a number of other drugs that affect the renal vasculature and can potentiate impaired renal perfusion. Calcineurin inhibitors (such as cyclosporine and tacrolimus)

†The proportions of etiologic groups for ARF exceeds 100% since in some patients more than one factor was present.

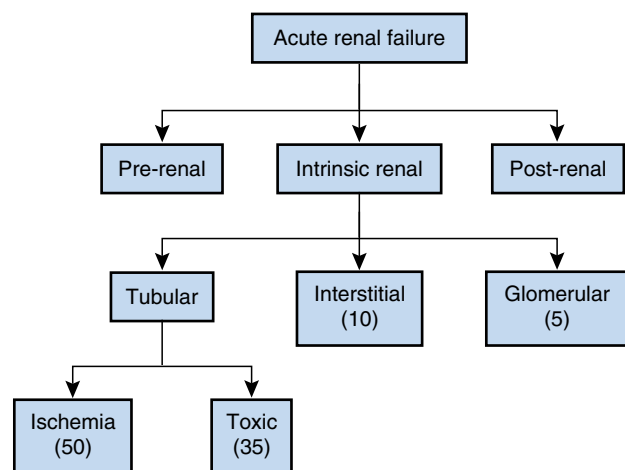
are used with increasing frequency in transplantation and as therapy for conditions where immunosuppression is required. One side effect of these reagents is intra-renal, pre-glomerular vasoconstriction. In addition, calcineurin inhibitors have a low therapeutic index and are metabolized by liver enzymes. Many drugs that affect liver metabolism can modify plasma levels of calcineurin inhibitors. In high concentrations, radio-contrast agents promote renal vasoconstriction, followed by intratubular contrast precipitation.[32] Cocaine, a widely used recreational drug, promotes cerebral, cardiac, and renal vaso-constriction. Often patients will not report cocaine use, making this diagnosis more challenging.[33]


Figure 43–2 Main categories of acute renal failure. Values () indicate approximate percentage of all ARF cases. (Thadhani R, Pascual M, Bonventre JV. Acute renal failure. N Engl J Med 1996; 334:1448-1460. Copyright (C) 1996 Massachusetts Medical Society. All rights reserved.)

Postrenal causes of ARF

Post-renal disease occurs commonly in the community and is frequently due to prostatic disease in men. This condition is readily diagnosed, and therapy to relieve both the obstruction and the ARF is fairly straightforward. One study showed that obstructive causes of ARF occurring in the community had a favorable outcome compared with all other causes of ARF.[9] Similar studies of obstructive disease presenting in the hospital confirm good renal prognosis if the diagnosis is made early.[34] Successful recovery of renal function requires careful attention to fluid balance and electrolytes during the post-obstructive diuretic phase of recovery during which the nephrons are less able to concentrate urine and re-absorb electrolytes.

There are however, many other forms of obstruction that are either silent or intermittent. Unilateral obstruction of the ureter is frequently silent, particularly when caused by neo-plastic lesions of the ureteric urothelium, or when caused by external ureteric compression from pelvic neoplasia or inflammation.[35] In one study of bilateral ureteric obstruction, neoplasia accounted for 76% of cases, with prostatic and cervical neoplasia accounting for more than 50%.[36] In such cases of ureteric obstruction, the patient may complain of a change in urinary frequency or vague loin discomfort.[34] When obstruction is unilateral, as is most frequently the case, the GFR in the contralateral kidney can compensate partially so that the net fall in GFR is less than half that of normal and may be reflected only a small rise in serum creatinine. However, if the contralateral kidney does not contribute equally to the overall renal function because of co-existing acute or chronic intrinsic kidney disease, ARF may ensue. In patients with pelvic neoplasia or pelvic inflammation, complicated pathology frequently leads to partial or complete obstruction of both ureters.[36] In these cases, complete understanding of the obstructing lesion

requires more detailed anatomical assessment than is afforded by ultrasound scanning alone. Furthermore, the classical features of dilated renal pelvices will not always be present because of encasement of the retroperitoneum.[37,38] Commonly, nephrolithiasis is a cause of unilateral ureteric obstruction. Nephrolithiasis can present with characteristic pain and fever, but like other forms of ureteric obstruction may be silent. In all cases where the normal flow of urine from the pelvis to the urethra is disturbed, the patient is at increased risk of sepsis. Thus frequently obstructive disease presents as part of multifactorial ARF. It is therefore wise to consider an obstructive component to many cases of ARF.

Intrinsic Renal Parenchymal Causes of ARF

Intrinsic renal disease can be subdivided according to the main anatomical site of the injury, including the renal vasculature, the glomeruli, the tubules, and the interstitium (see Figure 43–2). In most clinical settings of ARF, intrinsic causes comprise at least 50% of all ARF with acute interstitial nephritis, glomerulonephritis, and vasculitis making up relatively small proportions of acute renal disease (see Table 43–2). The majority of ARF is exclusively or predominantly as a result of tubular injury, often related to localized or generalized renal ischemia and/or nephrotoxins.

i. Acute Tubular Necrosis (ATN).

ATN is a pathological description and is the most common descriptor used for ARF. Histologically, tubular injury is characterized in the cortex by dilated tubules, and intratubular casts. There is wide variability in the extent of injury to the epithelial cells. With mild injury there is loss of polarity with dislocation of integrins from their usual basal-lateral localization, and loss of the apical brush border. With the change in localization of integrins, some viable cells come off the basement membrane and enter the lumen of the tubule. With more severe injury, tubular cells can undergo apoptosis or necrosis. The glomeruli are usually preserved. A continuum exists between the factors promoting pre-renal disease and ischemic ATN. Renal tubules, in particular the proximal tubules, are susceptible to ischemic injury. This is due to a combination of high metabolic demands, limited anaerobic respiration, and limited blood supply to the straight portion in the outer medulla (see below).[31,39–42] The distribution of tubular injury has been best studied in animals. In humans, where the biopsy data are limited, there may be more distal tubule injury to complement the proximal injury than there is in animals.[43] Those patients experiencing a greater diminution in effective renal perfusion, for a more protracted period, or those patients with predisposing factors affecting the underlying vasculature (diabetes, hypertension, vascular disease, cardiac failure) are more likely to develop ATN. One study of hospital-acquired ARF found sepsis to be the most predisposing factor for the development of ATN.[25] In the ICU setting, 48% of patients with ARF have sepsis as the primary predisposing factor.[12] In addition, a study of community-acquired bacteremia found a doubling of serum creatinine in 24% of patients.[44] Sepsis predisposes to ARF in part by diminished renal perfusion. In addition, however, the circulating toxic milieu of cytokines and chemokines promoting intra-renal local vasospasm and leukocyte activation likely plays an important role.[45–47]

In addition to ischemia and sepsis as contributing factors to ARF, renal tubules are susceptible to many toxins, which often are introduced as therapeutic reagents. Nephrotoxins are implicated in ARF in at least a quarter of all cases.[20,48] Because the nephron functions to filter and then concentrate the filtrate, the concentration of many therapeutic agents often increases along the length of the nephron. Agents commonly associated with ATN include aminoglycosides, amphotericin B, cisplatin, methotrexate, foscarnet, pentamidine, calcineurin inhibitors, and osmotic agents such as mannitol and sucrose (found in intravenous immunoglobulin preparations). In addition, ingestion of heavy metals and organic solvents and excessive ingestion of acetaminophen can induce direct tubular toxicity. Filtration and concentration of free heme pigments by the nephron during rhabdomyolysis or extensive hemolysis, or precipitation of myeloma kappa light chains or uric acid crystals in the tubule leads to direct tubular damage. In the ICU, ATN is associated with multi-organ failure in 90% of cases and is present in as many as 23% of patients at the time of ICU admission. In more than 70% of ICU patients with ATN, a combination of hemodynamic instability, nephrotoxins and sepsis can be implicated as causative.[12] Other patient groups predisposed to ATN include those with hematological malignancies, following cardiac bypass surgery, or with co-existing HIV disease.[19,35,49]

ii. Vascular Disease.

Acute vascular compromise of the large renal vessels is a rare but important cause of ARF. It occurs in patients with critical atherosclerotic vascular disease and is usually accompanied by anuria, and sometimes pain. This is a vascular emergency and requires urgent corrective intervention. Anatomically, this etiology of ARF falls within the category of pre-renal causes. However, it leads to ischemic injury of the parenchyma. On the other hand there are many primary vascular disorders of smaller vessels, which play an important role in ARF and fall under the category of intrinsic renal parenchymal causes. Atheroembolic disease, usually involving cholesterol rich emboli, occurs either spontaneously, especially in patients who are anticoagulated, or following arterial manipulation in those with advanced atherosclerotic vascular disease. In one study, this diagnosis was made in only 5% of those who underwent biopsy with ARF.[6] Although this disease can be characterized by embolic events to the flanks and extremities, presenting as a characteristic rash and the finding of eosinophilia, it is frequently underdiagnosed because it is a relatively silent condition with few diagnostic clues. Therefore a proportion of patients thought to have ATN will have atheroembolic disease as a contributing factor. These vascular diseases compromise blood flow in the kidney and as such will lead to ischemic injury of susceptible components of the nephron. Other vascular conditions such as medium vessel vasculitis as seen in Polyarteritis Nodosa are uncommon and rarely present with ARF. There are a large number of other diseases that primarily affect the vasculature and can present as ARF. These include scleroderma, hypercalcemia, hemolytic-uremic syndrome, malignant hypertension, and pre-eclampsia, to name a few.

iii. Acute Interstitial Nephritis.

Many cases of hospital-acquired ARF have a component of interstitial nephritis, when assessed histologically by biopsy. This is characterized by an excessive interstitial inflammatory infiltrate, often with notable eosinophils amongst the inflammatory cells. The urinary sediment will frequently contain erythrocytes, and leukocytes, less frequently seen in ATN, but this is by no means a reliable finding. There are often relatively few specific diagnostic indicators short of biopsy. In one large study of 748 patients with ARF, 12% had a biopsy, and 10% of those biopsies indicated primary acute interstitial nephritis (AIN) as the cause of ARF.[6]

When presenting as ARF, interstitial nephritis is frequently a response to drug therapy. There are case reports for many and diverse drug therapies that induce interstitial inflammatory response in the kidney. However, β-lactam antibiotics and NSAIDS are implicated in many of these cases.[50–52] Frequently, withdrawal of the drug and supportive management is sufficient to prevent further renal deterioration. In addition, there is an uncommon form of AIN, which is associated with anterior uveitis, known as the tubulo-interstitial nephritis with uveitis syndrome (TINU syndrome). While less common than drug-induced AIN, it can occur in all age groups, and the occurrence of uveitis may be temporally dissociated from the AIN.[53,54] This syndrome is sensitive to glucocorticoid therapy.[54]

iv. Glomerular Diseases.

Glomerular disease can exist as primary glomerular lesions, or alternatively as part of a systemic disorder. Frequently, glomerular disease presents as hypertension, hematuria, proteinuria, nephritic syndrome, or chronic renal dysfunction. There are, however, a proportion of patients who presents with ARF. In one study, 25% of biopsies of patients with ARF had microscopic vasculitis, 25% had primary (idiopathic) glomerulonephritis, and 20% had glomerulonephritis as part of a systemic condition (e.g., systemic lupus erythematosis).[6] A number of these studies point to the importance of the renal biopsy in ARF, even though this important diagnostic tool is used infrequently in these patients.

Diagnosis

History and Physical Examination

Careful assessment of the patient's medical history, current medical condition, recent procedures, medical management, and therapies provides the foundation of a comprehensive assessment of a patient with ARF. A nephrological evaluation will include assessment of risk factors for ARF, underlying CKD, exposure to potential nephrotoxins, and recent disturbance of renal perfusion. The physician should assess the ECF volume status with special attention to the intravascular volume status of the patient. Evidence for focal or systemic infection, focal or systemic injury, or inflammation should be reviewed, and evidence for urinary tract obstruction should be elicited.

Renal Function Tests

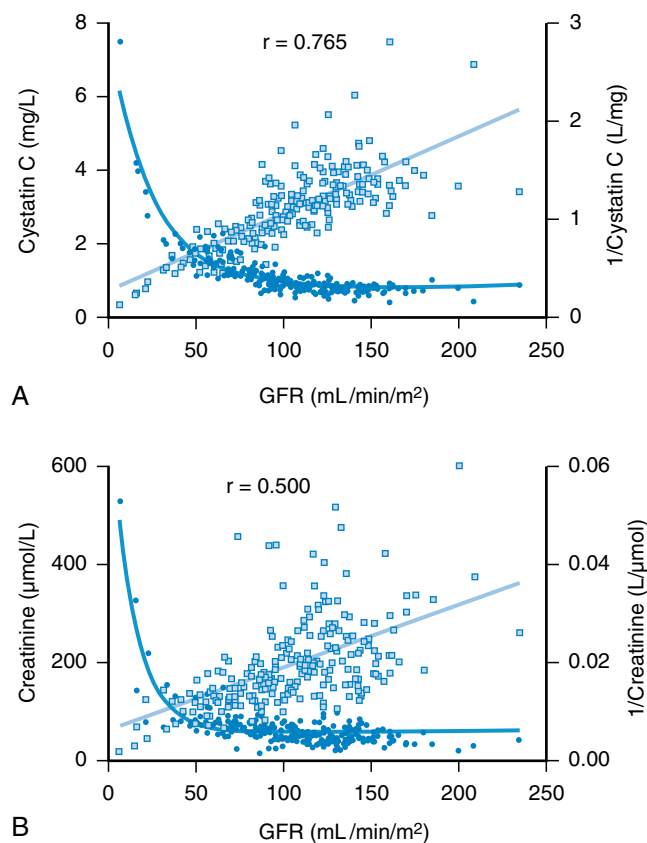
One of the major failings of nephrology has been the lack of development of a good marker of acute tubular injury. It is well recognized that an individual can experience an increase of serum creatinine within the normal range, yet lose 75% of GFR.[55] Too often, the diagnosis is delayed by lack of a sensitive marker. In addition to a tubular cell injury marker, it is important to have a sensitive measure of GFR, better than serum creatinine (Figure 43–3). The Cockcroft-Gault (CG) formula is a useful tool in translating the serum creatinine value into an estimate of clearance. It tends to be inaccurate, however, in patients with very high or low GFR, patients who are on drugs that alter renal tubular handling of creatinine, or patients with high body mass.[56] Recently, attempts have been made to introduce new assays to simplify accurate GFR assessment. Cystatin C, a non-glycosylated basic protein, has received significant attention as a more sensitive marker of renal dysfunction. It is synthesized by all nucleated cells and is released into the circulation. Synthesis appears independent of sex, age, and muscle mass. It is freely filtered but totally catabolized by tubules, so that it is neither returned to the circulation nor excreted in the urine.[57] A decline in renal function is associated with a rise in circulating levels. Several studies have compared plasma cystatin C with creatinine concentration and creatinine clearance as estimated by the CG equation, in patients with normal or mild renal dysfunction.[57–61] Overall, the cystatin C assay is


Figure 43–3 Plots of EDTA–measured GFR against **(A)** Cystatin C or reciprocal cystatin-C and **(B)** creatinine or reciprocal creatinine in the pediatric population. (Taken from Filler G, Priem F, Lepage N, et al. Clin Chem 2002; 48:729-736.) Note the tighter correlation of GFR with 1/cystatin C (r = 0.76 vs. 0.50) and the pronounced rise in Cystatin C at GFR between 50 and 75 mL/min compared with little change to creatinine.

more sensitive than creatinine alone, but comparable with CG creatinine clearance estimates. One advantage of cystatin C over CG equation is that cystatin C clearance declines more than creatinine clearance for mild reductions in GFR. In addition, cystatin C requires only a single measurement, whereas the CG equation requires three variables to be known. Further, several studies have highlighted the utility of cystatin C in specific patient groups, such as the pediatric population or adults with low body mass, whereas low GFR is associated with "deceptively" normal serum creatinine levels (see Figure 43–3).[62–64]

Biomarkers

A novel glycoprotein, KIM-1 is highly upregulated in injured proximal tubular cells, whether that injury is from ischemia or nephrotoxins in both animals and humans.[65–67] The ectodomain of this membrane-associated mucin-rich molecule is shed into the urine of human and rodent kidneys with renal injury, but is not detectable in urine produced by healthy kidneys. Recent evaluation in human disease indicates that it is highly upregulated in ATN, and mildly upregulated in non-ATN ARF and chronic renal failure.[67] Importantly it is not elevated in pre-renal ARF, and increased levels in urine can be detected 12 hours before granular casts in humans and 24 hours before a rise in plasma creatinine in rodents (Figure 43–4).[65,67] Thus assessment of KIM-1 may serve as a useful biomarker to identify tubule injury at an early stage so that aggressive, early, appropriate management can be established. Other biomarkers are being studied. The secreted, cysteine-rich, heparin-binding protein Cyr61 is rapidly induced in proximal straight tubules following renal ischemia, and excreted in the urine where it is detected 3 to 6 hours after the injury in rodents and peaks at 6 to 9 hours after renal injury has occurred, after which it declines rapidly.[68] This marker may serve as an early biomarker of kidney injury. Other studies are ongoing in this area of biomarkers, and the rapid growth of proteomic technologies will likely bring new candidate markers to the forefront of clinical medicine.[69]

Urine Assessment

Patients with ARF often have alterations in urine volume. Oliguria, defined as less than 400 mL/24 hr, is frequently, but not universally seen in patients with ARF. Of all patients developing ARF (defined as a change in serum creatinine of greater than 2.0 mg/dL), nearly 60% have oliguria at first presentation, and this finding tends to be associated with a higher mortality.[10,26,70]

Much information can be determined from careful assessment of dipstick testing and microscopic examination of the urine. Too often, clinicians fail to maintain competence at urine evaluation, yet diagnosis and approach to the care of the patient can often be determined by successful interpretation. The hallmarks of the different diagnoses as determined by assessment of functional analysis of the kidney by composition of the urine are summarized in Table 43–3. There are three considerations: the measurement of urine osmolality, urine sodium excretion, and fractional excretion of sodium. These markers of tubular function help greatly in the assessment and diagnosis of conditions causing ARF (see Table

43–3). Patients with pre-renal ARF, without underlying CKD, who are not taking diuretics, will often retain tubular concentrating capability as well as the ability to absorb sodium from the tubular fluid. Therefore, a concentrated urine specimen with effective resorption of sodium will be present. Similarly a patient with acute glomerulonephritis or obstructive disease will retain tubular function. Patients with ATN and AIN, however, lose tubular function, and will therefore have isotonic urine with high sodium content.

Other Aspects of the Diagnostic Work-Up

In patients in whom the diagnosis is uncertain, early evaluation with a diagnostic ultrasound is essential. Urinary tract obstruction is a common and treatable condition. Although bladder catheterization will expose urethral obstruction such as in prostatic hyperplasia, more proximal obstruction requires visualization. The results of ultrasound must be interpreted with caution, however, since a non-dilated collecting system does not exclude obstruction especially if the assessment is made early in the disease process. Furthermore, encasement of the renal pelvis and ureter may prevent dilatation. In these situations, repeat assessment may be useful or, further, more invasive imaging may be required. In addition to assessment of the collecting system, measurement of renal length with ultrasound may reveal CKD since chronically damaged kidneys are often small.[71–73] In addition to blood tests for evaluating GFR, other serological markers may be useful in diagnosis. Elevated serum calcium or urate may indicate malignancy. Serum or urine electrophoresis may reveal myeloma. Elevated serum creatinine phosphokinase or LDH may reveal rhabdomyolysis or hemolysis, respectively. Elevated neutrophil counts may point to sepsis while eosinophilia and/or eosinophiluria might indicate interstitial nephritis or cholesterol emboli. Where appropriate, tests for systemic immunologic diseases should be performed.
Figure 43–4 The early appearance of Kidney Injury Molecule 1 (KIM-1) in the urine of a patient following abdominal aortic aneurysm repair predates the appearance of granular casts and is seen even without a significant elevation of serum creatinine. (From Han WK, Bailly R, Abichandani R, et al. Kidney Int 2002; 62:237-244.)

Table 43–3 Typical Urinary Findings in Conditions That Cause Acute Renal Failure

Condition	Dipstick Test	Sediment Analysis	urine osmol (mOsm/kg)	fractional excretion of sodium (%)
Prerenal azotemia	Trace or no proteinuria	A few hyaline casts possible	>500	<1
Renal azotemia Tubular injury				
Ischemia	Mild-to-moderate proteinuria	Pigmented granular casts	<350	>1
Nephrotoxins	Mild-to-moderate proteinuria	Pigmented granular casts	<350	>1
Acute interstitial nephritis	Mild-to-moderate proteinuria; hemoglobin leukocytes	White blood cells and white blood cell casts; eosinophils and eosinophil casts; red blood cells	<350	>1
Acute glomerulo-nephritis	Moderate to severe proteinuria; hemoglobin	Red blood cells and red blood cell casts; red blood cells can be dysmorphic	>500	<1
Postrenal azotemia*	Trace or no proteinuria; can have hemoglobin, leukocytes	Crystals, red blood cells, and white blood cells possible	<350	>1

* Early in obstruction the urinary indices can mimic those seen in prerenal azotemia.

Kidney Biopsy

One of the great ironies in the field of ARF is that clinicians are still arguing over the pathology of this disease more than 60 years after the disease was first identified. This uncertainty is derived from the reluctance of clinicians to perform biopsies on their patients. Although it is true that it is not necessary for all patients with ARF to be subjected to renal biopsy, in large studies it has been found that it was only by biopsy that the correct diagnosis could be made.[6,10,74,75] Once pre-renal and obstructive causes have been excluded, and assessment suggests in intrinsic renal problem other than ischemic or nephrotoxic ATN, a renal biopsy may establish a diagnosis and direct management. In addition, patients who have protracted ARF despite recovery in other organ systems may benefit from biopsy to exclude occult diagnoses such as cholesterol embolization.[6,74]

Recovery

The normal sequence of events in acute renal injury is recovery of function. Not all patients who survive their illness recover function, however. Some experience partial recovery and a proportion of these later develop progressive kidney failure, as seen following many other forms of kidney injury. The mean duration of ARF (defined as an increase in serum creatinine > 3 mg/dL) has been reported to be 12 days in those surviving patients who do not require dialysis. But dialysis is required, the duration increases to a mean of 17 days.[76] There are surprisingly little data on long-term renal survival. Two recent studies, however, shed some light on this issue. At the more severe end of the spectrum, in those patients discharged from the hospital following ARF requiring renal replacement therapy with at least one other organ failure (e.g., respiratory failure), 10% remained dialysis–dependent, and more than 40% had chronic kidney failure (CKF).[77] This study group was taken from the ICU setting. In this instance, it is reasonable to assume that ATN accounted for most of the causes of ARF.

In another recent European study, investigators followed 1100 patients with dialysis-requiring ARF for up to 9 years. Of the survivors, 16% remained dialysis-dependent. A minority (6 patients) who were discharged from the hospital still on dialysis recovered renal function.[78] In a study from Minnesota conducted in the 1980s, among the survivors (31%) of dialysis-requiring ARF, 3% remained dialysis-dependent, 25% had moderate CKD, and a further 10% had severe CKD at 90 days.[79] In a large retrospective study of men with ARF, those with an acute decline in renal function, followed by recovery, had a longer-term (2 to 8 years) outcome that correlate with the severity of the initial insult. Forty percent of patients who had an initial rise in plasma creatinine exceeding three-fold above baseline experienced persistent renal dysfunction. By contrast, fewer than 1% of those whose creatinine increased by less than 50% above baseline developed longer-term renal dysfunction.[80,81]

In studies of mice, 30 minutes of ischemia is followed by return of the serum creatinine to normal within 72 hours; nevertheless, this short ischemic exposure results in progressive interstitial myofibroblast expansion and interstitial fibrosis for at least 12 weeks after reperfusion.[82] These data again point out the insensitivity of the serum creatinine as an indicator of renal parenchymal disease.

Renal Replacement Therapy

Patients with ARF who require renal replacement therapy are at highest risk for death and for developing CKF. Experimental data have been used to justify the approach to the maintenance dialytic therapy of patients with ARF. It has been proposed, but not proven, that in humans who suffer from ARF, the kidney is particularly susceptible to repeated injury because of loss of autoregulatory capacity,[83] persistent inflammation, and intratubular obstruction from tubular cell debris, which are features of the ischemia models of ARF in animals. Thus, while it may be necessary to

introduce renal replacement therapies support to help improve survival, there is concern that these therapies not contribute to kidney injury, further delaying recovery of renal function. The loss of autoregulation shown in isolated rodent renal vessel studies (see below) would predict that dialysis therapies that minimize large variations in systemic arterial pressure will benefit renal recovery. The persistence of inflammation in an acutely injured kidney would suggest that dialysis therapies that also minimize systemic inflammation would benefit recovery. Thus, the factors to consider when initiating renal replacement therapy are timing of introduction, choice of modality, choice of dialysis/filtration membrane, adequacy of clearance, potential clearance of inflammatory mediators, and potential loss of anti-inflammatory mediators.

i. Biocompatible Membranes.

The type of membrane used for dialysis or filtration has been shown to affect survival. With the introduction of new biocompatible membrane surfaces, there is less complement activation as a result of interaction of blood with the membrane surface. With greater hydraulic permeability and enhanced adsorptive properties, the biocompatible membranes serve to remove inflammatory mediators from the circulation.[84] Survival of patients dialyzed with biocompatible membranes has been shown in several studies to be enhanced when compared with dialysis using cuprophan membranes.[85] Although there has been controversy in the literature, a recent meta-analysis of survival data from 867 patients confirmed that the synthetic biocompatible membranes do confer substantial survival advantage with an odds ratio of 1.4.[86] Recovery from ARF was not significantly hastened, however.

ii. Dose of Renal Replacement Therapy.

Although it might seem intuitive that since dialysis provides only a small proportion (5%) of the clearance of normally functioning kidneys, more dialysis would be better; however, there are precedents to indicate that such a view might be simplistic. Intermittent hemodialysis (IHD) is not well tolerated in patients with hemodynamic instability and has been considered detrimental in such circumstances. Protracted activation of coagulation and complement cascades clearly could be more detrimental than intermittent activation, and since dialysis or hemofiltration does not selectively remove only harmful substances, the loss of beneficial compounds such as anti-inflammatory cytokines might be deleterious to overall outcome.

When considering the dose of dialysis, many reports indicate that prescribed dose of dialysis overestimates delivered dose in as many as 30% of patients with ARF. The difference between prescribed and delivered dialysis dose appears to be greater when using IHD than continuous venovenous hemofiltration (CVVH).[87,88] Factors such as increased catabolic state, increased total body water, and unusual urea kinetics in patients with ARF may contribute to this phenomenon. In addition, the practicalities of managing dialysis for ARF patients are different from patients with CKF. For example, coagulation of blood in the lines, periods of hemodynamic instability, and procedures requiring disconnection from the dialysis machine are more common in ARF.

Several studies indicate that adjustment of the dialysis dose is important in influencing patient outcome. In a large retrospective study, high Kt/V urea was associated with improved outcome in all patients with moderate disease severity and was subsequently confirmed in a smaller prospective trial (Figure 43–5).[89,90] Recently, Schiffl and colleagues[91] compared daily IHD with thrice-weekly IHD in 160 matched ICU patients. Weekly delivered Kt/V urea was 5.8 and 3.0, respectively. Mortality was 28% and 46%, respectively. There are a number of issues that bring into question the extent to which this study can be generalized.[92] One could look at the study as a comparison of adequate versus inadequate dialysis, since the alternate day group had a substandard (even for patients with CKF) Kt/V urea. Ronco and colleagues,[88] using exclusively CVVH, randomized patients to ultrafiltration rates of 20, 35, or 45 mL/hr/kg (1.3, 2.4, and 2.9 L/hr). Patients treated with the lowest dose had a significantly poorer outcome (41% survival vs. 57% and 58% survival, respectively) at 30 days. In addition the analysis indicated that patients with sepsis had improved outcome on the highest dose compared with the intermediate dose. Furthermore, patients with BUN greater than 60 mg/dL at the onset of CVVH had a worse outcome than those with a BUN less than 60 mg/dL. Thus this study indicates that, using modern dialysis and filtration techniques, more continuous dialysis than has been traditionally used may enhance patient survival (Figure 43–5).

iii. Intermittent Hemodialysis versus Continuous Renal Replacement Therapy.

If it is important to minimize hemodynamic instability to optimize recovery of renal function following the development of ARF, continuous renal replacement therapies (CRRTs), which are associated with less hemodynamic instability, would be superior to intermittent therapies. Consideration of the optimal dialytic modality for patients with ARF is complicated by variability in the delivered dose of dialysis. Several retrospective and three prospective studies have attempted to determine whether continuous dialysis is superior to intermittent therapies. The studies have provided conflicting results.[93–100] Observational retrospective studies have led to findings that patients treated with CRRT had improved survival over IHD patients despite having greater illness severity scores.[101–103] In a relatively small prospective randomized controlled trial of 166 patients, those on CRRT did not have a better outcome than those receiving IHD. This was attributed however, to higher disease severity scores in those on CRRT (despite randomization).[100] The conclusion from two meta-analyses is that there is insufficient evidence to conclude that CRRT is superior to IHD.[104,105] One of the meta-analyses from Kellum and colleagues,[104] however, stratified patients according to disease severity. Their data indicate that in all severity categories, CRRT provided a survival advantage over IHD. In the absence of a clear survival benefit of one modality, and in the absence of a large randomized controlled trial to determine definitively which modality should be used, the choice may rest with local factors such as equipment availability, staffing, and cost, in addition to hemodynamic stability of the patient and disease severity score.

Pathophysiology of Acute Renal Failure

i. Intra-Renal Hemodynamic Factors.

Although systemic or localized disturbance of renal blood flow is a major factor in the etiology of ARF, intrinsic renal factors contribute to the pathogenesis of the disease. Two foci of persistent vasoconstriction following injury have been identified. Persistence of pre-glomerular vasoconstriction is proposed to be triggered by a high salt load arriving in the distal tubule as a result of inadequate sodium resorption in the injured, more proximal parts of the tubule. In addition, studies of renal blood flow point to persistent loss of local blood flow to the outer medulla for many hours after renal injury in

both experimental models of injury in rodents and in human biopsy specimens.[106–112] Three factors may contribute to a reduction in perfusion in the outer medulla. The medullary blood flow is post capillary, and hence low pressure. Injured endothelial cells swell and, in combination with leukocyte adhesion to the injured endothelium, will impede low-pressure blood flow. In addition, coagulation cascades may become activated. Local production of vasoconstrictor agents is markedly upregulated following ischemic injury. Measurement of renal blood flow in rats 1 week following ischemic injury points to persistent dysregulation of vascular tone at rest and in response to vasodilators and constrictors. In essence, the renal vasculature is tonically more constricted,

is hyper-responsive to vasoconstrictors, is hypo-responsive to vasodilators, and responds inappropriately to a fall in perfusion pressure by vasoconstriction (Figure 43–6).[106,107] In the rodent model of ischemia in which the renal artery is clamped, the proximal tubule in the outer medulla is most affected following ischemic injury.[113–114] Even when total perfusion to the kidney is normalized, the outer medulla fails to recover normal blood flow promptly. In the outer medulla, the S3 portion of proximal tubules and the medullary thick ascending limb of Henle (MTAL) dominate. Both nephron segments require substrates for high levels of ATP production. Cell injury is most apparent in the S3 segment of the proximal tubule in most animal models. There is some controversy as to the relative extent of proximal versus distal tubule injury in humans with ARF.[115]

One obvious way to reduce injury and hasten recovery is to reverse inappropriate vascular constriction. Many potent vasoconstrictors have been identified in the ischemic kidney, including endothelin-1, angiotensin II, thromboxane A2, prostaglandin H2, leukotrienes C4, D4, adenosine and sympathetic nerve stimulation.[31,116] A number of studies indicate that blockade of endothelin receptors prior to an ischemic insult protects the rat kidney from injury.[117–120] There are two vascular smooth muscle cell receptors for endothelin, ER-A, and ER-B. The former appears to function primarily in vasoconstriction, and selective blockade in rats has proven beneficial to recovery. Angiotensin receptor blockade, however, is widely implicated in the induction of ischemic injury through paralysis of post glomerular arterioles.[121,122] Successful diminution of post-injury vasoconstriction in animal models with improved functional response has not translated into practical therapies for humans to date.[2] This may relate to the fact that animal studies are performed in a background of normal vasculature, whereas most patients with ARF have at least some degree of underlying vascular disease that could alter the response to vasodilatory drugs. In addition, the agents are given much later in the disease course in humans than they are in animals. These observations, however, suggest the need for directed research into new or combination vasodilators in ischemic injury.

An important finding in animal models of ischemic renal injury is that previous ischemic injury protects from future injury. This "preconditioning" effect lasts for several weeks. These studies indicate that the kidney can activate endogenous protective mechanisms. Endogenous mechanisms appear to protect vessels as well as tubules from injury.[123–125] Exploiting these mechanisms will likely lead to new therapies. Although the deliberate induction of sublethal renal ischemia may appear to have little practical application to patients, studies of pre-conditioning in the myocardium have shown that several pharmacological agents can mediate the same protection as ischemic preconditioning.[126–131] During coronary bypass surgery, ischemic injury sufficient to induce atrial fibrillation (for 5 minutes) protects the myocardium during subsequent surgery. In addition, the use of diazoxide to pharmacologically precondition the myocardium for 5 minutes prior to surgery has also afforded marked benefit to the myocardium during surgery.[132,133] Cardiac studies have highlighted signaling pathways involving protein kinase A, protein kinase D, and mitogen activated kinase pathways in preconditioning. We have found that nitric oxide, a pluripotential molecule derived from inducible nitric oxide synthase (iNOS) contributes to the preconditioning effect in the kidney.[82] Intrinsic cells of the kidney continue to generate NO through increased activation of iNOS for several weeks after injury. NO is the most potent vasodilator yet described. In inflammatory diseases, iNOS-derived NO has been shown to take over the function of eNOS-derived NO in regulating vascular tone.[134] One mechanism by which iNOS-derived NO protects the kidney from injury is by preventing inappropriate vasoconstriction directly as a vasodilator and indirectly by preventing upregulation of vasoconstrictors.[135] In support of this, others have shown that in the preconditioned kidney, production of the vasoconstrictor endothelin-1 is markedly attenuated during ischemia.[136]

ii. Inflammatory Factors.

Injury anywhere in the body promotes an inflammatory response. The kidney is no exception. Intense macrophage accumulation in the outer medulla of postischemic kidneys has been elegantly demonstrated *in vivo* by magnetic resonance imaging and in multiple histological studies (Figure 43–7).[113,137] Injured epithelial and endothelial cells upregulate the production and release of chemokines and cytokines. Although the inflammatory response can be beneficial by promoting repair, increasing evidence is accumulating that in the kidney, the inflammatory response to injury may impede recovery and promote scarring.

Injured endothelial and epithelial cells promote leukocyte adhesion. This combination leads to release of pro-inflammatory cytokines such as TNF-α and IL-1β, and positive feedback in the inflammatory response through generation of chemokines with resultant leukocyte accumulation.[138–141] One of the key molecules involved in leukocyte adhesion is intercellular adhesion molecule-1 (ICAM-1). In addition, other early factors in the inflammatory response, such as complement
Figure 43–6 (A) The effect of vasodilators and vasoconstrictors on post-ischemic renal arterioles. **(B)** The response to decreased renal perfusion pressure in normal and post-ischemic renal arterioles. (Adapted from studies by J.D. Conger et al.[106–108])

Localization of inflammatory macrophages in the outer medulla captured by MR imaging following administration of ultra-small paramagnetic iron oxide beads to rodents with ischemic injury. Normal kidneys **(A)**, 48 hr **(B)**, 72 hr **(C)**, and 120 hr **(D)** following ischemic injury. Note attenuation of signal, a sign of macrophage accumulation, in the outer medullary region only. (Adapted from Jo SK, Hu X, Kobayashi H, et al. Kidney Int 2003; 64:43-51.)
activation and leukotriene generation, are all found in the postischemic kidney.[141] Activated leukocytes release toxic enzymes (elastase) and reactive oxygen intermediates. Blockade of leukocyte adhesion molecules attenuates injury and intravascular accumulation of activated leukocytes with beneficial effects on renal function.[142–145] Blockade of leukocyte adhesion and migration by neutrophil depletion, ICAM-1 antibodies, or antisense oligonucleotides against ICAM-1 mRNA ameliorates ischemia-induced injury in animal models.[146–150] The role of ICAM-1, particularly in renal transplant ischemia-reperfusion injury, has gained significant attention, since ICAM-1 is highly upregulated following revascularization. Recently, a randomized control trial of ICAM-1 blockade was undertaken using humanized anti-ICAM-1 antibodies. There was no significant benefit in reducing delayed graft function, patient survival, graft survival, or acute rejection episodes at 3 months. The study design, however, included delivery of antibody only after reperfusion. Leukocytes accumulate in the kidney very soon after reperfusion. It is possible therefore that the cold-stored kidney has marked upregulation of ICAM-1 and the therapeutic window for ICAM-1 blockade was missed.[151]

Blockade of the effects of toxic products from inflammatory leukocytes and injured parenchymal cells have been proposed as a viable approach to protection of the kidney against ischemic and toxic injury. Targeting reactive oxygen species, such as H_2O_2 and O_2 using scavengers such as N-acetylcysteine, or transgenic animals overproducing oxygen radical scavengers, attenuate injury.[46,152–156] The value of such strategies has been suggested for many years, but has only been borne out in humans in a small clinical trial where patients with mild chronic renal failure were given oral N-acetylcysteine prior to radiocontrast agent administration. There were significantly more patients in the control group that had an increase in serum creatinine of more than 0.5 mg/dL (Figure 43–8).[4]

TNF-α, the prototypic pro-inflammatory cytokine, produced by lymphocytes and macrophages, is highly upregulated within 30 minutes following ischemic injury.[157] Blockade of TNF-α ameliorates inflammatory disease in other contexts and has led to the creation of blocking agents that are used in human diseases such as rheumatoid arthritis, Crohn's disease, and ankylosing spondylitis.[158] The functions of TNF-α are pluripotential, but include induction of cell death by apoptosis or necrosis, activation of proinflammatory cascades by activating the nuclear factor kappa-B (Nf-κB)–dependent genes, and by functioning directly and indirectly as a chemokine. Blockade of TNF-α reduces leukocyte infiltration, reduces tubular injury, and reduces renal dysfunction following ischemic insult to the kidney in animal models.[159,160]

The pathophysiology of sepsis-induced ARF has been elusive. The animal models have been inadequate, although recently published models capitalizing on increased susceptibility to sepsis-induced ARF in aged animals may change this research platform.[161] In our opinion the systemic inflammatory response syndrome (SIRS), characteristic of sepsis, results in intrarenal inflammation with microvascular and ischemic implications caused by leukocyte activation, pro-coagulant
Figure 43–8 *N*-Acetylcysteine protects renal function during radiocontrast-mediated injury. Patients treated with *N*-acetylcysteine 600 mg twice a day for 2 days, in addition to saline hydration (1 ml/kg/hr) for 24 hours, experienced an improvement in renal function compared with a deterioration in renal function in matched controls receiving saline alone (*P* <.001) (Adapted from Tepel M, van der Giet M, Schwarzfeld C, et al. N Engl J Med 2000; 343:180-184.).

effects, and advanced leukocyte-endothelial interactions and adhesion.[162] There is accumulating evidence that genetic predisposition in humans to production of high levels of TNF-α, and low levels of the anti-inflammatory cytokine IL-10, during SIRS associated with organ failure is detrimental to organ and patient survival. This lends further evidence to the view that inflammatory leukocyte-derived cytokines play crucial roles in renal injury during sepsis.[163]

NO may play a critical role in the regulation of the inflammatory response. The importance of NO in protecting the preconditioned kidney has been described previously. The actions of NO in the ischemic kidney are tripartite. NO is involved in maintaining vascular tone. It is known that following injury, endothelial-derived NO is reduced, presumably due to injury to the endothelium.[164,165] Thus generation of iNOS-derived NO by tubular cells and inflammatory cells assists in maintaining some degree of vasodilatation. In addition to a direct role on smooth muscle tone, NO regulates gene expression of endothelin and other vasoconstrictors, directly counteracting the upregulation of this potent vasodilator.[166] It is now widely accepted that a proportion of patients with vascular disease have endothelial dysfunction. In essence, the endothelium does not generate nitric oxide but favors generation of reactive oxygen intermediates (ROI). Thus, upregulation of perivascular NO by interstitial and inflammatory cells may serve to counteract the relative lack of NO generated by the endothelium of patients with endothelial dysfunction.[165] Secondly, NO can counteract the toxic effect of ROI by converting them to harmless nitrites and nitrates as end products. In rare circumstances NO interacts with ROI to generate nitrosyl compounds, which are nitrosylate tyrosine residues, and are very toxic to cells.[167,168] Although this has been observed in the kidney, it remains to

be elucidated when NO plays a primarily destructive or primarily beneficial role through interaction with ROI. Finally, NO itself is directly able to induce apoptotic cell death by engaging several mechanisms. It directly disrupts the cell cycle and regulates apoptosis gene expression, including apoptotic death proteases such as Caspase-3. In addition, it interferes with cyclic GMP intracellular signaling, which can also contribute to apoptosis.[169]

Thus in the preconditioned kidney, in addition to its role as a vasodilator, one mechanism by which nitric oxide generation by tubular cells and macrophages might be protective is through reduction of inflammation caused by neutralization of ROI. This protective mechanism has been reported in models of experimental glomerulonephritis in rats.[170] In addition, parenchymal cells generating high levels of NO themselves are resistant to the toxic effects of NO and ROI released from neutrophils and macrophages. Although NO is not currently used as a therapy for renal injury, small human studies of renal injury have confirmed that the use of L-arginine, the substrate for iNOS-dependent NO generation, reduces renal injury.[171]

Complement is deposited specifically on injured endothelial and epithelial cells following ischemic injury. In murine models, C3 is deposited within 2 hours, whereas C6 and C9, which are components of the membrane attack complex (MAC), are deposited later. Specific inhibition of C5 cleavage, which generates C5a, has been reported to inhibit the inflammatory infiltrate, to limit the MAC development, and to limit tubular cell death independently of the inflammatory response.[172,173] These investigations are, however, limited to rodent models.

Later phases of recovery from ischemic injury are characterized by T cell infiltration. CD4/CD8-deficient mice lacking T lymphocytes are protected from ischemia-reperfusion injury,[174] suggesting a causal role for T lymphocytes in mediating injury. In addition, blockade of the interaction of "co-stimulatory" molecules B7-1 and CD28 on antigen presenting cells and T cells, respectively, protects against ischemic injury in rats and significantly inhibits T cell and macrophage infiltration and activation *in situ*.[175,176] These molecular interactions are necessary to trigger an adaptive immune response. However, B7-1 expression by injured endothelium of the vasa recta may have a more general role in leukocyte adhesion, offering an alternative interpretation of these results.[177] Furthermore, mice deficient in both T and B cells are not protected from ARF induced by ischemia. In these experiments, histological assessment of postischemic kidneys found that both tubular necrosis and leukocyte infiltration were comparable with wild-type mice.[178] Thus, the exact role of T cells currently remains unclear.

Inflammatory mediators are generated not only by infiltrating leukocytes, but also by injured proximal tubular cells (PTC). While much of the data concerning inflammatory mediators derived from PTC come from *in vitro* studies, it appears that PTC can generate pro-inflammatory cytokines, including TNF-α, IL-1β, IL-6, growth factors such as M-CSF, and many chemokines including MCP-1, RANTES, IL-8 and fractalkines.[179,180] As indicated above, blockade of the inflammatory response following ischemic injury has been shown to be beneficial in animal models. One of the key functions of the innate inflammatory response is to debride tissue of injured cells, remove debris, destroy invading pathogens, and

then promote repair. It is clear that in carrying out these tasks, excessive cellular loss occurs. Tubular cells that could otherwise have recovered may be deleted and removed by the inflammatory response, resulting in an added burden to the repair process. More importantly, however, the inflammatory contribution results in local effects on the peritubular vasculature, causing upregulation of endothelial adhesion molecules and local activation of leukocytes and thus resulting in small vessel occlusion and secondary ischemia.[146]

Factors Affecting Tubular Cell Injury

i. Proximal Tubular Cell Injury.

The S3 segment of the proximal tubule is particularly susceptible to ischemic injury. This is in part due to vascular factors as previously discussed, but in addition, the proximal tubular cells have low glycolytic capacity. Although MTAL cells are subjected to equal hypoxia following ischemic injury, they are resistant to injury. *In vitro*, isolated rat MTAL tubular segments increase lactate generation by 1400% in response to blockage of mitochondrial respiration. Isolated proximal tubules do not generate lactate in identical conditions.[39] Although rat MTAL cells are less vulnerable to ischemia, nevertheless they respond promptly to the stress imposed by ischemia, switching on an array of inflammatory genes that may regulate local inflammatory responses.[181]

ii. Sublethal Injury.

In response to injury, the PTC initially loses polarity. Many molecules, normally polarized to one region or surface of the cell, becoming distributed equally through the cell or to different regions of the cell membrane. The loss of polarity is followed by disruption of the junctions that maintain a barrier between the lumen and the basolateral surface. Key junctions are the tight and adherens junctions.[182,183] Loss of the integrity of these junctions and incorrect targeting of ion transporters results in reduced vectorial transport of NaCl and water, which in turn leads to enhanced sodium delivery to the distal tubule.[184] This might be expected to generate afferent arteriolar vasoconstriction and contribute to post-ischemic vasoconstriction. By definition, this degree of injury is reversible and the altered polarity can ultimately be normalized.

In addition to the functional consequences of the loss of polarity, redistribution of integrins that anchor epithelial cells to the basement membrane allow viable epithelial cells to detach and be shed into the lumen.[185–188] These viable cells undergo a process of dedifferentiation, expressing molecules such as vimentin, NCAM, and the nuclear factor pax-2, normally associated with mesenchymal cells during nephron development and not normally present in epithelial cells.[189–192] Expression of these molecules, normally associated with mesenchymal cells during development, is characteristic of injured epithelial cells that have the potential to migrate to cover areas of denuded basement membrane.

We and others have shown that in animal models of ischemic injury to the kidney, there is expansion of the interstitial myofibroblast population as seen in many forms of renal disease in humans.[82,193] Following injury, there is new evidence that, in addition to acquiring a mesenchymal phenotype within the confines of the tubule, proximal tubular epithelial cells undergo transdifferentiation into interstitial fibroblasts. The normal kidney has a population of interstitial cells, which generate, amongst other molecules, erythropoietin.[194,195] However, during injury, these cells dedifferentiate into myofibroblasts, which produce a number of matrix proteins that, if not resorbed, potentiate scar formation.[196] The expansion of the myofibroblast population is as intrinsic to the inflammatory response as is influx of leukocytes. Renal epithelial cells frequently become myofibroblasts in tissue culture,[197–199] and epithelial cells of the eye, salivary gland, and liver and in tumors have been shown to transdifferentiate *in vivo*.[200–202] Evidence is accumulating from different models of renal injury that injured tubular cells *in vivo* transdifferentiate into myofibroblasts and contribute to the interstitial fibroblast population.[203–205] In a murine model of interstitial fibrosis, most of the interstitial myofibroblasts were derived from the proximal tubule.[203]

Thus it appears that, in addition to epithelial cells mediating repair through migrating to denuded areas of basement membrane, in areas where the basement membrane is damaged, production of extracellular matrix molecules by these cells maintains tissue integrity, preventing secondary damage resulting from tissue collapse (Figure 43–9). In addition to this potentially advantageous effect of enhanced matrix production, however, many studies show that interstitial fibrosis heralds poor outcome in the medium to long term. Repairing tissues, not capable of resorbing matrix, may develop persistent ischemia, progressive cell loss, and loss of function.[206,207] The accumulation of interstitial myofibroblasts appears to be under the regulation of the pluripotential cytokine TGFβ. A natural inhibitor of some of the functions of TGFβ, bone morphogenic protein-7 (BMP-7), is expressed in the developing and injured kidney. BMP-7 *in vitro* is able to counteract the tendency toward epithelial-mesenchymal transdifferentiation and in animal studies of nephritis, BMP-7 has markedly reduced progressive scarring and tubular atrophy.[169,208,209]

iii. Lethal Injury.

While the PTC adapts to injury (noted previously), sufficient injury will result in apoptosis or necrosis. Stimuli that induce necrosis can also induce apoptosis. The more intense the stimuli, the more likely it is that the PTC will not have time to engage the apoptotic death program. Although proximal and distal tubular cells are exposed to similar hypoxic stimuli, it appears that distal tubular cells die predominantly by apoptosis, whereas PTC die predominantly by necrosis.[210,211] The mode of death might be expected to have consequences for the inflammatory response. Removal of apoptotic cells by macrophages is in itself anti-inflammatory whereas removal of necrotic debris is pro-inflammatory.[212,213] Prior treatment with inhibitors of apoptotic and probable necrotic death protects rodent kidneys from functional tubular injury and the inflammatory response following ischemia.[214,215] Given the microvascular blood flow insufficiency, however, it is unclear whether it will be possible to deliver such agents clinically to the tubular structures in the outer medulla of the kidney.

iv. Resistance to Lethal Injury.

While some tubular cells die in response to hypoxia and ATP depletion, many tubular cells come under attack from ROI lib-
Figure 43–9 Tubular repair following injury. The initial response is loss of cell polarity, histologically and immunohistochemically. Many epithelial cells undergo death by either necrosis or apoptosis. Dead cells and cell debris are sloughed, generating tubular obstruction. Surviving epithelial cells can lift off the basement membrane or remain attached and dedifferentiate, displaying an embryological, mesenchymal phenotype. Some dedifferentiated cells cross the injured basement membrane and transdifferentiating into interstitial fibroblasts, where interstitial matrix is laid down, forming a scaffolding around the injured tubule. Finally, following proliferation of remaining tubular cells, clearance of the lumen and repair of the basement membrane, differentiation to mature epithelial cells can occur.

erated in part by neighboring epithelial cells, and in part by influxing leukocytes. Although cells have intrinsic antioxidant defense in the form of intracellular reducing agents (e.g, glutathione), this defense is frequently overwhelmed during the response to injury. The tubular cells, however, may have the capacity to enhance their ability to deal with the ROI by enhancing the levels of enzymes, which can detoxify these ROI. Following preconditioning of the kidney, one mechanism by which tubular cells resist injury is by generation of iNOS and nitric oxide.[82] It is also apparent that activated tubular cells may have other mechanisms that afford protection from ROI. Many growth factors and cytokines can activate intracellular stress signaling pathways following ligation and activation of specific cell surface receptors on the PTC. In addition, oxidative stress itself can activate the same pathways. These convergent intracellular signaling cascades act on the mitogen-activated protein kinases (MAPK) and involve sequential phosphorylation of proteins in the cascade that results in activation of genes ranging from pro-inflammatory response genes to pro-apoptotic genes. There are essentially three MAPK pathways of parallel signaling into the cell nucleus. It appears that the balance between signaling events in these three stress pathways deter-

mines outcome. For example, ROI predominantly activate the Janus kinase (JNK) pathway leading to apoptotic death, whereas growth factors predominantly activate the ERK pathway, which promotes survival. In cultured epithelial cells, inhibition of the JNK pathway prevents ROI-mediated death, whereas overexpression of members of the ERK pathway promotes cell survival in the face of ROI exposure.[123]

KIM-1 is a novel glycoprotein that is highly upregulated in PTC following ischemic injury. It is localized predominantly to the apical membrane and is shed into the urine. Tubular cells *in vitro* that constitutively express this protein are resistant to death induced by ROI.[216] In addition, these cells proliferate more vigorously than control cells. The mechanism by which KIM-1 mediates resistance to a toxic environment is yet to be elucidated.

REGENERATION

Following injury, many tissues engage a program of repair. Proximal tubular cells respond by proliferating and dedifferentiating. These cells alter their shape from cuboidal to fibroblast-like, either prior to or while they spread over the denuded

basement membrane to cover breaches in the epithelial lining as described previously (see Figure 43–9). This process is comparable to epithelial restitution after injury to the gut. In those regions of the proximal tubule characterized by extensive cell detachment, surviving cells at the edge of the wound engage the machinery necessary for cell migration.[217,218] The spreading cells also exhibit re-organization of stress fibers that enable migration. It is likely these cells synthesize new basement membrane components.

A proportion of those dedifferentiated epithelial cells leaves the confines of the basement membrane in the form of myofibroblasts.[203] This trans-differentiation may occur where the basement membrane is disrupted, since basement membrane proteins inhibit the process of transdifferentiation into myofibroblasts *in vitro*.[198] A part of the response to injury is the deposit of extracellular matrix (see above). Effective repair, however, leads to resorption of this matrix. It is unclear whether interstitial myofibroblasts redifferentiate or undergo apoptosis followed by phagocytic clearance when repair is effective.[219]

Proliferation of recovering tubular cells is dramatic.[189] This proliferation is under the guidance of autocrine and paracrine growth factors, and integrin-mediated signaling. Epidermal growth factor (EGF), insulin-like growth factors (IGF), hepatocyte growth factor (HGF) and transforming growth factor-β (TGFβ) have all been implicated in governing both proliferation and dedifferentiation. Growth factors are released from tubular cells, interstitial myofibroblasts, and interstitial macrophages. Enhanced recovery following ischemic injury in rodents has been repeatedly demonstrated with IGF-1 therapy. The efficacy of IGF-1 has been shown in tubular repair and proliferation as well as in improving renal blood flow.[220–222] A recent trial of recombinant IGF-1 in moderate human ATN, however, failed to show any benefit.[223]

Although it has been assumed that proliferating tubular cells are derived from remaining tubular cells, it has recently been reported that bone marrow stem cells are recruited to the injured kidney and replace up to 50% of the tubular cells lost to injury.[224,225] Using bone marrow chimeric mice, we have found that bone marrow–derived stem cells make only a minor direct contribution to the repair process.[2] Further work is required to clarify the role of stem cells in human renal repair.

Repair of the endothelium has also become a focus of attention. Without vessels, there cannot be effective repair of the tubules. In experimental models of ischemic injury, clamping of the renal artery for 60 minutes leads to permanent loss of endothelial cells.[193] This degree of ischemia is associated with partial initial recovery followed by progressive interstitial fibrosis, tubular atrophy, and progressive decline in renal function. Following only 30 minutes of arterial clamping we have found that interstitial fibrosis is present at 7 days and persists at 10 weeks.[82] One implication from these studies is that without endothelial repair, resolution of inflammation cannot occur. Further work is required in this area to determine whether there is inadequate or aberrant angiogenesis in the postischemic kidney, and whether this represents a primary mechanism in progressive renal attrition.[226] Work from Johnson and colleagues indicates that microvascular attrition is a central component of interstitial disease in the kidney. Application of pro-angiogenesis

factors in models where interstitial disease is prominent might reduce disease severity.[104,227–229]

What triggers redifferentiation of proximal epithelial cells? It is unclear whether cues from the inflammatory response are important or whether the departure of inflammatory cells is necessary. Also, there is evidence that integrity of the normal basement membrane is necessary. During development of the embryonic kidney, it has been proposed that laminin-integrin interactions are likely to be important in mesenchymal to epithelial differentiation. Mesenchymal cell α6β1 integrin interacts with the basement membrane laminin α chain, mediating polarization of the condensed mesenchyme to epithelium.[230] Laminin-5, also known as kalinin, a component of the anchoring filaments of skin basement membrane, is induced in the S3 proximal tubule segment of the post-ischemic kidney, along with its cognate receptor, integrin α3β1. Interactions of laminin-5 with α3β1 are required for epithelialization of skin after wounding, and are necessary for differentiation of enterocytes during migration from the crypt to the villus tip.[231,232] In the S3 segment of the post-ischemic kidney, the induction of laminin-5 and its cognate receptor, α3β1, late after injury during the recovery phase, suggests that this matrix-receptor combination may function in redifferentiation and repolarization critical for restoration of renal function and architecture. A recent study of BMP-7, a natural antagonist of some functions of TGF-β, indicates that it counteracts transdifferentiation of epithelial cells to myofibroblasts.[233] BMP-7 is highly expressed in proximal tubules in the normal kidney. Following ischemic injury in rat models, BMP-7 expression is markedly downregulated. Administration of BMP-7 during acute and chronic disease models promotes recovery and preserves epithelial cell function and morphology.[208,234,235] Thus, rather than promoting redifferentiation to the epithelial phenotype, this endogenous cytokine counteracts the natural tendency of the epithelium to promote interstitial scarring.

CONCLUSIONS

ARF remains a disease with serious consequences for the patient. Although there has been a lack of a unifying diagnosis for ARF, careful analyses of patient groups who acquire ARF indicate that it is a disease syndrome with high mortality, morbidity, and cost to health providers. Increased mortality is apparent even in those with minor increases in serum creatinine. In high-risk groups, such as those undergoing cardiac valvular replacement, patients have as much as a 1 in 2 chance of developing ARF. Trials in the 1990s suggest that, for patients with ARF requiring renal replacement therapy, early introduction of dialysis and achievement of basic lower limits of clearance are necessary to minimize mortality. A better understanding of the inflammatory response and the dysregulation of intra-renal arterioles observed in ARF has informed us that minimizing pro-inflammatory factors and maintaining stable renal blood flow may be applicable that will speed renal recovery.

Fundamental research has revealed that inflammation in the kidney is a hallmark of ARF. Accompanying this is inflammatory damage to intrarenal vessels and tubules. This inflammation adds to the inappropriate intrarenal vasoconstriction, which potentiates damage to susceptible segments

of the nephron. Although there are many candidate vasodilators that might counteract this deleterious vasoconstriction, none has emerged from clinical trials as a useful therapy. One aspect of the inflammatory process is that toxic reactive oxygen species play an important role in potentiating damage to injured tubules. Many animal studies indicate that minimizing kidney injury can be afforded by protecting renal cells from these radicals or by neutralizing them at the site of generation. Future management of ARF in humans may derive from modulation of other aspects of the inflammatory response such as leukocyte adhesion and/or generation of inflammatory cytokines by residing cells or transmigrating leukocytes, and such strategies will likely be directed at multiple components of the inflammatory response.

Human studies indicate that many patients with ARF do not recover or only partially recover renal function if they survive their illness. Many of these survivors experience subsequent decline in renal function accompanied by interstitial fibrosis as seen in other forms of renal disease. Animal studies indicate that interstitial fibrosis is a major factor complicating ischemic renal injury. Understanding the processes that lead the injured kidney to initiate and propagate the fibrogenic process is a desirable goal for the design of new therapies that can target this tissue response.

As we develop and evaluate putative therapies for ARF in humans, it becomes clear that we lack useful biomarkers of renal injury. A rise in serum creatinine occurs too late. We need a "troponin"-like biomarker for the kidney so that we can identify tubular epithelial injury early enough in order to intervene therapeutically in a timely fashion.

Pharmacologic Interventions in Acute Renal Failure

Richard Lafayette, M.D.

The incidence rate of acute renal failure (ARF) among patients admitted to the intensive care unit (ICU) has been increasing for several decades and is currently approximately 15%.[1,2] Among subpopulations within the ICU, including those who are aged, those with multiple comorbidities, those with multiple organ failure, and those with septic shock, the incidence rate of ARF can approach 50%.[3,4] Despite substantial advances in techniques of resuscitation and renal replacement therapy, mortality in the critically ill population with ARF remains alarmingly high. Recently, mortality rates in excess of 80% have been reported for ICU patients with multisystem organ failure requiring renal replacement therapy.[5] This scenario is becoming more prevalent as a result of the expansion of invasive medical and surgical procedures and the increasing expectation for aggressive medical management of critically ill patients. The high mortality rate associated with ARF has traditionally been attributed to associated comorbid conditions, but evidence exists to suggest that ARF has an independent negative impact on mortality.[6,7] Presently, there is no specific therapy for established ARF, making the development of agents that can prevent ARF or accelerate recovery from established ARF a priority.

Prerenal azotemia is the most common cause of ARF. When severe or prolonged, renal hypoperfusion is complicated by acute tubular necrosis (ATN). The typical course of ischemic ATN can be conveniently divided into three phases:

1. The *initiation* phase of renal ischemia (usually minutes to hours), during which parenchymal injury occurs
2. The *maintenance* phase (up to 21 days), during which the glomerular filtration rate (GFR) remains compromised and urine output is reduced.
3. The *recovery* phase, characterized by regeneration and repair of tubule epithelial cells and recovery of renal function

Several factors appear to act in concert to depress GFR during the maintenance phase. Studies in animal models of ARF reveal that tubular obstruction by casts is central to the decline in GFR and oliguria.[8,9] Ischemia disrupts osmolar gradients resulting in intracellular Na retention and cellular swelling.[10] If the hypoxic stimulus persists, cellular cytoskeletons are disrupted with the loss of tight junctions, altered epithelial polarity, and accumulation of intracellular Ca.[11,12] Apoptosis ensues with the sloughing of the epithelial brush border, which combines with proteinaceous material in the tubular lumen to form casts.[13] In addition, loss of tight junctions allows for back leak of glomerular filtrate.[14–16] Finally, a tubuloglomerular feedback mechanism may play an important role in the maintenance of prolonged renal insufficiency.[17] It has been postulated that due to tubular obstruction, an excess solute load is delivered to the macula densa resulting in renin release from the juxtaglomerular apparatus. The renin induced release of angiotensin II results in afferent arteriolar vasoconstriction.[18]

A plethora of therapeutic strategies have been tested or are in development directed at these key pathophysiologic events. This chapter critically reviews studies that evaluated the efficacy of low-dose dopamine and fenoldapam as well as atrial natriuretic peptide (ANP) in the treatment of ischemic ATN and discusses the existing evidence for growth factors as agents that promote tubule epithelial cell regeneration and renal recovery.

DOPAMINE

Low-dose dopamine (1–3 µg/kg/min) is prescribed worldwide for the treatment and prevention of ARF, to correct oliguria, and in conjunction with systemic vasopressors to preserve renal perfusion. The animal literature revealed optimistic results for both its use in the prevention and treatment of ARF.[19,20] In healthy persons, low-dose dopamine can cause selective renal vasodilatation and inhibit sodium reabsorption at proximal and distal portions of the nephron. The resulting increases in renal blood flow (RBF), natriuresis, and diuresis form the basis for the use of low-dose dopamine in ARF. Most clinical studies, however, have failed to demonstrate convincingly that low-dose dopamine either prevents ARF in high-risk patients or improves renal function or outcome in patients with established ARF. Further, some editorials have advised against its use, owing to the paucity of supportive scientific evidence and an increasingly recognized side-effect profile.[21,22] In the following section, we hope to clarify this controversial area by reviewing the renal effects of dopamine, discussing the rationale for administering dopamine in ARF, and summarizing the data from the numerous clinical studies in humans.

PHYSIOLOGY

Intrarenal Dopamine

Early studies in humans revealed that urinary dopamine levels exceed filtered dopamine levels and that the quantity of dopamine in the renal vein exceeds that in the renal artery. Furthermore, urinary dopamine levels increase with extracellular fluid volume expansion, and inhibition of renal dopamine synthesis results in an abrogation of the natriuresis induced by sodium loading.[23] It has subsequently been confirmed that the kidney is an important source of dopamine and that intrarenal dopamine is an important paracrine natriuretic agent.[24–26]

Proximal tubule epithelial cells synthesize dopamine from the substrate L-dopa using the enzyme L-amino acid decarboxylase.[27] L-Dopa enters the cell from the tubular fluid by a sodium-coupled cotransport mechanism. Dietary sodium intake is the major factor controlling intrarenal dopamine synthesis, but the mechanism by which increased salt intake leads to increased renal dopamine production is not fully understood.[26] Upon synthesis, intrarenal dopamine may act in an autocrine fashion by binding to dopamine receptors on the proximal tubule cell or may pass along the urinary space to bind to specific receptors in distal portions of the nephron. At the level of the proximal tubule, binding to the dopamine receptors DA_1 and DA_2 mediates inhibition of the basolateral Na^+-K^+-ATPase and luminal Na^+-H^+ exchange transporters, inhibiting sodium reabsorption and inducing natriuresis.[28] Dopamine also inhibits Na^+-K^+-ATPase at the medullary thick ascending limb of the loop of Henle, the distal collecting tubule, and the cortical and medullary collecting ducts. Finally, binding to DA_2 receptors in the inner medullary collecting duct stimulates both the synthesis and release of prostaglandin E_2 (PGE_2).[29] PGE_2 antagonizes the effect of antidiuretic hormone (ADH) on the collecting duct and increases inner medullary blood flow, resulting in medullary urea washout, two mechanisms by which dopamine leads to increased free-water clearance.

The influence of intrarenal dopamine on renal hemodynamics is less clearly defined and is probably species-dependent. Both DA_1 and DA_2 receptors are located on the renal vasculature, albeit at a lower density than that found on tubular cells. DA_1 receptors are localized within the vessel media, whereas DA_2 receptors are present in the adventitia and are probably localized presynaptically on sympathetic nerve terminals.[25] Experimental studies, however, have failed to show that intrarenal dopamine influences renal hemodynamics. Intrarenal infusion of dopamine antagonists abrogates the natriuresis induced by volume expansion without altering renal hemodynamics,[24] suggesting that intrarenal dopamine does not exert a basal influence over glomerular hemodynamics and that the natriuresis induced by intrarenal dopamine is mediated predominantly by its tubular effects. In agreement with these findings, studies have shown preferential release of dopamine from the proximal tubule into the tubular lumen rather than from the renal interstitium.[30]

Exogenous Dopamine

Dopamine can bind to at least three types of receptors: the dopamine receptor, the β-adrenoreceptor, and the α-adrenoreceptor.[31] Differences in these receptor's affinity for dopamine account for its distinct dose-response profile. To define the dose-response relationship for infused dopamine in humans, invasive hemodynamic and renal function tests were performed during graded dopamine infusions in the presence or absence of α- or β-adrenoreceptor blockade.[32] This study showed selective dopamine receptor stimulation within an infusion rate range of 0.5 to 3 μg/kg/min. Further increases in infusion rate between 3 and 10 μg/kg/min resulted in increasing β-adrenoreceptor stimulation, and increased α-adrenoreceptor stimulation occurred at a rate between 5 and 20 μg/kg/min.

Dopamine infusion increases RBF in healthy subjects.[32,33] At so-called renal doses, selective binding to dopamine receptors on the renal vasculature can result in renal vasodilatation and increased RBF, even in the absence of changes in systemic hemodynamics. Renal vasodilatation under these circumstances is mediated by stimulation of DA_1 receptors on both preglomerular and postglomerular vessels, resulting in vascular smooth muscle relaxation.[26] To confirm that low-dose dopamine can increase RBF purely through selective renal vasodilatation and independent of β-adrenoreceptor ligation, the effects of coadministration of the β-adrenoreceptor antagonist metoprolol in healthy adults were examined.[34] Although metoprolol inhibited the chronotropic effect of low-dose dopamine infusion, it did not abrogate the increase in RBF as assessed by para-aminohippuric acid (PAH) clearance, confirming predominant dopamine receptor stimulation at low infusion rates. With higher infusion rates, RBF is increased further by increases in cardiac output, mediated by β-adrenoreceptor stimulation.[34] More evidence for a direct vascular effect of low-dose dopamine is provided by studies comparing the effects of dopamine to dobutamine, a β- and α-receptor agonist deficient of dopamine receptor activity. When dopamine and dobutamine are infused into healthy adults at rates that lead to equivalent increases in cardiac index, dopamine induces a greater increase in RBF, in keeping with a selective effect on the renal vasculature.[35] Finally, dopamine-induced renal vasodilatation has been observed directly with Doppler ultrasound imaging.[36,37]

The effect of low-dose dopamine on the intrarenal distribution of blood flow is less clearly defined. Animal models have shown a preferential increase in cortical flow with dopamine.[26] In humans, preferential increases in cortical flow with dopamine has been confirmed in healthy kidney donors using the xenon washout technique,[38] and, more recently, in healthy volunteers using contrast-enhanced harmonic ultrasonography.[39] Dopamine-induced PGE_2 production by the inner medullary collecting duct results in enhanced inner medullary blood flow.[25] Low-dose dopamine may therefore result in shunting of blood away from the outer medulla, a potentially detrimental effect, given that the outer medulla contains the pars recta of the proximal tubule and the medullary thick ascending limb of the loop of Henle segments, two highly metabolically active portions of the nephron considered vulnerable to hypoxic injury.

Low-dose dopamine has a less dramatic effect on the GFR in healthy subjects. Most studies report only a mild increase in GFR on the order of 10% to 25%, at best.[35,40] Increases in GFR are mediated by preferential afferent arteriolar vasodilatation and an increase in intraglomerular pressure. The ultrafiltration coefficient remains unchanged with dopamine infusion.[26] Natriuresis, on the other hand, is the most consistent renal response to low-dose dopamine infusion. The effect is rapid in onset and may be profound, particularly in healthy persons.[35,40] It is abrogated by extracellular fluid volume depletion[41] and typically wanes after 24 hours of infusion,[42,43] perhaps as a result of counteractive effects of antinatriuretic agents or of dopamine receptor downregulation.

Like endogenous dopamine, inhibition of tubular sodium reabsorption is the predominant mechanism by which dopamine infusion induces a natriuresis. Comparison of sodium and lithium clearance rates in humans demonstrates that dopamine inhibits sodium reabsorption in both the proximal and distal tubule.[35] Low-dose dopamine infusion reduces plasma aldosterone concentrations, which may contribute to its natriuretic effect.[44] Additional effects of low-dose dopamine

infusion include phosphaturia and renal tubular acidosis mediated by inhibition of proximal tubule Na^+-phosphate cotransport and proximal tubule Na^+-H^+ exchange, respectively.

The hemodynamic effects of low-dose dopamine infusion differ at the extremes of age, which is likely a result of developmental differences in the maturation of receptor subtypes and differences in the metabolic clearance rates of plasma dopamine.[45] In neonates, activation of the α-adrenoreceptors occurs at a much lower infusion rate.[45] Although dopamine receptor maturation occurs early in life, some studies have demonstrated absence of selective vasodilatory effects of dopamine in children younger than 5 years of age. With increasing age, the effects of dopamine on RBF and GFR are attenuated.[46,47] This attenuated effect may be due to impaired renal prostaglandin production or organic changes in the renal vasculature with increasing age like atherosclerosis.

Whereas low-dose dopamine consistently causes renal vasodilatation in healthy adults, again this effect is often attenuated or absent in ill patients. Several factors may account for this, including hypertensive arteriopathy or counterregulatory effects of other vasoactive hormones, such as activity of the renin-angiotensin-aldosterone system or sympathetic nervous system. Both extracellular volume depletion and hypoxemia have been shown to abrogate the renal effects of dopamine.[42] Table 44–1 lists clinical settings in which studies have reported diminished renal hemodynamic effects of dopamine.

In patients with renal disease, the increase in RBF and GFR observed with low-dose dopamine infusion correlated with the baseline GFR. Patients with a baseline GFR of less than 50 mL/min showed no change in RBF or GFR with dopamine infusion.[48] Low-dose dopamine does not increase RBF in patients with clinical and radiologic heart failure,[40] which may be due to either downregulation of dopamine receptors or the counteractive effects of the sympathetic nervous system and angiotensin II on the renal vasculature in heart failure. In a group of patients who underwent infrarenal aortic surgery, dopamine (4 μg/kg/min) resulted in increased RBF; however,

this was entirely due to an increase in cardiac output. No selective renal vasodilatory effect was observed.[44] Furthermore, in a prospective crossover study comparing dobutamine (mean dose, 2.5 μg/kg/min) to dopamine (mean dose, 2.9 μg/kg/min) in critically ill patients, dopamine acted primarily as a diuretic and had no effect on creatinine clearance, whereas dobutamine, which had a greater effect on cardiac index, increased creatinine clearance.[49]

Potentially Deleterious Effects of Dopamine

Table 44–2 outlines common adverse effects of low-dose dopamine. Administration of dopamine requires a central venous catheter, and local extravasation of dopamine adjacent to an artery may provoke distal ischemia and gangrene. Even at low infusion rates all three receptor subtypes may be activated. Even low-dose dopamine can, through β-receptor agonism, increase myocardial oxygen demand and precipitate tachyarrhythmias and myocardial ischemia.[50] In fact, a trial assessing the use of the orally active dopamine agonist ibopamine in patients with chronic heart failure was discontinued early because of the excess mortality in the ibopamine group (25% vs. 20%). This excess mortality was considered to be secondary to ibopamine-induced tachyarrhythmias.[51]

Normally, dopamine is an inhibitory neurotransmitter in the carotid bodies, and dopamine infusion can suppress the respiratory drive induced by hypoxemia. Dopamine can also lower blood Pa_{O_2} by altering ventilation-perfusion matching within the lung, an effect arising from a shunt of blood away from alveolar capillaries.[49] Hypoxemia may worsen myocardial ischemia in susceptible patients and delay recovery from ischemic ATN. The natriuresis and diuresis induced by dopamine may cause severe volume depletion unless close monitoring of the patient permits appropriate fluid replacement. Potassium depletion is also a common result of the increased delivery of sodium to the distal tubule. Hypophosphatemia and hypomagnesemia have also been reported. Low-dose dopamine suppresses pituitary gland function and inhibits prolactin and growth hormone secretion and, hence, may exacerbate the catabolic state in critically ill patients.[52] Hypoprolactinemia suppresses T-cell proliferation.[53]

Table 44–1 Effects of Low-Dose Dopamine on Renal Hemodynamics and Na^+ Excretion in Disease States

Disease State	Reference	RBF	GFR	UNa+
Hypertension	Bughi[225]	↔	NR	↑
Cardiac failure	McDonald[40]	↔	↔	↑
Septic shock on NE	Lherm[93]	NR	↔	↔
After vascular surgery	DeLasson[226]	↑*	↔	↑
After vascular surgery	Girbes[44]	↑*	↔	↑
Critically ill	Duke[49]	NR	↔	↑
Critically ill	Parker[227]	NR	↔	↑
Hypoxemia	Olsen[228]	↔	↔	↑
Renal impairment	Ter Wee[48]	↔	↔	↑

*Increase in renal blood flow mediated by increase in cardiac output, not renal vasodilatation.
RBF, renal blood flow; GFR, glomerular filtration rate; NE, norepinephrine; NR, not recorded; UNa+, urinary sodium excretion; ↔, no change; ↑, increase.

Table 44–2 Deleterious Effects of Low-Dose Dopamine

Effect	Cause
Distal gangrene	Local extravasation of dopamine
Fluid and electrolyte imbalance	Inhibition of salt and water reabsorption
Tachyarrhythmias and myocardial ischemia	β-Adrenoreceptor stimulation
Hypoxemia	Reduced respiratory drive; pulmonary shunting
Gut ischemia and bacterial translocation	Shunting of blood away from mucosal capillary bed
Catabolic	Inhibition of growth hormone release
Immunosuppression	Inhibition of prolactin release

Although low-dose dopamine increases total splanchnic blood flow, elegant studies in experimental animal models have shown that absolute intestinal mucosal flow is decreased as a result of dopamine-induced shunting of blood away from the mucosa.[54,55] This complication is of extreme concern, particularly in the critically ill patient, in whom critical intestinal mucosal ischemia may lead to bacterial translocation and sepsis. When high-dose dopamine was compared with norepinephrine in patients with septic shock, dopamine was associated with a drop in gastric mucosal pH (an indicator of mucosal ischemia), compared with a rise in pH observed with norepinephrine.[56]

Prevention of Acute Renal Failure in High-Risk Patients

Renal hypoperfusion is the leading cause of ARF in humans. It may be caused by intravascular volume depletion, decreased cardiac output, systemic vasodilatation (e.g., sepsis and liver failure), or conditions that directly promote renal vasoconstriction, including drugs (e.g., cyclosporine), radiocontrast agents, hypercalcemia, liver failure, and sepsis. The renal vasodilatory effect of low-dose dopamine might be expected to be beneficial under these circumstances, particularly when the period of renal hypoperfusion is short-lived, such as during surgery and radiocontrast administration. However, as outlined previously, in a variety of conditions, including renal failure, the selective renal vasodilatory effects of dopamine are frequently absent, placing doubt on the rationale for using this agent in preventing ARF. Table 44–3 summarizes data from prospective, controlled trials performed to determine the value of low-dose dopamine infusion in a variety of high-risk clinical situations.

Numerous studies have compared the effects of perioperative administration of low-dose dopamine to usual care in patients undergoing cardiovascular surgery.[57–62] To date, no study has demonstrated a beneficial effect of low-dose dopamine as assessed by postoperative increase in serum creatinine,[61,62] creatinine clearance,[57–59] or 51Cr-EDTA GFR.[60] Similarly, no benefit in postoperative renal function in patients undergoing abdominal aortic surgery treated with a combination of low-dose dopamine and mannitol[63] or low-dose dopamine infusion alone[64] has been reported. In the first study, RBF assessed during the aortic clamp procedure decreased by 50% in both groups.[63] When low-dose dopamine was compared with intravenous nifedipine in patients undergoing aortic surgery, dopamine was less effective in preserving postoperative GFR.[65]

Five studies have examined the role of perioperative low-dose dopamine infusion during renal transplantation, including four prospective studies[66–69] and a retrospective studies.[70] End points measured included incidence of post-transplantation ARF, delayed graft function, requirements for dialysis, and graft GFR measured at various points after transplantation. Five studies indicated no beneficial effects of perioperative dopamine infusion on graft function. In fact, dopamine-induced natriuresis and diuresis were often associated with fluid and electrolyte management problems in these patients. A single prospective study reported a small but significantly higher GFR at 1 month in the dopamine-treated transplantation group; however, there were no significant differences in the rate of delayed graft function or in the requirement for

dialysis between groups in this study. In a recent study that measured renal blood flow velocity and vascular resistance by Doppler ultrasound, transplanted grafts were determined to be insensitive to the vascular effects of dopamine infusion.[71]

Patients undergoing liver transplantation have a high incidence of postoperative ARF precipitated by the major stresses of hepatobiliary surgery superimposed on the chronic renal hypoperfusion that complicates liver failure. In a study of 34 patients undergoing live transplantation, prophylactic dopamine was associated with a lower incidence of renal insufficiency as compared with controls (10% vs. 67%, respectively).[72] However, in a larger, prospective controlled study involving 48 patients, perioperative infusion of dopamine was not associated with lower blood urea nitrogen or creatinine clearance rates measured 24 hours after surgery or GFR measured 1 month later.[73] Similarly, when administered to patients undergoing elective surgery for obstructive jaundice, dopamine was not associated with improved creatinine clearance 5 days after surgery.[74]

Radiocontrast agents can cause potent intrarenal vasoconstriction and may result in transient renal impairment, particularly in patients with diabetic nephropathy and baseline renal impairment. The role of prophylactic dopamine therapy to prevent radiocontrast-induced nephropathy (RCIN) has been assessed in six controlled trials.[75–80] A randomized controlled trial involving 40 diabetic patients, with a mean baseline serum creatinine level of 1.5 mg/dL, showed that low-dose dopamine prevented a 25% increase in serum creatinine levels observed in the control group.[79] Similar results were reported in two other studies.[77,78] In one study, the beneficial effect was more striking in patients with baseline creatinine levels greater than 2 mg/dL.[78] In contrast, no decrease in the rate of RCIN was found with prophylactic dopamine therapy, and, unexpectedly, the patients within the dopamine group who subsequently developed RCIN exhibited the greatest increase in RBF.[81] The two most recent trials failed to show a benefit for dopamine infusion.[75,76] In one study, dopamine combined with furosemide and mannitol to achieve a forced diuresis did not reveal a difference in the change in serum creatinine at 48 hours compared to hydration alone.[75] In the second trial, dopamine prolonged the course of renal failure in patients with contrast nephropathy.[76]

Treatment of Established Acute Renal Failure

More severe or prolonged renal hypoperfusion can provoke ischemic renal parenchymal injury. It has been postulated that the renal vasodilatory action of dopamine is beneficial in established ATN, but several issues need to be considered:

1. Dopamine may not induce renal vasodilatation in patients with ARF because of counterregulatory factors causing preglomerular vasoconstriction, such as increased endothelin levels, inhibition of nitric oxide synthesis, and activation of tubuloglomerular feedback.
2. Tubular obstruction and back-leakage are thought to play a more important pathogenic role in maintaining a low GFR in these conditions. Indeed, GFR frequently remains low despite restoration of total RBF.
3. A consistent finding in established ATN is an abnormal distribution of RBF rather than an absolute reduction. This

Stevens[75] (N=76)	Coronary angiography	3 μg/kg/min during with furosemide and	SCr CrCl RCIN	2.55 ± 0.91 30.48 ± 12.95 —	3.08 ± 1.20 NR 30.9%	2.20 ± 0.38 33.73 ± 10.00 —	2.72 ± 1.19 NR 31.8%	No ? No	Parameters assayed at 48 hr postop. RCIN defined as 25% increase in SCr.
Abizaid[40] (N=)	Coronary angioplasty	2 μg/kg/min 2 hr prior and during procedure	SCr CrCl RCIN	2.3 ± 0.18 NR —	2.8 ± 0.24 NR 30%	1.9 ± 0.07 NR —	2.3 ± 0.16 NR 35%	No ? No	The SCr was expressed as the peak SCr post-procedure. RCIN defined as 25% increase in SCr.

Yes denotes *P*<.005 when comparing postoperative parameters.

*Data were expressed as means and were estimated from figures where not reported in original text. Standard errors of means are included where reported or derivable from figures.

BUN, blood urea nitrogen (mg/dL); *CABG*, coronary artery bypass grafting; *CrCl*, creatinine clearance (mL/min); *DGF*, delayed graft function; *GFR*, glomerular filtration rate (mL/min); *NR*, not reported; *RBF*, renal blood flow (mL/min); *RCIN*, radiocontrast-induced nephropathy; *SCr*, serum creatinine (mg/dL).

manifests in medullary hypoperfusion and persistent ischemia of the pars recta of the proximal tubule and the medullary thick ascending limb of the loop of Henle. Most studies report a selective increase in cortical rather than medullary perfusion with dopamine.

It has, however, been suggested that low-dose dopamine may improve the course of ARF by other mechanisms:

1. Through inhibition of Na^+-K^+-ATPase, dopamine may favorably alter the oxygen supply/demand ratio of the tubular epithelial cells, rendering them less prone to ischemic injury.
2. By causing natriuresis, dopamine may help to flush out obstructing tubular casts.
3. The frequent use of low-dose dopamine in ARF has evolved from the belief that increasing urine output improves outcome in this condition. This opinion is based on the improved prognosis and lower mortality rates observed in patients with nonoliguric ARF compared with patients who have oliguric ARF. Unfortunately, there is no evidence that converting oliguric ARF to a nonoliguric state improves prognosis.

Low-dose dopamine has been commonly prescribed to critically ill intensive care unit patients with established ARF. Early uncontrolled studies reported variable success with low-dose dopamine in established ARF.[82, 83] Multiple studies have confirmed the natriuretic and diuretic effects of dopamine in this patient population.[82–85] In critically ill oliguric patients, a response of greater than a 50% increase in urine output on low-dose dopamine has been documented.[84] Interpretation of these results, however, requires caution because oliguria is a notoriously poor indicator of ARF, and conversion from an oliguric to a nonoliguric state has not been shown to improve renal prognosis. In addition, such a response is not universal[86] and may wane over time.[87] Eight hemodynamically stable, critically ill patients with mild nonoliguric renal failure defined as a creatinine clearance between 30 and 80 mL/min, received 4-hour infusion periods with placebo alternating with low dose dopamine.[87] Urine flow rate, creatinine clearance, and FENa increased significantly with maximal changes in each parameter noted at 8 hours. However, the improvements waned considerably by 24 hours and were no longer detectable by 48 hours.

In an observational study, a subgroup of patients who received low-dose dopamine within the placebo arm of a multicenter intervention trial were analyzed.[88] All patients within the placebo arm were adults with ARF having a clinical history consistent with ATN. Dopamine had been administered to a portion of these patients at the discretion of the physician. A total of 86 patients received dopamine (<3 μg/kg/min), and 79 patients did not. Despite complex adjustment for treatment bias, low-dose dopamine treatment was not associated with reduced risk of death or with combined risk of death or dialysis in patients with ATN. A meta-analysis including 58 randomized clinical trials revealed that dopamine did not prevent mortality, onset of ARF, or need for dialysis.[89] Finally, a large, multicenter, randomized, controlled, double-blind trial enrolled 328 patients with ATN to either low dose dopamine (2 μ/kg/min) or placebo.[90] No difference in peak serum creatinine concentration, difference from baseline to peak serum creatinine concentration, the number of patients whose serum crea-

tinine exceeded 300 μmol/L, or the number of patients who required renal replacement therapy was detected. In addition, the durations of ICU and hospital stays were similar.

Low-Dose Dopamine in Conjunction with Systemic Vasopressors

Low-dose dopamine is commonly administered to critically ill patients requiring pressor support with systemic vasoconstrictors, with the goal of maximizing renal perfusion. Justification for combination therapy comes from experimental studies in animals. In dogs with septic shock treated with norepinephrine, low-dose dopamine improved RBF.[91] When pressor doses of norepinephrine are administered to healthy humans, RBF falls but can be normalized by coadministration of low-dose dopamine.[92] There is no evidence, however, that low-dose dopamine improves RBF or renal function in patients with septic shock already receiving norepinephrine. Indeed, it has yet to be demonstrated convincingly that therapeutic doses of norepinephrine compromise renal function. No change in GFR was demonstrated when low-dose dopamine was added to norepinephrine-treated patients with septic shock.[93] Norepinephrine has been shown to be more effective than high-dose dopamine in preserving RBF in patients with septic shock.[94] Finally, it has been demonstrated that the addition of norepinephrine alone is sufficient to restore renal perfusion and urine output in patients with septic shock.[95]

FENOLDOPAM

Fenoldopam mesylate is a specific agonist of the DA_1 receptor. Like dopamine, fenoldopam results in peripheral and renal vasodilation as well as diuresis and natriuresis via stimulation of vascular and renal tubular DA_1 receptors.[24,96] Studies in healthy, salt replete subjects have confirmed dose-dependent increases in renal plasma flow, urine flow rate, and urinary sodium excretion without changes in GFR.[24, 97–102] The lack of increase in the GFR is secondary to parallel vasodilation of both afferent and efferent renal arterioles rendering intraglomerular pressure constant.[103] Animal studies have demonstrated fenoldopam to be markedly more potent than dopamine in decreasing renal vascular resistance and augmenting RBF.[96] Its relative potency, in conjunction with the absence of the potentially deleterious cardiac side effects characteristic of dopamine due to β-adrenoreceptor stimulation[50] were the impetus for trials examining its potential to prevent and treat renal ischemia.

Both animal[104] and uncontrolled human observational studies[105–109] indicated that fenoldopam might have a role in the prevention of contrast-induced nephropathy. More recently, however, three double-blind, randomized, placebo controlled trials failed to confirm any benefit for fenoldopam in the prevention of contrast-induced nephropathy.[110–112] Although the smallest of the three trails revealed a statistically significant increase in renal plasma flow in the patients that received fenoldopam (16% above baseline) as compared to the placebo group (33% below baseline), the difference in the incidence of contrast-induced nephropathy was not significant (21% vs. 41%, respectively; $p = .148$).[112] A second trial randomized 123 patients with renal insufficiency (serum creatinine >1.6 mg/dL or creatinine clearance >60 mL/min) to receive either

saline, *N*-acetylcysteine or fenoldopam. The incidence of contrast-induced nephropathy defined as an increase in serum creatinine >0.5 mg/dL 48 hours after the procedure was 15%, 18%, and 16% in the saline, N-acetylcysteine fenoldopam groups, respectively ($p = 0.919$).[111] Finally, in the largest trial to date, 315 well-hydrated patients with renal insufficiency (creatinine clearance <60 mL/min) were randomized to fenoldopam (0.1 mcg/kg/min), beginning 1 hour prior and maintained for 12 hours after the procedure or placebo.[110] No difference was detected in the incidence of contrast-induced nephropathy (a 25% increase in serum creatinine within 96 hours of contrast), which was 34% in the fenoldopam group and 30% in the placebo group. In addition, no significant differences were detected in any of the secondary outcome measures, which included the 30-day rate of death, dialysis, or rehospitalization.

In both animals and humans, uncontrolled studies have demonstrated that fenoldopam can prevent and reverse cyclosporin A-induced renal vasoconstriction.[113,114] Similarly, small human trials that initiated fenoldopam prior infrarenal aortic cross-clamping noted rapid recovery to baseline kidney function[115] and less postoperative decrement in creatinine clearance compared to the placebo group.[116] During cardiopulmonary bypass, no patients at risk for developing postoperative renal failure required dialysis in an uncontrolled study of 70 patients.[117] A small, randomized trial of 31 patients revealed a significant decrease in the creatinine clearance after cardiopulmonary bypass in the placebo but not in the fenoldopam group.[118] This renoprotective effect following cardiopulmonary bypass was replicated in a larger prospective randomized controlled trial of 160 patients.[119] However, further studies are required to determine whether fenoldopam alters more clinically meaningful outcomes like allograft survival, need for renal replacement therapy, or mortality.

ATRIAL NATRIURETIC PEPTIDE

The existence of an atrial natriuretic substance was first postulated in 1981 with the discovery that an atrial myocardial extract from rats produced a potent natriuretic response on reinfusion.[120] This substance was originally named *atrial natriuretic factor* and then *peptide* after its characterization as a protein. Subsequent studies defining the physiology and pharmacology of ANP have cast light on its role in the maintenance of circulatory volume in health and disease. The pharmacologic properties of ANP suggested that it has the potential to reverse the impaired glomerular hemodynamics and tubular obstruction that characterize ARF. We now review the structure and physiology of ANP, discuss the rationale for its use in ARF, and describe the results of animal and human trials.

PHYSIOLOGY

ANP is a member of a family of related homologous natriuretic peptides, which includes brain natriuretic peptide, C-type natriuretic peptide, and urodilatin. ANP is released from secretory granules in the atria and, to a lesser extent, the ventricles. It is stored as a 126-amino acid peptide, pro-ANP, and circulates as a 28-amino acid peptide derived from the C-terminal end of pro-ANP. The main stimulus for ANP secretion is an increase in atrial pressure or stretch.[121] ANP is cleared by the kidney and has a short half-life, of the order of 1 to 4 minutes.[122]

The physiologic effects of ANP are mediated through its action on the systemic vasculature as well as on the renal glomerulus and tubules. Systemic effects of ANP include increased vagal tone,[123] inhibition of the renin-angiotensin-aldosterone system,[121] and preferential vasodilatation of the venous circulation with hypotension.[124] ANP can also reverse the vasoconstrictive effect of other peptides, such as endothelin.[125] ANP augments glomerular capillary hydraulic pressure and GFR by triggering afferent arteriolar dilatation.[126] Total RBF remains largely unchanged. The tubular effects of ANP are mediated at several segments. Micropuncture studies have shown that the natriuretic effects of ANP are exerted predominantly at the level of the inner medullary collecting ducts.[127,128] Here, ANP attenuates transport of Na^+ through epithelial luminal Na^+ channels.[121] This action is mediated through engagement of basolateral cell surface receptors, activation of guanylate cyclase resulting in an increase in intracellular cyclic guanosine monophosphate (cGMP) levels, and activation of a cGMP-dependent protein kinase, which closes the Na^+ channel.[129] At the level of the proximal tubule, ANP inhibits the reabsorption of Na^+, Cl^-, and water,[130] possibly through interactions with other modulators of proximal tubular function, such as angiotensin II or dopamine.[131,132] ANP may also modulate Na^+ reabsorption in the loop of Henle and the cortical collecting duct.[133,134] ANP attenuates the collecting tubule responsiveness to ADH, which promotes a diuretic action.[135]

EFFICACY IN EXPERIMENTAL AND HUMAN ACUTE RENAL FAILURE

ANP possesses several bioactivities that may prevent ischemic ARF or accelerate its resolution. Specifically, ANP can raise GFR, enhance urine flow, redistribute RBF to the medulla, inhibit Na^+ transport, and reduce tubular ATP and oxygen requirements. In addition, reversal of endothelin-related vasoconstriction may also improve blood supply to the renal medulla. These observations were the catalyst for numerous studies in animals and humans, which evaluated the efficacy of ANP as a therapeutic agent in ARF.

The initial studies examining the effects of ANP in experimental ischemic ARF were reported in 1986.[136,137] Improvements in GFR, urine volume, and fractional excretion of sodium and potassium were noted after intrarenal infusion of ANP in norepinephrine-induced renal failure in the rat.[137] In addition, pretreatment with ANP prevented norepinephrine-induced renal failure and GFR, urine volume and sodium, and potassium excretion improved with ANP infusion in a dose-dependent fashion.[136] Subsequent studies also demonstrated a beneficial effect of ANP infusion in experimental ischemic ARF due to renal vasoconstriction induced by norepinephrine[138] or arginine vasopressin[139] as well as by renal artery clamping.[140–150] Beneficial effects were also assessed in ARF induced by glycerol,[151,152] uranyl nitrate, gentamicin,[153] and cisplatin.[154,155] In addition to functional improvement, some studies demonstrated significantly less histologic damage in ANP-treated kidneys.[142,149,152] Although the bulk of experimental evidence favored ANP as a potential therapy for

ATN, several studies noted the beneficial effect of ANP to be transient and not sustained beyond its administration.[139,148] The tendency for ANP to result in systemic hypotension prompted investigators to use it in combination with low-dose dopamine.[138,144,150,155] The improvement in MAP due to the addition of dopamine to ANP may have been responsible for the improved, sustained benefit in these studies. Similarly, mannitol has been reported to potentiate the positive effects of ANP.[146]

The encouraging results in experimental ARF prompted evaluation of the efficacy of ANP in human disease (Table 44–4). Urodilatin is a 32–amino acid peptide generated by cleavage of the pro-ANP peptide 4 amino acids upstream from the usual cleavage site. The efficacy of urodilatin has been examined in patients after cardiac or liver transplantation.[156–158] Ninety-six hours of a low-dose urodilatin infusion was initiated in 51 patients after cardiac transplantation.[158] Compared to historical controls, significant reductions in the peak serum creatinine, peak serum urea, and incidence of hemodialysis were noted in the patients who received urodilatin. In a randomized, placebo-controlled trial, 24 patients were randomized to either urodilatin infusion or placebo immediately post cardiac transplantation.[157] Although urodilatin failed to reduce the incidence of ARF, the duration of hemofiltration and/or hemodialysis was reduced. Nine patients with ARF following liver transplantation were randomized in a double-blind, controlled study to receive either urodilatin or placebo.[156] The frequency of dialysis and the serum creatinine levels were significantly reduced in the treatment group compared with those in the placebo group. However, in trials that examined ARF in the ICU setting, urodilatin infusion did not consistently improve renal function.[159–161]

Improvements in urine flow, GFR, and RBF have been reported in patients with ARF and heart failure receiving ANP infusions after cardiac surgery.[162,163] In an open-label study, 53 patients with established intrinsic ARF were randomized to receive ANP infusion in addition to standard diuretic therapy or diuretic therapy alone.[164] A significant increase in creatinine clearance was found with ANP treatment, rising from 9.9 mL/min to 21 mL/min. No corresponding increase was noted in the control group. The need for dialysis was significantly reduced, from 52% in the control group to 23% in the ANP treatment group. A nonsignificant trend toward reduced mortality was noted in the ANP treatment group.

After these initial results, 504 patients with ATN due to ischemic or nephrotoxic insults were enrolled at centers across the United States and Canada in the largest trial to date.[165] Patients were randomized to receive either anaritide, a 25-amino acid synthetic form of ANP (ANP 4-28), or placebo in a double-blind study. No difference was noted between the anaritide-treated and placebo groups for either the primary end point (dialysis-free survival for 21 days after treatment) or any of the secondary end points (need for dialysis, serum creatinine level, and mortality). A subgroup analysis of patients who were oliguric (120 patients) revealed a greater dialysis-free survival in the anaritide group than in the placebo group (27% vs. 8%, respectively; $p = .008$). Conversely, a trend toward a worse outcome existed among the nonoliguric patients as dialysis-free survival was 59% in the placebo group compared to 48% in the ANP group ($p = .03$). These results prompted a follow-up study involving only oliguric patients. In this study, 222 patients were randomized to either ANP

infusion versus placebo. However, no benefit in dialysis-free survival was demonstrated.[166] Of note, in the anaritide multicenter study, hypotension was reported in 46% of the anaritide group.[165] Similarly in the follow-up study, which randomized only oliguric patients, 95% versus 55% of the patients had a systolic blood pressure less than 90 mmHg in the anaritide and placebo groups, respectively.[166] The maximal absolute decrease in systolic blood pressure was approximately 10 mmHg.

Similarly, the results of studies assessing the efficacy of ANP for prevention of contrast nephropathy and for the treatment of delayed graft function after cadaveric renal transplantation were equally disappointing. In an effort to prevent contrast nephropathy, 247 patients with stable chronic renal failure (estimated creatinine clearance ≤ 65 mL/min) were randomized to receive one of three doses of ANP infusion or placebo for 30 minutes before and after contrast administration.[167] The incidence of radiocontrast-induced nephropathy did not differ among the groups. ANP was evaluated in prospective, double-blind controlled trials in cadaveric renal transplantation.[168–170] ANP or vehicle was administered intravenously at the time of revascularization of the allograft to 20 recipients of 10 pairs of cadaveric kidneys.[170] No improvement in serum creatinine, GFR, need for dialysis, or allograft function was observed. In a study of 38 recipients of 19 pairs of cadaveric kidneys, escalating doses of atriopeptin III, a synthetic analogue of ANP, was administered over 12 hours in an intravenous infusion commencing at release of the vascular clamps.[169] No improvement was reported in creatinine clearance or sodium excretion compared with placebo. ANP was compared to a maximal hydration regimen as a means of preventing ATN after cadaveric renal transplantation in an open, randomized study involving 40 patients.[168] Although a nonsignificant trend toward a reduced need for dialysis was noted in the ANP group, no difference was detected in the median rate of renal recovery.

GROWTH FACTORS

Growth factors are known to be key players in renal development. To date, three growth factors have received the most attention in the literature for their ability to alter renal function/structure:

- Insulin-like growth factor-1 (IGF-1)
- Epidermal growth factor (EGF)
- Hepatocyte growth factor (HGF)

The kidney is a site of EGF, HGF, and IGF-1 synthesis.[171,172] These growth factors mediate specific growth-promoting, transport, and metabolic functions within the kidney.[173–176] HGF and EGF are mitogenic for cultured tubular cells *in vitro*.[177,178] IGF-1 is required for the development of the metanephric kidney *in vitro*,[177] a process that has many similarities to recovery from ATN in vivo. In addition, expression of some growth factors or their receptors is augmented after renal injury, suggesting that they may have therapeutic potential in ATN.[179,180]

Clinical recovery from ATN correlates temporally with the relief of intratubular obstruction and, more importantly, with the restoration of the continuity and function of the tubular epithelium.[181] Initial studies in experimental animals revealed

Table 44–4 Summary of Evidence of Benefit in Human Trials for Use of Atrial Natriuretic Peptide in Acute Renal Failure

Reference	Study Design	Total Patients	Treatments Compared	Patient Population	Outcome
Kuse[156]	Double-blind	9	Urodilatin, placebo	Liver transplantation	Increased need for dialysis; decreased serum creatinine, stable serum urea; trend towards increased diuresis
Brenner[157]	Double-blind	24	Urodilatin, placebo	Heart transplantation	Half the patients in each group required RRT, but the duration of RRT was significantly less in the urodilatin group
Hummel[158]	Open, nonrandomized	51	Urodilatin, historical controls	Heart transplantation	Urodilatin group significantly lower peak plasma creatinine and lower incidence of RRT
Herbert[159]	Double-blind	12	Urodilatin, placebo	Post major abdominal surgery	No significant difference in peak serum creatinine or need for RRT
Weibe[160]	Double-blind	14	Urodilatin, placebo	Post cardiac surgery	No patients in the urodilatin vs. 6 in placebo group required RRT ($p < .005$)
Meyer[161]	Double-blind	176	Urodilatin, placebo	Oliguric ARF	No significant difference in need for RRT
Sward[162]	Open, nonrandomized	11	Human ANP 1-28	ARF post cardiac surgery	Increased urine flow, GFR, renal blood flow; decreased renal vascular resistance
Valsson[163]	Open, nonrandomized	12	Human ANP 1-28	ARF and heart failure post cardiac surgery	Increased urine flow, GFR, renal blood flow; decreased renal vascular resistance
Rahman[164]	Open, randomized	53	Human ANP 3-28 or human ANP 4-28, diuretic	Intrinsic ARF	Increased GFR; decreased need for dialysis; trend toward decreased mortality
Allgren[165]	Double-blind	504	Anaritide, placebo	Ischemic or nephrotoxic ATN	No improvement in dialysis-free survival, need for dialysis, serum creatinine level, or mortality; increased dialysis-free survival in oliguric subgroup
Lewis[166]	Double-blind	222	Anaritide, placebo	Oliguric ATN	No benefit in dialysis free survival
Kurnik[167]	Double-blind	247	Anaritide, placebo	Contrast nephropathy	No reduction in the incidence of contrast nephropathy in patients with renal insufficiency, with or without diabetes
Gianello[168]	Open, randomized	40	Human ANP 1-28, maximal hydration regime	Renal transplantation	Trend toward decreased need for dialysis; trend toward decreased incidence of ATN
Ratcliffe[169]	Double-blind	38	Atriopeptin III, placebo	Renal transplantation	No difference in creatinine clearance; no difference in sodium excretion
Sands[170]	Open, nonrandomized	20	Human ANP	Renal transplantation	No improvement in serum creatinine or GFR

ANF, atrial natriuretic peptide; *ARF,* acute renal failure; *ATN,* acute tubular necrosis; *GFR,* glomerular filtration rate; *RRT,* renal replacement therapy.

that in either ischemic or nephrotoxic ATN, administration of these agents not only augmented the process of tubular regeneration, promoted earlier recovery of epithelial morphology, improved GFR and anabolism, but also decreased mortality.[182–185] The next section reviews the physiologic and pharmacologic effects of IGF-1, EGF, and HGF and their potential mechanisms of action in experimental and human ARF (Table 44–5).

Insulin-Like Growth Factor-1

Physiology

IGF-1 is a 70-amino acid peptide synthesized primarily in the liver.[186] The kidney is also a source of IGF-1. IGF-1 expression is normally regulated by growth hormone.[187] The cortical collecting duct is the major site of production in adult rats, and renal synthesis is increased in response to both growth hormone and EGF.[176,188] In blood, IGF-1 binds to one of at least six carrier proteins; these IGF-binding proteins modulate its activity.[186] The IGF-binding proteins are derived mainly from the liver but are also produced locally in most organs, where they act in an autocrine or paracrine fashion.[186] IGF-1 mediates its cellular action by binding to one of two membrane-bound receptors that have tyrosine kinase activity and are found throughout the nephron, especially in the inner medulla.[187] The rationale for the use of IGF-1 in the treatment of ATN is based on the following experimental findings[189,190]:

1. Via stimulation of nitric oxide, IGF-1 increases renal plasma flow and GFR in healthy rats and in the ischemic model of ATN.[191,192] Such an effect could be beneficial by increasing urine flow rates and relieving intratubular obstruction.
2. IGF-1 receptor expression and IGF-1 binding are increased in regenerating tubule cells after injury.[193]
3. At high concentrations, IGF-1 is mitogenic for the proximal tubule in vitro and increases incorporation of 5-bromo-2′-deoxyuridine in the nuclei of tubular cells after an ischemic insult in the rat model, reflecting stimulation of DNA synthesis.[194]
4. ARF is characterized by intense protein catabolism and weight loss. IGF-1 has anabolic effects that could ameliorate this detrimental effect.[195]
5. IGF-1 mRNA levels and immunoreactive IGF-1 decrease dramatically within 48 hours of induction of ischemic ATN in rats. Concomitant with this decrease, however, is the striking upregulation of IGF-1 receptor levels and a decrease in the circulating levels of IGF-binding proteins.[190]

In aggregate, these experimental findings suggest increased bioavailability of IGF-1 could contribute to recovery from ATN.

EFFICACY IN EXPERIMENTAL AND HUMAN ACUTE RENAL FAILURE

IGF-1 has been demonstrated to modify the course of the post-clamp model of postischemic ARF in the rat.[183, 195–197] In a series of studies, postischemic injury was induced by transiently clamping both renal arteries for between 35 and 70 minutes, and then commencing 2 to 7 days of IGF-1 treatment in divided doses, beginning 0.5 to 24 hours after clamp release and reperfusion.[183,195-197] Under these conditions IGF-1 therapy uniformly accelerated recovery from the ARF, such that the maintenance stage of ATN was markedly abbreviated. GFR determined on day 2 or 3 post-injury in the IGF-1 treated rats was elevated above corresponding placebo-treated levels by a factor of twofold to fivefold.[195,197,198] As a result, whereas azotemia persisted in placebo-treated animals, it had almost completely resolved within 7 days in animals that received IGF-1. Similarly, in animal models of delayed graft function, IGF-1 accelerates renal recovery and ameliorates cyclosporin nephrotoxicity.[199,200]

It is not clear whether these improved outcomes are due to specific growth-promoting activities of IGF-1 or to its hemodynamic effects, namely increased RBF and GFR. Increased immunostainable IGF-1 has been demonstrated in areas of regeneration after ischemic injury; however, this increase in IGF-1 was noted after the peak in mitogenesis and in noncycling dedifferentiated cells, suggesting that IGF-1 does not initiate renal recovery but may play a role in cellular differentiation after injury.[193]

Given this potential for therapeutic benefit, a randomized, double-blind, placebo-controlled trial of IGF-1 in patients undergoing major abdominal surgery, in whom interruption of RBF was necessary, was completed.[201] Although a statistically significant smaller proportion of patients in the IGF-1

Table 44–5 Renal Actions of Growth Factors

Growth Factor	Renal Effects
Insulin-like growth factor-1 (IGF-1)	Increases glomerular filtration rate and renal blood flow
	Mitogenic for proximal tubule cells in in vitro
	Stimulates NA^+ transport in renal epithelial cells
	Accelerates renal recovery in rat models of ATN
	Accelerates restoration of anatomic integrity after ATN
Epidermal growth factor	Decreases GFR
	Mitogenic for proximal tubule cells in vitro
	Renal vasoconstriction
	Natriuresis
	Augments IGF-1 levels after ATN
	Accelerates renal recovery and restoration of anatomic integrity after ATN
Hepatocyte growth factor	Accelerates renal recovery and restoration of anatomic integrity after ATN
	Stimulates DNA synthesis in tubular cells
	Induces tubulogenesis in renal epithelial cells in vitro
Erythropoietin	Cytokine-like effect inducing tubular cell proliferation

ATN, acute tubular necrosis; GFR, glomerular filtration rate.

treated group had a postoperative decline in renal function (22%) compared to the placebo group (33%), none of the study patients developed postoperative ARF. In addition, there was no difference between the two groups with respect to length of ICU stay, length of hospital stay, or discharge serum creatinine. A second multicenter, randomized, placebo-controlled trial involving 72 patients with established ATN failed to show any benefit of IGF-1 (100 μg/kg given subcutaneously twice daily for up to 14 days) versus placebo.[202] No differences were detected in GFR measured by iothalamate clearance, need for renal replacement therapy, or mortality. Like human trials in ANP, the primary criticism of this trial was the delay to initiation of therapy, which for some patients was as late as six days after the onset of ARF.

In an effort to circumvent the limitations that plague trials in the ICU setting, including multiple organ failure, recurrent renal injury, and a delay of several days before commencing treatment, a randomized, double-blind, placebo-controlled trial of IGF-1 in renal transplant recipients with delayed graft function was conducted.[203] Patients with a creatinine clearance of less than 20 mL/min immediately post-transplantation were treated with IGF-1 versus placebo for 6 days. As in the post-clamp model of postischemic ARF in the rat, the therapy was initiated within hours of the isolated, ischemic injury (5 hours). However, no statistically significant difference existed in the primary outcome measure, inulin clearance on day 7 post-transplantation, or in the secondary outcome measures, nadir serum creatinine at 6 months post-transplantation and need for renal replacement therapy. The authors proposed that delayed graft function could be used as a "human" model to screen future agents that show potential in animal trials prior to conducting large, expensive trials in the ICU. See Table 44–6 for a summary of these three studies.

Epidermal Growth Factor

Physiology

Epidermal growth factor is a 6-kD peptide. The kidney is a major site of EGF synthesis, and renal urine concentrations are typically higher than circulating serum levels. The main sites of EGF synthesis are the distal tubule and the medullary component of the thick, ascending limb of the loop of Henle. EGF is synthesized as prepro-EGF, which has a hydrophobic domain that anchors it to the apical cell plasma membrane. The extracellular domain contains several EGF-like domains. Cleavage of the extracellular domain by serine proteases releases mature EGF. EGF binds to a 170-kD receptor, which has tyrosine kinase activity. Receptors are found throughout the nephron on the basolateral cell membrane.[204]

EGF can induce renal vasoconstriction as well as cause diuresis and natriuresis when infused.[205] It is a potent mitogen for cultured proximal tubule cells in vitro.[174] The EGF-like protein transforming growth factor-α (TGF-α), which also binds to the EGF receptor, is necessary for the growth of the metanephric kidney in vitro.[206]

After acute ischemic injury, an increase in the quantity of mature bound EGF is observed.[207] During the same time period, renal levels of prepro-EGF mRNA decrease rapidly and remain depressed. This decrease is accompanied by a marked decrease in the urinary excretion of EGF, which persists for up to 21 days. Together, these observations suggest that the bound EGF found in ischemic kidneys is not of renal origin. Circulating EGF levels originating from nonrenal tissues are not affected by nephrotoxic insults and are therefore presumed to play a more important role than renally derived EGF in functional recovery from renal injury.

Infiltrating inflammatory cells at the time of tubular injury are another potential source of growth factors.[207] Activated macrophages are known to produce TGF-α, which has been demonstrated to accelerate recovery after ischemia. Local release of TGF-α could interact with the EGF receptor, promoting recovery after ischemic or nephrotoxic insult. Concomitant to an increase in the level of bound mature EGF within the kidney and decreased EGF synthesis, there is upregulation of EGF receptor expression.[180, 208] It is unclear how filtered or indeed renally derived EGF could act in an autocrine or paracrine fashion in vivo. Mature EGF is released after cleavage into the tubular lumen and thus cannot bind to receptors expressed on the basolateral membrane. It is possible that damage to the continuity of the tubular epithelium with sloughing of tubular cells into the lumen could permit

Table 44–6 Human Interventional Studies of Insulin-like Growth Factor-1 in Acute Renal Failure

Reference	Patient Population	Trial	Therapeutic Agent	End-Point	Outcome
Franklin[201]	Aortic aneurysm repair, Renal revascularization	Randomized Placebo controlled (n=54)	Recombinant IGF-1 100 μg SC × six doses	GFR	GFR statistically better in IGF-1 group; no difference in mortality
Hirschberg[202]	Established acute renal failure	Randomized Placebo controlled (N=72)	Recombinant IGF-1 100 μg SC bid × 2 wk	GFR, Mortality	No significant difference in outcome
Hladunewich[203]	Delayed Graft Function	Randomized Placebo controlled (N=72)	Recombinant IGF-1 100 μg SC bid × 6 days	GFR, Nadir SCr, RRT	No significant difference in outcome

GFR, glomerular filtration rate; IGF-1, insulin-like growth factor-1; SC, subcutaneous; SCr, serum creatinine; RRT, renal replacement therapy

intraluminal EGF to bind to the normally inaccessible EGF receptors on the basolateral membrane and cause growth promoting activity. Alternatively, superoxide anion and/or hydrogen peroxide generated during ischemia and reperfusion could activate the EGF receptor.[209]

EFFICACY IN EXPERIMENTAL ACUTE RENAL FAILURE

Administration of EGF to animals with ischemic or nephrotoxic ATN results in accelerated DNA synthesis as indicated by an increase in the incorporation of [3H]-thymidine. Several investigators have also noted accelerated histologic and functional recovery and reduced mortality rates after administration of EGF in these settings.[182,185,210] EGF is a regulator of IGF-1 expression and administration of EGF to rats after ischemic injury prevents the decline in IGF-1 levels, otherwise seen in this setting.[211] This potentially explains the mechanism of action of EGF in ATN. Likewise, the administration of thyroxine, which accelerates recovery after experimental ATN, leads to an increase in serine protease activity, resulting in enhanced cleavage of mature EGF from its membrane-bound precursor.[212] Currently, no data from human studies exist to support a potential role for EGF to facilitate recovery from ATN.

Hepatocyte Growth Factor

Physiology

HGF was first identified in the serum of rats after partial hepatectomy. It is a distinct growth factor consisting of a 68-kD α-subunit and a 34-kD β-subunit.[213] Its main renal site of synthesis is thought to be the interstitium.[214] The HGF receptor is a tyrosine kinase transmembrane protein encoded for by the c-met proto-oncogene.[215] This is expressed in the epithelium of the proximal tubule, thick, ascending limb and cortical collecting ducts.[214] Consistent with a paracrine mechanism of action, there is increased expression of mRNA for both HGF and c-met within the kidney after acute renal injury.[178]

EFFICACY IN EXPERIMENTAL ACUTE RENAL FAILURE

The administration of HGF to rats after ischemic renal injury results in lower serum urea and creatinine levels at 7 days, improved histologic outcome, and lower mortality in treated animals.[184] In contrast to IGF-1, HGF exerts no anabolic effect in experimental ARF. Similar findings have been demonstrated in mercuric chloride and glycerol induced renal injury.[216–218] In cell culture, HGF, but not IGF-1 or EGF, decreased death of MDCK cells after ischemic injury by decreasing necrosis and apoptosis.[219] However, no studies to date have evaluated the potential role of HGF in human ARF.

Erythropoietin

Erythropoietin (EPO) is a growth factor synthesized primarily in the renal cortex. Erythropoietin receptors have been found within the kidney, localized to mesangial cells as well as prox-

imal and distal tubular cells.[220] Although the normal kidney appears to be unresponsive to EPO, limited work in animals suggests that following ischemic injury, EPO may induce tubular cell proliferation.[221–223] Depressed plasma EPO levels have been documented in hemodynamically-mediated acute renal failure.[224] In a rat model of ischemic renal failure, EPO treatment has been demonstrated to ameliorate the anemia and decrease mortality.[221] In a rat model of cisplatinum-induced acute renal failure, EPO has been documented to improve GFR and RPF as well as hasten tubular regeneration.[222] These effects were independent of effects on hematocrit values and blood pressure.[223] Further studies will be required to demonstrate benefits in human disease.

CONCLUSION

Due to the significant incidence and consequences of acute renal failure, multiple efforts have been made to demonstrate the efficacy of hormonal therapies in preventing or treating acute tubular necrosis. Although preliminary studies in animals and small populations had suggested promise, large trials have recurrently failed to demonstrate efficacy of hormonal therapies. Additionally, growth factor therapy has failed to demonstrate efficacy in speeding tubular regeneration or recovery. Whether these failures are damning to the conceptual theory of ATN or due to difficulties in protocol (timing, dosing of agents) is difficult to know. Alternative therapeutic targets, such as oxidant stress and inflammation, are presently being studied. Future efforts may be successful in limiting the dramatic sequelae of ARF, but, presently, supportive therapy continues to be the best physicians can offer.

Dialytic Management for Acute Renal Failure

Geoffrey S. Teehan, M.D., M.S. • Ravindra L. Mehta, M.D. •
Glenn M. Chertow, M.D., M.P.H.

Over the last 2 decades, significant advances have been made in dialysis methods for replacement of renal function. These range from modifications in intermittent dialysis (e.g., biocompatible membranes, bicarbonate dialysate, dialysis machines with volumetric ultrafiltration controls) to the development of several modalities for continuous renal replacement therapy (CRRT).[1,2] Several of these techniques may be used to treat acute renal failure (ARF) in the intensive care unit (ICU), but little information exists for the most appropriate therapy in a given circumstance. The goals for treatment, indications and timing of dialytic intervention, choice of dialysis modality, and the effect of dialysis on outcomes from ARF need to be considered. This chapter outlines current concepts in the use of dialysis techniques for ARF and suggests an approach for selecting the optimal method of renal replacement therapy.

GOALS FOR RENAL REPLACEMENT FOR ACUTE RENAL FAILURE IN THE INTENSIVE CARE UNIT

The treatment of ARF with renal replacement therapy (RRT) has the following goals: (1) maintain fluid and electrolyte, acid-base, and solute homeostasis, (2) prevent further insults to the kidney, (3) promote healing and renal recovery, and (4) permit other support measures (e.g., provision of nutrition) to proceed without limitation. Ideally, therapeutic interventions should be designed to achieve the above goals, taking into consideration the clinical course. In practice, these issues are based on physician preferences and experience. No evidence-based criteria have been established, thereby making comparisons between any two centers or even two chosen strategies at the same institution difficult. An important consideration in this regard is to recognize that the patient with ARF is somewhat different than the one with ESRD. The rapid decline of renal function associated with multiorgan failure does not permit much of an adaptive response akin to what characterizes the course of the patient with chronic kidney failure. Consequently, the traditional indications for renal replacement (developed in chronic kidney failure, yet applied to ARF) need to be redefined. For instance, excessive volume resuscitation, a common strategy used for multiorgan failure, may be an indication for dialysis even in the absence of significant elevations in blood urea nitrogen (BUN). In this respect it may be more appropriate to consider dialytic intervention in the ICU patient as a form of renal support rather than replacement. This terminology serves to distinguish between the strategy for replacing individual organ function and one to provide support for all organs. Table 45–1 lists some of the revised indications for dialytic intervention using this approach. It is, thus, possible to widen the indications for renal intervention and provide a customized approach for the management of each patient.

MODALITIES FOR RENAL REPLACEMENT THERAPY (RRT)

Several methods of dialysis are available for renal replacement therapy (Table 45–2). Although most of these have been adapted from dialysis procedures developed for chronic kidney failure, several variations are available specifically for ARF patients. A key distinction among the techniques is the duration of application, that is, intermittent versus continuous dialysis.

Intermittent Procedures

Intermittent hemodialysis (IHD) has been used widely for the last four decades to treat chronic kidney failure and ARF. It remains the standard therapy for treating ARF in both the ICU and non-ICU settings. The vast majority of IHD is performed using single-pass systems with countercurrent dialysate flow at a rate greater than blood flow. Several advances have been made in this area, particularly with respect to availability of variable sodium, bicarbonate-based, and volumetrically controlled machines with precise ultrafiltration control.[3] The advantages offered by volumetric controlled ultrafiltration and bicarbonate dialysate are particularly appealing in the ARF setting, given the propensity for hemodynamic instability, although efficacy of these technologies in this population has not been formally tested. In patients with chronic kidney failure, these machine enhancements have led to the development of a wide variety of different therapeutic regimens of IHD, including variations of high flux and high efficiency dialysis with high blood flow and dialysate flow rates.[4] In contrast in most centers, IHD for ARF utilizes a standard approach with moderate blood flow rates (200–250 mL/min) and dialysate flow rates of 500 mL/min. Often this approach is dictated by the lack of a permanent vascular access capable of supplying a high blood flow rate and the absence of any standardized methods of dialysis prescription and dose delivery.

Sorbent system IHD that regenerates small volumes of dialysate with an in-line Sorbent cartridge has not been very

Continuous Therapies	
	Peritoneal(CAPD, CCPD)
	Ultrafiltration (SCUF)
	Hemofiltration (CAVH, CVVH)
	Hemodialysis (CAVHD, CVVHD)
	Hemodiafiltration (CAVHDF, CVVHDF)

popular, however, it is a useful adjunct if large amounts of water are not available or in disasters.[5] This system depends upon a sorbent cartridge with multiple layers of different chemicals to regenerate dialysate. In addition to the advantage of needing small amounts of water (6 L for a typical run), which does not need to be pretreated, the unique characteristics of the regeneration process allow greater flexibility in customizing the dialysate. For example, urea removed across the dialyzer is converted to ammonium carbonate by a layer containing urease. In a subsequent layer, zirconium phosphate adsorbs the cations, including ammonium, and exchanges these for sodium and hydrogen ions. The hydrogen ions then react with the carbonate ions to generate bicarbonate. Thus, the dialysate can be tailored to treat a wide range of acid-base disorders and is particularly useful in special circumstances (e.g., metabolic alkalosis). Unfortunately, the improved flexibility comes at the expense of a complex process that requires intense monitoring and is less efficient than single-pass IHD. Two factors account for this: the slower flow of dialysate and the adsorptive capacity of the sorbent cartridges. Cartridges of two different sizes are available and can remove between 20 and 30 g of urea. This degree of clearance may be inadequate for the hypercatabolic patient and may obligate the use of more than one cartridge during a single dialysis session. Additionally, Sorbent systems are infrequently utilized in most centers, and as a consequence, many nephrologists and nursing personnel are unfamiliar with them. Presently, this tech-

nique appears best reserved for special circumstances and should be utilized only by highly trained personnel.

In contrast to IHD, intermittent hemodiafiltration (IHDF), which uses convective clearance for solute removal, is popular in Europe but has not been used extensively in the United States, mainly because of the high cost of the sterile replacement fluid. Several modifications have been made to this therapy, including the provision of on-line preparation of sterile replacement solutions. Proponents of this modality claim a greater degree of hemodynamic stability and improved clearance of middle molecule (i.e., molecules in the range of 70–100 kD, relatively poorly cleared with diffusive dialysis).

Intermittent ultrafiltration (UF), in contrast to IHDF, utilizes the same machines as IHD but is used specifically for volume removal alone with minimal solute clearance. Most nephrologists use UF as a method of rapid fluid removal when the major indication for renal replacement or support is pulmonary edema or refractory congestive cardiomyopathy. In most instances where clearance is required, UF requires supplementation with IHD. Some centers use a combination of UF and IHD in the same session (sequential dialysis).[7] This strategy offers a greater degree of hemodynamic stability resulting from the dissociation of solute and fluid removal during the dialysis. The improved hemodynamic status may be related to the attenuation of osmotic flux during the UF phase. Although sequential UF–IHD can be easily implemented, a major potential disadvantage of this strategy is the reduction in time for diffusive solute clearance, if the overall treatment time is fixed. Since solute removal during UF alone is minimal, the treatment may be inadequate in some settings.

A newer modality, extended daily dialysis (EDD), is a hybrid therapy between IHD and CRRT and uses standard IHD equipment. In EDD, patients undergo HD for 6 to 8 hours daily, using blood and dialysate flows of 200 mL/min and 300 mL/min, respectively. Anticoagulation requirements tend to exceed those of IHD but are less than those in bicarbonate-based CRRT. Four major advantages of this modality include the ability to provide as good or better hemodynamic and solute control as that in IHD, less intensive monitoring required by dialysis nurses and ICU staff, training of nurses and support staff is minimal, and it allows sufficient time for patient procedures requiring mobility.[8] Results of a 2-year randomized clinical trial comparing CRRT to EDD are forthcoming.

Continuous Techniques

Although the concept of continuous dialysis was advocated as early as 1960 by Scribner and colleagues,[9] peritoneal dialysis (PD) was the first form of continuous renal replacement therapy and became popular largely because of its highly permeable natural membrane. In patients with ARF, two forms of PD have been used. Most commonly, dialysate is infused and drained from the peritoneal cavity by gravity. The procedure can be performed intermittently but is fairly labor intensive and is best done by personnel trained in PD procedures. More commonly, a variation of the procedure for continuous ambulatory PD termed *continuous equilibrated* PD (CEPD) is utilized.[10] Dialysate is instilled and drained manually every 3 to 6 hours continuously, and fluid removal is achieved by varying the concentration of dextrose in the solutions. Alternatively, the process can be less labor intensive with an

automated cycler device that is programmed to deliver a fixed volume of dialysate and the peritoneal cavity drained at fixed intervals. However, cyclic PD suffers from two basic problems: (1) the procedure is relatively inefficient, and total solute removal is limited by the amount of peritoneal effluent; and (2) peritoneal transport characteristics may be altered with hypotension and pressor agents. For instance, in the hypercatabolic postoperative patient, PD may not provide the required amount of solute removal for adequate control of azotemia. Intermittent peritoneal dialysis (IPD) continues to occupy a small niche for renal replacement, particularly in the pediatric population. The small body surface area allows for an adequate clearance without a large number of exchanges.[11]

Over the last decade, a variety of continuous renal replacement therapies (CRRT) have evolved. In general, these techniques use highly permeable synthetic membranes, and the modalities differ principally in the driving force for solute removal. When arteriovenous (AV) circuits are employed, the mean arterial pressure provides the pumping mechanism. Alternatively, external pumps utilize a venovenous (VV) circuit and permit precision in blood flow rates and transmembrane pressure. The letters *AAV* or *AVV* in the terminology serve to identify the driving force in the technique. Solute removal with these techniques is achieved either by convection, by diffusion, or by a combination of both. Convective techniques include ultrafiltration (UF) and hemofiltration (HF) and depend on solute removal by solvent drag.[12] Hemofiltration provides more efficient clearance of the so-called middle molecules that are inefficiently cleared with dialysis alone. While UF implies fluid removal only, HF necessitates partial or complete replacement of the fluid removed. The composition of the replacement fluid can be varied, and the solution can be infused pre- or post-filter.

Diffusion-based continuous techniques are based on the principle of a solute gradient between the blood and the dialysate, as with IHD. However, unlike IHD, the dialysate flow rates (typically 0.5 to 2 L/hr, or 8–34 mL/min) in continuous hemodialysis are significantly slower than the blood flow rates (typically 100–200 mL/min), resulting in complete or near complete saturation of the dialysate. Small molecules are preferentially removed by these diffusion-based methods. If both diffusion and convection are used in the same technique, the process is termed *hemodiafiltration* (HDF). With HDF, dialysate and a replacement solution (hemofiltrate) are used, and small and middle molecules can both be efficiently removed. The letters *UF, H, HD,* and *HDF* serve to identify the operational characteristics in the terminology. Once exposed to these principles, the terminology for the continuous dialysis techniques is easier to understand. As shown in Table 45–2, the letter *C* in all terms describes the continuous nature of the methods, the next two letters (*AV* or *VV*) depict the driving force, and the remaining letters *(UF, H, HD, HDF)* represent the operational characteristics. The exception is the acronym *SCUF* (slow continuous ultrafiltration), which remains as a reminder of the history of these therapies as simple techniques harnessing the power of AV circuits.[13]

Conceptually, it is important to recognize that CRRT are operationally very different from intermittent techniques. As shown in Table 45–3, the major difference is that time is no longer a limiting factor for blood purification. Consequently, it is possible to use slower blood and dialysate flow rates and achieve weekly clearances equivalent and often superior to intermittent techniques. Another major distinction is the ability to dissociate solute removal from fluid balance. For example, by varying the composition of the dialysate, hemofiltrate, or both, solute balance can be altered, while fluid balance over time can be kept negative, positive, or even. Although IHD provides efficient small solute clearance, and is often effective at ultrafiltration over the several hour period of therapy, 24 or more hours go by during which major changes in fluid balance may ensue, without the fine-tuning offered by CRRT.[14]

TIMING OF DIALYTIC INTERVENTION

Whether or not to provide dialytic support, and when, are two of the most fundamental questions facing nephrologists and intensivists in most cases of ARF. The optimal timing of dialysis for ARF is unknown. Relatively few studies have carefully examined this question[15–19]; none in the modern dialysis era, and most studies on timing are confounded by differences in intensity as a result of a chosen therapeutic strategy. Moreover, changes in illness severity, especially in later years, make comparisons of studies extremely difficult.

Fischer and colleagues[16] reported 15 years' experience (1950–1964) of ARF from a single institution (N = 235). The mean age was 41 years; 34% were women. Acute renal failure was associated with major surgery in 114 (49%), trauma in 33 (14%), transfusion reactions in 22 (9%), obstetrical complications in 13 (6%), and other conditions in 53 (22%) patients. One hundred and sixty-two (70%) patients underwent HD. Before 1961 (N = 120), dialysis was performed "only rarely" until the BUN exceeded 200 mg/dL, even when clinical deterioration was observed. Hyperkalemia was the most common indication for dialysis in the early years (1950–1956) of the series. From 1961 to 1964 (N = 115), dialysis was performed when clinical deterioration was first observed or before the BUN reached 150 mg/dL ("early dialysis"). The 1961 to 1964 group had a lower overall mortality rate (57% vs. 74%) that was more striking when only patients requiring dialysis were considered (51% vs. 77%).

The largest study in this area was completed by Kleinknecht and colleagues,[17] who described a comparative case series of 500 patients with ARF between 1966 and 1970. In this study, 279 patients were treated before, and 221 were treated after the institution of a "prophylactic hemodialysis" strategy. Prophylactic hemodialysis was defined as early and frequent dialysis to maintain the BUN below 200 mg/dL, while providing calorie and protein intakes of 30 kcal/kg/day and 1.0 g protein/kg/day, respectively. Prior to July 1968, dialysis was performed only if the BUN exceeded 350 mg/dL or if severe electrolyte disturbances were present. Acute renal failure was associated with surgery or trauma in 230 (46%), obstetrical complications in 142 (28%), and medical conditions in 128 (26%) patients. Overall, 358 patients underwent dialysis. Mortality rates were significantly reduced during the latter study period for patients receiving hemodialysis (29% vs. 42%, *P* <.05); the reduction in peritoneal dialysis patients (22% vs. 40%), although similar in magnitude, did not reach statistical significance. Furthermore, the authors noted a marked reduction in deaths due to gastrointestinal hemorrhage (27% vs. 55%, *P* <.01) and septicemia (12% vs. 24%, *P* <.02) in the prophylactic dialysis group, attributing these findings to improved control of uremia.

Table 45–3   Renal Replacement Therapy: Comparison of Techniques

SCUF, slow continuous ultra-filtration; CAVH, continuous arteriovenous hemofiltration; CVVH, continuous venovenous hemofiltration; CAVHD, continuous arteriovenous hemodialysis; CVVHD, continuous venovenous hemodialysis; CAVHDF, continuous arteriovenous hemodiafiltration; CVVHDF, continuous venovenous hemodiafiltration; IHD, intermittent hemodialysis.

In the studies reviewed previously, there were no inter-era comparisons of patient characteristics or nondialytic therapies and no efforts made to adjust for comorbidity or severity of illness. Therefore, it is difficult to ascribe improvement in outcomes to earlier institution of dialysis, in each case administered in the latter years of the study period. Conger[18] and Gillum and colleagues[19] performed prospective studies of the intensity of dialysis, the former showing beneficial trends in improved survival, although neither was well controlled for timing of intervention.

Case mix clearly differs today compared with these studies dating back several decades. A much smaller proportion of patients require dialysis because of obstetric complications, and many more are elderly and suffer from multiorgan failure accompanying ARF. Furthermore, what was considered *early* in the previous studies would not be considered early by most criteria. Currently, most nephrologists intervene when the BUN exceeds 100 mg/dL, for fear of impending uremic complications.

Two factors tend to dissuade nephrologists from initiating dialysis in the ICU. First, there are well-known risks of the dialysis procedure, including hypotension, arrhythmia, and complications of vascular access placement. Second, strong concern exists that some element of the dialysis procedure may slow the recovery of renal function and increase the risk of developing ESRD.[20–22] This contention is supported by experimental data showing renal lesions consistent with fresh ischemia in animals dialyzed without systemic hypotension, long after their initial renal injury. However, it is difficult to document that earlier initiation of dialysis is of harm, because patients with more severe forms of renal injury may (1) develop indications for dialysis earlier in their ICU course and (2) may be more likely to develop irreversible disease independent of therapy.

In current practice, the decision to dialyze is based most often on clinical features of volume overload and biochemical features of solute imbalance (e.g., azotemia, hyperkalemia). Data from a randomized controlled trial comparing IHD to CRRT[23] suggest that the *indication* for dialysis is an important determinant of outcome. In this study, patients dialyzed predominantly for solute control experienced better outcomes than those dialyzed predominantly for volume overload. Patients dialyzed for control of both azotemia and volume overload experienced the worst outcome. Mukau and colleagues[24] found that 95% of their patients with postoperative ARF had fluid excess of more than 10 L at the time of dialysis. The amount of fluid overload was a strong independent determinant of outcome. Volume resuscitation is a common strategy used in the treatment of multiorgan failure, particularly when accompanied by sepsis syndrome and hypotension. It is often applied indiscriminately in the setting of oliguric ARF, where it is assumed that providing additional volume will improve renal perfusion, prompting correction of renal dysfunction. Although this may be of great benefit to patients with prerenal azotemia, excessive volume administration can lead to pulmonary edema, compromising oxygenation and ventilation, hastening the need for dialysis. These factors collectively suggest the need to develop evidence-based, patient-specific, and nonbiased indications for the initiation of dialysis in ARF.

We favor utilizing an approach that recognizes that the strategy in treating ARF is to minimize and avoid uremic complications, whereas in chronic kidney failure the aim is to keep the patient off dialysis as long as possible, commensurate with maintaining good health and quality of life. Thus, it is not necessary to wait for progressive uremia to initiate dialytic support. As discussed earlier, the indications for dialysis should include a consideration of the need for renal support (as well as renal replacement), and the timing of dialysis should be based on the goals to be achieved.

SELECTION OF DIALYSIS MODALITY

Several factors influence the choice of a dialytic therapy in the ICU. The general principle is to provide adequate renal replacement without adversely affecting the patient. Unfortunately, no consensus exists on the timing, dose, frequency, and duration of dialysis in ARF. Therefore, the choice of dialysis modality is often based on experience with the technique most commonly used in one's facility and availability. In a survey of nephrologists in the United States,[25] IHD was the modality most frequently used for treating ARF, followed by CRRT and PD. An informal survey at the Fourth International Conference on CRRT in 1999 suggested a shift toward even more CRRT. According to the survey participants, the major reasons for choosing IHD in preference to CRRT or PD were the efficacy, ease of use, and familiarity with the IHD technique. CRRT techniques were largely reserved for hemodynamically unstable patients or for those judged to be hypercatabolic or needing aggressive nutritional support. The minority of nephrologists who used PD reported that their choice was related to the facts that PD could be performed effectively without anticoagulation needed and tended to cause less hemodynamic compromise. Nevertheless, a randomized controlled trial (RCT) by Phu and colleagues[26] compared mortality rates among patients with infection-associated ARF in Vietnam assigned to PD or CVVH and found significantly lower mortality rates in the CVVH group (15% vs. 47%, $P = .005$), limiting the likelihood of choosing PD initially to treat ARF. Overall, these findings support the statement that as of 1999, no standard methods exist for the dialytic treatment of ARF. Ideally, therapeutic decisions should be based on some or all of the considerations described below, and future prospective evidence gained.

Patient Factors

Indication for Renal Replacement

The primary indication for dialytic intervention can be a major determinant of the modality chosen, because different procedures have varying efficacy for solute and fluid removal. In the ICU, indications for renal replacement are more diverse and more prone to modification based on the clinical situation. For instance, if the indication for dialysis is to facilitate the removal of a drug such as theophylline, or potassium in the case of severe hyperkalemia, IHD is a logical choice given its efficiency for removal of small molecular weight solutes and the rapidity of response. Conversely, if volume overload is the principle indication for dialysis, particularly where there is hemodynamic instability, CRRT is preferable. In most patients, the indication(s) for dialysis are not clear-cut and both solute and fluid removal is desired. In this setting, the

time course of the desired response will also influence this decision.

Presence of Other Organ Failure

Although several studies have aimed to determine factors predicting mortality in ARF, none have uniformly identified factors that prove critical in all populations studied to date. Several investigators have developed independent ARF scoring systems.[27–44] Most of these systems were derived from retrospective analysis of data obtained from relatively small series of ICU and non-ICU patients.[30,31] The predictive variables have differed in many of the studies, and the majority of them have not been validated. One study has been prospectively validated at the same hospital and in an external group of 25 patients.[32] Liano and colleagues[37] developed a linear discriminant model, identifying age, gender, nephrotoxic ARF, oliguria, hypotension, jaundice, coma, level of consciousness, and assisted respiration as risk factors. Using this index, the authors derived a discriminant score of 0.9 beyond, which no patient has survived. It is unclear how this model performs outside of their geographic setting. Paganini and colleagues[30] published a severity system derived from ICU patients with ARF requiring dialysis and identified eight risk factors associated with poor outcome. Although three of Paganini's factors were common to the Liano model (gender, bilirubin, assisted respiration), five were unique. When these authors tested other models in their population, discrimination was poor.[37] Poor generalizability is an obvious limitation of existing systems.

Failure of nonrenal organ systems has been the most widely recognized risk factor across studies.[39,40] Data from the European Dialysis and Transplant Association (EDTA) show that patients with isolated ARF (61 of 474) experience a mortality rate of only 8%, lending support to the fact that ARF per se is not the only reason for the exceptionally high mortality seen.[39] Indeed, several investigators[40–43] have shown that mortality is proportional to the number of failing organ systems. Lohr and colleagues[44] derived a clinical index to predict survival in patients with ARF undergoing dialysis, finding that associated organ system failure in the form of respiratory failure, GI dysfunction, CHF, sepsis, and hypotension were significantly associated with mortality.

When ARF complicates the course of a critically ill patient in the ICU, it worsens the prognosis and contributes to increased mortality.[39] In this setting, ARF is usually associated with multiple organ failure (MOF) that can influence the choice of RRT in two ways. First, the presence of MOF may limit the choice of modalities (e.g., patients with abdominal surgery may not be able to receive peritoneal dialysis because it may increase the risk for wound dehiscence and infection.[9] Further, hemodialysis may be impossible in hemodynamically unstable patients.[45] Second, the requirement for anticoagulation is dependent on the presence of coagulation abnormalities. Peritoneal dialysis avoids anticoagulation, and IHD can usually be performed anticoagulant-free, with frequent saline flushes of the hemodialyzer. In contrast, CRRT can only rarely be performed without anticoagulation. In our experience, patients with thrombocytopenia (<50 K) and liver failure may be treated successfully with no heparin or citrate; otherwise, some degree of anticoagulation is usually required.

Furthermore, the anticipated effect of the modality chosen on previously compromised organ systems is an important consideration. Rapid removal of solutes and fluid during IHD can result in a disequilibrium syndrome and worsen neurologic status. Patients with hepatic encephalopathy, underlying neurologic disorders, and preexisting hyponatremia may be at increased risk for this complication. The risk of disequilibrium can be reduced with the use of continuous techniques, either peritoneal dialysis or CRRT. Peritoneal dialysis may be attractive in ARF complicating acute pancreatitis but would contribute to additional protein losses in the hypoalbuminemic patient with liver failure.[46] Continuous therapies afford hemodynamic stability; however, if not monitored carefully, they can lead to significant volume depletion. The effects of these therapies on respiratory status are an additional area of concern. Peritoneal dialysis may compromise respiratory status by limiting diaphragmatic excursion, especially in patients who are kept supine. A final consideration is the influence of these therapies on drug dosing, particularly of antibiotics and inotropes.[47–50]

Access

The availability of appropriate venous angioaccess is crucial for IHD and CRRT (CVVH, D, or HDF); and an intraperitoneal catheter is required for PD. A variety of vascular catheters are now available that obviate the need for surgically placed central venous catheters and can sustain blood flows consistently above 350 L/min. Arteriovenous shunts are still used in the occasional patients with severe peripheral vascular disease.[51,52] If vascular access cannot be obtained, PD may be the only alternative, particularly in the pediatric patient. The type of catheter and the technique of insertion are important to minimize complications. Access related complications depend on the expertise of the operator and are exacerbated by underlying coagulopathy.[53] It may be possible to use a single needle for access,[54] however, this requires pumped equipment that permits single needle methods.

Requirement for Mobility

A major consideration in the choice of modality is the requirement of patient mobility. If patients are to be moved for different investigations—trips to the operating room or in the bed for different procedures—it becomes more difficult to perform continuous therapies. Similarly, the use of an arterial access for CAVH and CAVHD restricts patient ambulation. In pumped CRRT (CVVH, HD, and HDF), most of the pumps currently available are not equipped with battery packs, thereby making transportation difficult. The location of the patient (ICU or non-ICU) is an additional determinant of therapy because CRRT should only be performed where constant monitoring and 1:1 nursing is available. Extended daily dialysis offers time off dialysis to attend to various investigations.[8]

Anticipated Duration of Treatment

Renal replacement for ARF is based on the premise that there will be a return of kidney function allowing discontinuation of dialysis. Although this is the desired outcome, it does not always occur. This is particularly true for the patient with ARF

complicating MOF, wherein the ultimate prognosis depends on recovery of other organ systems. Traditional teaching suggests that most patients with ARF will improve within 4 to 6 weeks, and dialysis requirement beyond this period likely represents chronicity. Although this is true in most instances, two important factors need to be considered: (1) some patients with ARF in the ICU setting may require prolonged dialysis support (>8 weeks) before recovering renal function and recovery may be incomplete,[55] and (2) the duration of dialytic support may need to be predefined in some patients with ARF when other organ system failure accompanies ARF. For instance, a patient with respiratory, cardiac, and liver failure secondary to sepsis requiring dialytic support for ARF should have a finite (1–2 weeks) trial period of dialysis and be reassessed for evidence of improvement in all organ systems. Obviously, dialysis cannot improve nonrenal organ function, and withdrawal of dialysis should be considered in selected patients with severe ARF accompanying MOF who are extremely unlikely to recover organ function. The ultimate prognosis depends on recovery of all organ systems, and dialytic support may serve only to prolong the time to death. Woodrow and Turney[56] reviewed the causes of death in all patients with severe ARF seen at a single center over 33 years. They found that the most important factor contributing to death was the underlying cause of ARF, whereas deaths due to secondary complications had declined over time. Interestingly, withdrawal of active therapy accounted for approximately 6% of all deaths before 1970 but was responsible for 13.3% in 1970 to 1979 and 15.4% cases in 1980 to 1989.[56]

Modality-Specific Factors

Components

Choice of Membrane

One of the key components of any dialysis system is the membrane. In addition to the well-recognized effects of each membrane on solute and fluid removal, two additional factors must be considered in the choice of membranes for renal replacement in ARF.

Biocompatibility   Membrane interactions leading to complement activation and neutrophil sequestration have been described predominantly for IHD.[57] However, the exposure time to the membrane is considerably greater in continuous therapy, and membrane effects may also influence outcome in CRRT. Although various membranes have been shown to have different intensities of complement activation,[58,59] polysulfone and polyacrylonitrile membranes do not appear to result in this activation.[58] Development of newer membranes with heparin bonding[60–63] is promising, although they have been associated with increased complement activation.[64] An additional area is the finding of cytokine induction by various membranes during dialysis.[65] Some data suggest that this may be related to the passage of endotoxin fragments across the membrane from the dialysate.[66] Use of an ultrapure dialysate has been found to markedly reduce production of tumor necrosis factor (TNF)-α.[67,68] Additionally, the role of various soluble receptors and natural antagonists to cytokines in this setting is still unclear.[69,70]

Two conflicting meta-analyses were published in 2002, looking at trials comparing biocompatible (BCM) and bioin-compatible (BICM) membranes and mortality. In the first meta-analysis 722 patients were examined, after selecting the most inclusive and updated trials to maximize the sample size. Overall death rate was not different between BCM and BICM (45% vs. 46%). Using a random effects model, a more conservative model for combining data that incorporates both within and between study variability, the relative risk of death was not significantly lower among patients dialyzed with BCM (RR = 0.92; 95% CI = 0.76, 1.13; P = .44).[71] The second meta-analysis added one study, which markedly affected the overall result.[72] Indeed, this study was an observational study of patients with ARF, where dialysis modality was not limited to IHD, and where dialysis membrane use reflected the practice pattern of the participating centers. Further, it contributed more patients than any other study in the meta-analysis (n = 169).[73] The inclusion of this study carried significant weight in the compiled meta-analysis, resulting in a statistically significant overall lower relative risk of death among patients dialyzed with BCM compared with BICM (RR = 0.73; 95% CI = 0.55, 0.98; P = .03). Neither meta-analysis demonstrated an overall impact of dialysis membranes on recovery of renal function.

Cytokine Modulation   An additional area of intense interest is the effect of the dialytic techniques in removing mediators of inflammation, such as TNF-α, interleukin-1, and interleukin-6. Because these cytokines are an integral component of the response to sepsis and may mediate some of the detrimental hemodynamic consequences, it is theoretically possible that their removal might be beneficial. Clearance of molecules in the size range of these inflammatory mediators (10–30,000 Da) is increased in the hemofilters used with CRRT compared with hemodialyzers used with IHD. It has been previously shown that TNF-α and IL-1 are removed from the circulation by CRRT.[74,75] In fact, cytokine extraction may be dependent on the membrane used.[76] In an in-vitro model of CRRT, the AN69 polyacrylonitrile (PAN) membrane was twofold to threefold more efficient at removing TNF compared with polysulphone and polyamide membranes.[76] Hemofiltration was found to be useful in initial studies from animal models of sepsis and in some patients.[77–86] Similar membranes can be used for IHD, however, the potential for cytokine removal will be limited. Any assessment of cytokine removal has to consider the influence of cytokine induction by various membranes and the induction of receptors and receptor antagonists of these mediators. Although complex, and thus far unsuccessful, additional investigation into the use of dialysis for modification of the inflammatory milieu should be pursued. Combination of dialysis techniques, for example, coupled filtration adsorption[87,88] and the bioartificial renal assist device developed by Humes and colleagues[89] may play a role in this area in the near future.

Dose of Dialysis

The ideal dialysis prescription for ARF should incorporate an assessment of the dose of dialysis delivered. Unfortunately, no standard methods for assessing dose of dialysis exist in ARF. In chronic kidney failure, the dose of dialysis prescribed and delivered is usually based on an assessment of the amount of urea removed, using urea kinetic modeling either via direct

dialysis quantification or using regression formulas or urea reductions.[90–93] A key feature of these methods is the assumption that patients with chronic kidney failure are in steady state with respect to urea generation, volume status, and renal and extrarenal clearance. However, dialysis dosing in ARF needs to account for highly variable body water volumes and varying urea generation rates, as well as different methods of dialysis and changes in renal and extrarenal clearance. Unfortunately, these issues have not been properly quantified or studied sufficiently to date.

In general the dose of dialysis is based on modality-specific criteria (e.g., membrane choice, operational characteristics, and the duration of each dialysis session). For patients treated with IHD, the frequency of dialysis is another determinant of the overall dose of dialysis delivered. Table 45–4 shows a comparison of the factors affecting dose of dialysis for IHD and CRRT. Several investigators have attempted to quantify the dose of dialysis delivered in ARF using methods used for patients with chronic kidney failure. Clark and colleagues[94] compared IHD to CRRT techniques using a computer model to derive the required IHD frequency (per week) or required CRRT for a given patient weight for desired BUN values of 60, 80, and 100 mg/dL. For the attainment of intensive IHD metabolic control (BUN = 60 mg/dL) at steady state, a required treatment frequency of 4.4 dialyses per week was predicted for a 50-kg patient. However, the model predicted that the same degree of metabolic control could not be achieved even with daily IHD therapy in patients 90 kg or more. On the other hand, for the attainment of intensive CRRT metabolic control (BUN = 60 mg/dL), required urea clearance rates of approximately 900 mL/hr and 1900 mL/hr were predicted for 50 and 100 kg patients, respectively. These data suggest that, for many patients, rigorous control of azotemia equivalent to that readily attainable with most CRRT programs can be achieved with intensive (nearly daily) IHD regimens only. In practice, the frequency of dialysis usually depends on the patient's clinical and biochemical status. It is noteworthy that reimbursement policies currently do not support the practice of daily IHD. In the absence of obvious uremic symptoms, the height of the interdialytic rise in BUN is usually paramount, although there are few data to support this approach (see previous text).

The role of aggressive dialysis on outcome from ARF has been addressed in previous studies[18,19] A controlled study done several years ago failed to show any difference in outcome (e.g., survival, need for long-term dialysis) in patients dialyzed daily to maintain BUN levels less than 60 mg/dL compared with those dialyzed to BUN levels of greater than 100 mg/dL.[18] Although this study is often cited as evidence against early and intensive dialysis, it has several weaknesses, which should be considered: (1) the study did not evaluate the role of early dialysis as patients were enrolled only after their serum creatinine levels were greater than 8 mg/dL, (2) the aggressively treated patients were treated to levels of only BUN 60 mg/dL, (3) the study compared only a single modality of renal replacement (i.e., IHD) without the option of CRRT, and (4) only cellulosic dialysis membranes were used (see previous text).

Recently, Schiffl and colleagues conducted a randomized clinical trial comparing conventional every other day dialysis to daily dialysis among 160 patients with ARF, assessing 14-day survival. The groups were similar with respect to baseline characteristics and illness severity and were analyzed by intention to treat. In the daily group, the weekly delivered Kt/V was 5.8 ± 0.4, and in the conventional group it was 3.0 ± 0.6. The duration of therapy was 3.3 hours per session in the daily group and 3.4 hours per session in the conventional group. The daily HD group had improved survival (28% vs. 46%, $P = .01$) and recovered renal function more quickly (9 ± 2 days vs. 16 ± 6 days, $P = .001$). Factors significantly associated with an increased odds of death included alternate day HD (vs. DHD) (OR 3.92, 95% C.I. 1.68–9.18, $P = .002$), higher APACHE III scores (OR 1.06, 95% C.I. 1.01–1.12, $P = .02$), oliguria (OR 3.02, 95% C.I. 1.35–6.77, $P = .007$), and sepsis (OR 3.27, 95% C.I. 1.43–7.50, $P = .005$).[95, 96]

This was a landmark study. It was as large as any to date, randomized, and showed that patients with ARF benefited from more frequent HD and, consequently, a higher weekly Kt/V. Unfortunately, a formal expression of concern regarding potential scientific misconduct during the trial was published a year later in the same journal, rendering the findings of the trial suspect. A full report is forthcoming.[97]

From another perspective, a retrospective analysis of patients with ARF showed a mortality rate of 75% in patients dialyzed once, 67% and 50% in those dialyzed between 2 to 10 times, and 10 to 20 times, respectively.[98] An additional consideration is that unlike intermittent techniques the dose of dialysis delivered in CRRT is not time dependent.[99] In IHD, hemodynamic instability, shortened dialysis times, and logistic factors often impact adversely on the delivered dose of dialysis.[100] Paganini and colleagues[101] found that in patients with ARF, 65% of all IHD treatments resulted in lower Kt/V than prescribed. In a subsequent study the same group reported that nonsurvivors had significantly lower dose of dialysis delivered.[102]

Intermittent Versus Continuous

The choice of intermittent or continuous therapy is currently largely based on the availability of CRRT and the familiarity of the nephrologist and other personnel, particularly ICU staff, with the procedure. In centers where CRRT is routinely done, this choice is usually based on the experience of the nephrologist. Currently, only limited information exists comparing

Table 45–4 Factors Affecting Dialysis Dose in CRRT and IHD

CRRT with IHD; however, results with these techniques should be compared to those obtainable with the gold standard, IHD. It is helpful to compare the operating characteristics of the two therapies to recognize the strengths and weaknesses of each modality (Table 45–5). Although difficult, comparisons of solute control, fluid balance, nutritional support, and outcome are relevant for the choice of modality and are discussed briefly in the following text.

The shorter duration of intermittent techniques results in higher levels of solutes and a greater difficulty in achieving fluid and nutritional balance in comparison to continuous techniques.[103,104] These effects are further influenced by differences in the dose prescribed and delivered. In practice this shortcoming goes largely unrecognized and probably contributes to decreased solute clearance. Because continuous therapies provide renal replacement 24 hours a day, they compensate for some of the factors resulting in decreased dose delivery.

Fluid removal is a desirable component of any renal replacement therapy and is a major goal of renal replacement for ARF.[105] There is some evidence that volume overload may be an independent contributor to mortality in ICU patients, even in the absence of uremia. Fluid removal in IHD is easily achieved in many cases, however, because the process has been typically prescribed over 3 to 4 hours, the rate of volume removal has to be high (>1 L/hr). As a consequence, large shifts in fluid balance generally result and contribute to hemodynamic instability.[106–109] Additionally, fluid removal and, hence, fluid balance, is limited to the period of dialysis. If the patient is hemodynamically unstable during this period, it may be difficult to remove any fluid. By contrast, CRRT has the advantage of providing renal replacement continuously and, hence, fluid removal, or replacement can be precisely adjusted for each patient. Ronco and colleagues[110] randomly assigned 425 ICU patients with ARF requiring CVVH to an ultrafiltration rate of 20 (group 1), 35 (group 2) and 45 (group 3) mL/kg/hr, and found higher survival in groups 2 and 3 compared with group 1 (*P* <.001), leading the authors to conclude that the ultrafiltration rate in ARF should be at least 35 mL/kg/hr. Because the process is gradual, hemodynamic stability is usually maintained, and these therapies allow ongoing modulation of fluid balance. The high efficacy of these therapies in continuous fluid removal lends them for use in situations other than renal failure.[111,112] Pediatric patients are better suited for PD and CRRT, and these modalities have been used successfully in the management of ARF in neonates.[113,114]

Continuous therapies have a major advantage over IHD in permitting optimal nutrition provision because fluid removal is not a limiting factor of therapy. In the overall nutritional balance of the patient, two other factors need to be recognized: the composition of the dialysate and composition of hemofiltrate or replacement fluid. Lactate-based dialysis and hemofiltration solutions can rarely result in hyperlactatemia and worsening of acid-base status. Additionally, the lactate-buffered substitution fluids used in CRRT tend to have higher urea generation rates, as compared to bicarbonate solutions.[115,116] Second, glucose containing dialysate solutions result in glucose absorption during the dialysis procedure, which contributes to the caloric load. This glucose content is also associated with an increase in endogenous insulin secretion in most patients, and some patients may require exogenous insulin.[117] Avoidance of peritoneal dialysate and the use of a lower dextrose concentration-based dialysate in CRRT usually obviates this complication. A second nutritional factor is the dialysance of amino acids, vitamins, and trace elements across the filter. Losses appear to depend more on the serum levels than on the underlying clinical status of the patient.[118–123]

A major question, still unanswered, is the effect of the dialysis modality on outcome. Two issues are pertinent: the outcomes of interest and the causal link of choice of modality to the outcome. Dialysis has been utilized in the management of ARF over the last 3 decades. In spite of improvements in technology and enhanced understanding of the pathobiology of ARF and its treatment, mortality rates remain distressingly high (>60% in series limited to ICU patients). Both IHD and PD were the major therapies until a decade ago. Although continuous therapies appear promising in some regards, the effect of CRRT on overall patient outcome is still unclear.[124,125] The absence of an effect on mortality may represent an initial bias in patient selection because, in general, continuous therapies have until recently been given only to patients who were hemodynamically unstable and "too sick" to receive IHD.[126] In this situation CRRT is likely to be used infrequently and, as a result, there might be an increased risk of failure related to lack of expertise and experience with the procedure. Critical evaluation of CRRT in comparison with IHD is scant. As shown in Table 45–6 only two prospective, randomized controlled trials have evaluated this question, and both failed to show a survival advantage for CRRT.[127,128] It appears that the underlying severity of illness is a more important determinant of outcome than the modality.

Recently, two meta-analyses were published on the available trials comparing IHD and CRRT and led to conflicting results.[129,130] In the first, Kellum and colleagues included 13 publications in the analyses, which consisted of 3 RCTs, 1 non-RCT, and 9 prospective cohort studies. The inclusion criterion was the use of some form of CRRT compared to IHD. Methods and results were appraised with a predefined study instrument and a numeric score assigned to each study. The APACHE II score assessed illness severity. The authors also attempted to deal with modality switches after treatment allocation, a potential source of bias. Using a less conservative estimate (fixed effects model), the unadjusted cumulative relative risk of death among patients receiving CRRT in all 13 studies was not significantly lower than IHD (relative risk = 0.93, 95% confidence interval = 0.79, 1.09; *P* = .29). However, CRRT was associated with a significantly decreased relative risk of death after adjustment for study quality, baseline severity of illness or both (relative risk = 0.72, 95% confidence interval = 0.60, 0.87; *P* <.01). Despite this reduced relative risk, the authors cautiously concluded that there were not enough data to answer the question and that more studies were needed.

Table 45–5 Operating Characteristics of IHD and CRRT

Membrane Characteristics	IHD Variable Permeability	CRRT High Permeability
Anticoagulation	Short duration	Prolonged
Blood flow rate	>200 mL/min	<200 mL/min
Dialysate flow	>500 mL/min	17–34 mL/min
Duration	3–4 hr	Days
Clearance	High	Low

Table 45–6   Clinical trials of Intermittent Hemodialysis vs. Continuous Renal Replacement Therapies

| Investigators | Type of Study | IHD | | CRRT | | |

RCT, randomized controlled trial.

Tonelli and colleagues[130] examined the same question but came to a different conclusion. The authors identified six RCTs, of which two were published in abstract form. The selection process was equally systematic, except the appraisal was not conducted with a systematic scoring system, and instead qualitative details of the individual studies were reported. The relative risk for death of CRRT, as assessed with a random effects model, was not significantly different from IHD (relative risk = 1.03, 95% confidence interval = 0.86, 1.22; *P* = .74). Of note, the dialysis modality also had no impact on recovery of renal function. The authors concluded that CRRT does not improve survival if used for unselected patients with ARF.

The results of these two meta-analyses highlight the importance of case definition in the selection criteria of trials comparing treatment effects. Indeed, whereas Tonelli and colleagues restricted their analysis to RCTs, Kellum and colleagues combined RCTs, non-RCTs, and cohort studies, which further compromised the quality of the overall analysis, due to the inevitable introduction of confounders. Of note, Tonelli and colleagues attempted to minimize publication bias by including two non–peer-reviewed publications. In one of the highest quality RCT, at randomization, the sickest patients were by chance assigned to CRRT.[127] Further efforts to determine an *optimal* therapy in ARF will require rigorous evaluation of only the highest quality randomized trials to avoid the pitfalls inherent in nonrandomized studies.[131]

Although mortality is obviously an important end point for consideration, it has become the *only* outcome of interest in most publications. This preoccupation with mortality tends to obscure some other issues pertinent to the patient with ARF, forced to make decisions in the throes of critical illness. It is thus helpful to consider that in ARF, dialysis is offered under the premise that there will likely be a return of renal function. Renal functional recovery, thus, becomes an important proximate outcome of interest. There is some evidence that the choice of modality may influence this outcome. Hemodynamic instability, reflected by hypotension and cardiac arrhythmias, is encountered in approximately 25% to 50% of dialysis patients.[132] A major area of concern is that episodes of hypotension during dialysis can adversely influence renal outcome.[133] Development of oliguria following initiation of dialysis is fairly common and may be more frequent with IHD in comparison with CRRT or PD.[134]

As the modalities differ also in their efficacy of solute and fluid removal, another area for consideration is whether the dialysis dose delivered is an important determinant of mortality and other outcomes. Evidence from the Cleveland Clinic suggests that the dose of dialysis may play an important role in survival following severe ARF. There was a difference in the delivered dose of dialysis in survivors (Kt/V 1.09) and nonsurvivors (Kt/V 0.89) in ARF patients treated with equivalent prescriptions of dialysis (similar membrane, blood flow rate, time).[135]

In ARF there is a marked discrepancy between prescribed and delivered dose of dialysis. Indeed, whereas delivered Kt/V in patients with chronic kidney failure is 10% lower than prescribed,[136] observed Kt/V values in patients with ARF have been shown to be 30% lower than prescribed.[95,137] These differences are thought to be related in part to early discontinuation of dialysis due to hypotension, dialyzer hollow-fiber clotting due to constrained use of anticoagulation, and vascular access blood recirculation, an unavoidable complication of central venous catheters.[138]

Table 45–7[126] summarizes the studies examining the removal of urea by IHD in patients with ARF.[95,137,139–141] In these studies, treatment time ranged from 3 to 4 hours, and venous catheter blood flow rates were limited to less than 300 mL/min. Furthermore, there was wide variability in heparin use, ranging from 15% to 64% of treatment sessions. More importantly, mean URR and mean Kt/V were less than 65% and less than 1.2, respectively. Using the minimally accepted dialysis dose defined by the DOQI guidelines for patients on chronic HD, only 15% to 32% of treatment sessions achieved a Kt/V greater or equal to 1.2.[137,140,141]

A further concern relates to the suitability of BUN as the surrogate marker of dialysis adequacy in ARF. Van Bommel and colleagues[142] found no difference in the BUN amongst deceased and surviving patients with ARF who were treated with dialysis. Other possibilities include the role of removal of middle molecules, including cytokines. Storck and colleagues compared spontaneous hemofiltration (CAVH) to pump-driven hemofiltration (CVVH) and found that both treatments adequately controlled uremia and fluid overload. However, survival was significantly higher with CVVH than with CAVH (29% vs. 13%). Because ultrafiltrate volumes were higher with CVVH as compared to CAVH, the authors postulated that improved middle- and large-molecule clearance may have had a salutary effect on survival.[143] However,

Table 45–7 Summary of Observational Studies Examining Urea Removal by Hemodialysis in Acute Renal Failure

Authors and Colleagues	Year	Treatment Time (min)	Blood Flow Rate (mL/min)	Heparin Use (%)	URR* (%)	Kt/V*
Lo	1997	190	194	NR	NR	0.82
Evanson	1998	233	263	50	55	1.04
Evanson	1999	223	260	64	54	0.96
Jaber	2001	188	291	15	51	0.83
Schiffl	2002	195	243	NR	NR	0.94

NR, not reported; URR, urea reduction ratio.
*The minimally accepted dialysis dose defined by the Dialysis Outcomes Quality Initiative (DOQI) guidelines for patients on chronic HD, corresponds to a URR ≥ 65% or Kt/V ≥1.2. (From Mehta RL, McDonald B, Pahl M, et al: ARF Collaborative Study Group: Indications for dialysis influence outcomes from acute renal failure. J Am Soc Nephrol 1997; 8[9].)

Journois and colleagues[144] found no relationship between ultrafiltrate volumes and patient outcome, but they did find a negative correlation between ultrafiltrate volume produced and recovery from oliguria. Still unclear is whether any one of these therapies is superior in terms of outcome.

It is clearly evident that further research is warranted in the area of ARF treatment, including modality, as it relates to dose. Once dose of dialysis can be identified, the ability of a modality to deliver a particular dose (possibly higher than that currently delivered with three to four times per week IHD) may be an important determinant for its choice. It would appear that in this circumstance CRRT would have an edge over IHD. However, it should be emphasized that CRRT provides increased opportunities for complications, and prolonged exposure to the membrane increases the risks of bioincompatibility.[145]

Other Factors

Procedure - Related Complications

Complications associated with continuous therapies are due mostly to the potential for volume depletion, particularly if monitoring is inadequate and calculations are inaccurate, hemostatic alterations related to anticoagulation, and metabolic changes.[120–122] Since large volumes of fluid can be rapidly removed, meticulous monitoring is essential and often requires a nursing to patient ratio of 1:1, if not more.[132] Access-related problems include peripheral embolism and dissection resulting in limb ischemia with arterial catheters. Fortunately, these complications are rare, but it should be emphasized that intra-arterial catheters should be of an appropriate size and be placed by experienced personnel.[133] In addition to the usual luer-lock mechanisms, connections should be reinforced with tape to reduce the risk of accidental disconnection. Other vascular complications can occur with the arteriovenous techniques, including the undesired development of arteriovenous fistulas, and large hematomas, which can become secondarily infected. Bellomo[145] has shown that venovenous techniques offer equivalent, if not slightly enhanced, clearance characteristics compared with arteriovenous techniques and a significantly lower risk of vascular access-related complications.[145]

Complications with IHD (Table 45–8) are usually related to the rapid changes in fluid and solutes resulting in hypotension and rarely, disequilibrium. As blood flow rates and transmembrane pressures are higher, membrane leaks are more common. Because CRRT requires anticoagulation for a longer period of time, the risk for complications related to anticoagulation may be higher; however, this has not been the case in our experience.[146] In EDD, moderate blood flow rates and anticoagulation requirements may limit hypotension relative to IHD and bleeding complications relative to CRRT.[8]

Cost

Information on the costs of the three dialytic techniques for ARF is scanty. Most investigators have found that CRRT costs are somewhat greater than IHD.[147,148] Our experience suggests that to a large extent the major difference pertains to the costs of supplies for CRRT. In most centers the costs for hemofilters, tubing, dialysate, and so forth, for IHD are significantly discounted for bulk buying because the same membranes are used for patients with chronic kidney failure. In contrast, hemofilters for CRRT are usually priced 3 to 4 times higher than comparable IHD filters. This disparity may be greatly reduced if continuous therapy is used more frequently, allowing for further reduction in prices of the filters. It has also been our experience that physician time is greater for CRRT, however, this represents a learning curve with these techniques. In our institution, we have standardized protocols and have found that as physicians become experienced with CRRT the time required is reduced. Whether these techniques are cost-effective still requires further research,[147,148] especially in the cost of ICU nursing labor.

Nursing Expertise and Other Support

IHD, CRRT, and APD are renal nursing procedures, however, CRRT and APD requires a significant effort by ICU nurses in addition to nephrology nursing support.[149,150] It is impossible to institute CRRT without an adequate in-servicing of ICU nurses and their active participation in the procedure. This is usually facilitated by the availability of flow sheets, manuals (for pumped circuits), and backup attending physician support. Additionally, since CRRT requires changes in drug dosing, nutrition pharmacy, and clinical nutrition, personnel should be actively involved.[49,151] If CRRT is performed infrequently, there is a greater chance of problems and the continued need for frequent in-servicing of dialysis and ICU personnel to maintain skills.[149,150]

Table 45–8　Selected Major Complications of Intermittent Hemodialysis and Methods of Prevention

Complication	Preventive Measure(s)
Hypotension	Extend dialysis time
	Perform sequential ultrafiltration hemodialysis
	Discontinue antihypertensive (not antianginal) agents
	Decrease dialysate temperature
	Increase dialysate calcium concentration
	Increase hemoglobin concentration
	Consider administration of colloid
	Consider change in estimated dry weight
Arrhythmia	Increase dialysate potassium concentration
	Consider discontinuing digoxin and other antiarrhythmic agents
	Supplemental oxygen during dialysis
Muscle cramps	Extend dialysis time
	Consider hypertonic saline
	Consider vitamin E
	Consider quinine sulfate
Pyrogen reaction	Culture dialysate
	Immediate water testing for LPS
Dialysis disequilibrium	Attenuate clearance by limiting time, dialyzer surface area, blood flow, and dialysate flow consider mannitol
Hypoxemia	Use noncellulosic dialyzer
	Supplemental oxygen during dialysis
Hemolysis	Examine blood lines
	Immediate water testing for chloramine

Recommendations for Initial Choice of Renal Replacement

Despite the lack of definitive results derived from randomized clinical trials, it is possible to develop a rational approach to the selection of a dialysis modality for the initial treatment of ARF in critically ill patients. A primary consideration is the availability of a technique at the center and familiarity and comfort of personnel with the technique. The latter point is extremely important with respect to continuous techniques as infrequent use may be associated with a higher incidence of iatrogenic complications.[152,153] The next consideration is the complexity of the patient, the location in the hospital, and need for mobility.

Patients with uncomplicated ARF can be treated with IHD or PD, and the choice is based on other patient characteristics (e.g., pregnancy, hemodynamic tolerance, access and urgency for treatment). Patients with multiple organ failure and ARF can be treated with CRRT or IHD. In general, hemodynamically unstable, catabolic, and excessively fluid overloaded patients are ideally treated with CRRT, whereas IHD may be better suited for patients requiring early mobilization and who are more stable.[126] Table 45–9 depicts a potential therapy for several different clinical scenarios. Amongst continuous thera-

Table 45–9　Renal Replacement Therapy for ARF: Initial Choice

Indication	Clinical Setting	Modality
Uncomplicated ARF	Antibiotic nephrotoxicity	IHD, PD
Fluid removal	Cardiogenic shock, CP bypass	SCUF, CVVH
Uremia	Complicated ARF in ICU	CRRT (CVVHD, CVVH, CVVHDF) IHD
Increased intracranial pressure	Subarachnoid hemorrhage, Hepatorenal syndrome	CRRT (CVVH, CVVHDF)
Shock	Sepsis, ARDS	CRRT (CVVH, CVVHDF)
Nutrition	Burns	CRRT (CVVHD, CVVHDF, CVVH)
Poisons	Theophylline, barbiturates	Hemoperfusion, IHD, CVVHD
Electrolyte abnormalities	Marked hyperkalemia	IHD, CVVHD

pies, those that include hemofiltration (CVVH, CVVHDF) may be superior in sepsis or the systemic inflammatory response syndrome because of the ability to more efficiently remove (or adsorb) larger molecular weight solutes.[154,155] For most clinical scenarios, we favor the use of hemodiafiltration techniques that combine hemodialysis and hemofiltration and are thus providing optimal clearance for both small and large molecules. It is important to stress that one of the key factors in the choice of renal replacement is to tailor the therapy to the patient. This implies an ongoing assessment of the patient and modification of the therapy used based on clinical criteria (e.g., in a hemodynamically unstable patient CRRT may be an initial choice, however, when the patient is more stable and needs to be mobilized IHD may be more appropriate). We would suggest that flexibility in utilizing the entire range of renal replacement therapies is an important overall philosophy in the management of ARF.

SUMMARY

Several new methods of dialysis are now available to treat ARF. Rational use of these techniques requires an understanding of factors influencing the choice of a modality and appreciation of the advantages and disadvantages of each technique. Management of ARF is different from that of chronic kidney failure, and the dialysis prescription should incorporate the unique characteristics of each patient. Therapeutic alternatives to traditional IHD now permit nephrologists to match the modality to the patient. This approach (and additional research) will allow better management of patients with ARF and ultimately improve survival and other important outcomes.

Extracorporeal Treatment of Poisoning

Stuart Abramson, M.D., M.P.H.

The 2001 Annual Report of the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System recorded 2,267,979 human exposure cases reported by 64 poison centers during 2001.[1] This was an increase of 5% compared with 2000. A total of 218.5 million people were served by the participating centers, with an average of eight exposures per 1000 people. Of the exposures, 93% were acute and 92% involved a single poison.[1]

Approximately 22% of recognizably poisoned patients require admission to the hospital, and less than 1% of these patients die.[2] Ten percent of the recognizably poisoned patients require intensive medical care, including hemodynamic and ventilatory support with close monitoring in an intensive care unit.[1] The remainder recover with general support and ward nursing supervision. Fewer than 5% of cases of recognizable poisoning are amenable to techniques that facilitate the elimination of poisons.[3]

Certain types of exposures still carry a high morbidity and mortality secondary to the toxic effect of the poison or its metabolic by-products. For example, conversion of methyl alcohol to formate, and of ethylene glycol to oxalic acid, can lead to severe metabolic abnormalities and end organ damage. Accidental or intentional poison exposure or drug overdose can cause reversible illnesses, such as arrhythmias, congestive heart failure, noncardiogenic pulmonary edema, aspiration pneumonia, brain swelling with subsequent seizures and decreased mentation or psychosis, and hypotension with tissue hypoxia and lactic acidosis or permanent end organ damage (prolonged coma and permanent neurologic deficits, blindness, renal and liver failure, and pancreatitis), and, subsequently, death.

Initial treatment modalities are fairly standardized. The first intervention is decontamination, which consists of the following:

- Dilution or irrigation
- Activated charcoal
- Cathartics
- Gastric lavage
- Syrup of ipecac
- Bowel irrigation

These methods are used in the majority of cases. Of the cases of poisoning reported in 2001, 1,335,900 were treated with one of these therapeutic modalities.[1]

The AAPCC describes the number of patients receiving a specific mode of decontamination or specific antidote. Primarily owing to limitations in reporting and data gathering, the values reported in Tables 46–1 and 46–2 should be interpreted as the minimum frequency with which a particular therapy was administered. Substances of exposure that accounted for the largest number of deaths were anal-

gesics (531 total), sedatives (266 total), and antidepressants (255 total).[1] Tables 46–1 and 46–2 summarize the 2001 data according to the distribution of the exposures and deaths compiled by age, gender, and substance, along with the type of therapy received and the percentages requiring medical intervention.

This chapter reviews the general approach to the poisoned patient, focusing on techniques used to increase removal of drugs and toxins. We begin with a brief discussion of strategies to minimize toxin accumulation, and then focus on the use of extracorporeal therapies to increase elimination of toxins, poisons, or endogenous compounds. We examine the following:

1. Removal of alcohols, lithium, and salicylate with hemodialysis.[2]
2. Use of hemofiltration for the elimination of N-acetylprocainamide,[4] methotrexate,[5] lithium,[6] theophylline,[7] and metal-chelator complexes.[8]
3. Use of hemoperfusion for the removal of lipid-soluble drugs, such as barbiturates,[9] digoxin,[10] and theophylline[11,12]; hemoperfusion can also be used to greatly enhance the clearance of salicylates.[13]

We mention briefly other techniques that are more limited in their application, such as peritoneal dialysis, plasmapheresis, and exchange transfusion.

APPROACH TO THE POISONED PATIENT

After supplying supportive measures to maintain airway, breathing, and circulation ("ABCs"), the management for a poisoned patient should be directed toward decreasing or limiting toxin accumulation.[14]

Prevention of Further Absorption

The first therapeutic intervention should be directed at preventing further absorption of the compound in question. Gastrointestinal lavage, with a solution of electrolytes and polyethylene glycol in a dose of 25 mL/kg/hr in children and 1.2–1.8 L/hr in adults, for a total of 4 liters, can be beneficial in the elimination of undissolved tablets or pills. This mode of therapy, also referred to as *whole bowel irrigation*, may be helpful in the management of toxins that are poorly adsorbed by activated charcoal, such as arsenic[15] and lithium. It is time-consuming and contraindicated in patients with an ileus, hemodynamic instability, or a compromised airway.[16] Cleansing of the skin with soap and water helps bind and remove unabsorbed drug or toxin from the surface of the body.

Table 46–1 Exposures and Treatments of Reported Poisonings in the United States for 2001

Exposure	
Exposure	
Number	2,267,979
Age	<6 years of age (52%)
Gender	
Unintentional: male = female	
Intentional: female = 61%	
Treated in health care facility	22%
Treated and released	54.5%
Intensive care unit	14.1%
Noncritical care	7.3%
Treatment	
Decontamination*	1,335,900
Urine alkalinization	6944
Hemodialysis	1280
Hemoperfusion	45
Other extracorporeal therapy	26
Transplant	8
ECMO6	
Antidotes	44,772

ECMO, extracorporeal membrane oxygenation. (From Litovitz TL, Klein-Schwartz W, Rogers GC, et al: 2001 Annual Report on the American Association of Poison Control Centers Toxic Exposure Surveillance System. Am J Emerg Med 2002; 20:391-401.)

Table 46–2 Fatalities of Reported Poisonings in the United States for 1995

Number	1074
Age >19 years old (89%)	
Age (intentional) >19 years old (>93%)	
Route	
Ingestion	77%
Inhalation	9.4%
Substances accounting for death	
Analgesics	531
Sedatives	266
Antidepressants	255
Stimulants	207
Cardiovascular drugs	153
Alcohols	108
Chemicals	60

(From Litovitz TL, Klein-Schwartz W, Rogers GC, et al: 2001 Annual Report on the American Association of Poison Control Centers Toxic Exposure Surveillance System. Am J Emerg Med 2002; 20:391-401.)

Oral sorbents (primarily activated charcoal) can bind unabsorbed drug in the gastrointestinal tract and therefore promote its elimination by decreasing its absorption. Activated charcoal is most helpful in the elimination of salicylates,[17] phenobarbital,[18] β-methyl-digoxin,[19] and theophylline.[21] It is administered as an aqueous suspension with a minimum of 8 mL of water to each gram of powder. Commercial pre-mixed formulations are available that may contain activated charcoal with a lubricant (i.e., propylene glycol or carboxymethylcellulose) or a cathartic (i.e., sorbitol). The mean transit time of activated charcoal in fasting subjects is 25 hours; this can be reduced to 1.1 hours with sorbitol.[21] The American Academy of Clinical Toxicology recommends limiting cathartic use to a single dose to lower the risk of adverse effects.[22] Activated charcoal can be administered orally or via nasogastric tube.[23] The recommended dose is 10 times the weight of the ingested chemical or as much as possible, if the dose of poison is unknown up to 1 g/kg. Single-dose activated charcoal has been shown to be most effective if given within 1 hour of ingestion. It should be used only in patients with an intact or protected airway.[24] Multidose activated charcoal has been shown to increase drug elimination significantly, but there have been no studies that show that it decreases morbidity or mortality. The American Academy of Clinical Toxicology recommends that its use be considered only in patients who have ingested a potentially lethal amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.[25] The standard regimen is to administer activated charcoal 1 g/kg then 0.5 g/kg at 2- to 6-hour intervals.[25,26]

Gastrointestinal lavage can directly remove ingested chemicals from the gastrointestinal tract and therefore prevent their absorption.[27,28] The efficacy of gastrointestinal lavage decreases as the time increases from ingestion to treatment. The efficacy of gastrointestinal lavage is enhanced, if it is preceded and followed by a dose of activated charcoal.[29] The lavage fluid of choice for patients more than 2 years of age is tap water.[30] Gastrointestinal lavage should be considered only when a patient has ingested a life-threatening amount of a poison and the lavage can be performed within 1 hour of ingestion.[31]

Forced Diuresis

The second step in minimizing toxin accumulation or promoting its removal is to facilitate endogenous excretion through forced diuresis or decreasing tubular reabsorption. Forced diuresis is useful only for compounds and metabolites that are excreted by the kidneys; even then, it is limited to very few poisonings. Alkaline diuresis can be used to enhance the elimination of salicylates[32] and phenobarbital,[33,34] and acidification can be used to enhance the elimination of chloroquine,[35] amphetamine,[36,37] quinine,[38,39] and phencyclidine.[40] If this maneuver decreases the concentration in the "toxic compartment," it may be adequate, but in most instances forced diuresis is not used as the sole method of treatment.

The kidneys are perfused with plasma at a rate of 36 L/hr; only one fifth of the plasma entering the kidney is filtered. Nearly all of the remaining plasma flows past the proximal tubules, where solutes are extracted from the plasma by tubular cells and actively secreted into the urine. Thus, plasma is filtered, then modified by a combination of tubular secretion and reabsorption processes. Even at maximal tubular secretion rates, production of urine volumes of 200 to 300 mL/hr limits tubular reabsorption because a large concentration gradient is prevented by urine dilution.[41–43] If high urine flow rates are applied with either acidification or alkalinization, elimination of certain toxins can be enhanced.

Manipulation of the urine pH can enhance the excretion of acidic or basic chemicals through a mechanism known as *ion trapping*.[44,45] The membranes of the nephron are generally more permeable to nonionized and nonpolar molecules. Compounds are filtered and secreted in a nonionized form of weak acids or bases by nonionic diffusion across cell membranes. They subsequently become ionized in extreme pH conditions and become trapped in urine.

Alkalinization of the urine helps promote elimination of weak acids, such as salicylates[32] and barbiturates[33,34] (phenobarbital and barbital). Acidification techniques help promote elimination of weak bases, such as amphetamine,[36,37] quinine,[38,39] phencyclidine,[40] and fenfluramine.[46,47] This change in the intraluminal pH promotes the formation of a higher intratubular fraction of ionized drug, effectively trapping the ionized moiety in the urinary space secondary to the impermeability of the nephron to charged substances. Thus, reabsorption is decreased and renal elimination enhanced.

Table 46–3 summarizes the methods for alkalinization and acidification of the urine.[48] Intravenous sodium bicarbonate is most commonly used for alkalinization. The carbonic anhydrase inhibitor acetazolamide can be used as well but should be used with caution and only with sodium bicarbonate because of the risk of systemic acidosis. Acidification techniques are no longer recommended because of their questionable effectiveness and the complications of the acid diuresis, which include myoglobinuria, acute renal failure, and hyperkalemia.

The limitation of forced diuresis is that it requires volume expansion with the possible induction of volume overload. Alkalinization or acidification of the urine occurs through systemic loading of the agents listed in Table 46–3 and can lead to systemic acid-base and electrolyte disturbances. Hypokalemia is a common consequence of attempts at forced diuresis or alkalinization of the urine, and addition of potassium chloride to the fluids used is often necessary. These techniques require adequate renal function, and, therefore, their use is limited to only a few poisonings and a few clinical situations.

Antidotes

The third strategy is to convey protection against the toxin by administering specific antidotes, antibodies, or substrate inhibitors. Antidotes and antibodies are available for a limited number of poisonings (Table 46–4). The timing of their administration can be crucial, and most antidotes are only adjunctive therapy to aggressive supportive care.[49] For example, with opiate poisoning, naloxone may reverse or prevent cardiac or respiratory arrest when administered rapidly.[49] This agent can prevent hypoxic brain damage or death when administered early in the course of treatment. As well, flumazenil is very beneficial in benzodiazepine poisoning or overdose. Additional therapy with vasopressors or ventilatory support is occasionally necessary until other means of therapy have been initiated or have taken effect. Ethanol and fomepizole are employed in methanol and ethylene glycol intoxications (see later). Deferoxamine is used for acute iron poisoning.

Digoxin-specific (digoxin immune Fab) antibody is one example of an antidote used in life-threatening *digitalis* intoxication. This antibody should be administered early, if the patient has digitalis-induced ventricular arrhythmias, high-grade atrioventricular block, severe hyperkalemia, or cardiac arrest.[50] There is great variability in the threshold of serum digoxin level at which cardiotoxicity may develop. Therefore, clinical judgment is paramount in the evaluation of

Table 46–4 Drugs and Poisons Treated with Specific Antidotes

Poison	Antidote
Acetaminophen	N-acetylcysteine
β-Blocking drugs	Glucagon, atropine, isoproterenol
Carbon monoxide	Oxygen (100% or hyperbaric)
Cyanide	Amyl nitrite, sodium nitrite, sodium thiosulfate, oxygen
Digoxin	Digoxin-specific Fab antibody fragment
Ethylene glycol	Fomepizole, ethyl alcohol,
Methanol	Fomepizole, ethyl alcohol
Isoniazid	Pyridoxine
Metallic poisons	
Arsenic	Dimercaprol
Iron	Deferoxamine
Lead	Dimercaprol, edetate disodium calcium, penicillamine
Mercury	Dimercaprol, penicillamine
Nitrates, nitrites, phenacetin	Methylene blue
Opioid drugs (codeine, heroin, meperidine, morphine, propoxyphene)	Naloxone HCl
Organophosphates	Atropine, pralidoxime
Sympathomimetic agents	β-Blockers, phentolamine,
Benzodiazepines	Flumazenil

(From Goldberg MJ, Spector R, Park GD, et al: An approach to the management of the poisoned patient. Arch Intern Med 1986; 16:1381–1385; Mokhlesi B, Leikin JB, Murray P, Corbridge TC: Adult toxicology in critical care: Part I: General approach to the intoxicated patient. Chest 2003; 123:897-922.)

Table 46–3 Urine Alkalinization and Acidification*

To Achieve an Alkaline Diuresis
Sodium bicarbonate, 1–2 mEq/kg every 3–4 hours
Goal: urine pH = 7.5–8.5
For example: 1 amp sodium bicarbonate bolus followed by 3 amps of sodium bicarbonate per liter of 5% dextrose in water to run at 250 mL/hr

To Achieve an Acid Diuresis
10 g arginine or lysine hydrochloride IV over 30 minutes
Then ammonium chloride, 4 g every 2 hours orally
Goal: urine pH = 5.5–6.5

*Both therapies require some degree of volume expansion. (From Mudge GH, Silva P, Stibitz GR: Renal excretion by non-ionic diffusion. Med Clin North Am 1975; 59:681–698.)

digitalis-intoxicated patients. Loss of digitalis effect after Fab antibody administration may lead to congestive heart failure, increased ventricular rate in the setting of atrial fibrillation, or hypokalemia, especially when there was previous treatment of hyperkalemia.[51] Patients with anuria may have a rebound in the digoxin level because of slow clearance of the digoxin-antibody complex.[52] One vial of Digibind (Burroughs Wellcome), the proprietary formulation of this agent, contains 38 mg of digoxin-specific antibody; each vial neutralizes 0.6 mg of absorbed digoxin. When the ingested dose of digoxin is unknown, 1 to 20 vials (38 to 760 mg) should be administered for acute ingestions and 6 vials for chronic toxicity.[53]

Cyanide poisoning is difficult to diagnose but may be suspected in victims of smoke inhalation, especially those exposed to burning plastic or polyurethane.[54] An elevated anion gap metabolic acidosis secondary to lactic acidosis with an oxygen (O_2) saturation gap[55] (a decreased measured arterial percent O_2 saturation with a normal calculated percent O_2 saturation) may be present. Blood cyanide levels greater than 0.5 mg/L are considered toxic.[56] The treatment includes an amyl nitrite–sodium nitrite–sodium thiosulfate combination, which is marketed as the Lilly Cyanide Antidote Kit (Eli Lilly). Nitrite-induced methemoglobin (Fe^{3+}) has a greater affinity for cyanide than does the ferric iron moiety of cytochrome oxidase and attracts cyanide from the respiratory enzyme. Sodium thiosulfate allows for the formation of thiocyanate, which is renally excreted.[51] Recent work with hydroxycobalamin has shown that it will safely reduce red blood cell and plasma cyanide levels. The currently recommended dose is 5 g IV.[57]

Poisoning due to *anticholinesterase pesticides* (organophosphates, carbamates) and *military nerve agents*[58] can be treated with atropine and pralidoxime. Atropine is a physiologic antidote acting by competitive inhibition of acetylcholine at muscarinic receptor sites, blocking the clinical effect of excessive parasympathetic activity. The dose of atropine is 2 mg by the intravenous route (IV) every 15 minutes, with therapeutic response being judged from drying of excessive secretions.[59] Pralidoxime (Protopam Chloride, 2-PAM) reactivates cholinesterase that has been phosphorylated by the organophosphate. The recommended dose for pralidoxime is 1 to 2 g IV over 10 to 20 minutes.[60] By 24 to 36 hours after exposure, the efficacy of pralidoxime decreases as the cholinesterase is irreversibly bound. However, ongoing release of organophosphate from fat stores may warrant treatment with pralidoxime.[61]

Laboratory Evaluation

A few measurements that are commonly done in the emergency room can give a hint about the nature and amount of the toxin ingested. Three simple calculations are most helpful in determining the type of ingestion: anion gap, osmolar gap, and oxygen saturation gap.

Anion Gap

The calculation of the difference between the measured cations and the measured anions can be used to estimate the difference between the *unmeasured* anions and the *unmeasured* cations. The normal anion gap is 8 to 12 mEq/L, and a value above 12 mEq/L can signify an increase in unmeasured anions. The most common intoxications to cause a high anion gap acidosis are ethylene glycol, methanol, and salicylates. Also, an elevated anion gap from lactic acidosis can signify an intoxication with acetaminophen, carbon monoxide, metformin, phenformin and NSAIDs.[62] It is important to note that a normal anion gap does not rule out an intoxication because many toxins do not cause a gap or there may be a coexisting condition that lowers the gap. The most common condition to lower the gap is hypoalbuminemia: the anion gap falls 2.5 mEq/L for every 1 g/dL drop in serum albumin.[63] A few toxins, such as methanol and ethylene glycol, need to be metabolized before they create an anion gap acidosis. In these cases, intoxication may not be associated with an anion gap early on, especially when there is ethanol coingestion.[64]

Osmolar Gap

Ingestion of low molecular weight toxins will increase the difference between the measured and the calculated plasma osmolarity or osmolar gap. The calculated osmolarity is

$$2 \times Na + BUN/2.8 + glucose/18 + ethanol/4.6 \quad \text{[65,66]} \quad (1)$$

$$\text{Osmolar gap} = \text{measured Osm} - \text{calculated Osm}$$

An osmolar gap greater than 10 mOsm indicates the presence of osmotically active substances, such as ethanol, methanol, isopropyl alcohol, and ethylene glycol.[67] Hospitalized patients may develop an osmolar gap from glycerol, IV immunoglobulin, propylene glycol, radiocontrast media, and sorbitol.[14] Propylene glycol is a common vehicle for intravenous medications and can cause an osmolar gap, and its metabolite, lactic acid, can contribute to a high anion gap acidosis.[68] Accumulation of propylene glycol in patients receiving high doses of IV medications, such as diazepam, which have propylene glycol as their carrier, may cause severe acidosis with hemodynamic instability and can be treated with hemodialysis.[69] Table 46–5 lists the contribution to the osmolar gap of various drugs and toxins.

A number of toxins, such as ethylene glycol and methanol, will no longer produce an osmolar gap because they are metabolized, and, in these cases, a normal gap does not exclude intoxication—only a late presentation.[70] Another factor that lowers the sensitivity of the osmolar gap is the considerable variation in the normal osmolar gap in the general population. Indeed, patients may have an increased gap that is still below 10 mOsm/kg.[71] Thus, a high osmolar gap is supportive of intoxication, but a normal gap does not rule it out. On the other hand, the osmolar gap can also be falsely elevated. Patients who are critically ill may have an elevated gap because of the presence of endogenous substances, such as amino acids. Patients with hyperlipidemia or hyperproteinemia will have spurious hyponatremia leading to an elevated gap.[71] There is also an accumulation of osmotically active substances in chronic renal failure.[72]

Oxygen Saturation Gap

A saturation gap exists when there is more than a 5% difference in the calculated saturation from the partial pressure of oxygen and the measured saturation with co-oximetry. Co-

Table 46–5 Osmolar Contribution of Various Toxins and Drugs

Alcohol	Osmolar Gap (mOsm/L)	Serum Concentration (mg/dL)
Ethanol	10	46
Methanol	10	32
Ethylene glycol	10	62
Isopropanol	10	60
Acetone	10	58
Propylene glycol	10	76
Mannitol	10	182

Osm, osmolar gap: measured Osm – calculated Osm.

oximetry is often performed on blood gas samples and can measure the levels of four different hemoglobin species: oxyhemoglobin, carboxyhemoglobin, methemoglobin, and reduced hemoglobin.[73] Pulse oximetry will measure carboxyhemoglobin and methemoglobin as oxyhemoglobin and will therefore overestimate the oxygen saturation in cases of carbon monoxide intoxication or methemoglobinemia.[74] This difference between oxygen saturation as measured by co-oximetry and that measured by pulse oximetry is often referred to as the pulse oximetry gap and suggests carbon monoxide poisoning or methemoglobinemia.[73,75]

DRUG OR TOXIN REMOVAL BY EXTRACORPOREAL TECHNIQUES

To determine the ability of a drug or toxin to be removed by a specific extracorporeal technique, one should consider both dialysis-related factors and drug-related factors. The characteristics of a drug that determine whether it can be removed by a specific extracorporeal technique are molecular weight, protein binding, volume of distribution, lipid or water solubility, rebound, charge, and membrane binding. The type of extracorporeal therapy, whether hemodialysis, peritoneal dialysis, or hemofiltration, also influences drug or toxin removal. Some of the important properties of the hemodialysis system that are discussed are properties of the dialysis membrane, blood flow rate (Q_b), dialysate flow rate (Q_d), pH, and temperature.

Drug-Related Factors

Molecular Weight

The molecular weight of a compound is the most reliable predictor of drug removal by a dialysis system.[76,77] The molecular size, which comprises the molecular weight, shape, charge, and steric hindrance of a molecule, is also an important determinant of the molecule's ability to permeate a dialysis membrane pore. *Low-molecular-weight* compounds or small molecules are those classified as being less than 500 D. These molecules cross conventional low-flux (low porosity, low surface area) dialysis membranes readily, with the extent depending more on Q_b, Q_d, and effective membrane surface area. *High-molecular-weight* compounds or "large solutes" are those greater than 5000 D; they diffuse slowly across membranes. *Middle-molecular-weight* compounds are those between 500 and 5000 D. Their removal is intermediate to the other two categories mentioned.

Drugs with molecular weights of more than 1000 D depend more upon convection for dialytic clearance[77] and are substantially removed only with high-flux dialysis because of the higher rate of water movement across the membranes. Common features of high-flux dialysis are (1) Q_b greater than 300 mL/min, (2) urea clearance greater than 200 mL/min, and (3) ultrafiltration coefficients (K_{Uf}) greater than 15 mL/mm Hg/hr for the dialyzers and the dialysis membranes utilized. Removal of large solutes is enhanced by the use of a porous membrane with a large surface area along with high Q_b and Q_d. Over the past 5 years, there has been a trend toward higher flux dialysis membranes. Most membranes in use today have considerably higher ultrafiltration fractions as compared to filters used 5 years ago allowing for greater clearances of *middle-molecular-weight* compounds.

Protein Binding

Protein binding renders the drug or compound pharmacologically inactive; only the unbound fraction of the drug can be readily metabolized and excreted. Unbound drug is the pharmacologically active form because it can be distributed to receptor sites, metabolic inactivating sites, or excretory sites (the kidney or dialyzer). Malnutrition and proteinuria lower serum protein levels and therefore lead to a higher fraction of free drug owing to a reduced number of protein binding sites.[78]

Drug-protein complexes are too large to cross conventional dialysis membranes and are therefore not available for removal by most renal replacement therapies. The accumulation of compounds during uremia decreases the affinity of albumin for drugs, such as penicillin, digitoxin, phenobarbital, phenytoin, warfarin, morphine, primidone, salicylate, theophylline, and sulfonamides.[79,80] If the affinity for albumin is decreased, more free or unbound drug is available for both pharmacologic effect and elimination.

Because of the chronic organic acidosis that accompanies renal failure,[81] acidic drugs have a higher free fraction than basic drugs in patients with renal failure. Examples of acidic drugs are cephalosporins, imipenem, vancomycin, and ciprofloxacin. The free fraction of basic drugs, on the other hand, is often decreased as a result of elevations of the acute-phase reactant α_1-acid glycoprotein, which binds these drugs readily.[81,82]

Free fatty acids can compete with drugs, such as tryptophan, sulfonamides, salicylates, phenylbutazone, phenytoin, thiopentone, and valproic acid for protein-binding sites. Use of heparin during hemodialysis stimulates the activity of lipoprotein lipases, subsequently increasing free fatty acid levels by triglyceride breakdown.[83–85] This increases the free fraction of the previously mentioned drugs during the time that heparin is used. Elevated free fatty acids can displace a drug, such as cefamandole, but may enhance the binding of other cephalosporins, such as cephalothin and cefoxitin.[86]

The molar ratios of drug to protein can also affect protein binding or fraction of free drug. Altered protein binding becomes clinically important in the setting of highly bound drugs with a low therapeutic index.

Volume of Distribution

The *volume of distribution* (Vd) is defined as that volume of water into which a specified amount of an agent would have to be diluted to yield the concentration found in plasma (Cp). Avid tissue binding expands the apparent Vd. The relationship can be defined as:

$$Vd \ (L) = dose \ (mg) \ / \ Cp \ (mg/L) \qquad (2)$$

The Vd does not necessarily correspond to a particular anatomic compartment or fluid space but denotes a mathematical relationship that assumes the body is homogenous. Substances, such as alcohols, atenolol, 2,4-dichlorophenoxyacetic acid, paracetamol, phenobarbitone, paraquat, salicylate, sotalol, aminoglycosides, and theophylline, have a relatively small or moderate Vd of less than or equal to 1 L/kg. These compounds are more likely to be removed by extracorporeal techniques.

Compounds with high degrees of tissue binding or protein binding are not substantially removed by hemoperfusion or hemodialysis. For most other β-blockers, calcium channel blockers, chloroquine, colchicine, diazepam, digoxin, flecainide, quinidine, tricyclic antidepressants, organochlorine pesticides, strychnine, quinine, and phenothiazines, the Vd is 2 L/kg or greater. These compounds are ineffectively cleared by any extracorporeal technique because of a low plasma concentration relative to the total body burden.

As discussed by Gibaldi,[87] the fraction of unbound drug in the blood and tissue can influence the Vd. In patients with impaired plasma protein binding, there is an increase in the apparent Vd of the drug. This is seen in patients with renal failure, owing to decreased albumin and impaired binding capacity of albumin. Renal failure decreases the Vd for digoxin but increases the Vd for phenytoin.

Rebound

If the rate of distribution of an agent from the extravascular tissues is slower than the elimination of the substance from the vascular space, the agent is removed from the blood more rapidly than it can be replaced from tissue stores. This is most noticeable with compounds with a large Vd (>1 L/kg) because the largest burden of drug is outside the vascular space.

Rebound refers to the movement of drug or compound from peripheral storage compartments (cells or tissues) to plasma or blood. This is characteristic of lithium, which distributes predominately within cells and exhibits slow diffusion across cell membranes.[88] After a short hemodialysis treatment, lithium plasma levels rebound or rise,[89] and repeated dialysis or continuous therapy may be required to effectively remove a substantial amount of the drug.[90] With middle- and large-molecular-weight solutes, intracellular equilibration with extracellular fluid can be slow.[91] There may be a post-hemodialysis rebound of 10% to 25% with intercompartmental equilibration.[92] The removal of other compounds, such as methotrexate,[93] paraquat,[94] and tricyclic antidepressants,[95] is hindered by slow distribution from peripheral tissues to the blood even after the blood compartment has been depleted.

Dialysis-Related Factors

In addition to drug or toxin characteristics, extracorporeal removal is also determined by the properties of the dialysis system. For hemodialysis, these factors are (1) membrane type, (2) dialyzer size, (3) dialysate composition, (4) blood flow, and (5) dialysate flow. Solute removal during hemodialysis is accomplished primarily by diffusion, with a smaller contribution coming from convection.

The factors in peritoneal dialysis that contribute to drug or toxin removal are (1) transport characteristics of the peritoneal membrane, (2) composition of the dialysate solution, (3) frequency of exchanges, and (4) dwell times. For hemofiltration, the solutes, drug, or toxin is removed primarily by convective mass transfer, meaning that solutes dissolved in plasma water are removed in the filtrate. Thus, toxin removal depends on high rates of ultrafiltration.

Hemodialyzer Properties

Removal of small solutes depends on the concentration gradient between blood and dialysate. Therefore, countercurrent flow combined with increased blood and dialysate flow rates creates a high concentration gradient for maximal solute removal. The gradient can also be maximized by enlarging the surface area of the dialysis membrane, thus exposing more undialyzed blood to areas of fresh dialysate. As the solute increases in molecular size or volume, its removal becomes limited by the pore size of the membrane and is more dependent on the property of *convection*, which is the net flow or ultrafiltration of plasma water from the blood to the dialysate. For larger molecules, diffusion across the membrane is decreased. Drug removal is limited by the membrane area times the permeability. The overall clearance of compounds can be enhanced by an increase in (1) the surface area of the membrane, (2) Q_b, and (3) the ultrafiltration rate.[96] Furthermore, drugs may bind to dialysis membranes and are removed from the circulation by adsorption, as first noted by Rumpf and associates.[97]

Peritoneal Dialysis

Although employed infrequently for toxin removal, peritoneal dialysis can be used for compounds with low molecular weight, low Vd, low protein binding, and high water solubility. Depending on the transport characteristics of the peritoneal membrane (high, average, or low), the composition of the dialysate solution, the frequency of exchanges, and dwell times can be altered to enhance clearance or removal of certain compounds or toxins. For example, the addition of albumin to the dialysate may enhance or promote removal of protein-bound substances, and modification of the pH with alkalinization may promote removal of weak acids.

Exaire and associates[98] have shown that the addition of albumin to peritoneal dialysate solutions can increase the dialytic clearance from 8 to 20 mL/min in barbiturate intoxication. With hypertonic dialysate solutions, such as 4.25% dextrose rather than 1.5% dextrose, water-soluble compound removal should be enhanced owing to higher convective losses.

When hemodynamically unstable patients are being treated with peritoneal dialysis, dopamine would be the pressor agent of choice because, at least in animal studies, it has been shown to increase peritoneal solute transport.[99] Peritoneal dialysis is the least effective method of removing drugs and should be used only if other methods are unavailable.

Hemofiltration

Hemofiltration depends on adequate blood flow (150 to 250 mL/min) to the filter for maximal performance. The removal of drug depends on its delivery to the filter, which, in turn, depends on the Vd of the drug or toxin in question. If a drug is displaced from protein, its pharmacologic effect, metabolism, and removal are enhanced.

As already described, many factors can affect drug-protein binding and Vd. Drug removal may be partially due to drug-membrane binding. Kraft and Lode[100] noted membrane binding of gentamicin to an RP-6 hemofilter, whereas Kronfol and associates[101] described the binding of both tobramycin and amikacin to AN69 filters. The *sieving coefficient* (S) is also an important factor in hemofiltration; it is the permeability of a membrane to a certain solute during ultrafiltration. A sieving coefficient of 1 means the membrane is fully permeable to the compound in question, whereas a value of 0 indicates total impermeability.[102] This relationship can be described as follows:

$$S = C(f)/C(p) \qquad (3)$$

where C(f) is concentration in ultrafiltrate and C(p) is concentration in plasma.

In hemofiltration, the clearance rate is proportional to the sieving coefficient and the ultrafiltration rate:

$$\text{Clearance rate} = \text{ultrafiltration rate} \times \text{sieving coefficient.}$$

EXTRACTION RATIO

The extraction ratio (ER) is determined by measuring the concentration of the drug (plasma or blood levels) before it enters (A) the hemoperfusion cartridge or hemodialyzer filter and just after it exits (V). The ER can refer to the removal or the extraction of a drug from whole blood or plasma. It is calculated by the following formula:

$$ER = (A - V)/A \qquad (4)$$

A value of 1.0 indicates that the drug was completely removed (extracted) in one pass through the extracorporeal system. The clearance rate can thus be calculated by knowing the flow rate (blood or plasma) through the system:

$$\text{Clearance rate} = \text{flow rate} \times \text{extraction ratio} \qquad (5)$$

High ER can be misleading with respect to total body removal of a drug or compound. After absorption, the drug is distributed in various body compartments in different ways according to its (1) molecular weight, (2) ionization at various body fluid pH values, (3) lipid solubility, (4) protein binding, and (5) tissue binding. These factors determine the amount of drug in various body tissues, extracellular fluid, and plasma as well as the ease with which the drug moves between compartments.

Both hemodialysis and hemoperfusion are directed at drug or compound available in plasma or blood. The ease with which a compound moves from the peripheral tissue compartments to the central blood compartment must be considered when determining the practicality of these therapies for removal of the compound in question. In other words, the availability of the drug for removal is important in determining the total body clearance and decreasing toxicity with extracorporeal therapy. High ERs or clearance rates are only prerequisites to suggest the effectiveness of hemoperfusion or hemodialysis; they indicate nothing about the clinical efficacy of the removal technique.[2] They indicate the amount of drug or toxin removed only from the blood compartment not from the total body. Pharmacokinetically, hemodialysis is an appropriate removal technique when the drug or toxin is primarily distributed in extracellular water, is not highly protein bound, and has a small Vd.

Techniques of Extracorporeal Drug Removal

Dialysis to treat poisonings was introduced by Doolan and associates,[103] was championed by Schreiner and associates[104] in the 1950s, and became widely accepted in the 1960s and early 1970s. By 1972, it was believed that dialysis could treat practically all known toxic exposures.[105] The first successful treatment of a poisoned patient was achieved in 1955 by Schreiner and associates[104] for the removal of aspirin.

Anionic exchange resins were first proposed for the removal of uremic toxins in 1948[106] and for the extraction of exogenous poisons in 1958.[107] Hemoperfusion was first applied by Muirhead and Reid[106] in 1948, who used mixed ion exchange resins to remove "uremic toxins" from animals. Coated charcoal for hemoperfusion was introduced in the 1970s.[108]

Hemodialysis, Hemofiltration, and Hemoperfusion

Hemodialysis is most useful for removal of compounds with the following characteristics:

- Vd less than 1 L/kg
- Low molecular weight
- Less than 80% protein bound

These compounds include alcohols, salicylates, theophylline, and lithium.[109]

Lithium can readily be removed by hemodialysis. However, because of its moderate Vd (0.7–0.9 L/kg) and intracellular distribution with slow diffusion across cell membranes,[77] multiple treatments or continuous therapy may be required to effectively decrease the body burden of lithium.

The efficiency of hemodialysis depends not only on drug-related factors or characteristics but also on the extracorporeal system in regard to Q_b, Q_d, and dialysis membrane properties. Increasing Q_b and Q_d helps maintain a large concentration gradient with greater diffusion.

In hemofiltration, convective transport of solutes is affected by the ultrafiltration of plasma water with its dissolved constituents. The clearance of a toxin is proportional to the sieving coefficient for that toxin and the ultrafiltration rate. Therefore, to maximize the clearance in hemofiltration, one must maximize the ultrafiltration rate. In most cases, clearances of small molecules are 2 to 5 times greater with hemodialysis as compared to hemofiltration due to the limit on ultrafiltration.[110] High-volume hemofiltration may be able to overcome this difficulty by allowing for ultrafiltration rates up to 6 to 10 L/hr.[111] Hemofiltration can be employed in the removal of metal-chelator complexes, such as aluminum-deferoxamine and iron-deferoxamine. Aluminum toxicity, although now rare, can be treated with deferoxamine

and the aluminum-deferoxamine complex then removed with hemodialysis or hemofiltration. Hemofiltration has been shown to be more efficient than other methods for this therapy.[8]

In hemoperfusion, blood is passed through a cartridge of sorbent material, such as coated charcoal[112] or polystyrene resin.[113] Resins were initially introduced for the removal of lipid-soluble compounds but offered little advantage over charcoal hemoperfusion, and they were withdrawn from the market in the early 1980s. In 1964, Yatzidis[114] demonstrated that a column containing activated charcoal could adsorb from plasma a considerable amount of barbital, phenobarbital, pentobarbital, salicylic acid, and glutethimide. Activated charcoal cartridges now contain charcoal covered with an ultrathin, porous coating (microencapsulation).[115] This coating decreases the direct contact between constituents of blood and charcoal, minimizing trauma to all cellular elements. Platelets are the most vulnerable; the average platelet loss is 30% with conventional hemoperfusion devices using coated charcoal.[116] There are also reductions in serum calcium and glucose levels.[13] Complications of hemoperfusion include thrombocytopenia, hypocalcemia, hypoglycemia, hypothermia, and charcoal embolization. To prevent the latter, the system contains a filter in the venous line to remove loosened charcoal particles prior to returning blood to the patient. It has been shown to be effective in removal of theophylline, phenobarbital, phenytoin, carbamazepine, paraquat, and glutethimide.[117] Hemoperfusion is not beneficial in control of electrolyte disturbances, acid-base disorders, or fluid overload but may be applied concurrently with hemodialysis or hemofiltration to correct these disorders.

Peritoneal Dialysis and Plasma Exchange

Peritoneal dialysis can be used for removal of compounds with low or middle molecular weight, low Vd, low protein binding, and polar substances that readily dissolve in water. They include alcohols, lithium, salicylates, and theophylline. Peritoneal dialysis is less efficient than other extracorporeal techniques because clearances rarely exceed 10 mL/min. In some situations, however, it may be beneficial, especially if it is the only extracorporeal therapy available.

With the use of hypertonic dialysate, convective forces can increase recovery of water-soluble compounds. Other modifications can be made to promote drug removal; for example, adding albumin to the dialysate may help promote removal of protein-bound substances,[118] and modification of the pH through alkalinization of the dialysate may promote the removal of weak acids.[119]

Plasma exchange is most applicable to removal of drugs that have an extremely high affinity for circulating proteins. It has been used rarely in chromic acid and chromate poisonings.[120] It has also been used to remove antibody-digoxin complexes following treatment with digoxin-specific antibody for patients with digoxin toxicity and anuria.[121] Exchange transfusion is not applicable to poisonings. It has been used for treatment of hemolysis and methemoglobinemia secondary to various poisonings.[122]

Continuous hemofiltration techniques are useful for patients in need of renal replacement therapy along with continuous drug removal. These techniques are particularly useful for removal of drugs that have high degrees of tissue

binding or intracellular distribution and slow intercompartmental transfer, such as lithium.[88,111]

Indications for Extracorporeal Therapy

Indications for extracorporeal elimination of drugs or toxins depend most strongly on the clinical severity and potential complications of the poisoning. The following issues must be considered:

1. Characteristics of the individual patient (age and other comorbid conditions, such as congestive heart failure, end-stage renal disease, and liver failure).
2. Toxic side effects of the compound ingested, along with dose ingested, potential complications, and impaired pathways of metabolism.
3. Nature, dose, and plasma concentration of the toxic substance.

Appropriate interpretation of the drug concentration must take into account hepatic or renal elimination, delayed gastrointestinal absorption, active metabolites, altered distributional characteristics, and saturable elimination pathways. Extracorporeal elimination that increases the total body clearance by 30% or more is believed to be a worthwhile intervention in the proper clinical setting.[123,124]

Extracorporeal therapy may be considered when all of the following conditions are met:

1. The drug or toxin diffuses readily through the dialysis membrane (e.g., alcohol) or is readily bound by the adsorbent (e.g., barbiturate).[125]
2. A clinically significant proportion of the poison is present in plasma water or is capable of rapid equilibration with plasma water (e.g., alcohols).
3. The pharmacologic effect of the toxin is directly related to its blood concentration (e.g., lithium).
4. Dialysis or hemoperfusion will add significantly to total body elimination (>30%) (e.g., alcohols or procainamide).

Indications for extracorporeal removal of poisons are not universally agreed on, however. Table 46–6 lists characteristics of poisonings for which there is general agreement that extracorporeal therapy should be used.[109,126]

SPECIFIC TOXINS

The rest of the chapter will focus on specific toxins and drugs that are frequent causes of intoxication and whose elimination is significantly enhanced with either hemodialysis or hemoperfusion. They include ethanol, methanol, ethylene glycol, isopropyl alcohol, salicylates, lithium, and theophylline. Table 46–7 shows the number of reported exposures and the mortality rates for these toxins.[1]

Alcohols

Alcohols are readily dialyzed because of their rapid diffusibility, water solubility, poor protein binding, and small Vd.

Ethanol

Ethanol is rapidly metabolized without toxic metabolites. A level greater than 350 mg/dL is dangerous, and a level greater

Table 46–6 Indications for Extracorporeal Therapy

1. A patient whose status is deteriorating despite full supportive care.
2. Normal routes of detoxification and elimination of the toxic agent are impaired.
3. A patient who has ingested a compound that will cause serious morbidity (tissue damage) or death and for which supportive care is ineffective. Examples: (a) Methyl alcohol metabolism to a toxic byproduct: poisoning of concentration >50 mg/dL or >16 mmol/L can lead to blindness; (b) theophylline intoxication can cause seizures with permanent neurologic impairment or death.
4. A patient who is unduly susceptible to the effect of an overdose because of age or comorbid conditions. These patients poorly tolerate prolonged coma and its complications (intubation, respirator support, pneumonia, septicemia, or hemodynamic instability or immobilization).
5. Severe central nervous system depression, primarily of midbrain function, leading to hypoventilation, hypothermia, and hypotension.
6. Patient who presents with overt signs and symptoms of toxicity.

than 500 mg/dL may be fatal.[2] The total body clearance of ethanol is increased by 50% with hemodialysis.[127] There may be circumstances in which hemodialysis is indicated for ethanol intoxication (i.e., pediatric intoxication). However, the relevance of a 50% reduction in ethanol concentration by hemodialysis is better applied when ethanol is used to treat poisonings with other alcohols. Severe acidosis is not usually seen with ethanol intoxication. There is a rise in the osmolar gap of 22 mOsm/kg for every 100 mg/dL rise in serum ethanol concentration.[128] Table 46–5 lists the osmolar contributions of the various alcohols and other low–molecular-weight toxins.

Methanol

Methanol is a highly toxic alcohol that is found in a variety of commercial products, including antifreeze, windshield wiper

Table 46–7 Exposures and Fatalities from Toxins Substantially Removed by Extracorporeal Techniques

Toxin	Exposures (% of total)	Fatalities (% of total)	Mortality (% of exposures)
Methanol	1142 (0.05)	12 (1.1)	1.0
Ethylene glycol	5833 (0.2)	34 (3.1)	0.6
Isopropyl alcohol	9745 (0.4)	0 (0)	0
Salicylates	17,075 (0.7)	66 (6.1)	0.4
Lithium	4607 (0.2)	8 (0.7)	0.2
Theophylline	1146 (0.05)	18 (1.6)	1.5

(From Litovitz TL, Klein-Schwartz W, Rodgers GC Jr, et al: 2001 Annual report of the American Association of Poison Control Centers Toxic Exposure Surveillance System. Am J Emerg Med 2002; 20:391-452.)

fluid, paint thinner, and canned solid fuel for keeping food warm.[129] There were 12 reported deaths from methanol exposure in 2001.[1] The estimated minimum lethal dose for adults is approximately 10 mL. There are also reports of patients surviving ingestions greater than 400 mL without sequelae.[130]

Methanol is rapidly absorbed after ingestion. It has a distribution volume of 0.6 L/kg and a molecular weight of 32 g/mol. The metabolism of methanol to its end products is displayed in Figure 46–1. Methanol is oxidized by alcohol dehydrogenase in the presence of NAD to formaldehyde. Formaldehyde is then quickly oxidized to formate. Formate produces much of the toxic effect as well as the high anion gap acidosis. The formation of lactate also contributes to the anion gap acidosis. Pyruvate is metabolized to lactate because of the reduction of NAD to NADH during the oxidation of methanol.[131,132] Ethanol and fomepizole will slow the oxygenation of methanol by inhibiting alcohol dehydrogenase.[133,134]

Most of the clinical effects of methanol intoxication are due to the accumulation of formate. Before it is metabolized, methanol's major effect is to cause central nervous system depression. This is of short duration and is followed by a latent period. The latent period is due to the time it takes for formate to accumulate and lasts 14 to 18 hours or longer with ethanol or fomepizole treatment.[135]

The latent period is followed by a number of systemic findings as formate accumulates. Metabolic acidosis can be severe and a pH less than 7.0 has been found to be the strongest predictor of mortality. Patients with a pH less than 7.0 have 20 times the mortality as compared to patients with pH greater than 7.0.[130] Central nervous system effects in this stage can include headache, lethargy, convulsions, delirium, and coma. Patients who present with seizure or coma have over 10 times the mortality as patients without these symptoms.[136] Serum methanol levels have very little prognostic value for either permanent visual changes or death.[130,136]
Figure 46–1 Metabolism of methanol to its toxic intermediates. See text for explanation.

Ocular findings can be prominent and may include photophobia, central scotoma, visual field defects, fixed pupils, and difficulty with light adaptation. Pupillary dysfunction has also been shown to be a strong predictor of mortality.[136] Funduscopic signs include hyperemia, disk edema, and possible optic atrophy.[137] The ocular findings are due to the direct cytotoxic effect of formate on the retina. Other systemic findings can include nausea, vomiting, diaphoresis, and abdominal pain. The abdominal pain is often due to pancreatitis.[138]

As already stated, the accumulation of formate produces a high anion gap metabolic acidosis. Some of the anion gap is from the increased lactate production. A patient who presents early after an ingestion or later after a coingestion ethanol, may have little or no acidosis making the diagnosis of methanol intoxication much more difficult. These same patients receive the most benefit from alcohol dehydrogenase inhibition since the ingested methanol still needs to be metabolized to formate to have its toxic effect.[131]

Methanol also produces an osmolar gap. A serum level of 32 mg/dL increases the measured serum osmolarity by 10 mOsm/kg, and the serum methanol level can be estimated by multiplying the osmolar gap by 3.2. A high serum methanol level should therefore cause a gap between the calculated serum osmolarity and the measured osmolarity by freezing point depression.[139] However, patients with methanol intoxication may have a normal gap (<10 mOsm/kg), if they present late after ingestion and the methanol has been converted to formate. Formate does not contribute to the serum osmolarity because it is balanced by sodium, which is included in the calculated osmolarity. For this reason, the osmolarity gap should be used to help support the diagnosis of methanol intoxication, but it is not sensitive enough to rule out intoxication when there is no gap.[64]

Supportive treatment for methanol intoxication includes airway protection, circulatory support, correction of metabolic abnormalities, and control of seizures. Bicarbonate is indicated for patients with pH less than 7.3.[140] The use of folate has not been rigorously studied in humans but has been shown to increase the metabolism of formate to carbon dioxide and water. It can be given as a 50 mg intravenous dose every 4 hours for five doses then once a day.[141] Symptomatic patients should be given one dose of 1 mg/kg of folinic acid intravenously.[140]

The main objective of treatment of methanol intoxication is to limit the accumulation of formate. This is achieved by inhibiting alcohol dehydrogenase with either ethanol or fomepizole. Both have been shown to slow the metabolism of methanol to formate.[130,132,142–144] One of these two antidotes should be used as soon as possible to prevent the production of formate.[140] Indications for the use of either ethanol or fomepizole include a serum level greater than 20 mg/dL, a high osmolar gap after ingestion of methanol, or a high index of suspicion for methanol intoxication in a critically ill patient (Table 46–8).[140]

Ethanol has been used as an inhibitor of alcohol dehydrogenase in ethylene glycol intoxication for 50 years but has not been approved by the FDA.[144] The standard loading dose of ethanol is 0.6 g/kg followed by a constant infusion to keep the blood ethanol level between 100 and 200 mg/dL. The average maintenance dose of ethanol is 100 mg/kg/hr but is significantly higher for alcoholics and for patients on dialysis. Blood ethanol levels should be checked every 1 to 2 hours until a

Table 46–8 Indications for Fomepizole or Ethanol Therapy in Methanol or Ethylene Glycol Intoxication

1. Serum level of ethylene glycol or methanol >20 mg/dL
   or
2. History of ingestion of ethylene glycol or methanol and osmolar gap >10 mOsm/L
   or
3. Strong suspicion of ingestion of ethylene glycol or methanol and at least two of the following:
   a. Arterial pH <7.3
   b. Serum bicarbonate <20 mEq/L
   c. Osmolar gap >10 mOsm/L
   d. Calcium oxalate crystals in urine (for suspected ethylene glycol ingestion)

(From Barceloux DG, Bond GR, Krenzelok EP, et al: The American Academy of Clinical Toxicology Ad Hoc Committee on the Treatment Guidelines for Methanol P: American Academy of Clinical Toxicology practice guidelines on the treatment of methanol poisoning. Ad Hoc Committee. J Toxicol Clin Toxicol 1999; 37:537-560.)

steady state has been reached and then every 2 to 4 hours (Table 46–9). The potential adverse effects of ethanol include central nervous system depression, hypoglycemia, respiratory depression, and aspiration.[67,78,146]

Fomepizole should be given at a loading dose of 15 mg/kg followed by 10 mg/kg every 12 hours for 48 hours. After 48 hours, the dose should be increased to 15 mg/kg every 12 hours.[142] Fomepizole should be continued until the serum methanol level is less than 20 mg/dL and the patient is asymptomatic with a normal pH. Fomepizole is dialyzed and therefore needs to be dosed every 4 hours during dialysis (Table 46–10).[147]

The dose of both inhibitors of alcohol dehydrogenase have to be increased during dialysis.[148,149] Fomepizole may be the preferred antidote in methanol intoxication because levels do

Table 46–9 Ethanol Dosing in Methanol and Ethylene Glycol Intoxications

- IV loading dose 0.6–0.7 g/kg
- Followed by 66 mg/kg/hr constant infusion
- Keep serum concentration between 100–150 mg/dL
- Check serum concentration every 1–2 hr
- Increase maintenance dose to 154 mg/kg/hr for chronic drinkers
- Increase maintenance dose to 169 mg/kg/hr during dialysis
- Increase maintenance dose to 257 mg/kg/hr for chronic drinkers during dialysis

(From Barceloux DG, Krenzelok EP, Olson K, Watson W: American Academy of Clinical Toxicology Practice Guidelines on the Treatment of Ethylene Glycol Poisoning. Ad Hoc Committee. J Toxicol Clin Toxicol 1999; 37:537-560.)

Table 46–10 Fomepizole Dosing in Methanol and Ethylene Glycol Intoxications

- IV loading dose 15 mg/kg (1 g/mL, 1.5 mL/vial)
- Followed by 10 mg/kg every 12 hr for 48 hr
- Then 15 mg/kg every 12 hours until ethylene glycol or methanol levels <20 mg/dL
- All doses should be administered over 30 minutes
- Increase the frequency to every 4 hours during hemodialysis

(From Brent J, McMartin K, Phillips S, et al: Fomepizole for the treatment of ethylene glycol poisoning. Methylpyrazole for Toxic Alcohols Study Group [Comment]. N Engl J Med 1999; 340:832-838.)

not need to be followed, it has fewer side effects, does not cause further sedation, and it has a much simpler dosing scheme both with and without concurrent dialysis. Finally, because of the low side effect profile, some patients treated with fomepizole may not need observation in an intensive care unit, if they are otherwise stable.[142] With either antidote, the treatment should be continued until the methanol level is undetectable or both symptoms and acidosis resolve and the level is less than 20 mg/dL.[129]

Hemodialysis will remove both methanol and formic acid efficiently and will help correct the acidosis. It should be considered in any patient with severe acidosis or other refractory metabolic disturbance, high formate levels, seizures, visual changes, funduscopic abnormalities, or mental status changes (Table 46–11).[140,149] Since the serum methanol level has not been linked to permanent visual changes or death and with the availability of fomepizole, a less toxic antidote as compared to ethanol, some authors have argued that a high methanol level is no longer an indication for dialysis, if no other indication for dialysis is present.[151,152] Patients with a high methanol level that are not treated with dialysis should be watched closely for the development of acidosis or vision changes that would indicate the need for urgent dialysis. Clearance constants with high efficiency membranes have been as high as 200 mL/min for both formate and methanol.[148] The dose of both ethanol and fomepizole need to be increased during hemodialysis.

Table 46–11 Indications for Dialysis in Patients with Methanol Intoxication

1. Metabolic acidosis with pH <7.30
2. Vision or funduscopic abnormalities
3. Deteriorating vital signs, seizures or mental status despite supportive care
4. Renal failure
5. Refractory electrolyte imbalance
6. Methanol level >50 mg/dL (controversial if fomepizole is available)

(From Barceloux DG, Bond GR, Krenzelok EP, et al: The American Academy of Clinical Toxicology Ad Hoc Committee on the Treatment Guidelines for Methanol P: American Academy of Clinical Toxicology practice guidelines on the treatment of methanol poisoning. J Toxicol Clin Toxicol 2002; 40:415-446.)

Hemodialysis can hinder the maintenance of adequate ethanol levels, and a number of authors have described the use of ethanol enriched dialysate solutions.[153] Hemodialysis should be continued until the serum methanol level is undetectable or the patient is asymptomatic with a normal serum pH and the level is less than 20 mg/dL.[154]

Ethylene Glycol

Ethylene glycol is a sweet-tasting substance that is a common constituent of antifreeze. Because of its sweet taste and its ability to intoxicate, it is sometimes used as a substitute for ethanol. It is also often found as an accidental ingestion in children, or as a suicidal agent, accounting for approximately 0.2% of all exposures and 3.0% of all deaths due to poisonings. In 2001, there were 5833 exposures to ethylene glycol and 34 deaths reported to the Toxic Exposure Surveillance System (TESS) (see Table 46–7).[1] The estimated minimum lethal dose for adults is approximately 100 mL. A number of patients have survived ingestions of over 2000 mL.[155–157] In a case report by Johnson and associates,[155] one patient who underwent rapid treatment with ethanol infusion and hemodialysis in the emergency room survived an ingestion of 3000 mL without sequelae. The ethylene glycol level was found to be 1889 mg/dL.

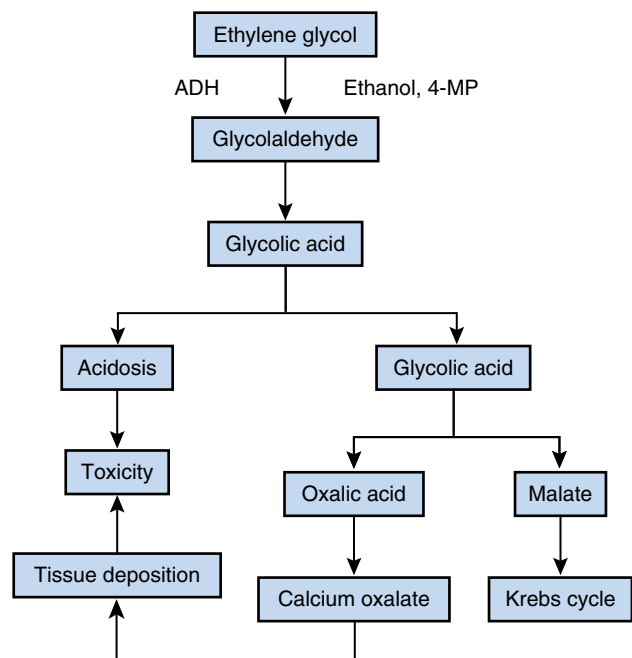
Ethylene glycol reaches a peak serum level 2 to 4 hours after ingestion. It is water-soluble and has a volume of distribution that is equal to total body water (0.6 L/kg). It has a molecular weight of 62 g/mol. Figure 46–2 displays the metabolism of ethylene glycol to its end products. Ethylene glycol is oxidized by alcohol dehydrogenase in the presence of nicotinamide


Figure 46–2 Ethylene glycol elimination. The metabolite glycolic acid produces the acidosis, and calcium oxalate damages tissue. Metabolism to these toxic species can be diminished if one saturates alcohol dehydrogenase (ADH) with ethanol. *4-MP*, 4-methylpyrazole.

adenine dinucleotide (NAD) to glycoaldehyde, which is then rapidly oxidized to glycolate.[158] Ethanol and fomepizole slow the metabolism of ethylene glycol by inhibiting the enzyme alcohol dehydrogenase.[144] Glycolate is the toxic metabolite and produces the high anion gap acidosis. Glycolate may be metabolized to oxalate, α-hydroxy-β-ketoadipate, and glycine. Oxalate causes some of the end organ damage as a direct toxin and through calcium oxalate deposition. Some part of the acidosis stems from the production of lactate and is due to the reduction of NAD to NADH, which drives the conversion of pyruvate to lactate (see Figure 46–1).[159] Without treatment, the elimination half-life of ethylene glycol is 3 to 8 hours. Ethanol and fomepizole will prolong the half-life fivefold to 15 to 20 hours.[141,160]

The clinical course of ethylene glycol intoxication can be divided into three phases.[161] The first phase occurs less than an hour after ingestion and is characterized by mental status depression similar to alcohol intoxication. In severe intoxication, coma, seizures, and respiratory depression can complicate this phase. This stage lasts about 12 hours as the ethylene glycol is oxidized to glycoaldehyde and glycolate.[72] In the second phase, glycolate has a toxic effect on the cardiopulmonary system. In severe intoxications, patients can develop acidosis, heart failure, pulmonary edema, or adult respiratory distress syndrome (ARDS).[72] The timing of this stage depends on the metabolism of the ethylene glycol to glycolate and usually starts approximately 12 hours after ingestion but will be delayed by alcohol coingestion. Review of data from TESS suggests that most deaths occur during this stage.[1] The final stage occurs 24 to 72 hours after ingestion and is characterized by flank pain, acute tubular necrosis, hypocalcemia, and renal failure. During this stage, the production of oxalate leads to calcium oxalate precipitation in the kidney and other tissues and hypocalcemia. The renal toxicity is probably due to a combination of hydronephrosis from calcium oxalate crystals and a direct toxic effect from the metabolites of ethylene glycol.[162] Most renal damage is reversible, and renal recovery, which may take a few months, is the norm even after anuria.[163]

There is very little correlation between serum ethylene glycol levels and clinical outcome. Indeed, patients may have a very high mortality, if they present after their serum levels have begun to decrease and the ethylene glycol has been converted to its toxic metabolites.[158] There is better correlation between the arterial pH, serum bicarbonate, or glycolate level and the clinical outcome. A number of studies of patients treated with fomepizole have shown that those who present without acidosis or a high glycolate level do well.[160,164]

Ethylene glycol intoxication is characterized by a high anion gap acidosis, osmolar gap, and hypocalcemia. The anion gap acidosis is due to both the production of glycolate and the reduction of NAD to NADH during the oxidation of ethylene glycol to glycolate. A patient may have no acidosis soon after ingestion before the ethylene glycol has been converted to glycolate. The gap will grow as the ethylene glycol is metabolized.[165] Ethylene glycol will also form an osmolar gap because it is osmotically active and has a relatively small molecular weight. In ethylene glycol intoxication, the serum level of the toxin can be estimated by multiplying the osmolar gap by 6.2.[166] An osmolar gap lacks the sensitivity and specificity to be an ideal screening test for intoxications. Glycolate does not contribute to the osmolar gap so that as the ethylene glycol is metabolized to glycolate, the osmolar gap will, in fact, fall.

Therefore, patients who present late after an ingestion, may have a normal osmolar gap.[70]

The urine may contain two forms of calcium oxalate crystals in ethylene glycol intoxication. The dumbbell-shaped monohydrate forms are more common, but the octahedral-shaped dihydrate form is more specific for ethylene glycol intoxication.[156] Individuals who ingest a large amount of vitamin C or urate-containing foods may have monohydrate calcium oxalate crystals in their urine. The dihydrate form requires higher oxalate concentrations for its formation and therefore is more indicative of intoxication with ethylene glycol.[159]

Supportive treatment includes airway protection, circulatory support, correction of metabolic abnormalities, and control of seizures. Bicarbonate is indicated for patients with pH less than 7.3.[158] Asymptomatic hypocalcemia is generally not treated because of the risk of increasing the formation of calcium oxalate crystals. Seizures may be due to hypocalcemia but should be first treated with standard anticonvulsants. There is no role for activated charcoal, cathartics, or gastric lavage in ethylene glycol intoxication.[158] Alcoholics and patients likely to be malnourished should be given thiamine and pyridoxine. The addition of thiamine, 100 mg intramuscularly (IM) or IV, and pyridoxine, 50 mg IV every 6 hours, should shunt the metabolism of ethylene glycol to less toxic metabolites.[67] Thiamine promotes the metabolism of glyoxylate from glycolic acid to a nontoxic metabolite, α-hydroxy-β-ketoadipate, and pyridoxine promotes the metabolism of glyoxylate to glycine.[169]

As with methanol intoxication, fomepizole and ethanol will slow the metabolism of ethylene glycol to its more toxic metabolites. The indications for the use of one of the antidotes have been outlined by the American Academy of Clinical Toxicology.[158] These indications include a plasma ethylene glycol concentration greater than 20 mg/dL, a recent ingestion of ethylene glycol and an osmolar gap greater than 10 mOsm/kg, or a high clinical suspicion and two of the following: pH less than 7.3, serum bicarbonate less than 20 mEq/L, osmolar gap greater than 10 mOsm/kg, or urinary oxalate crystals (see Table 46–8). The dosing schedule of each antidote is the same as that for methanol intoxication and is listed in Tables 46–9 and 46–10.

As with methanol intoxication, fomepizole may be the preferred antidote in ethylene glycol poisoning because of its ease of administration and because it does not cause CNS depression or hypoglycemia. Some patients treated with fomepizole may not need observation in an intensive care unit if they are otherwise stable.[142] Fomepizole is removed with dialysis and therefore needs to be dosed every 4 hours during dialysis.[147]

Hemodialysis is very effective at clearing ethylene glycol and its metabolites. The clearance rate of ethylene glycol ranges between 200 and 250 mL/min, depending on the filter and blood flow. Glycolate, which is the major toxic metabolite, has a half-life of up to 18 hours without hemodialysis, but the half-life is reduced by a factor of 6 with hemodialysis.[159] Patients with acidosis may therefore still benefit from hemodialysis even in the face of a low serum ethylene glycol level.[168]

The indications for hemodialysis include those patients who have or are likely to develop the major sequelae of ethylene glycol ingestion. These include patients with metabolic acidosis (pH <7.3) or deteriorating clinical status with respiratory failure or hypotension. Patients with acute renal failure

and a metabolic derangement that is unresponsive to standard therapy should be considered for hemodialysis as well (Table 46–12). In the past, an ethylene glycol level of 50 mg/dL was considered an indication for hemodialysis. Recent experience suggests that patients with normal renal function and no acidosis may be treated with fomepizole without hemodialysis even in the setting of an ethylene glycol level greater than 50 mg/dL.[164] These patients would require close monitoring for the development of renal insufficiency or acidosis.

Both fomepizole and ethanol are cleared during dialysis. The addition of ethanol to the dialysate has been shown to maintain blood ethanol levels during dialysis.[157] The use of fomepizole during hemodialysis is more straightforward and only requires an increase in the frequency of the doses to every 4 hours to maintain adequate levels.[160]

Dialysis should be continued until the ethylene glycol level is less than 20 mg/dL, the acidosis has resolved and there are no signs of systemic toxicity, or until the ethylene glycol level is undetectable. Prolonged dialysis up to 8 to 10 hours may be required for very high ethylene glycol levels and severe acidosis.[155] First-order kinetics can be used to estimate the required dialysis time in both methanol and ethylene glycol intoxication. Using the kinetics equation $C_1/C_0 = e^{-kt/V}$ where C_1 = desired drug level, C_0 = current level, k = clearance constant ($\sim$0.2 L/min), and Vd = volume of distribution (0.6 L/kg), and t is time in minutes,[154] the required dialysis time in minutes is therefore:

$$t = -Vd/k \times \ln(C_1/C_0) \qquad (6)$$

For example, a 100 kg man with an ethylene glycol level of 100 mg/dL will need dialysis for

$$t = -(60 \text{ L}/0.2 \text{ L/min}) \times \ln(20/100) = 483 \text{ minutes} \sim 8 \qquad (7)$$
$$\text{hours.}$$

Alternatively, dialysis can be continued until the serum osmolar gap and anion gap resolve, suggesting that ethylene glycol and glycolate levels have dropped.

Isopropyl Alcohol

Isopropanol is a colorless liquid with a bitter taste. It is used in the manufacture of acetone and glycerin. It is often used as the solvent in rubbing alcohol. Most rubbing alcohol contains 70% isopropanol.

There were 9745 exposures to isopropanol and 0 deaths reported to TESS in 2001.[1] This represents 0.4% of all expo-

Table 46–12 Indications for Dialysis in Patients with Ethylene Glycol Intoxication

1. Metabolic acidosis with pH <7.30
2. Deteriorating vital signs or mental status despite supportive care
3. Renal failure
4. Refractory electrolyte imbalance
5. Ethylene glycol >50 mg/dL (controversial if fomepizole is available)

(From Barceloux DG, Krenzelok EP, Olson K, Watson W: American Academy of Clinical Toxicology Practice Guidelines on the Treatment of Ethylene Glycol Poisoning. Ad Hoc Committee. J Toxicol Clin Toxicol 1999; 37:537-560.)

sures reported (see Table 46–7). It has a much smaller percentage of deaths per exposure as compared to either ethylene glycol or methanol. The estimated minimum lethal dose for adults is approximately 100 mL. Patients have survived ingestions of over 1000 mL.

Isopropanol reaches a peak serum level 15 to 30 minutes after ingestion. It is water-soluble and has a volume of distribution that is equal to total body water (0.6 L/kg). It has a molecular weight of 60 g/mol. Isopropanol is oxidized by alcohol dehydrogenase to acetone. The elimination half-life of isopropanol is 3 to 7 hours but is prolonged with ethanol coingestion.[167] The elimination of acetone is much slower and is due to excretion in the breath and urine.[171]

Unlike ethylene glycol and methanol, most of the clinical effects in isopropanol intoxication are due to the parent compound. Acetone causes only mild central nervous system depression.[139] The clinical signs of isopropanol intoxication will occur within an hour of ingestion and include effects on the central nervous system, gastrointestinal, and cardiovascular systems. The CNS effects include ataxia, confusion, stupor, and coma. The GI effects include nausea, vomiting, abdominal pain, and gastritis. Patients with severe intoxication can present with hypotension due to cardiac depression and vasodilatation.[172] Hypotension is the strongest predictor of mortality.[173] Many patients will have fruity breath from the acetone elimination via respiration.

A serum level of isopropanol equal to 60 mg/dL will increase the serum osmolarity by 10 mOsm/kg. A high serum level should therefore produce a gap between the calculated serum osmolarity and that measured by freezing point depression.[174] Acidosis is rare following isopropanol ingestion because neither the parent compound nor its metabolites are organic acids. Therefore, a finding of a high serum or urine acetone level with an osmolar gap but without acidosis is suggestive of a recent isopropanol ingestion.[167] Renal failure can occur in the setting of significant hypotension. Hypoglycemia can result from the interference of gluconeogenesis by isopropanol.[139]

Supportive treatment for isopropyl alcohol intoxication includes circulatory support with fluids or vasoconstrictors in patients with hypotension. Inhibition of alcohol dehydrogenase is not indicated because acetone is less toxic than isopropanol. Hemodialysis is indicated for patients with an isopropanol level greater than 400 mg/dL and significant CNS depression, renal failure, or hypotension.[173] Hemodialysis will remove both isopropanol and acetone effectively.[175] High-efficiency membranes can produce clearance constants greater than 200 mL/min for both acetone and isopropanol.

Salicylates

Salicylate intoxication accounted for approximately 0.7% of all exposures and 6.1% of all deaths reported to the TESS (see Table 46–7).[1] Salicylates are found in many commonly used medications. The most common is acetylsalicylic acid or aspirin. Acetylsalicylic acid is converted to salicylic acid in the stomach and is then rapidly absorbed. The symptoms of salicylate intoxication differ according to the age of the patient and whether the intoxication is acute or chronic.[176] Most people will have some clinical effects of intoxication with serum levels greater than 40 mg/dL.[177] In chronic intoxication and in the elderly, symptoms will occur at lower levels.[178]

The common symptoms in all settings are nausea, vomiting, hyperventilation, tinnitus, stupor, coma, and convulsions. The acidosis is due to uncoupling of oxidative phosphorylation in the Krebs cycle and accumulation of lactic acid and ketoacids.[179,180] Hyperventilation occurs from direct stimulation and can lead to a respiratory alkalosis. Children are more likely to demonstrate fever and severe metabolic acidosis,[181–183] whereas adults are more likely to experience noncardiogenic pulmonary edema, especially among those with a history of smoking.[176,184–186]

Activated charcoal is effective in reducing the gut absorption of salicylate in acute intoxication.[187–189] Salicylate undergoes both glomerular filtration and tubular secretion. Renal excretion is very important at toxic and therapeutic serum salicylate levels. Reabsorption of salicylate in the proximal convoluted tubule depends on the urine flow rate and urine pH. In an acid environment, salicylate is nonionized. For this reason, urinary alkalinization can increase the renal clearance significantly through ion trapping.[190] Sodium bicarbonate can be used to increase serum pH and raise urine pH to greater than 7.5.[191] Forced diuresis does not appear to increase clearance and may lead to volume overload. The use of acetazolamide should be avoided because it can increase the risk of systemic acidosis.

Salicylates have a small Vd (0.21 L/kg), a low molecular weight (138 D), and a moderate degree of protein binding (about 50% at toxic levels).[192] All of these characteristics enable salicylates to be removed by hemoperfusion or hemodialysis.[105] Hemodialysis is the preferred method because of the inability of hemoperfusion to correct acid-base and electrolyte disorders and volume disturbances.[193] Hemodialysis should be considered for serum levels greater than 100 mg/dL in acute ingestion and as low as 60 mg/dL in chronic ingestion.[109] Hemodialysis can be advantageous in the patient with a high serum salicylate level, fluid overload, and metabolic acidosis associated with clinical deterioration and coma.[194, 195] The end point of dialysis is considered to consist of:

1. Return to a nontoxic level of the serum salicylate level.
2. Clinical improvement.
3. Correction of acid-base disturbances.[180]

Lithium

Lithium is a commonly used mood stabilizer. It has a low therapeutic index and can therefore cause inadvertent toxicity fairly easily. The risk of toxicity increases when it is used as long-term therapy, both when lithium is ingested in overdose and when a patient's elimination pathways are impaired. Few patients require intervention with extracorporeal therapy, especially if treated promptly. The severity of intoxication is related to the duration of the poisoning, the possibility of delayed absorption, and the actual serum lithium level.[196–198] In 2001, there were 4607 toxic exposures but only 8 deaths reported to TESS (see Table 46–7).[1]

Lithium Absorption and Elimination

An alkali metal, lithium is well absorbed in the stomach and proximal small intestine,[199] with a peak serum concentration in 5 hours for regular-release preparations and 4 to 12 hours for sustained-release preparations. It is not bound to plasma proteins and has a low molecular weight (74 D), but its Vd is moderate (0.7 to 0.9 L/kg), approximately that of total body water.[200] Lithium is predominately intracellular but diffuses across cell membranes slowly,[200] making its removal by extracorporeal techniques a slow process, requiring up to 8 to 10 hours and repeated treatments for thorough removal.[90]

Lithium elimination is almost exclusively renal.[201] This drug is freely filtered and 60% reabsorbed, mostly in the proximal tubule by the same active process that promotes sodium reabsorption.[90,202] Conditions associated with a reduction in either glomerular filtration rate or tubular sodium concentration result in decreased elimination secondary to greater reabsorption. These conditions include sodium and volume depletion, cardiac failure, liver failure, use of thiazide diuretics, nonsteroidal anti-inflammatory drugs, or angiotensin-converting enzyme inhibitors.[196,200,203]

Toxicity

Extracorporeal therapy for lithium intoxication should be based on clinical criteria rather than on serum lithium levels.[196,204–206] Patients with serum lithium levels as high as 8.0 mEq/L have survived lithium intoxication without hemodialysis.[196,207,208] The serum lithium level is a more reliable indicator of intracellular lithium levels in chronic intoxication or acute intoxication superimposed on chronic intoxication.[206,209]

For acute intoxication, the failure of severe or moderate clinical signs or symptoms to improve within 6 hours of supportive therapy is an indication for hemodialysis. The correlation between serum lithium level and clinical presentation is not always close; therefore, clinical symptoms must be the main determinant of the need for dialysis. Hemodialysis is recommended for all patients with severe clinical manifestations. If the clinical condition fails to improve or progresses after 6 hours of corrective or supportive care, or if renal clearance is impaired, dialysis should be considered even in the patient who has moderate clinical manifestations.[206,210–213]

Table 46–13 categorizes the clinical symptoms of lithium intoxication as mild, moderate, or severe, irrespective of whether the intoxication is acute or chronic. The hallmark of the lithium-intoxicated patient is the CNS toxicity. This effect may range from coarse tremor to mental status changes,

Table 46–13 Toxic Manifestations of Lithium

Mild (lithium level <2.5 meq/L)
Tremor, ataxia, photophobia, nystagmus, light-headedness, weakness
Nausea, emesis
Moderate (lithium level 2.5–3.5 mEq/L)
Hyperreflexia, twitching, tinnitus, apathy, drowsiness, confusion
Diarrhea
Bradycardia, hypotension
Severe (lithium level >3.5 mEq/L)
Seizure, clonus, delirium, coma
Severe bradycardia, cardiovascular collapse

(From Timmer RT, Sands JM: Lithium intoxication. J Am Soc Nephrol 1999; 10:666-674.)

ataxia, and subsequent coma. The cardiovascular manifestations range from benign flattening and inversion of the T waves on electrocardiogram to severe hypotension and cardiovascular collapse.[214,215] Lithium-related intraventricular conduction defects are observed only with toxic concentrations of lithium, in patients with established heart disease, or in those taking other cardiotoxic agents.[216,217] Severe ventricular arrhythmias occur almost exclusively with acute intoxications.[218] With severe acute ingestion, vomiting and profuse diarrhea develop soon afterward secondary to the high lithium concentrations in the gastrointestinal tract. If the patient fails to improve or deteriorates after 6 hours of supportive care, the status of the CNS and cardiovascular systems dictates the need for extracorporeal therapy.[196] As an unmeasured cation, severe lithium intoxication will decrease the anion gap.

It is estimated that 75% to 90% of the patients given long-term lithium therapy have some signs of toxicity.[210] Eighty percent report a fine tremor that may resolve spontaneously to a decrease in lithium dose or to administration of a β-blocker. Manifestations of mild chronic lithium toxicity[219,220] include:

- Poor memory
- Loss of concentration
- Fatigue
- Muscle weakness
- Slowed reaction time
- Lack of spontaneity

Long-term lithium use can lead to tubular atrophy, polyuria secondary to decreased urine-concentrating ability, and, ultimately, nephrogenic diabetes insipidus.[221,222] Factors associated with an increased risk of renal damage[223] include:

- A history of lithium intoxication
- Advanced age
- Underlying renal disease
- A multiple-dose regimen
- Duration of therapy

Therapeutic Interventions

The lithium-intoxicated patient should be managed like other intoxicated patients, with supportive care, enhancement of lithium elimination, and prevention of further absorption. Gastrointestinal lavage for pill fragments and whole bowel irrigation with polyethylene glycol can help decrease absorption, especially with ingestion of sustained release tablets or if started within 1 hour of ingestion.[224,225] Sodium polystyrene sulfonate (Kayexalate) administration has been shown to bind lithium and decrease absorption in both healthy volunteers and in toxic ingestions.[226,227] The dehydrated patient should be given crystalloid resuscitation but there are no data to support the use of forced diuresis or large volume saline infusion to increase elimination when the patient is not dehydrated.[224] Both techniques run the risk of causing volume overload and electrolyte disturbances.

Extracorporeal therapy for lithium intoxication should be based more on clinical criteria not on serum lithium levels.[196,204–206] The serum lithium level can be a poor indicator of toxicity in acute ingestion. Patients with serum lithium levels as high as 8.0 mEq/L from an acute ingestion have survived without hemodialysis.[196,207,208] The serum lithium level

is a more reliable indication of intracellular lithium levels in chronic intoxication or acute intoxication superimposed on chronic intoxication.[206,209]

Lithium is readily dialyzable because of its low molecular weight, water solubility, and lack of protein binding. It does have a moderate Vd (0.7 to 0.9 L/kg), is predominantly intracellular, and diffuses slowly across cell membranes.[200] For this reason, 8 to 10 hours or more of treatment are needed, to bring the serum level to less than 1 mEq/L.[196,219,228] The serum lithium level should be measured 6 to 8 hours after dialysis is completed to evaluate for rebound.[199,209,229] The indications for hemodialysis are listed in Table 46–14. The correlation between serum lithium level and clinical presentation is not always close; therefore, clinical symptoms must be the main determinant of dialysis. For acute intoxication, the failure of severe or moderate clinical signs or symptoms to improve with 6 hours of supportive therapy is an indication for hemodialysis. Hemodialysis is recommended for all patients with severe clinical manifestations. If the clinical condition fails to improve or progresses after 6 hours of corrective or supportive care, or if renal clearance is impaired, dialysis should be considered even in the patient who has moderate clinical manifestations.[196,206,210–213]

Because of the slow equilibration between intracellular and extracellular lithium stores, continuous renal replacement therapy may be advantageous. Leblanc and associates[6] suggest that continuous renal replacement therapy should be performed instead of conventional intermittent hemodialysis for the treatment of lithium intoxication, particularly in cases of chronic poisoning associated with a large intracellular accumulation of the drug. In these cases, it may be advisable to first start with conventional hemodialysis and then switch to a continuous modality because the initial clearance will be higher with standard hemodialysis.[230]

If the patient's clinical condition (1) has failed to improve or (2) again deteriorates after initial improvement, further dialysis may be needed. Specifically, if the patient continues with moderate or severe clinical toxicity 6 to 8 hours after dialysis is terminated, another dialysis treatment is recommended. Neurologic improvement may lag behind improvement in

Table 46–14 Indications for Dialysis in Patients with Lithium Intoxication

1. Serum lithium >3.5 mEq/L

   b. Renal insufficiency
   c. Conditions that increase renal sodium reabsorption (heart failure, cirrhosis)
   d. Chronic ingestion and moderate to severe symptoms
3. Any lithium level with one of the following:
   a. Severe symptoms
   b. Moderate symptoms that have failed to improve with 6 hours of support
   c. Large ingestion where rising levels are anticipated

(From Okusa MD, Crystal LJ: Clinical manifestations and management of acute lithium intoxication. Am J Med 1994; 97: 383-389.)

serum lithium levels, cardiac toxicity, or gastrointestinal symptoms because of the slow equilibration of lithium from brain to blood.[198,229,231]

Theophylline

Theophylline is a methylxanthine bronchodilator used for obstructive airway disease. Although the number of patients using it and the number of toxic exposures are declining, toxic exposure to theophylline continues to have a very high morbidity and mortality (see Table 46–7).[1] It is metabolized by the liver, with 10% being recovered unchanged in the urine. Its half-life is prolonged in patients with liver disease[232–234] or congestive heart failure,[232,235,236] with the use of supratherapeutic doses, and if it is ingested with cimetidine[237–239] or erythromycin.[240,241] Raoof and associates[242] observed an average increase in the serum theophylline level of 87% when ciprofloxacin and theophylline were administered concurrently. In addition, 61% of the patients these researchers evaluated had a mean increase in the serum theophylline level of 10.5 mg/L, resulting in toxic concentrations of the drug.[242] The half-life of theophylline is decreased by smoking, phenobarbital,[243] and phenytoin (secondary to hepatic enzyme induction).[244]

Signs of mild theophylline toxicity are nausea, vomiting, abdominal pain, tachycardia, and muscle tremor.[245,246] Severe toxicity consists of cardiac arrhythmias, hypotension, impaired consciousness, seizures, cardiorespiratory arrest, and, ultimately, death.[247–249] The risk of major toxicity is influenced by the method of intoxication. Patients who use theophylline as long-term therapy have a greater risk of major toxicity at lower serum theophylline concentrations than patients with acute intoxication. The serum levels are more predictive of major toxicity with acute theophylline intoxication. Toxicity usually appears when the serum level is around 20 to 25 mg/L and increases with rising serum levels.[250]

Theophylline is 60% protein bound; the free fraction distributes in interstitial fluid and the intracellular space with a Vd equal to 0.4 to 0.6 L/kg. Activated charcoal can bind theophylline in the gastrointestinal tract and should be used initially in intoxication. The dose of activated charcoal is 20 g every 2 hours[251,252] in adults for 6 to 12 hours, depending on the serum theophylline level. Because of its enterohepatic circulation, multidose activated charcoal has a role in increasing the elimination of theophylline.[25]

Conventional hemodialysis using a hollow-fiber filter with a Q_b of 180 to 250 mL/min and a Q_d of 500 mL/min can result in plasma ER of 0.5, a dialysis clearance rate of 75 to 98 mL/min, and the removal of 40% of the administered dose of theophylline in 3 hours.[253] Hemoperfusion is more effective than hemodialysis, achieving an ER of 0.6[254] to 0.9.[255] Extracorporeal therapy should be performed for the patient with:

1. Severe acute theophylline intoxication and whose serum theophylline level is higher than 80 mg/L.
2. Chronic theophylline intoxication and whose serum theophylline level is higher than 60 mg/L.
3. Inability to tolerate oral charcoal and who is either at least 60 years of age or who has underlying liver or heart disease.[256,257]

Hemodialysis should be considered when hemoperfusion is indicated but unavailable. Charcoal hemoperfusion appears to be the most efficacious therapy to treat severe toxicity.[254,258,259] β-Blockade has been used to treat refractory hypotension[260–262] and dysrhythmias.[249,261,262] Hypokalemia may be present secondary to intracellular shift of potassium; one must take care to avoid hyperkalemia[263] when giving supplementary potassium. The end point for dialysis in theophylline intoxication is met when the patient has improved clinically and the serum drug level is well below the upper limit of therapeutic (about 15 mg/L).

OTHER TECHNIQUES FOR DRUG REMOVAL

Additional techniques for removing protein-bound drugs or toxins were introduced by Stange and associates[264] in 1993. The categories of these toxins are quite varied and include:

- Albumin-bound toxins that accumulate in hepatic failure with encephalopathy[265–268]
- Ingested drugs that have high protein binding[269,270]
- Albumin-bound toxins that accumulate in chronic renal failure[264] and sepsis

This system involves an asymmetric, highly permeable dialysis membrane that is albumin-coated before use on both blood and dialysate sides. An albumin dialysate is used in a closed-loop system for regeneration of the albumin.[264] A column of activated charcoal is used to deligandize the albumin in the dialysate for regeneration of free albumin. This arrangement was found to be advantageous over other methods of hemoadsorption because (1) there is no direct contact between cellular components of blood and the charcoal cartridge, and (2) the albumin is cleaned (deligandized and regenerated). The hemocompatibility of this system appears to be better than that of conventional systems because the patient's blood comes in contact with only tubing and a dialysis membrane coated with albumin.

Chapter 47

Chronic Kidney Disease: Cost of Care in this High-Risk Outlier Population

Allan J. Collins, M.D., F.A.C.P.

Amendments passed in 1972 expanded the Medicare program to include end-stage renal disease (ESRD) as a covered condition. The enabling legislation envisioned that the number of ESRD patients to be covered at a given time would be approximately 40,000. It was not anticipated that the program would grow to cover more than 400,000 individuals by the year 2002, a doubling over the previous 10 years and 10 times greater than the estimates made in the early 1970s. Projections suggest that 650,000 individuals will be under treatment in 2010 and that this number may reach 2.2 million by 2030, if the patterns of the previous 30 years continue.[3] The growth of the ESRD patient population is fueled by a reservoir of patients with progressive chronic kidney disease (CKD) in the general population. Until recently, the size of this reservoir was unknown. Coresh and associates[1] investigated the size of the CKD pool in the United States, using data from the Third National Health and Nutrition Examination Survey (NHANES III), taking advantage of the extensive biochemical data collected and applying criteria that reasonably would reflect evidence of kidney damage. Based on these methods, the National Kidney Foundation (NKF) published a classification system for CKD and estimated the total population to be 8 to 20 million individuals, depending on the severity of the kidney damage.[2] Although there has been some debate regarding the precise number of individuals in the general population who show evidence of CKD, there is little doubt that the burden is significant and that the CKD pool is the feeder population for the ESRD program. Although 100,000 individuals begin receiving ESRD care every year, it is clear that others with advancing disease die before ESRD treatment.[3,4]

The CKD population has predominantly been studied in a cross-sectional manner, with researchers investigating reductions in kidney function and identifying associated complicating conditions, biochemical abnormalities, and demographic characteristics of those affected.[1] Little information is available on the cost of CKD. To investigate this important area, one needs a data set containing both clinical and cost information. Unfortunately, large data sets that contain information on both kidney function and cost are not available. Data from the available alternatives are less precise regarding the degree of kidney damage but are drawn from patients with clinically recognized disease. Administrative claims represent the best source of information on kidney disease and cost. The Medicare claims data and information from employer group health plans can be used to study the population of patients who have a diagnosis of CKD, identifying the clinical services rendered to these patients and determining the expenditures paid to providers for the cost of these services. For example, the Medicare+Choice risk adjustment payment system contains data on a variety of patients who have been diagnosed with kidney disease, such as diabetics with nephropathy, patients with hypertensive nephropathy, patients with kidney failure due to other primary causes, and those with combinations of comorbid conditions that are strongly associated with advancing kidney disease. Although the use of this approach identifies patients with more advanced disease, the patients identified are the ones that providers have found to require specific services that generate increased cost.

Using data in the 5% sample of the Medicare population, investigators can identify CKD patients from diagnosis codes recorded on claims for services.[3–5] These codes have allowed United States Renal Data System (USRDS) investigators to determine that 1.1 million elderly individuals (age ≥ 65 years) carry a diagnosis of CKD. This number represents only one fifth of the 5.9 million elderly with an estimated glomerular filtration rate (GFR) of less than 60 mL/min, as determined from the NHANES III cohort.[1,3] With this approach to identifying individuals with CKD, associated expenditures can be identified and categorized into cost groups for sake of comparison. To illustrate this investigative approach, this chapter reports on Medicare patients who advance to ESRD, identifying services rendered and associated costs in a period preceding the start of dialysis. Material presented includes information on the range of clinical conditions associated with advancing kidney disease.

Chronic Kidney Disease and Complicating Conditions

The complicating medical conditions associated with CKD are discussed elsewhere in this book. The reader is referred to other chapters for detailed discussions of cardiovascular disease, peripheral vascular disease, lipid disorders, and bone and mineral diseases that are associated with CKD. Investigators have demonstrated associations between increasing degrees of kidney damage and blood pressure elevations,[6] ischemic heart disease, congestive heart failure, and peripheral vascular disease.[7] The largest population studied is the Medicare population assessed by the USRDS. In diabetic patients, CKD is highly associated with congestive heart failure, ischemic heart disease, and peripheral vascular disease. Proteinuria has been associated with a range of cardiovascular disease in both diabetic and nondiabetic patients.

Cardiovascular disease appears to advance at almost twice the rate in the CKD population than in the non-CKD population, with CHF being the leading complicating condition.[3] Heart failure hospitalization rates are four times higher in CKD patients than in non-CKD patients; infectious complications, almost five times higher. These rates of disease generate large expenditures from services to treat the conditions.

Transitional Comorbidity and Expenditures Associated with CKD Patients Entering ESRD Treatment

Because CKD patients who advance to ESRD appear to have complications that advance at a rate comparable to the rate observed in those who die before reaching ESRD, an assessment of the patients approaching ESRD would provide insight into their services and expenditures. Investigators have reported information on Medicare and non-Medicare patients who advance to ESRD.[8,9] In the elderly population, almost two-thirds of patients who were age 67 years or greater and entered dialysis between 1995 and 1998 carried a diagnosis of congestive heart failure. Sixty percent carried a diagnosis of ischemic heart disease, with almost 20% carrying a diagnosis of acute myocardial infarction. Forty percent carried a diagnosis of cardiac dysrhythmias, and 43% carried a diagnosis of peripheral vascular disease. In addition, almost 60% carried a diagnosis of diabetes (primary or secondary). Therefore, it is clear that patients who finally enter ESRD have significant comorbid conditions. Looking at the period between 24 months before (Month −24) and 6 months after (Month +6) dialysis initiation, average expenditure was $932 per member, per month (PMPM) at Month −24. These costs increased between Month −5 to Month −2 to $1740 PMPM. Between the months just before and after initiation of dialysis, the cost was $8600 PMPM. The cost stabilized at $5490 PMPM between Months +4 and +5. As expected, those who died after initiation of dialysis had costs that were higher, by 20% to 50%.

A similar analysis is shown in Figure 47–1. The changing composition of the primary causes of hospitalization is shown for individuals age 67 years or greater who advanced to ESRD from 1995 to 1997. Congestive heart failure, ischemic heart disease, and other cardiovascular disease accounted for half of the hospitalization events. These events steadily increased as the patients advanced toward ESRD, with vascular access emerging as the dominant cause of hospitalization near dialysis initiation. Figure 47–2 shows that the number of hospital days per month increased with advancing CKD (as patients approached ESRD). Diabetic patients had more hospital days than nondiabetic patients until the last 2 months before ESRD; from Month −2 to Month +2, the nondiabetic patients had more hospital days per month than the diabetic patients. Figures 47–3 and 47–4 show that expenditures escalate (as expected), with the most rapid growth occurring in the final 6 months before dialysis initiation. Peak expenditures occur in the month of dialysis initiation ($14,000 PMPM). These transitional expenses are driven by hospitalization for cardiovascular disease and vascular access. Table 47–1 shows the
Figure 47–1 1995 to 1997 admission rates by category: 24 months before (Month −24) to 6 months after (Month +6) dialysis initiation. *FSD,* first service date.

principal diagnoses related to the hospitalizations before, at, and after the ESRD first service date. Congestive heart failure, ischemic heart disease, renal failure complications, and infections are major sources of complication. As expected, vascular access represents a major cost component near and after initiation of dialysis. These data suggest that efforts to preemptively address the cardiovascular complications, metabolic and electrolyte disturbances, and infectious events may reduce the high cost of care in this population.

Expenditures Associated with the CKD Population

The magnitude of the expenditures associated with the large population of patients with evidence of CKD is undetermined.

This is mainly because a lack of information precludes our ability to identify the at-risk group and link the clinical evidence of reduced kidney function to associated expenditures. Two recent attempts to develop information in this area are of note, one by the Centers for Medicare & Medicaid Services (CMS), in its aforementioned risk adjustment payment system and the other by the USRDS. Each of these efforts has yielded convincing evidence that the CKD population is very costly and an important outlier population that consumes considerable resources.

Work by the USRDS investigators was preliminarily presented in 2003 at the annual meeting of the American Society of Nephrology. Drs. Lawrence Hunsicker and John Brooks of the University of Iowa, investigators for the USRDS Economic Special Studies Center, in collaboration with investigators at the

USRDS Coordinating Center in Minneapolis, Minnesota, assessed associations in Medicare patients with a diagnosis of CKD. This study, which evaluated 1997 to 1998 patients in the fee-for-service Medicare system, compared costs between those with CKD diagnosis codes and those who did not have CKD diagnosis codes, and also considered Medicare patients with ESRD. The non-CKD population consisted of 1.07 million individuals; almost 39,000 had a diagnosis of CKD. The dialysis population of comparable age (=67 years) was taken from 1999 and consisted of 62,000 individuals. Inpatient, outpatient, and physician services were assessed on a PMPM basis. Table 47–2 summarizes the age, gender, and race distribution of individuals in the CKD, non-CKD, and dialysis groups. Of note, the CKD patients were older and the dialysis patients were younger than the non-CKD patients. There was also a more equal distribution of males and females who carried a diagnosis of CKD and who were on dialysis, compared to the general Medicare population. This observation suggests that the survival advantage for women in the general population is not present in women who carry a diagnosis of CKD or women who reach dialysis. There was also

an increasing representation of black patients who were carrying a diagnosis of CKD or were on dialysis. The follow-up year was 1999; Figure 47–5 shows the distribution of Medicare expenditures for the three groups for the follow-up year in comparison with 1997 to 1998. Whereas the Medicare patients aged 67 years or greater who were on dialysis represented only 0.28% of the Medicare population, they generated almost 10 times the expenditures in the Medicare system. The Medicare patients age 67 years or greater who were carrying a diagnosis of CKD represented 3.5% of the Medicare population, yet they generated 9% of the Medicare expenditures. Together, the dialysis and CKD patients identified by a diagnosis code represented 3.8% of the Medicare population and accounted for 12.5% of the Medicare budget annually. This is an underestimate, because only the dialysis population is known (because of a registration system) and the CKD population is only one-fifth of those with the most advanced disease identified by the providers. A greater accounting of this population is needed.

Figure 47–6 shows the unadjusted average PMPM allowable Medicare expenditures in 1999 by patient group. Table 47–3

provides detail by age, gender, and race. Given advancing age, the non-CKD patients showed the expected increase in expenditures; however, this was not the case in the CKD and dialysis patients, who had expenditures that were more consistent, regardless of age. Table 47–4 summarizes the results from regression estimates addressing the CKD population as a group, compared to the non-CKD population. Of particular note, after adjustments for age, gender, and race, Medicare expenditures for CKD patients are 467% greater than expenditures for non-CKD patients. These data are very consistent with the reported differences in the event rates noted earlier for cardiovascular disease and infectious complication.[3] These relative costs were not equally distributed across all age groups. The interaction between age, gender, race, and CKD also appeared to be associated with different degrees of comparative expenditures, as shown in Figure 47–7. Interestingly enough, the youngest group (aged 67 to 74 years) had the highest relative costs between women and men as well as between blacks and whites. At older ages, the difference between blacks and whites decreased, and the difference between CKD and non-CKD patients also decreased. Therefore, on a population

basis, those with a diagnosis of CKD carry a heavy burden of comorbidity and associated expenditures.

CKD and the New Medicare+Choice Risk Adjustment Payment System

The evolution of the Medicare capitated payment system is beyond the scope of this chapter. However, it is important to note that the effort to identify patients with increased comorbid conditions is not new. Comorbidity profiling methods have been developed to relate disease intensity to cost of care; examples include the Johns Hopkins Adjusted Clinical Groups (ACG) system, the Brandeis risk adjusters, and quality of life adjusters. Such efforts ultimately led to Congressional passage of a Budget Reconciliation Act that included a directive to CMS to develop a more comprehensive risk adjustment

payment system for the Medicare population. After considerable work and discussion, in May 2003 CMS announced the new payment system for Medicare+Choice enrollees (see the May 12, 2003, announcement of the Medicare+Choice payment rates for calendar year 2004 at *www.cms.hhs.gov/healthplans/ rates/2004/cover.pdf*). This payment system is unique in that it is based on the identification of groups of diseases analyzed through standard actuarial regression models to determine their relative costs to the Medicare program, with a resulting hierarchical order of diseases applied to the payment system. Because this model is being implemented in the United States over the next 4 years, it will attract increasing attention, particularly for its handling of chronic diseases, such as CKD.

A full description of the Medicare+Choice hierarchical care model can be viewed at *www.cms.hhs.gov/healthplans/rates/ default.asp*. The expenditure models used by CMS created risk adjusters with dollar coefficients, which are then divided by the national average to create a predicted expenditure ratio determined by the fee-for-service beneficiaries. The average dollar expenditures for the base year (2002) were $5129, which were used to establish the 2004 rates. As in most risk adjustment systems for payment of individuals, age and gender were strongly predictive of expenditures in the Medicare system. Not surprisingly, disability or receipt of combinations of Medicare and Medicaid payments were also predictive of high expenditures. For example, higher costs were associated with AIDS, metastatic cancer, and acute leukemia. Of particular note are categories of diseases that were indicated to have renal failure among their major manifestations. The risk-adjusted disease groupings that were identified as significantly associated with renal failure are given in Table 47–5.

Within Table 47–5, the hierarchical condition categories are additive to previous adjustments for age, gender, disability status, and other medical conditions that the patient may have. Within the renal failure categories is that patients undergoing dialysis were the most expensive in the Medicare system, with dialysis alone adding almost three times the cost per year. For patients not on dialysis, a diagnosis of renal failure resulted in an expenditure increase almost twice that of those with diagnoses associated with primary kidney diseases other than from diabetes. The interaction of kidney failure with heart failure and diabetes also significantly increased the costs. On the basis of Medicare's findings, it is clear that renal failure, heart failure, and diabetes, especially in combination, are associated with major increases in expenditures for the disabled and the elderly in the United States. The renal failure categories established in the Medicare+Choice system are well known to medical practitioners: diagnoses associated with hypertension and renal failure or hypertension with congestive heart failure and renal failure, as well as chronic renal failure and cystic kidney disease, to name a few.

The second major category of renal failure diagnoses (beyond diabetes and the renal failure category) is the group of kidney diseases associated with relatively acute onset. Conditions, such as proliferative nephritis, acute nephritis, and rapidly progressive nephritis, as well as nephrotic syndrome, dominate the disease defined as nephritis. The new Medicare+ Choice hierarchical payment system is unique in that each individual's associated chronic diseases are additive to the payment system. Because this was the first attempt to identify the various diseases associated with increased expenditures, insight was gained into the additive nature of the costs of treating renal failure in the elderly and/or disabled population. As this new payment system is adopted, it will be evaluated to determine whether it provides a better fit between the complexities of the individual patient and the payments a health plan receives as compensation for care delivered by providers.

CKD and Associated Costs in the Non-Medicare Population

Findings regarding the cost of treating CKD in the elderly Medicare population cannot necessarily be extrapolated to younger populations. Unfortunately, few economic analyses have assessed the cost of caring for younger patients with CKD. Because CKD patients have significant comorbid conditions, it is likely that the younger CKD population has similar differential costs as the older CKD population. To a certain extent, younger CKD patients may have greater proportional costs than their non-CKD counterparts because of the high association between CKD, ischemic cardiovascular disease, heart failure, hypertension, and diabetes. Compared to Medicare patients, younger patients tend to have fewer complicating medical conditions, thereby potentially magnifying the effects of CKD. Economic evaluations are sorely needed to assess the cost of CKD in the non-Medicare population.

Cost-Effectiveness of Screening for CKD

Boulware and associates studied the cost-effectiveness of screening for proteinuria in U.S. adults.[10] These investigators used a Markov decision analytic model to compare annual screening to no screening for proteinuria in patients at age 50 years. For those without a diagnosis of hypertension or diabetes,

Table 47–5   Disease Groups Associated with Renal Failure in the Medicare+Choice Hierarchical Risk-Adjustment Model

Disease Group	Description	Relative (Community) Weight	Institutional Weight
HCC #15	DM with renal failure or peripheral circulatory manifestation	0.764	0.612
HCC #130	Dialysis	3.076	3.112
HCC #131	Renal failure	0.576	0.420
HCC #132	Nephritis	0.273	0.420
Interaction terms	Renal failure + CHF	0.234	
Interaction 6	Renal failure + CHF + DM	0.864	

CHF, congestive heart failure; *DM,* diabetes mellitus; *HCC,* hierarchical condition category.

screening appeared cost-prohibitive, with quality-adjusted life years adding $282,000 for the investment in screening. However, for individuals age 60 years or greater or those with a history of hypertension, the cost per quality-adjusted year of life saved was approximately $20,000. Cost-effectiveness appeared improved with use of angiotensin- converting enzyme inhibitor or an angiotensin II-receptor blocker therapy. The investigators concluded that proteinuria screening efforts were not particularly cost-effective unless directed at high-risk groups, such as individuals with hypertension.

The conclusions reached by Boulware and associates appear to be borne out by the recent reposting of results for the NKF's Kidney Early Evaluation Program (KEEP). The KEEP program is directed at individuals with a family history of diabetes, hypertension, or kidney disease as well as those who currently have a diagnosis of diabetes or hypertension. Started in 2000, this nationwide effort has resulted in the screening of more than 27,000 individuals through December 2003. The first 11,000 individuals screened were reported in October 2003.[6] In this target population, 2% to 3% of screened individuals knew they had evidence of CKD before screening, yet 50% had evidence of albuminuria or an estimated GFR of less than 60 mL/min. Of individuals with stage 3+ kidney disease, 80% had a blood pressure higher than 130/85. These findings in a targeted population are consistent with the high yield needed to be cost-effective. Health plans and providers need to develop methods to more actively identify those at high risk of kidney disease because this population carries a heavy burden of cardiovascular disease and expenditures. On the basis of the emerging evidence, it appears that CKD plays a much greater role in the morbidity, mortality, and cost of care of the general population than previously appreciated.

Drug Dosing in Chronic Kidney Disease

George R. Aronoff, M.D., F.A.C.P.

The number of patients with impaired renal function has increased. Advances in the treatment of chronic diseases have permitted patients to live longer. Many of them develop decreased renal function over time. Kidney function also decreases with age, and older patients make up the most rapidly growing patient group for which special understanding of drug disposition is important. When chronic renal failure occurs, age, diabetes mellitus, and coronary artery disease are no longer barriers to renal replacement strategies.

Because uremia affects every organ system in the body, the physiological changes associated with renal disease profoundly alter the pharmacology of many drugs. Caregivers must consider how decreased renal function changes the bioavailability, distribution, metabolism, and elimination of medications and their active or toxic metabolites. Hypertension, diabetes mellitus, and heart disease compound the management of drugs in patients with renal diseases.

Novel strategies for treating renal failure contribute to the need for understanding drug removal during extracorporeal therapies. New dialysis membranes and devices, acceptance of intermittent and continuous peritoneal dialysis, and the application of continuous extracorporeal renal replacement therapies require that clinicians understand drug transport across biological and artificial membranes. This chapter outlines a rational approach to pharmacotherapy for patients with chronic kidney disease and those requiring renal replacement therapies.

PATIENT ASSESSMENT

Figure 48-1 shows a practical clinical approach to drug prescribing for patients with renal insufficiency. Pharmacotherapy for patients with kidney disease begins with a careful history and physical examination. Previous medications, adverse drug reactions, and concurrent medications influence the choice and dose of drugs in patients with impaired renal function.

On average, dialysis patients routinely receive 11 different medications and have three times the incidence of adverse drug events as patients with normal renal function.[1-3] Limiting the number of different drugs and choosing medications carefully decreases the potential for adverse drug effects, as does establishing a specific diagnosis before beginning treatment. Individualizing treatment can take advantage of using one medication to treat several conditions. For example, a calcium channel antagonist used to lower blood pressure in a hypertensive patient can also decrease angina or prevent certain tachyarrhythmias.

Physical examination to assess hydration status allows an estimate of the volume of distribution of many drugs.

Water-soluble drugs are distributed in the extracellular fluid. Dehydrated patients have smaller distribution volumes, whereas patients with edema or ascites demonstrate expanded volumes of distribution.

Appropriate dosing requires measurements of the patient's height and weight. In dosing obese patients, many clinicians use the average of the patient's measured weight and the calculated ideal body weight (IBW) as a guide. For men, IBW is 50 kg plus 2.3 kg for each inch over 5 feet. For women, IBW is 45.5 kg plus 2.3 kg for each inch over 5 feet.[4]

Liver disease alters drug therapy in patients with renal insufficiency by limiting alternative pathways for drug and metabolite elimination. Finding the stigmata of liver failure is a strong indication of the need to further decrease drug doses in patients with decreased kidney function.

Measurement of Renal Function

The rate of elimination of drugs or drug metabolites excreted by the kidneys is proportional to the glomerular filtration rate. The serum creatinine or creatinine clearance is needed to determine renal function before prescribing any drug. The Cockcroft and Gault[5] equation is useful for this purpose as shown in the formula:

$$Clcr = \frac{(140 - age) \times (IBW)}{72 \times Scr} \times (0.85 \text{ if female})$$

where:

Clcr = Creatinine clearance (mL/min)
Scr = Serum creatinine (mg/dL)

IBW (in kg)	= Ideal body weight (men)	= 50 kg + 2.3 kg per inch over 5 feet
	= Ideal body weight (women)	= 45.5 kg + 2.3 kg per inch over 5 feet

For obese men and women, the equation should be modified:

$$Clcr(\text{obese men}) = \frac{(137 - age) \times [(0.285 \times wgt) + (12.1 \times hgt^2)]}{51 \times Scr}$$

$$Clcr(\text{obese men}) = \frac{(146 - age) \times [(0.287 \times wgt) + (9.74 \times hgt^2)]}{60 \times Scr}$$

where:
wgt = patient's weight in kg
hgt = patient's height in cm

In cases of changing renal function, the serum creatinine will no longer reflect the true clearance rate. In these cases, a timed urine collection is needed to estimate renal function.

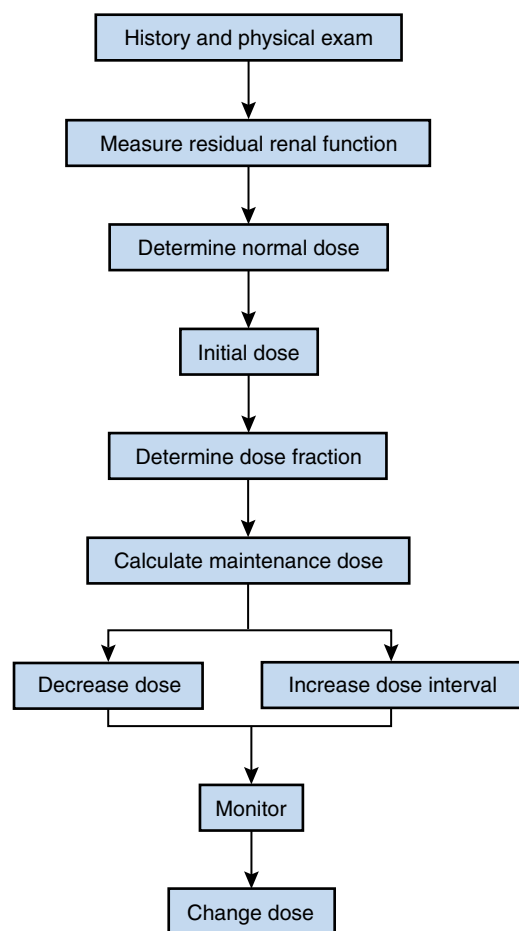

Figure 48–1 A clinical approach to drug dosing in renal failure.

The midpoint serum creatinine is useful to calculate the creatinine clearance for the collection period.

The serum creatinine reflects muscle mass as well as glomerular filtration rate. Serum creatinine measurements within the "normal" range are frequently used to establish "normal" renal function. This erroneous assumption may cause serious overdose and resultant toxic drug accumulation in elderly or debilitated patients with decreased muscle mass. A 72-kg man with a serum creatinine of 1 mg/dL has half the renal function at the age of 80 years as he did with the same body mass and serum creatinine at the age of 20 years. If the same doses of medications are given to the 80-year-old as to the 20-year-old, adverse drug events are likely because of drug and metabolite accumulation.

The serum creatinine measurement alone does not accurately estimate renal function in dialysis patients and should not be used to estimate drug dosing. Some patients may still have substantial renal function when they initiate dialysis therapies. The presence of residual renal function in dialysis patients increases the rate of drug or metabolite elimination. However, residual renal function decreases over time and may be assumed negligible for estimating drug doses in oliguric patients or in those who have required dialysis for longer than a year.

Serum creatinine measurements are a poor measure of intrinsic renal function in dialysis patients. Residual renal function in non-oliguric dialysis patients is difficult to estimate, because the serum creatinine reflects the adequacy of dialysis and muscle mass, as well as residual glomerular filtra-

tion. Unfortunately, creatinine clearance measurements do not accurately estimate the glomerular filtration rate in patients with renal failure requiring dialysis. The plasma clearance of radioisotopes or inulin can be a precise measure of renal function, but their use is cumbersome and expensive.

EFFECTS OF UREMIA ON DRUG DISPOSITION

Bioavailability

The bioavailability is the rate and extent to which a drug enters the systemic circulation. The rapid onset of action observed with intravenously administered drugs is the result of entering the central circulation directly. When drugs must cross biological membranes or pass through metabolizing organs, only a fraction of the dose reaches the site of action. Bioavailability is the percentage of the dose that reaches the systemic venous circulation. The rate of drug absorption determines the time required to achieve the maximum concentration of the drug in venous blood.

As oral drugs traverse gastrointestinal membranes, they may be metabolized by enzymes in the intestinal epithelium.[6,7] Once in the portal circulation, they must next pass through the liver, where hepatic biotransformation or excretion into the bile may prevent the drug from reaching the systemic circulation.

Gastrointestinal drug absorption is decreased in patients with renal failure. Nausea, vomiting, and gastroparesis are common in uremia and may discourage patients from taking oral medications. Unfortunately, little is known about bowel function in renal failure, but some drugs are not well absorbed when given orally. For example, ferrous iron salts require acid hydrolysis for absorption. It has been postulated that salivary urea is converted to ammonia in the stomach of uremic patients, buffering gastric acid and causing decreased absorption of drugs requiring acid hydrolysis.[8]

Patients with renal impairment often ingest large quantities of antacids to bind dietary phosphate. Chelation and the formation of non-absorbable complexes with multivalent cations frequently used in antacids decreases the bioavailability of some drugs.[9,10] This effect is particularly important for the absorption of some antibiotics and digoxin.

Gastrointestinal absorptive function is decreased in patients with impaired renal function. Craig and colleagues[11] showed the absorption of D-xylose is diminished in patients with renal failure. Gastroparesis prolongs gastric emptying and delays drug absorption in diabetics with renal impairment. Conversely, diarrhea shortens gut transit time and diminishes drug absorption by the small bowel.

The interaction between absorption and first-pass hepatic metabolism is complex and causes variable drug bioavailability in patients with renal impairment. Decreased hepatic or gastrointestinal biotransformation increases the active drug entering the systemic circulation from the portal system. However, impaired protein binding results in more free drug at the site of hepatic metabolism and more drug removal during the hepatic first pass.

Distribution

At equilibrium, the amount of drug in the body divided by its plasma concentration is the drug's apparent volume of

distribution. This mathematical construct is used to estimate the dose of a drug to be given in order to achieve a desired plasma concentration, rather than an actual anatomical space. Highly protein-bound drugs, or those that are water soluble, are restricted to the extracellular fluid space and have small distribution volumes. Lipid-soluble drugs penetrate body tissues and exhibit large volumes of distribution.

A drug's apparent volume of distribution can be altered by factors frequently present in patients with renal insufficiency. Water-soluble drugs demonstrate increased distribution volume in patients with edema or ascites. Drug doses will need to be increased somewhat for edematous patients to avoid ineffectively low plasma levels. Dehydration or muscle wasting decreases the volume of distribution of water soluble and highly protein bound drugs. In these cases, initial drug doses should be decreased to avoid toxic plasma concentrations.

Protein-bound drugs attach reversibly either to albumin or glycoprotein in plasma. Binding to serum proteins may be decreased in uremic patients. This protein-binding defect is believed to be the result of a combination of decreased serum albumin concentration and a reduction in albumin affinity for the drug, but it may be present even when the plasma albumin concentration is normal.[12–14]

The extent of drug binding to serum proteins influences the volume of distribution, the amount of free drug available for action, and the degree to which the drug is eliminated by hepatic or renal excretion. Decreased plasma protein binding in patients with renal insufficiency increases drug action, but may also increase the rate of drug removal because it is the free fraction that is available for hepatic biotransformation.[15]

Impaired plasma protein binding in uremia has important clinical effects. Toxicity can occur if the total plasma concentration of a protein bound drug is pushed into the therapeutic range by increasing the dose. In cases where there is a significant protein-binding defect, the concentration of free drug may be toxic. For highly protein bound drugs, it may be useful to measure total and unbound plasma concentrations. The variable effects of protein binding on elimination and toxicity make predicting the clinical effects of altered protein binding in uremia difficult.

Metabolism

Surprisingly, renal failure slows the rate of non-renal drug elimination. The rate of reduction and hydrolysis reactions can be decreased in patients with renal failure, while glucuronidation and sulfate conjugation usually occur at normal rates.[16] Uremia in rats may decrease the protein expression of CYP450 isoforms up to 50% as well as their mRNA.[17]

The biotransformation of drugs to active or toxic metabolites is important in patients with renal failure, because polar metabolites are frequently eliminated by the kidneys. Metabolite accumulation explains, in part, the increased incidence of adverse drug reactions seen in renal failure.

Drug dosing calculations for dialysis patients are usually derived from studies in patients with stable, chronic renal failure. These recommendations are frequently extrapolated to seriously ill patients with acute renal failure. Although metabolic drug removal is often decreased in patients with chronic renal failure, acute renal failure may spare non-renal drug clearance.[18] Extrapolation of drug dosing recommendations from patients with stable chronic renal failure could result in potentially ineffectively low drug concentrations in patients with acute renal dysfunction.

DRUG DOSING CALCULATIONS

The initial dose of a drug given to patients with renal failure should be the same as that given to a patient with normal renal function, unless there is evidence of edema, ascites, dehydration, or severe muscle wasting. This initial loading dose of any drug can be calculated from the following expression:

$$\text{Loading Dose} = \text{Vd} \times \text{IBW} \times \text{Cp}$$

where Vd is the drug's volume of distribution in liters per kilogram, IBW is the patient's ideal body weight in kilograms, and Cp is the desired steady state plasma drug concentration.

For subsequent drug doses, the fraction of the normal dose recommended for a patient with renal failure can be calculated as follows:

$$\text{Df} = \text{t}\tfrac{1}{2} \text{ normal} / \text{t}\tfrac{1}{2} \text{ renal failure}$$

where Df is the fraction of the normal dose to be given; $\text{t}\tfrac{1}{2}$ normal is the elimination half-life of the drug in a patient with normal renal function; and $\text{t}\tfrac{1}{2}$ renal failure is the elimination half-life of the drug in a patient with renal failure. To maintain the normal dose interval in patients with renal impairment, the amount of each dose, following the loading dose, can be determined from the following relationship:

$$\text{Dose in Renal Impairment} = \text{Normal Dose} \times \text{DF}$$

The resulting dose is usually given at the same dose interval as that for patients with normal renal function. This method is effective for drugs with a narrow therapeutic range and a short plasma half life. Figure 48–2 illustrates plasma concentrations following an initial loading dose and reduction of the individual doses.

A convenient method for decreasing the amount of drug given to a patient with renal insufficiency is to prolong the dose interval. This method is used for drugs with a wide therapeutic window and long plasma half-life. The dose interval in renal impairment can be estimated from the following expression:

$$\text{Dose interval in renal impairment} = \text{Normal dose interval} / \text{Df}$$

The resulting plasma concentrations from prolonging the dose interval in an individual with impaired renal function are shown in Figure 48–3. If the range between therapeutic and toxic levels is too narrow, either potentially toxic or subtherapeutic plasma concentrations result.

Combining dose reduction and interval prolongation is a practical and convenient approach to reducing the amount of a medication given to a patient with renal impairment. The daily dose is calculated by multiplying the normal daily dose by the dose fraction. This modified dose can be divided into convenient dosing intervals.

The decision to extend the dosing interval beyond a 24-hour period should be based on the need to maintain therapeutic peak or trough levels. The dosing interval may be prolonged if the peak level is most important. When the minimum trough level must be maintained, it is preferable to modify the individual dose or use a combination of dose and interval methods to determine the correct dosing strategy. Drugs removed by dialysis and given once daily should be given after

Figure 48–2 A normal loading dose and reduced maintenance doses avoids high peak and low trough concentrations. This approach is best for drugs with a narrow range between the therapeutic and toxic concentrations.
Figure 48–3 A normal loading dose and repeated normal doses at a prolonged dose interval result in higher peak and lower trough concentrations.
the dialysis treatment. Recommendations for drug dosing in patients with renal impairment are given in Table 48–1.[19]

DRUG REMOVAL BY DIALYSIS

Drug removal by hemodialysis occurs primarily by the process of drug diffusion across the dialysis membrane down a concentration gradient from the plasma to the dialysate. It is most effective for drugs that are less than 500 Daltons (Da), are less than 90% protein bound, and have small volumes of distribution. Removal of small molecular weight drugs is enhanced by increasing the blood and dialysate flow rates and by using large surface area dialyzers. Larger molecules require more porous membranes for increased removal. The hemodialysis clearance of a drug can be estimated from the following relationship:

$$Cl_{HD} = Cl_{urea} \times (60/MW_{drug})$$

where Cl_{HD} is the drug's clearance by hemodialysis, Cl_{urea} is the clearance of urea by the dialyzer, and MW_{drug} is the molecular weight of the drug.[20] The urea clearance for most standard dialyzers is about varies between 150 and 200 mL/min.[21]

The use of porous dialysis membranes to perform high flux dialysis decreases the importance of drug molecular mass in determining drug removal during extracorporeal circulation. During high flux dialysis, the volume of distribution and percent protein binding of the drug are more important determinants dialysis drug clearance. The removal of drugs during high-flux dialysis depends more on treatment time, blood and dialysate flow rates, distribution volume, and binding of the drug to serum proteins. Much more drug is removed during high-flux dialysis than previously estimated for conventional hemodialysis.

Peritoneal dialysis is less efficient at removing drugs than is hemodialysis and most effective for smaller molecular weight drugs that are not extensively bound to serum proteins.[22] Larger molecular weight drugs are removed by peritoneal dialysis by secretion into peritoneal lymphatic fluid. Drugs that have small volumes of distribution are more effectively removed than those that are distributed in adipose tissue or have extensive tissue binding. Removal of small molecular weight drugs is dependent on the number of peritoneal dialysis exchanges done daily. Peritoneal drug clearance can be estimated from the relationship:

$$Cl_{PD} = Cl_{urea} \times \frac{\sqrt{60}}{\sqrt{MW_{drug}}}$$

where Cl_{PD} is the peritoneal drug clearance; Cl_{urea} is the peritoneal urea clearance; and MW_d is the molecular weight of the

Table 48–1 Recommendations for Drug Dosing in Patients with Renal Impairment

Drug	Dose Method	GFR > 50 (mL/min)	GFR 10-50 (mL/min)	GFR < 10 (mL/min)	Supplemental dose after hemodialysis	CAPD	CRRT

Table 48–1 Recommendations for drug dosing in patients with renal impairment—cont'd

Drug	Dose Method	GFR > 50 (mL/min)	GFR 10-50 (mL/min)	GFR < 10 (mL/min)	Supplemental dose after hemodialysis	CAPD	CRRT
Quazepam	D	Unknown	Unknown	Unknown	Unknown	Unknown	NA
Quinapril	D	100%	75%-100%	75%	25%	None	Dose for GFR 10-50
Quinidine	D	100%	100%	75%	100-200 mg	None	Dose for GFR 10-50
Quinine	I	q8h	q8-12h	q24h	Dose after dialysis	Dose for GFR <10	Dose for GFR 10-50
Ramipril	D	100%	50%-75%	25%-50%	20%	None	Dose for GFR 10-50
Ranitidine	D	75%	50%	25%	1/2 dose	None	Dose for GFR 10-50
Reserpine	D	100%	100%	Avoid	None	None	Dose for GFR 10-50
Ribavirin	D	100%	100%	50%	Dose after dialysis	Dose for GFR <10	Dose for GFR <10
Rifabutin	D	100%	100%	100%	None	None	Dose for GFR 10-50
Rifampin	D	100%	50%-100%	50%-100%	None	Dose for GFR <10	Dose for GFR <10
Ritonavir		100%	100%	100%	None	Dose for GFR <10	Dose for GFR 10-50
Saquinavir		100%	100%	100%	None	Dose for GFR <10	Dose for GFR 10-50
Secobarbital	D	100%	100%	100%	None	None	NA
Sertraline	D	100%	100%	100%	Unknown	Unknown	NA
Simvastatin	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Sodium valproate	D	100%	100%	100%	None	None	None
Sotalol	D	100%	30%	15%-30%	80 mg	None	Dose for GFR 10-50
Sparfloxacin	D,I	100%	50%-75%	50% q48h	dose for GFR <10	No data	Dose for GFR 10-50
Spectinomycin	D	100%	100%	100%	None	None	None
Spironolactone	I	q6-12h	q12-24h	Avoid	Not applicable	Not applicable	Avoid
Stavudine	D,I	100%	50% q12-24h	50% q24h	Dose after dialysis	No data	Dose for GFR 10-50
Streptokinase	D	100%	100%	100%	Not applicable	Not applicable	Dose for GFR 10-50
Streptomycin	I	q24h	q24-72h	q72-96h	1/2 normal dose	20-40 mg/L day	Dose for GFR 10-50
Streptozotocin	D	100%	75%	50%	Unknown	Unknown	Unknown
Succinylcholine	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Sufentanil	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Sulbactam	I	q6-8h	q12-24h	q24-48h	Dose after dialysis	0.75-1.5 g/day	750 mg q12h
Sulfamethoxazole	I	q12h	q18h	q24h	1 g after dialysis	1 g/d	Dose for GFR 10-50
Sulfinpyrazone	D	100%	100%	Avoid	None	None	Dose for GFR 10-50
Sulfisoxazole	I	q6h	q8-12h	q12-24h	2 g after dialysis	3 g/d	Not applicable
Sulindac	D	100%	100%	100%	None	None	Dose for GFR 10-50
Sulotroban	D	50%	30%	10%	Unknown	Unknown	Unknown
Tamoxifen	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Tazobactam	D	100%	75%	50%	1/3 dose	Dose for GFR <10	Dose for GFR 10-50
Teicoplanin	I	q24h	q48h	q72h	Dose for GFR <10	Dose for GFR <10	Dose for GFR 10-50
Temazepam	D	100%	100%	100%	None	None	NA
Teniposide	D	100%	100%	100%	None	None	Dose for GFR 10-50
Terazosin	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Terbutaline	D	100%	50%	Avoid	Unknown	Unknown	Dose for GFR 10-50
Terfenadine	D	100%	100%	100%	None	None	NA
Tetracycline	I	q8-12h	q12-24h	q24h	None	None	Dose for GFR 10-50

Drug	Method	GFR >50	GFR 10–50	GFR <10	Hemodialysis	CAPD	CAVH
Theophylline	D	100%	100%	100%	1/2 dose	Unknown	Dose for GFR 10-50
Thiazides	D	100%	100%	Avoid	Not applicable	Not applicable	Not applicable
Thiopental	D	100%	100%	75%	Not applicable	Not applicable	NA
Ticarcillin	D,I	1-2 g q4h	1-2 g q8h	1-2 g q12h	3 g after dialysis	Dose for GFR <10	Dose for GFR 10-50
Ticlopidine	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Timolol	D	100%	100%	100%	None	None	Dose for GFR 10-50
Tobramycin	D,I	60%-90% q8-12h	30%-70% q12h	20%-30% q24-48h	2/3 normal dose	3-4 mg/L d	Dose for GFR 10-50
Tocainide	D	100%	100%	50%	200 mg	None	Dose for GFR 10-50
Tolazamide	D	100%	100%	100%	Unknown	Unknown	Avoid
Tolbutamide	D	100%	100%	100%	None	None	Avoid
Tolmetin	D	100%	100%	100%	None	None	Dose for GFR 10-50
Topiramate	D	100%	50%	25%	Unknown	Unknown	Dose for GFR 10-50
Topotecan	D	75%	50%	25%	Unknown	Unknown	Dose for GFR 10-50
Torsemide	D	100%	100%	100%	None	None	NA
Tranexamic acid	D	50%	25%	10%	Unknown	Unknown	Unknown
Tranylcypromine	D	Unknown	Unknown	Unknown	Unknown	Unknown	NA
Trazodone	D	100%	100%	Unknown	Unknown	Unknown	NA
Triamcinolone	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Triamterene	I	q12h	q12h	Avoid	Not applicable	Not applicable	Avoid
Triazolam	D	100%	100%	100%	None	None	NA
Trihexyphenidyl	D	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown
Trimethadione	I	q8h	q8-12h	q12-24h	Unknown	Unknown	Dose for GFR 10-50
Trimethoprim	I	q12h	q18h	q24h	Dose after dialysis	q24h	q18h
Trimetrexate	D	100%	50%-100%	Avoid	No data	No data	No data
Trimipramine	D	100%	100%	100%	None	None	NA
Tripelennamine	D	Unknown	Unknown	Unknown	Unknown	Unknown	NA
Triprolidine	D	Unknown	Unknown	Unknown	Unknown	Unknown	NA
Tubocurarine	D	75%	50%	Avoid	Unknown	Unknown	Dose for GFR 10-50
Urokinase	D	Unknown	Unknown	Unknown	Unknown	Unknown	Dose for GFR 10-50
Vancomycin	D,I	500 mg q6-12h	500 mg q24-48h	500 mg q48-96h	Dose for GFR <10	Dose for GFR <10	Dose for GFR 10-50
Vecuronium	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Venlafaxine	D	75%	50%	50%	None	Unknown	NA
Verapamil	D	100%	100%	100%	None	None	Dose for GFR 10-50
Vidarabine	D	100%	100%	75%	Infuse after dialysis	Dose for GFR <10	Dose for GFR 10-50
Vigabatrin	D	100%	50%	25%	Unknown	Unknown	Dose for GFR 10-50
Vinblastine	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Vincristine	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Vinorelbine	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Warfarin	D	100%	100%	100%	None	None	None
Zafirlukast	D	100%	100%	100%	Unknown	Unknown	Dose for GFR 10-50
Zalcitabine	I	100%	q 12 h	q 24 h	Dose after dialysis	No data	Dose for GFR 10-50
Zidovudine (AZT)	D,I	200 mg q8h	200 mg q8h	100 mg q8h	Dose for GFR <10	Dose for GFR <10	100 mg q8h
Zileuton	D	100%	100%	100%	None	Unknown	Dose for GFR 10-50

drug. Peritoneal urea clearance is approximately 20 mL/min. In general, if a drug is not removed by hemodialysis, it will not be removed by peritoneal dialysis.

Drug transport by the peritoneal membrane is unidirectional.[23] Although peritoneal dialysis does not rapidly remove drugs, many are well absorbed when placed in peritoneal dialysate.

Molecular weight, membrane characteristics, blood flow rate, and the addition of dialysate determine the rate and extent of drug removal during continuous renal replacement therapies (CRRT). Molecular weight effects drug removal by diffusion during dialysis more than during convection during CRRT because of the large pore size of membranes used for CRRT. Because most drugs are less than 1500 Da, drug removal by CRRT does not depend greatly on molecular weight.

The volume of distribution of a drug is the most important factor determining removal by CRRT. Drugs with a large volume of distribution are highly tissue bound and not accessible to extracorporeal circuit in quantities sufficient to result in substantial removal by CRRT. Even if the extraction across the artificial membrane is 100%, only a small amount of a drug with a large volume of distribution is removed. A volume of distribution greater than 0.7 L/Kg substantially decreases CRRT drug removal.

Drug protein binding also determines how much is removed during CRRT. Only unbound drug is available for elimination by CRRT. Protein binding of more than 80% provides a substantial barrier to drug removal by convection or diffusion. During continuous hemofiltration, an ultrafiltration rate of 10-30 mL/min is achieved. The addition of diffusion by continuous dialysis increases drug clearance, depending on blood and dialysate flow rates. As during high flux dialysis, drug removal parallels the removal of urea and creatinine. The simplest method for estimating drug removal during CRRT is to estimate urea or creatinine clearance during the procedure.[24]

Recommendations for dosing selected drugs in patients with impaired renal function are given in Table 48–1. These recommendations are meant only as a guide and do not imply efficacy or safety of a recommended dose in an individual patient. A loading dose equivalent to the usual dose in patients with normal renal function should be considered for drugs with a particularly long half-life. The table indicates potential methods for adjusting the dose, either by decreasing the individual doses (D) or increasing the dose interval (I). In the table, when the dose method is suggested, the percentage of the dose for normal renal function is given. When the interval method is suggested, the actual dose interval is provided.

Prolonging the dose interval is often more convenient and less expensive. When the dose interval can safely be lengthened beyond 24 hours, extended parenteral therapy may be completed without prolonging hospitalization. In patients requiring chronic hemodialysis, many drugs need to be given only at the end of the dialysis treatment. Further, compliance with any drug regimen may be better when fewer doses can be taken at convenient times. In practice, a combination interval prolongation and dose-size reduction is often effective and convenient.

The effect of the standard clinical treatment on drug removal is shown for hemodialysis, chronic ambulatory peritoneal dialysis, and continuous renal replacement therapy. Most of these recommendations were established before very high efficiency hemodialysis treatments were practical, continuous cycling nocturnal peritoneal dialysis was common, and diffusion was added to hemofiltration in continuous renal replacement therapies. Some drugs that have high dialysis clearance do not require supplemental doses after dialysis, if the amount of the drug removed is not sufficient, as would be the case if the volume of distribution were large. To ensure efficacy when information about dialysis loss is not available and to simplify dosimetry, maintenance doses of most drugs should be given after dialysis.

Peritonitis is a major complication of peritoneal dialysis, and treatment usually involves intraperitoneal administration of antibiotics. For some drugs, sophisticated pharmacokinetic studies are available, whereas for others use is still based on empirical dosage recommendations. In general, there is excellent drug absorption after intraperitoneal administration of common antibiotics. Factors favoring absorption include inflamed membranes and concentration gradients. For many drugs, peritoneal fluid levels after intravenous or oral administration are inconsistent.

DRUG LEVEL MONITORING

If there is a known relationship between drug efficacy or toxicity and plasma drug concentrations, blood levels may serve as a guide to drug therapy. These measurements are most important for drugs with a narrow therapeutic range and they are useful when pharmacological effects are difficult to determine.

To ensure that steady state serum concentrations have been obtained, three or four doses of the drug should be administered before serum levels are measured. Peak levels are most meaningful when measured after rapid drug distribution has occurred. Conversely, minimum concentrations are usually measured just before giving the next scheduled dose.

Patients with renal disease are heterogeneous and their response to drug therapy is variable. Dosage nomograms, drug tables, and computer-assisted dosing recommendations provide guidelines for an initial drug administration in patients with decreased renal function. Individualizing the dose regimen for each patient requires continuing evaluation of the therapeutic response for drug efficacy and toxicity.
