Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedication

I face the dual challenges of looking forward and back as the Second Edition of *Chronic Renal Disease* emerges into print. I am delighted with the reception the First Edition received and took it as a summons to create an even better second effort. We have sought to put new information into perspective, vital for the care of patients, and to recruit the best authors to update the text and present complex new concepts in a meaningful way.

This Second Edition is dedicated to my teachers, who showed me the beauty of physiology, pathophysiology, and treatment, as well as the interconnections between ourselves as teachers and physicians, and our patients and their families. The greatest teachers fostered critical thinking and inspired me to ask and try to answer many different questions about renal disease. Each one had a distinctive persona. I am both impressed by and amused by the multiplicity of viewpoints in our discipline. Countless colleagues worked with me on projects, helping me to see findings in different ways, enhancing my approaches to understanding data. In addition, I recognize the role of my parents and sister in this effort. They would have truly loved to have seen this book.

This Second Edition has new authors and new chapters, making it more comprehensive, useful, and focused on our patients worldwide. The chapter authors—all recognized experts in their fields—have done a remarkable job of conceptualizing their subjects in clear language and pictures, as well as responding to many and diverse editorial quibbles and cavils. The interaction between authors and editors has been both scholarly and very productive. I thank the returning authors as well as the new ones heartily. My coeditor has been a joy to work with, complementing my deficiencies with thoughtfulness, equanimity, good sense, and good humor. I thank the staff at Elsevier for their guidance and perseverance. They all understood and immediately shared the goal of creating a scientific, well-written, useful, and beautiful book. I hope we have achieved those goals.

This book is also meant to improve the care and lives of our patients. The last five years have witnessed a sea change in clinical research in nephrology, including patients as partners and collaborators in all aspects of the research enterprise. This book is for them as well. Finally and perhaps foremost, this book is for our students, who continue to teach as well as challenge us, in addition to hopefully learning from us. I hope they will find this book helpful in thinking about the kidney and renal disease, and in caring for their patients. And how could I not thank my wife? This book could certainly have been written without her, but it would not have been as much fun. I deeply appreciate her wisdom and consideration.

Paul L. Kimmel

This book is dedicated to the many students, residents, and fellows who continue to inspire me to teach and learn, to my mentors who have shown me the pathways to follow in medicine and life, and to the patients I have cared for who have taught me about the perseverance and courage needed to live with a chronic illness. Heartfelt thanks to the many authors who have contributed to this book and to the editorial team at Elsevier for their outstanding work. Most of all, I dedicate this book to my wife Monica and my children Joel, Madeline, and Jack—thanks for your unending love, support, and motivation, and for teaching me how to have fun!

Mark E. Rosenberg

List of Contributors

Blaise Abramovitz Renal-Electrolyte Division, Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA, United States

Dwomoa Adu Honorary Senior Research Fellow and Consultant Nephrologist, School of Medicine and Dentistry, University of Ghana, Accra, Ghana

Farsad Afshinnia Division of Nephrology, Department of Internal Medicine, University of Michigan, Ann Arbor, MI, United States

Anupam Agarwal Division of Nephrology, University of Alabama at Birmingham, Birmingham Veterans Administration Medical Center, Birmingham, AL, United States

Sarah C. Andrews Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States

Gerald Appel Division of Nephrology, Columbia University Medical Center, New York, NY, United States

About the Editors

Paul L. Kimmel, MD, MACP, FRCP, FASN, was educated at Yale College and the New York University School of Medicine. He completed his internal medicine residency at Bellevue Hospital in New York City and Nephrology fellowship at the Hospital of the University of Pennsylvania. He was a member of the faculty at the University of Pennsylvania and the George Washington University, where he attained the rank of professor. From 2001 to 2006, Dr. Kimmel served as Director of the Division of Renal Diseases and Hypertension at George Washington University. From 2006 to 2008, he was the Director of Education of the American Society of Nephrology. Dr. Kimmel currently is Clinical Professor of Medicine at George Washington University in Washington, DC. His interests include psychosocial adaptation to chronic renal disease, sleep disorders in patients with kidney disease, zinc metabolism in renal diseases, HIV-associated kidney diseases, the clinical genetics of common kidney disease, and the interrelationships between acute kidney injury and chronic kidney disease.

Mark E. Rosenberg, MD, FASN, attended medical school at the University of Manitoba in Winnipeg, Canada, and did his internal medicine residency and nephrology fellowship at the University of Minnesota. He served as Director of the Division of Renal Diseases and Hypertension at the university from 2000 to 2009. From 2009 to 2012, he was the Chief of Medicine and Director of the Primary and Specialty Medicine Service Line at the Minneapolis VA Health Care System. Dr. Rosenberg currently serves as Vice Dean for Education and Academic Affairs, and Professor of Medicine at the University of Minnesota Medical School in Minneapolis, Minnesota. In this position, he is responsible for the continuum of medical education. He served as Chair of the Postgraduate Education Committee and Education Director for Kidney Week for 6 years before being elected in 2013 to the Council of the American Society of Nephrology. Dr. Rosenberg served as President of the American Society of Nephrology in 2019. His interests include pathophysiology and progression of chronic kidney disease, kidney regeneration following acute injury, models of care delivery including telehealth, and workforce issues in nephrology.

Abbreviations

ACEI	Angiotensin-converting enzyme inhibitor
ACR	Albumin:creatinine ratio
ADPKD	Autosomal dominant polycystic kidney disease
AIDS	Acquired immunodeficiency syndrome
AKI	Acute kidney injury
ARB	Angiotensin receptor blocker
BMI	Body mass index
bpm	Beats per minute
CCB	Calcium channel blocker
CHF	Congestive heart failure
CKD	Chronic kidney disease
CPAP	Continuous positive airway pressure
CRS	Cardiorenal syndrome
CrCl	Creatinine clearance
CRP	C-reactive protein
CT	Computed tomography
CVD	Cardiovascular disease
DM	Diabetes mellitus
DN	Diabetic nephropathy
DR	Diabetic retinopathy
EPO	Erythropoietin
ESA	Erythropoiesis-stimulating agent
ESRD	End-stage renal disease
FDA	Food and Drug Administration
FGF-23	Fibroblast growth factor 23
GFR	Glomerular filtration rate
eGFR	Estimated glomerular filtration rate
mGFR	Measured glomerular filtration rate
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HD	Hemodialysis
HIV	Human immunodeficiency virus
HIVAN	Human immunodeficiency virus−associated nephropathy
HTN	Hypertension
HUS	Hemolytic uremic syndrome
IL	Interleukin
LN	Lupus nephritis
MN	Membranous nephropathy
MCD	Minimal change disease
MGUS	Monoclonal gammopathy of unknown significance
MRI	Magnetic resonance imaging
NAD	Nicotinamide adenine dinucleotide
NIH	National Institutes of Health
NIDDK	National Institute of Diabetes and Digestive and Kidney Diseases
NSAID	Nonsteroidal antiinflammatory drug
OSA	Obstructive sleep apnea
PCR	Protein:creatinine ratio
PD	Peritoneal dialysis
RAAS	Renin−angiotensin−aldosterone system
RBC	Red blood cells
RVD	Renal vascular disease
RCT	Randomized controlled trials
RRT	Renal replacement therapy
RT	Renal transplantation
SC	Subcutaneous
SCD	Sickle cell disease
SCN	Sickle cell nephropathy
SLE	Systemic lupus erythematosus
S[Alb]	Serum albumin concentration
S[Ca]	Serum calcium concentration
S[Cr]	Serum creatinine concentration
S[K]	Serum potassium concentration
S[Mg]	Serum magnesium concentration
S[P]	Serum phosphate concentration
S[UA]	Serum uric acid concentration
S[X]	Serum X concentration
T1DM	Diabetes mellitus, type 1
T2DM	Diabetes mellitus, type 2
TGF	Transforming growth factor
TNF	Tumor necrosis factor
TTP	Thrombotic thrombocytopenic purpura
UNA	Urinary nitrogen appearance
UAlbV	Urinary albumin excretion
UACR	Urine albumin:creatinine ratio
UProV	Urinary protein excretion
UPCR	Urine protein:creatinine ratio
USRDS	United States Renal Data System
VEGF	Vascular endothelial growth factor
$25(OH)D_3$	25 hydroxyvitamin D
$1,25(OH)_2D_3$	1,25 dihydroxycholecalciferol, calcitriol

CHAPTER

1

Introduction
Chronic Renal Disease

Paul L. Kimmel[a], *Mark E. Rosenberg*[b]

[a]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States; [b]Division of Renal Diseases and Hypertension, University of Minnesota Medical School, Minneapolis, MN, United States

INTRODUCTION TO THE FIRST EDITION

In our discussions as we planned this work, we were struck that no major textbook had considered the relatively new field of chronic kidney disease—CKD—as a coherent whole. It must be acknowledged that the CKD revolution has transformed the clinical and scientific landscapes of nephrology, by systematizing the classification of the protean aspects of the discipline, and setting boundaries that have allowed clinical epidemiology and clinical research to advance, perhaps exponentially. CKD classifications have led to new nomenclature for acute renal disease as well, which has proved useful. In addition, the approach has led to advances in considering acute kidney injury (AKI) and CKD as interrelated syndromes. Nevertheless, the classification approach must not narrow the richness of clinical observation and diagnostic etiologic clarity that has characterized our field over the last century or so. This book covers broadly, but comprehensively, the history, pathophysiology, and practical approaches to diagnosis, patient care, and treatment issues in CKD. The scope of this book is limited to CKD—up to the initiation of end-stage renal disease (ESRD) care. This delineated population, however, entails the vast majority of CKD patients.

We have specifically solicited preeminent authors who are experts in the scientific underpinnings and the clinical implications of their chosen topics to contribute to the book. Basic biologic knowledge of course is the foundation of pathophysiologic approaches and clinical therapeutics. Over the past decade, enormous advances have been made in our understanding of the genetics of kidney disease. Our appreciation of an important cause of CKD as a common disorder that has Mendelian aspects as well has made us reassess approaches to screening and treatment and may revolutionize patient care, bringing personalized medicine to the CKD clinic. We understand CKD as a disease that varies across the globe, as a result of complex interactions of genetics and the environment, including poverty. Great strides have been made in our understanding of the breadth and natural history of pediatric CKD, in part because of the establishment of well-designed observational studies more than a decade ago. The role of common comorbidities such as diabetes mellitus and hypertension has been studied, but as with nutrition and its improvement in this population, much work remains to be done. Over the past two decades, the role of inflammation in CKD has been increasingly determined, but treatments using this knowledge have been elusive. Treatments of organ system complications of diminution in glomerular filtration rate (GFR) and uremia are at widely varying stages of development and maturity, and our evidence base in a few of these domains and in specific patient subpopulations is woefully inadequate. Although several pathways culminating in kidney disease have been identified, with diverse treatment opportunities and implications, we have learned to our chagrin that more treatment is not necessarily better treatment. We must develop and test novel therapies and interventions to prevent the initiation and ameliorate the progression of CKD. If and when the time comes, we must help our patients prepare for ESRD care. Advances in the clinical trials and basic sciences

Chronic Renal Disease, Second Edition

associated with CKD may help us achieve our goals—improving the quantity and quality of life of our patients with CKD.

This book, we hope, will be a reference for all who want to know about or increase their knowledge regarding any or all aspects of CKD. As befits a 21st century publication, it is available in paper and electronic versions. There are specific chapters regarding considerations of certain patient scenarios or syndromes. Each chapter is grounded in the experience of a specific patient—whom we have seen, and that you have seen or will encounter over your career. Perusing the Table of Contents, a few chapters may at first blush seem duplicative, but they in fact approach problems from very different angles, with different expertise. The problems in CKD are necessarily interdigitated and overlapping. We did not want the authors to be artificially limited by chapter titles. It is hoped that each chapter is comprehensive and can stand on its own as a reference. We owe a great debt to the individual authors and thank them sincerely for their exemplary work. This book is after all just paper and bytes without them.

We set a high bar for this text. We intended the book to be patient-oriented, to deal with common clinical problems, but at the same time to be synoptic in scope, broadly inclusive, scientific, and useful as a reference for therapy. We believe that the authors have achieved this goal!

This book is knowingly and specifically titled *Chronic Renal Disease* to highlight its embedding in the scientific literature. "Kidney" is the Middle English term for the organ we love. "Renal" and "nephrology" (from the French and Greek, respectively) are scientific terms for use by professionals. As we grappled with "hypertension" compared with "high blood pressure" in our educational youth, we had to learn a nomenclature as we developed medical expertise. As "hypertension" and "high blood pressure" mean the same thing, "kidney" and "renal" are the same, while at the same time having different, important connotations. The intellectual mansion built by our predecessors, Bright, Addis, Peters, Richards, and Smith, to name a few, has many rooms. In keeping with the scientific focus of *Chronic Renal Disease*, all the book chapters are grounded in basic and clinical scientific principles, so the clinical characteristics and therapy of the individual topic under consideration in each chapter can be appreciated as a logical development from previous knowledge. Controversial issues are highlighted and dealt with clearly, directly, and emphatically. When there are gaps or deficiencies in the literature, or in our therapeutic knowledge—and there are—these are clearly acknowledged. This is a book for clinicians and scientists, not necessarily the lay public.

We hope this book will serve people interested in clinical CKD—ranging from medical students, to residents, internists, and pediatricians, to renal fellows, nephrology faculty, and practitioners. Educational principles have advanced as well over the last decades. We know that different readers, including those who tackle a subject from varying levels and perspectives, learn in different ways. Each chapter is accompanied by multiple choice questions. We conceived the questions as an integral part of the book—complementing the chapters, and functioning as both self-study tools and the point of departure for discussion in clinical conferences. The electronic version of the text and questions will help mobile users keep current on the go. In keeping with current notions of CKD, a set of abbreviations has been used consistently throughout the text.

We are interested in your feedback and constructive and other criticisms. Please let us know what you think of the book—including overall perceptions and comments regarding individual chapters. You are encouraged to contact us—with your kudos and concerns—by contacting our publisher. We hope you enjoy the book and find it useful simultaneously.

INTRODUCTION TO THE SECOND EDITION

The reception of the first edition of *Chronic Renal Disease* has been very gratifying. The publication of the second edition allows one to consider the changes that have occurred in understanding and treating kidney disease over the last half decade, as well as factors that have not changed appreciably over time. In many ways, progress has been incremental, rather than radical.

The clinical utility of apolipoprotein L1 (APOL1) variants still remains to be determined, as do the underlying mechanisms of injury. We still do not know how to use knowledge regarding APOL1 variants to assist patients in making choices or how to craft preventive or therapeutic approaches, although prospective studies to evaluate the course of kidney transplant patients may hold promise.

We await the identification and validation of biomarkers that will enhance the value of measuring GFR and proteinuria, and their longitudinal assessments, in patients with CKD and at risk for developing CKD, to provide better prognostication of course and response to therapies, with hope but healthy skepticism. The clinical utility of these simple metrics developed in the early 20th century must be acknowledged as simply remarkable, while admitting that their robust value highlights the lack of progress we have been able to achieve in this field. In nephrology, we truly stand on the shoulders of giants.

The interrelationship between AKI and CKD appears to have been strengthened by evidence garnered over the last several years, but how to treat patients after the development of AKI, in the clinic after hospital discharge, to prevent the development of CKD, or to ameliorate its progression is unknown, and stands as a major gap in clinical practice.

The mediators of progression of CKD appear to be unchanged from those outlined in the first edition: pathogenic fibrosis as a result of attempts to repair injury, vicious cycles set up by components of the renin−angiotensin−aldosterone system, and the deleterious effects of inflammation and hypertension. Single nephron GFR (SNGFR), an important parameter for our understanding of common mechanisms of progressive kidney disease in animal models, can now be estimated in humans. Such studies have provided confirmatory evidence that hyperfiltration may truly be an important pathogenic factor in disease in our patients. Perhaps advances in imaging techniques will allow the measurement of SNGFR in humans in the near future.

Advances in addressing fibrosis remain stubbornly resistant to translation into clinical practice. Efforts to use kidney tissue to elucidate pathways of repair, injury, and progressive dysfunction are needed and in fact, beginning, but therapeutics in this field are in their infancy.

The SPRINT trial has led to advances in understanding approaches to treating hypertension in patients with CKD, but the precise sweet spot for the goal blood pressure, and optimizing the balance between therapeutic responses and adverse effects remain to be determined.

We do not yet know how to better address the ravages of inflammation in our patients, with either relatively prevalent causes of CKD or with the rarer but devastating multisystem autoimmune disorders, to achieve better outcomes. Advances in understanding the genetics of pediatric renal disease have not culminated in the development of therapeutic agents for children.

This edition of *Chronic Renal Disease* highlights the importance of consideration of pain in our patients, as well as the potentially devastating effects of opioid prescriptions in this population. More research remains to be done to improve the quality of life of patients with CKD.

Meanwhile, poverty and racism remain key social determinants of outcomes for CKD patients across the globe. The role of maternal deprivation in causing incipient CKD in offspring is increasingly appreciated. Improvements in these arenas, however, will take more than the combined work of physicians and patients to achieve salutary change and will require the efforts of policy makers across the globe, as well as the assent of the populations and politicians.

We have endeavored to highlight patient-centered issues in CKD, although we acknowledge that this is in large part an asymptomatic illness, until very late stages are encountered. Nonetheless, patients, physicians, and health systems must cooperate in the identification of CKD patients, and in the provision of the best treatments to all, in the US as well as across the globe.

Progress has been made in our understanding of the role of complement biology in the pathogenesis of C3 glomerulopathies and complement-mediated thrombotic microangiopathies, as well as possibly in other kidney diseases. Monitoring levels of circulating phospholipase A_2 receptor during therapy for membranous nephropathy has been a great advance in the treatment of glomerular diseases—truly a landmark biomarker, depending on a rigorous set of preceding basic and clinical studies. As precision medical techniques evolve, we have improved our therapeutic

approaches to patients with lupus nephritis, through well-designed clinical trials. Evidence points to the importance of tubulointerstitial disease as a key prognostic factor in this disorder.

Development of other novel therapeutics has however lagged. CKD is indeed a tough nut to crack.

Advances in research, in addition to the work done in basic and preclinical laboratories, include enhancement of the role of participants in research. As patients assist in designing the research, sit on Steering Committees and Data Safety Monitoring Boards, and help disseminate the triumphs and failures of our work, our joint ability to translate research into cures will be necessarily enhanced, by better research strategies and communication of results.

All these challenges remain as opportunities for future research, as well as for up-and-coming researchers, hopefully with patients as participants and partners in the enterprise.

We have invited authors who wrote well-received chapters to contribute to the second edition. We also have invited new authors to tackle problems and have tried to include new experts to weigh in on issues.

We have added chapters on CKD as a global challenge and enhanced consideration of the social determinants of CKD to a text which already covered the field comprehensively. In addition, this book has been expanded by chapters considering CKD in a global context, focusing on particular regions around the world. The scope of the second edition remains unchanged from the first: the history, pathophysiology, and practical approaches to diagnosis, patient care, and treatment issues in CKD—up to the initiation of ESRD care.

We have been pleased by the feedback regarding the beauty of this book, its scholarly excellence, timeliness, usefulness, and scope, from a spectrum of readers, ranging from medical students to Professors of Medicine. We thank our publishers, and Mara Conner, for guiding us through our first efforts, and Tari Broderick and Tracy Tufaga for making the second edition a reality.

This edition has the clinical multiple choice questions included in the text, which we hope will advance its use as a teaching tool, on many levels. This book is again available in paper and electronic versions to enhance its accessibility and accommodate different learning styles and needs.

Most importantly, we thank the exceptional authors of the first and second editions for producing an important, scholarly, and useful text. Once again, we note that this book is just paper and bytes without the input of the authors. As in the first edition, we sought to combine basic scientific underpinnings with best approaches to practice, to ensure a text that would be satisfying to a broad range of readers. We hope this second edition of *Chronic Renal Disease* will be useful for students, teachers, practitioners, and, perhaps most importantly, for our patients.

We have elected to continue with an old-fashioned title. New therapies build on the collected experience of many years of patient care, when chronic renal disease as terminology was *au courant*. We hope the conjoint perspective on the past and the future is one of the distinctive, unique aspects of this book. Once again, please let us hear from you about what you liked, and what you did not, about this second edition. We hope, again, you enjoy the book and find it useful as well.

CHAPTER

2

From Bright's Disease to Chronic Kidney Disease

Steven J. Peitzman

Drexel University College of Medicine, Philadelphia, PA, United States

Abstract

In the 1820s and 1830s, Richard Bright of Guy's Hospital in London showed that dropsy (edema) when associated with heat-coagulable urine (albuminuria) predicted one or another form of pathologically altered kidneys at autopsy. His first cases were of hospitalized patients, but he later recognized and described indolent cases, what we would call chronic disease. Subsequent pathologists created classification schemes for chronic renal disease. In the late 19th century, a movement called "functional diagnosis" turned attention to the kidney's "power" in health and disease, using tests of excretion and concentration. Here arose terms such as "chronic renal failure," which persisted into the 1990s. The notion of renal "work" led to attempts to "rest" the presumably overworking nephrons of impaired kidneys with the low-protein diet. Key figures were Thomas Addis in the 1920–1940s and Barry Brenner in the later decades of the 20th century. Meanwhile, clinicians identified various causes of chronic kidney disease, only in recent decades including diabetes. Treatment from Bright's time onward aimed at reducing symptoms, such as edema, until concepts of hyperfiltration and the injurious effects of proteinuria prompted therapies (beyond diet) aimed at slowing progression. With a sense that the course of chronic renal disease if identified early might be favorably influenced (particularly by inhibition of the renal–angiotensin–aldosterone axis), nephrologists in the US and elsewhere through their organizations effected changes in nomenclature (e.g., "kidney" not "renal") and other measures to demystify and raise awareness of kidney disease. The hope was that earlier detection might allow interventions to slow progression and thus avoid or delay the need for renal replacement therapy.

BRIGHT'S DISEASE

In 1840, Richard Bright (1789–1858) (Figure 2.1), the first authority on proteinuric kidney disease, who unintentionally provided the disorder's earliest name, described what we would call a chronic case. The patient, presumably from Bright's private practice, was a "man, aged about 25, pale and scrofulous in appearance, and deeply pitted with the smallpox," who, in early March of 1835, "came to me, laboring under anasarca, and having albuminous urine." His illness began with a bout of diarrhea. As he recovered, the young man was able to spend a month in the country, but there "his legs began to swell, and anasarca proceeded up his thighs and abdomen." Bright found the urine "exceedingly coagulable" and "frothy on agitation." The patient tended to pass large, not small, quantities of urine. "I ordered him to adopt most strictly a milk diet, and to put on warm clothing, with flannel next to the skin." Because the stomach "sympathized" with the skin and kidneys, its irritability had to be quieted with an easy diet and gentle medicines such as bicarbonate of soda.

The patient improved briefly, with less coagulability of the urine, but in April he developed some cough, and his "skin inclined to be dry." Bright prescribed again some ipecac, as a diaphoretic and "expectorant." By June, the patient had improved greatly, his swelling was almost gone, though the urine still "froths much." Then, a painful "periosteal enlargement" appeared on his left shin, which the patient feared was the reappearance of "some venereal symptoms," presumably syphilis. Bright prescribed a concoction for this. By July 9, the patient was again "greatly improved," and the reader now learns that he was able to return to his work as a bookbinder. Bright desired him "to persist in all his cares and precautions [the restricted diet and flannel on the skin], to abstain from all spirits, and carefully avoid atmospheric exposures."

In February of 1836, Bright "saw him casually" and found that he still worked and had "no complaint to make." But the bookbinder admitted to a slight headache now and then. In addition, the patient himself (a craftsman who worked with his hands) tested his ankles from time to time and found that sometimes pressure of the finger made a pit. He slept well early in the night but became "restless" later and had to get up once to pass urine. The urine was "natural in quantity," but both

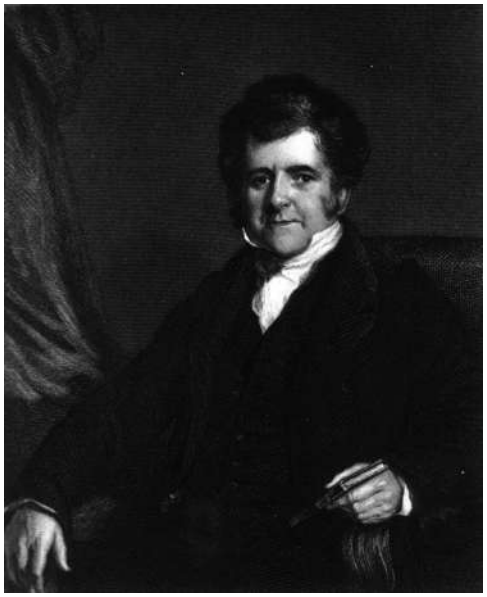

FIGURE 2.1 Richard Bright (1789–1858) as a physician to Guy's Hospital in London showed in the late 1820s that dropsy (generalized edema), when associated with albumen in the urine, predicted diseased kidneys if a patient with these findings came to autopsy. Later, Bright recognized and treated persons with more indolent, or chronic, forms of nephropathy. *Courtesy of the National Library of Medicine.*

heat and nitric acid detected that it was still "very decidedly coagulable." Thus, the disease persisted, though the patient felt generally well. Importantly (in Bright's assessment), the skin was "freely perspirable" and had been for so long now "that he forgets it ever was otherwise." But the young man had ceased taking his medications regularly. The pox-marked bookbinder chose to define himself as among the working, nonsick. However, if he felt some flank pain, or noted some other hint of his complaints returning, for a few weeks he took the powders Bright had prescribed, with "he fancies…the best effect." And he was always very careful to "guard his body with flannel next to the skin."

Then, in October 1839, the gentleman consulted Bright after a 4-year absence ("lost to follow-up" as we would say). He had continued in seeming good health with normal urine output until 3 or 4 months ago. Lately, he suffered "frequent calls to pass it after going to bed," and he complained of headache, nausea, and vomiting. A few days later, Bright was able to test the urine: it coagulated slightly to heat, but readily with nitric acid. He passed now "a large quantity of urine at night, but little in the day; his ankles had swollen slightly of late." Bright commented that "it is difficult to say" to what extent the medicines, or the precautionary measures of diet and clothing, had earlier contributed "to the relief of his disease." There is even a hint in Bright's language (the patient "fancies" the powders did him good) that the prescriber himself felt some skepticism about the actual power of the powders. Here, Bright concludes his patient's story, one that is, in many of its essentials, representative of chronic and slowly progressive proteinuric renal disease at any time. Of course, the story of Richard Bright's bookbinder offers arcane medications and strange therapeutic ideas, and a peculiar sort of pathophysiology involving "sympathy" between the skin, stomach, and kidney, by which a disturbance in one could effect injury and dysfunction in another. In the surprising manner by which old concepts sometimes return with new refinements, when I first wrote this chapter numerous articles in the medical literature refer to the "cross talk" between organs. We shall see some other furloughed ideas enjoy a revival within nephrology later in this chapter.

From a 21st century perspective, the patient described above had "CKD"—chronic kidney disease—and likely nephrotic syndrome. In Bright's day, most physicians came to call that malady comprising edema, albuminous urine, and a variety of symptoms Bright's disease (*morbus Brightii*, *maladie de Bright*), likely the first widely used medical eponym in the English language, and a term that endured roughly through the 1940s (with one revival, as will be seen). Richard Bright, working at Guy's Hospital in London during the era of clinical–pathological correlation, had shown that the urine of some patients with dropsy (edema or anasarca) was coagulable by heat (albuminuric) and that when such patients became available for autopsy, the kidneys showed one of several forms of alteration, particularly a "granular degeneration."

Bright published his discovery of proteinuric renal disease (and much else) in 1827 in the first volume of his magisterial *Reports of Medical Cases Selected with a View of Illustrating the Symptoms and Cure of Disease by a Reference to Morbid Anatomy*. This work included magnificent colored engravings and is a landmark in nephrology, pathology, and medical publishing. Richard Bright and Bright's disease represent the beginning of a modern understanding of diffuse, chronic renal disease. His fundamental findings linking edema, albuminuria, a set of symptoms, and structurally abnormal kidneys were soon confirmed by other workers such as Robert Christison (1797–1882) in Britain and Pierre Rayer (1793–1867) in France. Bright also came to recognize and describe virtually all elements of uremia including pallor, "lassitude," "hard pulse," vomiting, seizures, pericarditis, and cardiac hypertrophy.

Since, by purpose, the *Reports of Medical Cases* sought to correlate clinical findings in hospitalized patients with findings at necropsy, the renal cases are mostly of short duration, the outcomes necessarily fatal. The term Bright's disease long tagged the process of becoming ill through the kidneys. Perhaps owing to its

early association with the hospital and the dissection table, the disease maintained an ominous reputation in the popular mind as something close to a death sentence, a diagnosis that would extinguish all hope. ("CKD" is likely more obscure to patients than was "Bright's disease," though at least not as uniformly frightening.) Bright, however, came to recognize the more indolent, or chronic, picture, as seen in the dropsical bookbinder. In an article published in 1840, after much experience with renal disease, he offered the sound advice that "whatever remedy is given to overcome a disease so chronic and confirmed, must be administered with exemplary patience and perseverance."[1] That a diagnosis of Bright's disease could be compatible with decades of living was well understood by some later 19th century nephrological authors. British physician Lionel S. Beale in his popular treatise on renal disease assured his readers in 1870 that "with judicious management, a patient may live twenty or twenty-five years although afflicted with incurable renal disease."[2]

My aim is not a detailed exposition of scientific accomplishment, but rather an investigation of several themes. At times, nonetheless, the narrative will seem like a linear, almost inevitable, march toward the present—a type of story most distasteful to modern historians of science, who call its production *presentism*. A short account such as this recalls those individuals whose ideas survived, as it ignores the countless errors, fancies, and failed hypotheses—as well as possibly valid and useful practices which nonetheless sunk into the medical shadowland. The history of treatment of irreversible renal failure by dialysis or transplantation is not covered in this chapter in keeping with the overall intent of the volume. Once the patient has reached "end-stage renal disease," the failed kidneys themselves are no longer much under consideration, and are not being treated. A variety of historical accounts of dialysis and transplant, however, exist.[3–7]

For convenience, I will sometimes use the terms "nephrology" and "nephrologist" anachronistically—that is, before there was a defined specialty and before these words were even known.

PATHOLOGIES

In 1761, the Italian physician Giovanni Battista Morgagni (1682–1771) published his massive *De Sedibus, et causis morborum per anatomen indagatis libri quinque*, or, *On the Seat and Cause of Diseases Shown by Anatomy.* Into the later 18th and early 19th centuries, particularly in post-revolution Paris, but also in other cities of Europe, physicians fervently embraced clinical–pathological correlation as an objective method to study diseases. The object was to correlate patterns of findings in the ill person with localized structural abnormalities deep within the autopsied body. Classifications derived from morbid anatomy would replace nosographies based only on patients' symptoms.

Richard Bright, a major figure in this movement, added an early laboratory manifestation, albuminuria, to the complex. His initial 1827 publication, the *Reports of Medical Cases,* based on 24 cases, suggested three forms of deranged kidney structure, accompanying albuminuric dropsy. The first was a kind of softening with yellow mottling. The second form was one in which "the whole cortical part is converted into a granulated texture…" The third "is where the kidney is quite rough and scabrous to the touch externally, and is seen to rise in numerous projections not much exceeding a large pin's head … [and there is a] contraction of every part of the organ.…"[8] These three descriptions hold little meaning for the nephrologist of the 21st century, who rarely sees or touches a fresh diseased kidney. Bright allowed that the three forms might be only stages of one process, though he seemed to favor three categories. So from the first publication on the disorder, Bright's disease was not held to be one specific entity, not even by Bright.

Although not all subsequent physicians and pathologists would agree that Bright's disease was inflammatory in nature (as did Bright), the term "nephritis" entered use by 1840 for pathological classification, though the broad category of illness remained Bright's disease. The story of the superseding and competing classifications is far too complex to explore except in the broadest of strokes. The microscope came to supplant gross observation and the touching of the renal surface. The great pathologist and theorist Rudoph Virchow (1821–1902) in 1858 suggested "parenchymatous nephritis," "interstitial nephritis," and "amyloid degeneration." Briton George Johnson in 1873 proposed the separation of an acute form ("acute nephritis"), and three chronic varieties: "red granular kidney," "large white kidney" and "lardaceous kidney" (which is the same as amyloid kidney). William Osler (1849–1919) in his popular text *The Principles and Practice of Medicine* favored "acute Bright's disease," "chronic parenchymatous nephritis," and "chronic interstitial nephritis." Amyloid was dispatched to its own pathological category. Into the 20th century, the extremely influential monograph by Franz Volhard (1872–1950) and Theodor Fahr (1877–1945) published in 1914, *Die Brightsche Nierenkrankheit*, provided a fresh—but still trinitarian—organization: degenerative diseases, the "nephroses"; inflammatory diseases, the "nephritides"; and arteriosclerotic diseases, the "nephroscleroses."[9–12] Thomas Addis of Stanford University in the 1920s offered a modification of this last framework which gained some popularity: "hemorrhagic Bright's disease,"

"degenerative Bright's disease," and "arteriosclerotic Bright's disease."[13] It is likely significant that an arteriosclerotic category appeared in the early 20th century, probably an early reflection of our modern manner of becoming chronically ill (see below, "Causes"). Today, we find utility in thinking in terms of glomerular disease, tubulointerstitial disease, or vascular disease, but when appropriate seek a specific, causal diagnosis using biopsy or detection of marker molecules in blood or urine. Of interest here, *chronic* as applied to renal disease for a long time referred to the pathological appearance more than to a defined clinical course. Chronic in good part meant sclerosis or fibrosis. Now, a diagnosis of CKD emphasizes a uniform clinical picture and implies a disinterest in underlying structure. "CKD" repudiates pathology.

PHYSIOLOGIES

Into the 1830 and 1840s, Richard Bright assembled a team of colleagues and pupils at Guy's Hospital and its medical school to study albuminous kidney disease. For part of 1842, they were given two wards to use for their investigations, connected by what we would call a conference room and a small laboratory "fitted up and decorated entirely to our purpose." This arrangement, somewhat prefiguring the metabolic ward, was likely a first in Western medicine. Several of Bright's chemically adept colleagues were able to crudely measure urea retained in the blood of patients with diseased kidneys.[14,15] Physicians of this period of course understood the kidneys as excretory organs, the body's "filters" or "great depurators." One important waste discharged was urea, a nitrogenous product of ingestion of meats and other "proteid" foods. How the kidneys did this was unknown. In the same year that found Richard Bright and his colleagues collecting renal patients in two assigned wards of Guy's Hospital, a young William Bowman (1816–1892) published his paper "On the Structure and Use of the Malpighian Bodies of the Kidney" in which he deduced from the nephron's structure that the glomerulus creates filtrate (he did not use that word) which is then modified by the tubules.[16] Much debate for the next 80 years centered on the validity of filtration–reabsorption versus dominant secretion as the kidney's primary way of making urine.

Into the later 19th century, the center of gravity of medicine shifted from the deadhouses of France and England to the laboratories of Germany, where the experimental approach exemplified by Claude Bernard (1813–1878) and Virchow best took hold. In Germany, beginning in the 1870s, several physiologically minded physicians, most notably Ottomar Rosenbach (1851–1907), apparently fatigued with a half century of pathological classification, advanced a program known as "functional diagnosis." They pursued two objectives. One was to replace static classifications based on structure with a new exploration of what a diseased organ could, or could not, *do*—this information held to be more helpful in the clinic. The second, related notion, was to identify illness in a posited early functional phase, before the development of changes in an organ's fabric. Particularly, thought Rosenbach, "in chronic diseases it must above all be the object to recognize the disease in its very early stage, i.e., the incipient functional disorder."[17] The 21st-century physician likely finds this idea fanciful, even mystical—that some alteration in an organ's function precedes an identifiable change in its structure, especially if we reduce structure to the molecular level. But the belief persisted throughout the 19th century. Richard Bright thought it true of renal disease that a "functional derangement of the organ may sometimes precede the structural change for a period of many weeks and many months."[1]

The clinician-researchers who created functional diagnosis used the language of *work*. One German author wrote in 1903 that "one seeks to become acquainted with the organ when it is at work, and where one's chief desire is to learn whether this work is sufficient for the system or not."[18,19] An American physician's 1907 manual on kidney disease suggested "Nephritis clinically is a question of going beyond the limit of efficiency of the kidneys."[20] Very likely, this language and approach reflected the cultural environment of late 19th and early 20th century Europe and North America. Industrialization enlarged and spread as never before, and the machine (especially the steam engine) ruled. Not unexpectedly, the old idea of the body as machine gained new plausibility: one should analyze the physiological apparatus of an organ as one would measure the maximal work output of a machine. "Efficiency," applied to engines, and all else, became the byword of the Progressive Era, at least in the US.

Rosenbach and other German workers in functional diagnosis relied on the concept and phrase "insufficiency" (*insufficienz*), though it would acquire varying meanings. The method required challenging an organ to measure its "reserve"—a certain kind of test meal to the stomach, a period of brief intense exercise to stress the cardiac muscle, a urea load to assess the renal excretory work. "Relative insufficiency" existed if the organ could not fully call on its reserve (or "compensation") to deal with a challenge, whereas "absolute" or "complete insufficiency" denoted findings of inadequate function at baseline, such as nonprovoked retention of urea in the blood in the case of the kidney.[21] By 1934, the distinguished British authority on kidney disease Robert Platt (1900–1978) used the terms "renal

insufficiency" and "renal failure" to describe the two phases of impaired function.[22] Eventually, "chronic renal failure" ("CRF") came to somewhat loosely label any irreversible rise in blood creatinine concentration (or decrease in glomerular filtration rate (GFR)), even though patients with only small deviations from normal usually felt fine and did not consider themselves, nor their kidneys, to be failures, nor did their doctors, for the most part, though the seniors among us recall readily using the phrase. CRF endured until forcefully struck down by the nephrology discipline in 2000. Few nephrologists by then realized that the newly scorned nomenclature went back 100 years, to the forgotten movement called functional diagnosis.

During the era of functional diagnosis, reliance on creatinine measurement and even the confirmed reality of glomerular filtration were in the future. The kidney was probed as an excretory black box. The European workers saw its "work" as the excretion of concentrated solutes. The Hungarian physician Sandor (Alexander) von Koranyi (1866–1944) applied cryoscopy (measurement of osmolality by freezing point determination) and deemed a kidney "hyposthenuric"—literally "of low urine power"—if it did not adequately concentrate. Others assessed the kidney's ability to discharge urea, salt, or water after a defined load. A variety of investigators devised dye markers, whose excretory rate might aid in the functional diagnosis of renal disease. The most successful of these was the phenolsulfonphthalein excretion test of Leonard Rowntree and John T. Geraghty described in 1912, and mercifully shortened to "PSP" or "phthalein" once in regular use. The dye would be injected, then its appearance determined in timed urine collections. Delayed excretion indicated renal insufficiency. The PSP test was simple and remained in use into the 1950s, later in some areas.[23]

Into the first decade of the 20th century, renal function was tested, as described above, through some measurement of the urine. Urine was, after all, what the kidney made, and usually adequate amounts stood ready for use. Feasible techniques for measuring urea, or other solutes, in small samples of patients' blood did not exist before about 1910. In fact, drawing blood from a vein into a syringe rarely occurred. This changed quickly over the subsequent two decades with the invention of colorimetric techniques suitable for small samples by the Scandinavian Ivar Bang (1869–1918) and (more enduring) by Swedish-American Otto Folin (1867–1934), and the creation of gasometric assays by the American chemist Donald D. Van Slyke (1883–1971). These ingenious systems allowed fairly rapid measurement of urea, uric acid, creatinine concentrations, and acid–base parameters, and clearly aided the early growth of nephrology.

Once urea could be readily measured in urine and blood, early students of renal insufficiency such as the Frenchman Leon Ambard (1876–1962) and the Scots-born American Thomas Addis (1881–1949) learned that neither the simple measurement of retained urea in the blood, the urea concentration in the urine, nor even a day's total urea excretion seemed to reliably correlate with other indicators of the kidney's loss of excretory function or mass. They then tried to establish that some expression of urea excretion in relation to blood urea concentration might predict actual function. After much experimental trial, Ambard in 1910–1912 proposed a complex relationship among the concentrations of urea in blood (B) and urine (U) and the urinary flow rate or volume in a unit of time (V):

$$\text{Ambard's coefficient} = B^2/(UV\sqrt{V})$$

Thomas Addis (1881–1949) of Stanford University, one of the most comprehensive observers of renal disease at the bedside and in the laboratory, also in the 1910s set himself the same task—to find an expression of urea excretion that would answer the question "how can the extent of a renal lesion be measured in a living man?"[24,25] Through extensive and meticulous investigation, Addis and coworkers showed that under conditions of high urine flow, the ratio of the rate of urea excretion to the blood urea concentration (D/B as Addis called it in his 1928 Harvey Lecture, but more familiarly UV/B) correlates with functioning renal mass. Donald D. Van Slyke and coworkers at the Rockefeller Institute for Medical Research and its Hospital eventually arrived at a ratio essentially identical to Addis'. Supposedly, the term "clearance" arose in 1926, when Van Slyke, on a train to Baltimore where he was to lecture, hit on the "word definition": the ratio of urea in 1 h urine over the urea in 100 mL of blood really equals the volume of blood "cleared" of urea by the kidney in that unit of time.[26]

The 1920s saw an international outpouring of new findings and ideas in renal physiology and disease. In 1921, A. Newton Richards and colleagues in Philadelphia succeeded in micropuncturing the frog glomerulus and obtained results strongly supporting the filtration–reabsorption (Ludwig-Cushny) model of urine formation.[27] In 1926, the Danish physiologist Poul Brandt Rehberg (1895–1985) published his investigations nominating creatinine as a suitable "marker" for glomerular filtration, suggesting a value of between 100 and 200 mL/min for man.[28] Thomas Addis in the 1940s used creatinine clearance in his research and proposed a simple method for using serum creatinine concentration (S[Cr]) as an indicator of renal function in clinical work.[29] Probably not too many clinicians used Addis' fond method, which depended on picric acid and

naked-eye color matching, but by the 1950s creatinine (or its clearance) was beginning to replace urea in renal medicine. And so it has been ever since, with regression equations supplanting urine bottles. Chronic renal disease is defined as sustained elevated S[Cr].

The desire to understand the actual disorders of homeostasis caused by chronic renal disease invited more complex analysis than that seen with "functional diagnosis." Robert Platt and others recognized and worked to understand the remarkable adaptations which occur in the chronically diseased kidney (Figure 2.2). Such adaptations, he explained, until the most advanced phase of the disease, maintain normal blood concentrations of potassium, sodium, and phosphate and allow the daily excretion of these substances in amounts to match intake. Accounting for these "compensations" required, for the electrolytes, the concept of glomerular–tubular balance—the now familiar idea that in the face of diminished GFR, tubules adapt to reabsorb less sodium and phosphate and secrete more potassium. Platt described the essentials of these concepts in his Lumleian Lectures to the Royal College of Physicians of London in 1952.[30] Early in his lecture, he clearly stated that the "common structural basis" of "chronic renal failure" is "a diminution in the number of functioning nephrons," heralding a central and enduring principle.[30] (Of interest, many of the authors Platt cited were American. The post-World War II era saw the epicenter of medical research shift to the US, owing in good part to funding from the National Institutes of Health and major foundations, and postwar disruption in Germany.)

In 1960, Neal Bricker published his "exposition of the 'intact nephron hypothesis'," further advancing the notion that in chronic renal disease some nephrons are gone altogether (this is evident histologically), whereas remaining intact nephrons function normally, or adaptively.[31,32] Bricker in this paper tried to revive the term "chronic Bright's disease," because it "tends to group together a number of diseases of diverse etiology, differing pathogenesis and widely varying pathologic characteristics. A singular term implies the existence of a common denominator in these disease entities which supersedes their differences."[31,32] It is no anachronism to assert that Bricker's "chronic Bright's disease" is our "CKD." He added that "the more advanced the pathological process becomes, the less evident are the differentiating features."[31,32] This review from 1960 of course cited Platt, John Merrill,[33] and other experimental workers, as well as studies from his laboratory at Washington University in St. Louis.

In 1972, Bricker offered another "exposition," this time of the "trade-off hypothesis," based on studies of phosphate handling and parathyroid gland activity in "chronic progressive renal disease" or "the uremic state"[34] ("Bright's disease" was reconsigned to the past). The key notion, of course, was that an instrument of compensation for nephron loss—here the elevation of parathyroid hormone level to effect less reabsorption of phosphate—may come at a cost, in this case bone disease. Subsequent decades would see the various adaptations chased down to their oppressively complex molecular level—channels, signaling molecules, growth factors, and the genes for all of these. But the essential

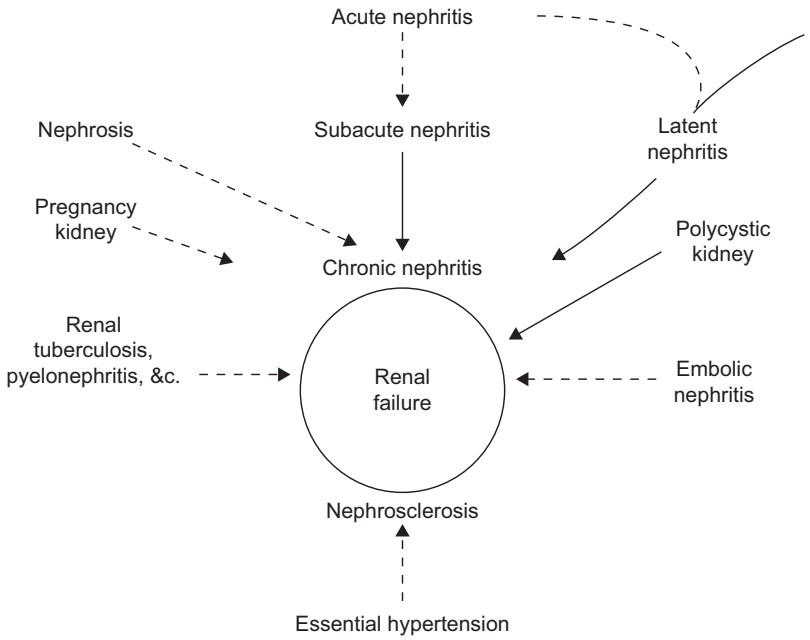

FIGURE 2.2 Robert Platt (1900–1978) was a leading 20th-century British authority on the kidney. Shown here is his concept of the etiology of chronic renal disease. Platt advanced the use of the terms "renal insufficiency" and "renal failure." Platt also was among the first to define the tubular adaptations to nephron loss. *From: Nephritis and allied diseases: their pathogeny and treatment (1934), diagram from p. 37. By permission of Oxford University Press.*

concept of a common set of adaptive physiological processes as the hallmark of the slowly failing kidney, regardless of cause, seemed well established by the early 1970s.

Alterations in tubular function allowed intact nephrons to adapt to overall loss of functioning renal mass. Both in this regard and in the study of normal physiology, academic nephrologists of the 1960 and 1970s mostly attended to the tubule. If you were not micropuncturing somewhere in a tubule to study transport, you weren't anybody. The tubule was the cognitive part of the nephron. Carl Ludwig, Arthur Cushny, and A.N. Richards handed down the concept of the glomerulus as a passive ultrafilter. But in 1982, nephrologist Barry Brenner, of Harvard Medical School and the Peter Bent Brigham Hospital in Boston, with his colleagues, published a review summarizing their micropuncture work in the rat glomerulus. Their proposal was that in chronic renal disease "remnant" glomeruli adapted by hyperfiltering to sustain GFR, but at the cost of further loss of nephrons from a sort of wear and tear injury.[35] The implications of this hypothesis will be discussed under "Treatments."

TABLE 2.1 From Bright's Disease to Chronic Kidney Disease

Repeated attacks of acute nephritis
Overindulgence in meat and canned foods
Intestinal indigestion
Overindulgence in alcohol, especially beer
Prolonged hypertension
Pregnancy
Loose kidney
Syphilis
Gout
Arteriosclerosis
Chronic lead poisoning
Long continued use of mercurial and certain drugs
Repeated exposure to severe cold

Selected causes of "chronic nephritis" from a representative manual of kidney disease from 1917, Oliver T. *Osborne's Disturbances of the Kidney* (Chicago: American Medical Association, 1917), p. 114.

CAUSES

Even if the pathophysiology of chronic renal disease varies little with underlying causation, etiology can matter. The correct diagnosis may critically guide treatment in early phases of some renal disorders—the approach to lupus nephropathy differs greatly from that for adult polycystic kidney disease, though both can go on to the chronic stage. General awareness of causes of kidney disease can suggest prevention: avoiding diabetes would mean fewer destroyed kidneys. Finally, both patients and doctors want to know "why did this happen?".

It has always been legitimate to ask if the cause of cholera is the *vibrio* microbe or a bad water supply, and similar questions. The meaning of causation has never been free of ambiguity and has grown more murky with increased reference to risk factors, genetic predisposition, and even, perhaps, probabilistic or Bayesian thinking. But from an earlier (and simpler?) time, a manual of kidney disease from 1917 included the causes of "chronic nephritis" shown in Table 2.1 (not all from that source are listed).[36]

Readers will tend to mentally rate these from the familiar, through the odd, to the bizarre. Obviously, ideas about causation change over time with shifts (or advances, if you like) in medical theory and practice. *Causes* necessarily come and go: radiocontrast nephropathy could not occur before the invention of radiocontrast. But factors beyond medicine can determine pathogenic causes, or at least the perception of causes. Richard Bright saw the causation of granular kidney this way: "An intemperate course of life, or some such cause, has predisposed the kidney to suffer. The patient has, in this state, been exposed to vicissitudes of temperature; the irritable kidney has immediately sympathized with the skin, and morbid action has been induced in that organ…"[37] Bright meant that excess alcohol ingestion sets the circumstances for renal injury, by way of the skin, when the miscreant endures exposure to *cold*, especially cold and wet. Such a chill would suppress the "insensible perspiration," whose flow early physicians deemed essential for health. Such suppression led, *via* "sympathy," to inflammation or congestion, or some sort of perturbation, in another organ such as the kidney. Hospitals in Bright's time looked after mainly the indigent and working poor—so Bright or his pupils readily obtained histories of drinking, and exposure to cold and damp (England, after all) on the way home from the gin house, or at outdoor labor. Arthur M. Fishberg (1898–1992) still took seriously the notion of cold as a cause of renal disease in his book *Hypertension and Nephritis* of 1930, even reviewing experimental findings that chilling the skin may indeed cause renal vasoconstriction. But soon this purported connection disappeared from books, though it persisted in the popular mind.[38]

The Philadelphia internist and author James Tyson (Figure 2.3) in 1881 held "habitual exposure to cold"

FIGURE 2.3 James Tyson (1841–1919), a professor of medicine at the University of Pennsylvania in Philadelphia, was author of *A Treatise on Bright's Disease and Diabetes*, published in 1881, with a second edition in 1904. This wood engraving from the first edition shows testing for proteinuria using acid precipitation. Tyson also published a widely used manual of urinalysis, a pamphlet on decapsulation as treatment of chronic Bright's disease, and an article on "cardiovascular-renal disease." *Author's collection.*

as a cause of chronic renal disease, but also *scarlatina.* That dropsy and Bright's disease could follow this ailment was clear in the early 19th century. This was, of course, poststreptococcal glomerulonephritis.[9] This cause could only enter the textbooks with the maturation of the germ theory (microbial understanding of disease) in the 1890s and beyond with the work of Louis Pasteur (1822–1895) and Robert Koch (1843–1910). Tyson also cited contemporary reports that malaria might cause renal disease and also listed gout and lead toxicity.

The very late 19th and early 20th centuries brought a novel etiologic possibility to chronic renal disease, which by 1900 in the US was the sixth leading cause of death.[39] William Osler in his *Principles and Practice of Medicine* of 1892 stated that a factor accounting for the prevalence of chronic Bright's disease among men in the US was "the intense worry and strain of business, combined as they often are, with habits of harried and over eating and a lack of proper exercise."[40] In a later edition (1909), he referred to these middle-aged men as the "victims of the strenuous life." A physician in Rochester, New York, Seelye W. Little (1867–1937) in his 1907 book on nephritis confidently identified the likely victim this way: "The ruddy, healthy looking man with a little too much abdominal fat, who is a good liver, who uses alcohol moderately but regularly, and who uses tobacco, is the type of man who in middle life or soon after suffers from certain forms of kidney disease." The cause of most chronic Bright's disease, Little continued, "is generally speaking and most often, simply civilization, especially with reference to food and drink."[20] Richard Bright in the early 1800s had associated renal dropsy with the lower-class working man or woman, the English charity patient too much given to the drinking of spirits, and subject in their daily labors to cold and wet. By the Gilded Age 1890s, chronic renal disease had risen to become a characteristic disorder of the affluent banker or industrialist, a mishap of capitalism at its other pole. As with many diseases, nephropathy, or at least ideas about it, arises within a social and economic framework.

Such a notion continues with diabetic nephropathy and the "epidemic" of diabetes and obesity of the late 20th and 21st centuries, clearly spreading around the developing world. Paul Kimmelstiel and Clifford Wilson described nodular glomerulosclerosis in eight persons with what would now be type 2 diabetes in a pathology, not clinical, journal, in 1936.[41] But even as late as the 1960 and 1970s, textbooks gave very little attention to diabetic renal disease—fewer pages than "hypokalemic nephropathy" in *Diseases of the Kidney* edited by Maurice Strauss and Louis G. Welt, one of the first multiauthor nephrology texts, published in 1963![42] Even the third edition from 1972 of the popular British title *Renal Disease* edited by Douglas Black contained only a few paragraphs on the subject.[43] With the increased availability of maintenance dialysis, at least in the US, by the 1970 and 1980s, it became clear that diabetes was a common substrate for renal failure, particularly when coexistent with hypertension in persons of African background. As with type 2 diabetes itself, diabetic renal disease seemed to be everywhere. Similarly, the number of journal articles dealing with diabetic nephropathy showed a sharp slope upward beginning in the 1980s, from 137 in 1979 to 722 by 2000.[44]

The grievously high prevalence of renal disease among some populations of African background found explanation in the revelatory discovery of variants for the apolipoprotein L1 gene that sharply raise susceptibility to nondiabetic nephropathies, especially focal segmental glomerulosclerosis.[45] An example of the interaction of genetic vulnerability and the social environment, but with the requirement of a microbe, is of course HIV-associated nephropathy. In large regions of Africa where poverty and endemic warfare hinder efforts at public health, partly preventable parasitic

diseases such as malaria and schistosomiasis account for much of the burden of renal disease.

The causes, understood broadly, of chronic renal disease, then, have come and gone with changing social and environmental conditions, the decline of old microbes but appearance of new ones, and, of course, refinement in medical thought and evolving ways of determining what is "evidence."

TREATMENTS AND PROGRESSION

By definition, chronic disease cannot be cured, so treatment of chronic renal disease has aimed at alleviating symptoms and avoiding further injury to the kidneys. Richard Bright saw exposure of the skin to cold as the inciting event for albuminuric renal disease, and in the 1830s recommended warm clothing and travel. Thereafter, seemingly so did every physician who wrote about Bright's disease for the next 80 or so years.

"On the subject of clothing," wrote Bright in 1836, "I have already said all that is necessary: let flannel be worn constantly, and every precaution be habitually adopted which may obviate the effects of whatever is calculated to chill the surface or check the perspiration."[1] Lionel Beale's text of 1870 insisted on "Shetland wool garments, socks, &c," and even specified a shop where such could be obtained year-round.[2] James Tyson in 1881 demanded "*woolen garments next to the skin*" (his italics).[9] Oliver Osborne in his manual of 1917 urged that "warm clothing be worn during the cold season."[36] And although recognizing that "the disease being, unfortunately, most apt to occur in those least able to submit to the absence from business," Bright had advised in his 1836 article that removal to "some decidedly southern abode…One of the more healthy of the West-India islands, as St. Vincent's, would probably be beneficial."[1] Bright admitted, however, that he so far had not encountered any patient who could actually *manage* this recommendation. Tyson, like Bright 50 years earlier, recommended "residence in a warm equable climate."[9] This seemed a favorite phrase, as presumably one author dutifully read (and copied from) his predecessors. Osler also liked "a warm equable climate" in the chapter on chronic Bright's disease in his 1909 edition, specifying Southern California.[11] Elwyn, as late as 1926, mentioned "a warm, dry, equable climate," though with minimal conviction.[21] Removal to a more salubrious place long had been advised for chronic diseases, particularly tuberculosis, but how many nephritic travelers ever found their "equable climate" remains unknown. For that matter, historians can know little about how well general doctors followed the experts' printed advice, or how diligently patients followed their doctors' prescriptions.

No doubt adhering to the plan proves most difficult for diet, which has been varyingly deemed an essential component of therapeutics since the time of Hippocrates. Virtually, all the authors referred to in this chapter, and many others who gave special attention to renal disease, recommended some restriction of meat. Broadly, they saw the main work of the kidney to be excreting nitrogenous waste, and thought it wise to rest the impaired organ. Many renal patients of the 19th and early 20th centuries endured periods of time on a milk regimen. French physiologist Fernand Widal (1862–1919) made clear the association of sodium with edema, so dropsical patients were told to limit salt and intake of water.

In the early decades of the 20th century, diet had become part of the technology of hospital medicine—hospital diet manuals of the 1930s could list as many as 50 diets for all manner of disorders and needs. In this context, Thomas Addis of Stanford (Figure 2.4), more than any other physician focusing on kidney disease, supported the low-protein diet with experimental work. As one example, he and his laboratory "group" (as he called his coworkers) showed that protein feeding induced hypertrophy in the rat remnant-kidney model, which he interpreted as a response to excess work. Addis came to believe that the need to excrete urea against an osmotic gradient constituted a major part of renal work, and that overworking remaining functioning nephrons would eventually destroy them. He

FIGURE 2.4 Thomas Addis (1881–1949) at Stanford University School of Medicine in the 1920–1940s studied chronic renal disease in the clinic and laboratory. He was among the first to recognize the progressive nature of chronic renal disease regardless of cause. Believing that remaining nephrons must suffer injury from an obligatory increased "work" in excreting urea, he designed and prescribed a low-protein diet. *Courtesy of the Stanford Medical History Center.*

prescribed amounts of protein precisely, to the gram, and with his wife, a dietician, did all that was possible to ensure compliance. Among those who succeeded was Linus Pauling, who became Addis' patient and friend when he developed nephrotic syndrome. Pauling's very capable wife, Ava Helen, learned quantitative dietetics as she assumed the responsibility for preparing meals. Pauling recovered completely, whether owing to his 14 years of protein restriction or to a spontaneous remission.[46–49]

The low-protein diet to slow the course of chronic renal disease did not fare well after Addis' death in 1949. But it was not discredited by any clinical trial; these did not exist at the time. Rather, a variety of incidental factors played a role.[47,48] With the 1950s came penicillin and other "wonder" drugs, the intensive care unit, and other new forms of medical technology. Dietary therapy came to seem archaic, and not very interesting. Thomas Addis published his findings and philosophy in an idiosyncratic (but in some ways delightful) book called *Glomerular Nephritis*,[25] at a time when the new and relevant appeared in journals. Addis, working in relative isolation at Stanford University College of Medicine (then in San Francisco), preferred his stable "group" of lab associates and volunteers, including his Chinese-American dieners. He did not raise up disciples. Ironically, the one major figure in nephrology who attributed his interest in the kidney to working with Tom Addis (as a senior student) was Belding Scribner, whose achievement was, of course, the creation of chronic dialysis. With the spread of maintenance dialysis, interest among practitioners centered on, and reward derived from treating patients when they reached the point of uremia, not so much on delaying this outcome. Meanwhile, nephrologists in American academia chose mainly to explore normal renal physiology, a preference readily catalyzed by funding from the National Institutes of Medicine.

Barry Brenner's experimental work showing hyperfiltration in remnant nephrons provided support for dietary interventions for patients with chronic renal disease. Supposing such hyperfiltration to cause further loss of nephrons, Brenner (who cited Thomas Addis) and colleagues coupled this concept with the established knowledge that GFR in mammals varies, to some extent, with protein ingestion. Brenner's group published their synthesis in the prestigious and widely read *New England Journal of Medicine* in 1982, and other researchers advanced compatible findings.[35] The low-protein diet reawakened. But confirming its effectiveness in slowing the progression of chronic renal disease proved elusive. The largest trial, the Modification of Diet in Renal Disease Study, produced equivocal results of sufficient complexity to sustain years of debate following the initial 1994 publication.[50] The availability of angiotensin-converting enzyme inhibitors in the 1990s stimulated a new model, and the benefit of "RAAS inhibition" to slow progression more easily gained acceptance following favorable trials. Along the way, hyperfiltration as culprit gave way to proteinuria (or albuminuria), as studies determined that protein passing through the glomerular sieve itself induces further damage. Protein restriction never vanished altogether, however, at least as a means for reducing symptoms in the patient with uremia.

The concept of "progression" merits further discussion. Physicians going back to Richard Bright understood that persons with renal disease could live and feel well for years or even decades, though eventually uremia (not a term used in Bright's era) would ensue. This was what is sometimes termed "tacit" knowledge: thinking that was not explicitly thought about, almost a given. Of course, there were exceptions, such as Thomas Addis. This changed in the late 1970 and 1980s, when "progression" became reified as something to be discussed, studied, written about, indexed, and taught. Brenner's 1982 paper, the full title of which was "Dietary Protein Intake and the Progressive Nature of Kidney Disease," no doubt played a role. In 1976, William Mitch and colleagues published data which supported the idea that a plot of 1/[creatinine], the reciprocal of S[Cr] and in effect a surrogate for GFR, declined linearly in any given patient with chronic renal disease.[51] Although their findings were challenged and the plot of 1/[creatinine] failed to win lasting use, "progression" had gained a credible scientific image in the form of a *slope*. Journal articles dealing with chronic renal disease containing the word "progression" in their title went from 1 in 1976 to 15 in 1983, then 30 or more by 1988. William Mitch edited a volume titled *The Progressive Nature of Renal Disease* which appeared in 1986.[52] Slowing progression became not only a fruitful subject for research but also a dominant objective of outpatient nephrology. By the mid-1980s, many nephrologists viewed the ceaseless march of patients into dialysis units with frustration, if not despair, and warmly embraced the optimistic notion that end stage might be deferred or even avoided.

Treatment to slow progression, more fully described in a later chapter, fits well into a practice known only to medicine of the last 50 years or so—the prescribing of many medicines for persons who feel well. This is, of course, exemplified by the treatment of hypertension, itself usually a component of management in chronic renal disease. Other medications such as phosphate binders, vitamin D analogues, and sodium bicarbonate have been added over the years to right abnormal laboratory values and (it is hoped) avoid complications, and to protect GFR.

Physicians caring for persons with renal disease have had to seek ways to deal with edema (dropsy), whether from nephrotic syndrome or eventual loss of GFR. The mainstays of traditional Western medicine, purgatives and emetics, probably *did* work for this need, if for little else, as their effect would be to eject salt and water from the body. The same would have been true for drugs considered sudorifics. Some of the plant agents used, or mercurial salts such as the popular preparation calomel (mercurous chloride), might have acted as saluretics. In the 19th century, some practitioners used a contrivance called the hot-air bath, a simple device to flow warm air onto the edematous patient. Clearly effective mercurial diuretics (mainly mercurhydrin) came into use, mainly for heart failure, in the 1920s, following an accidental discovery in 1919 by Alfred Vogl (1895–1973), while a medical student in Germany. He found that the injectable antisyphilitic Novasurol, a mercurial drug, induced a brisk diuresis. From work on sulfonamide carbonic anhydrase inhibitors came the first reliable oral diuretics, chlorothiazide, in 1958, and hydrochlorothiazide in 1959. These proved feeble, however, in the face of severe loss of GFR or intense renal sodium avidity. The first loop diuretic, furosemide, appeared in 1964, and soon won the market. Edema was never the same.[53,54]

CHRONIC KIDNEY DISEASE

Although certain interventions seemed able to delay the onset of terminal renal failure, nephrologists of the 21st century still regularly confronted persons presenting in emergency departments with end-stage disease, already in need of dialysis. Some never knew that they had kidney disease. More awareness and earlier detection seemed imperative. But the lay and professional leaders concerned with kidney disease realized that they first had to overcome a problem with "branding"—that is, among organs, the kidney suffered from poor name recognition and inattention. People contemplated their hearts and attended to their colons, but not their kidneys. A president of the American Society of Nephrology in his annual address at the 2002 meeting said:

> First, we have to market kidney disease better. The people who are interested in stroke, cardiovascular disease, and cancer have done a far more effective job than we have in delivering a message to the lay population and to practicing physicians than we have accomplished.[55]

Some thought that one obstacle to raising awareness of kidney disease was faulty language, particularly "chronic renal failure." Presumably, few persons knew what "renal" meant, and (this is my own speculation) "failure" seemed an unattractive term to the leadership of nephrology in the US. Americans do not like "failure." At the beginning of the "Executive Summary" of the important new set of guidelines for the detection and care of kidney disease from 2002, called the "K/DOQI" or Kidney/Dialysis Outcomes Quality Initiative, sponsored by the National Kidney Foundation, the reader sees this explanation:

> Why "kidney"? – The word "kidney" is of Middle English origin and is immediately understood by patients, their families, providers, health care professionals, and the lay public of native English speakers. On the other hand, "renal" and "nephrology," derived from Latin and Greek roots, respectively, commonly require interpretation and explanation. The Work Group [for these guidelines] and the NKF are committed to communicating in language that can be widely understood…"[56]

Thus, national leaders urged that the simple phrase "chronic kidney disease" shortened to "CKD" replaces "chronic renal failure" to label long-standing and usually progressive loss of kidney filtering capacity, regardless of underlying cause. To bring more order to nomenclature and to aid the development and use of practice guidelines, CKD was stratified into five stages based on GFR estimations from blood creatinine concentration values. "Staging" long had been used for cancer and heart disease. The demystification of language and the staging scheme rapidly won approval following the 2002 publications and presentations. "See-kay-dee" was instantly and everywhere on the lips of American nephrologists and particularly their fellows. Only careless old-timers would occasionally refer to "chronic renal failure." Understanding the merits of the new system and language, I (an old-timer) was still amazed at how quickly the new names and framework "took." Perhaps, hierarchy and authority play a greater role in the conduct of modern medicine and science than we like to think.

Levels of creatinine once deemed of no concern could now denote early-stage chronic renal disease. By extrapolation, eight million or more persons in the US in the early 2000s would have had a "disease" only recently looked on as relatively rare. In 2004, the Council of American Kidney Societies launched a "Chronic Kidney Disease Initiative" in part to further the detection of persons who would fit into an early stage based on blood creatinine concentration (albuminuria came to play a larger role in later revision of the stages).[57] Eventually, the concept spread internationally, including the genesis of a "World Kidney Day" in 2007.[58,59]

Despite the widespread acceptance of the new framework, at least in the US, the United Kingdom,

and Australia—or because of it—controversy and dissent arose. To what extent, it was fair to ask, were the new name and the CKD Initiative part of the identity politics of diseases, and indicative of a propensity for overmedicalization of society? As I worked on this chapter for the first edition, an "Analysis" article appeared in *BMJ* (formerly the *British Medical Journal*) within a "Too Much Medicine" series questioning the validity of diagnosing so many persons as renally diseased.[60] The authors hinted at the possibility of bias, given the pervasive ties between nephrology and its organizations, and the pharmaceutical industry. Those attending the planning workshop for the CKD Initiative had included nephrologists and nurses from private practice and medical schools, one patient, and (among others) representatives from the National Institutes of Health, a large health maintenance organization, Medicare, the dialysis industry, a national laboratory company, foundations, health policy institutes, and four pharmaceutical companies that helped fund the meeting. At least it cannot be denied that Bright's disease, under whatever new name, has come to dwell in an interlocking array of components making up the medical–industrial–governmental complex.

I have reintroduced the term Bright's disease at this point with a purpose. Earlier I suggested an analogy between "Bright's disease" and CKD. Both names referred, or refer, to generalized disease of the kidney, usually producing proteinuria and loss of excretory function, but without implying any cause or very specific pathological alteration. But they differ as well. Bright's disease existed in nature: persons had it and would swell up and eventually feel sick. A *specimen* could be identified, shown, and illustrated—the granulated kidney. Many physicians of Bright's era were skilled naturalists who gathered and classified specimens. Richard Bright particularly knew rocks; like his father, he was a thorough student of geology. Atlases of birds, plants, and minerals of the 18th and 19th centuries were probably the models for colored atlases of pathology, such as the *Reports of Medical Cases*. CKD, on the other hand, is a social construction within the enterprise of medicine and nephrology. It is not an illness born of nature, but rather a concept designed by a committee. Its purpose, as a name, is not to enable a sick person to know "what is my affliction?" but to categorize in a scientific and bureaucratic manner, and to enable the physician to more confidently prescribe a management which is not therapy. However valid might be the CKD concept and "Initiative," it is striking to consider that never before in the history of medicine has the measurement of one innocuous chemical in the blood effected the sudden creation of "disease" in millions of people.

And so it is not surprising, and historically fitting perhaps, that the revised KDIGO guidelines of 2012 gave more attention to proteinuria and some to the specimen—the changed kidney.[61,62] The work group, now notably international, saw albuminuria, investigated in the 1820s with spoon and candle, as having gained greater importance since 2002 not just as a marker of renal disease but also as a process whose inhibition could slow progression. As other "markers of kidney damage," the urine sediment, histologic findings, and "structural abnormalities detected by imaging" were highlighted within the "Criteria for Chronic Kidney Disease," though a GFR consistently less than 60 mL/min per 1.73 m^2 (GFR categories G3a-G5) still could alone qualify for CKD, and the fundamental framework for defining CKD and estimating prognosis remained largely a grid integrating eGFR and albuminuria. The 2012 revisions brought a stronger acknowledgment that cause can matter, though attention to etiology was perfunctory, acknowledging that once a person had an advanced degree of Bright's disease (or CKD!), cause mattered little, and virtually not at all once renal replacement therapy was needed. A qualification that a definition of CKD still based on abnormalities largely of function required "implications for health" likely arose from an acknowledgment that many persons, especially of older age, might have some degree of CKD, but no "D" in the traditional sense. A great deal of attention in the 2012 reworking—an immense deal of work of great value—still centered on GFR, estimating equations, and where cystatin fits in.

The historian of nephrology might hope that some of the regrounding in cause, sediment, morphology, and increased reliance on measurement of albuminuria, grew out of knowledge of the cumulative understanding of generalized kidney disease, but in fact Richard Bright turns up but once in the full report of the 2012 guideline published as a supplement to *Kidney International*, and that to a passing suggestion he made regarding the use of alkali in patients with albuminuric kidney disease. Thomas Addis shows up not at all. Still, though likely unintentionally, the modest concessions in the 2012 KDIGO guidelines did, however gently, draw the elusive disease/nondisease "CKD" back into the broadly understood and historically derived foundations of Western medical thought and practice which preceded the easy ability to measure markers in blood or urine. That is, disease is seated somewhere in a deranged organ (the "Paris Clinical School"); classification and knowing cause are important (nosology); and that always in front of us is not merely a GFR × albuminuria grid, but individuals worried about their health, or loss of it (Addis' book *Glomerulonephritis*). And so the author of this historical chapter hopes that the (probably few) users of this volume who stopped here first have found it a stimulating foundation for the timely coverage of science and practice which follows.

Note: Some of the ideas and content in this chapter appeared in my earlier publications on the history of renal disease, particularly my book *Dropsy, Dialysis, Transplant: A Short History of Failing Kidneys* (Baltimore: Johns Hopkins University Press, 2007).

CHAPTER

3

Classification of Chronic Kidney Disease—Historic Perspective: From Insufficiency and Failure to Chronic Kidney Disease

Joseph A. Vassalotti

Division of Nephrology, Department of Medicine, Icahn School of Medicine at Mount Sinai, and National Kidney Foundation, Inc., New York, NY, United States

Abstract

Chronic kidney disease (CKD) was introduced in 2002 as a set of clinical practice guidelines (CPGs) that defined the term, stratified it into stages on the basis of severity, and described its clinical course and complications. The result has been a paradigm shift which has not only transformed nephrology as a discipline but also affected the practice of medicine in general. A practical list of the most common risk factors to target for CKD testing includes diabetes, hypertension, family history of kidney failure, and age 60 years and older. The estimated GFR and urinary albumin:creatinine ratio guide detection, assess prognosis, and determine management. The majority of care for CKD patients will necessarily be delivered by primary care clinicians, as CKD is common, with a prevalence of approximately 10−15% of the population of industrialized nations. Nephrology referral is recommended for advanced CKD and is essential for preparation for renal replacement therapy and the delivery of optimal care during patients' transitions to kidney failure. Preliminary data support an impact of the CKD CPG, increasing clinical research and improving patient management. Health services research in the coming years will more clearly characterize the impact of the CKD CPG on patient outcomes.

INTRODUCTION

The treatment of end-stage renal disease (ESRD) with dialysis ultimately focused attention on the broader and more prevalent issue of chronic kidney disease (CKD). Started successfully by Willem Kolff in Kampen, the Netherlands, as an exploratory effort to sustain the life of acute kidney injury (AKI) patients in the years that followed World War II, dialysis then began to disseminate to other developed nations.[1] In the US, Shana Alexander's grim article in *Life* magazine in 1962, "They Decide Who Lives, Who Dies," described the medical miracle as well as the moral burden of a small committee that determined the allocation of scarce hemodialysis (HD) treatment slots.[2,3] Seattle's "life or death committee" was instructed to reject children and those over the age of 45 years for treatment.[2] The deliberations of this group of seven individuals regarding the selection of patients for treatment were chillingly arbitrary. By the mid-1960s, there were fewer than 800 Americans sustained by HD compared with 10,000 qualified patients.[1] This led the US government to commission a group chaired by the eminent renal physiologist Carl Gottschalk, charged with informing kidney failure treatment policy.[3] The 1967 report of the committee on CKD presciently used the term CKD for the first time.[4] "Prevention is obviously preferable to treatment of disease. Unfortunately, knowledge concerning the causes…is limited and this is an area in which an expanded research effort is required." The Gottschalk report recommended "a national treatment program aimed at providing chronic dialysis and/or transplantation for all of the American population for whom it is medically indicated."[4]

Dialysis and kidney transplantation evolved in the 1970s into a life-saving therapy for patients whose CKD had progressed to kidney failure.[3] For most of

Chronic Renal Disease, Second Edition

the three decades that followed, the problem of kidney disease came to be viewed in the context of ESRD. As a result, what guided the research agenda and preoccupied national health agencies were the complications, costs, and disparities in access to dialysis for ESRD patients, who comprised less than 0.1% of the population. As administrative data from national dialysis registries accrued in the 1980s, it became evident that the care of patients with ESRD should have started in advance of preparation for renal replacement therapy (RRT), before the patients sustained the ravaging consequences of progressive loss of kidney function. This new concern at the turn of the millennium prompted the initial efforts at the definition, classification, and evaluation of CKD.[5–7]

Little can be done to promote patient awareness of a condition if the clinicians who care for the patients cannot achieve consensus on nomenclature, definition, or classification. This problem of confusing terminology was perhaps best described by Hsu and Chertow who listed 23 designations (Table 3.1) used to describe CKD in the American Society of Nephrology 1998 and 1999 abstracts.[8] Interestingly, Gottschalk's influential health policy report was neglected by nephrologists, because CKD was not included in the designations. In addition to inconsistent terminology, these 23 names were associated with a variety of definitions of kidney disease.[8]

TABLE 3.1 Terms Used to Describe States of Reduced Glomerular Filtration Rate in 1998 and 1999 American Society of Nephrology Abstracts[8]

1. Chronic renal failure
2. Chronic renal insufficiency
3. Mild renal insufficiency
4. Moderate chronic renal insufficiency
5. Moderate or advanced renal insufficiency
6. Severe renal insufficiency
7. Renal dysfunction
8. Severe renal dysfunction
9. Decreased renal function
10. Pre-end-stage renal disease
11. Low clearance (predialysis) patients
12. Pre-uremic
13. Renal failure
14. Renal disease
15. Renal insufficiency
16. Predialysis
17. Mildly elevated serum creatinine (S[Cr])
18. Chronic renal failure patients not on dialysis
19. Pre-end-stage chronic renal failure
20. Pre-end-stage renal disease chronic renal failure
21. Mild renal failure
22. Chronic renal disease
23. Chronic renal failure requiring dialysis

DEFINITION AND CLASSIFICATION OF CKD

In 2002, the Kidney Disease Outcomes Quality Initiative (KDOQI) workgroup co-chaired by Andrew Levey and Josef Coresh published the first guideline for a working definition of CKD, independent of the cause of the disease, based on the presence of either kidney damage (proteinuria, abnormal kidney biopsy, or imaging studies) or a glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2 for more than 3 months.[5] This clinical practice guideline (CPG) also proposed a classification of CKD based on severity, determined by the level of kidney function calculated from the S[Cr] and expressed as the estimated GFR (eGFR). The KDOQI guideline proposed the classification of CKD into five stages. Stages 1 and 2 represent covert disease requiring the presence of kidney injury (proteinuria, abnormal biopsy, or imaging studies). Overt disease is present when the eGFR is less than 60 mL/min/1.73 m^2 and is categorized into stages 3 (eGFR 30–59 mL/min/1.73 m^2), 4 (eGFR 29–15 mL/min/1.73 m^2), and 5 (eGFR <15 mL/min/1.73 m^2). The conceptual model of CKD used in proposing this classification is shown in Figure 3.1.[9] The five stages of CKD do

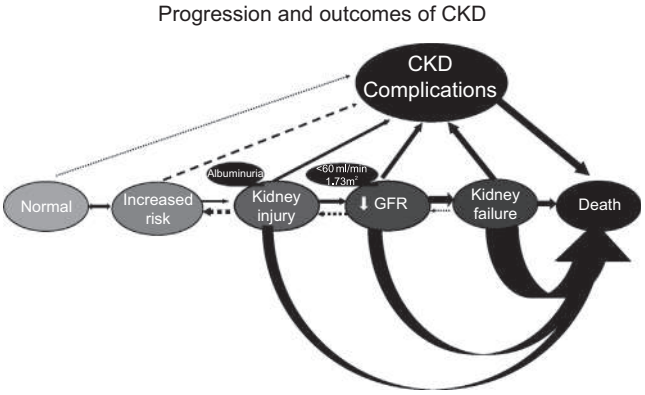

FIGURE 3.1 A conceptual model of the course, complications, and outcomes of chronic kidney disease (CKD). The ellipses represent the progressive stages and complications of CKD. The first two ellipses are antecedent stages representing cohorts at increased risk of developing CKD. The next two ellipses are flagged for the two hallmarks used in the definition and staging of CKD: albuminuria and a glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2. The increasing darker shading of the ellipses represents progressive worsening stages of the disease. The ellipse at the top indicates the complications of CKD (anemia, mineral and bone disorders, hypertension, hyperparathyroidism). The arrows at the bottom indicate the risk multiplier effect of CKD on the outcome of coexisting comorbidities, principally cardiovascular disease. The gradually increasing thickness of the arrows connecting the ellipses represent the increased risk of the complications and multiplier effect of CKD as the disease progresses from one stage to the next. The dotted arrows connecting the ellipses indicate the potential for improvement from one stage to its preceding stage, due to treatment or variable natural history of the primary kidney disease. *Modified from Reference 9 with permission.*

not appear in this figure. Rather, stages 1 and 2 are grouped together and implicitly represented in the ellipse labeled "kidney injury" and flagged for albuminuria. Stages 3 and 4 are in the ellipse labeled "decreased GFR" and flagged <60 mL/min/1.73 m^2. The KDOQI guidelines were a major step forward in nephrology as they provided a uniform definition of CKD that replaced the inchoate, ambiguous, and descriptive terms that had been used previously. The common terminology and standardized classification provided new tools whereby kidney disease could be studied and the results compared across different parts of the world.[5,7]

In defining CKD as kidney damage for at least 3 months, the guidelines set the stage for the identification of another form of kidney disease, the potentially reversible form of AKI of less than 3 months' duration that is now the subject of its own guidelines.[10] Familiarity with AKI is essential for the care of CKD patients who are at high risk for development of AKI. CKD patients with AKI sustain poor morbidity and mortality outcomes and undergo the additional loss of residual kidney function and accelerated progression to ESRD.[10–12]

Based on available evidence then, the KDOQI guidelines documented the increased number of systemic complications (cardiovascular disease [CVD], hypertension, metabolic acidosis, mineral and bone disorders, and anemia), morbidity and mortality associated with declining eGFR, and described the greater risk of death from CVD than from progression to kidney failure and ESRD. During the decade that followed, epidemiologic data have validated, refined, and provided convincing evidence that CKD is common, underdiagnosed, treatable, and a major public health problem worldwide. CKD is more common than had been appreciated until then. The estimated prevalence of CKD in the general population is 10–15% and increases in high-risk populations (diabetic, hypertensive, obese, seniors), racial and ethnic minority groups (Hispanic Americans, African Americans, Asians-Pacific Islanders, American Indians), and in those with specific genetic predisposition.[13,14] There is now convincing evidence that the presence and severity of CKD adversely affects the outcome of other prevalent chronic diseases, notably CVD, diabetes, hypertension, and obesity. The reciprocity of these major chronic diseases in their interaction with CKD can be viewed as an overlap phenomenon whereby the presence of CKD emerges as a risk multiplier of the morbidity and mortality of other major chronic diseases, with the magnitude of detrimental effect related to the severity of CKD. Hence, it is important not only to detect the presence of CKD in other chronic diseases but also to evaluate its severity and progression, to estimate the impact of CKD as a modifier of outcomes of the underlying comorbid illnesses.[13,14]

Awareness of CKD

The guideline was a first step to promote awareness of CKD. Diseases for patients and public are defined to some degree by their treatment. The lay perception of dialysis as encompassing the disease was prominent before 2002 and may persist to some degree to this day. Among the general public, knowledge of kidneys and what they do is uncommon. Additionally, national surveys in the US suggest that CKD awareness among affected patients is only approximately 10%.[14,15] Moreover, perceived susceptibility to CKD is also low, including among low-income Americans with hypertension. The wisdom of the unifying simple name, CKD, including both elements of kidney function and kidney damage, has withstood the test of time. The workgroup understood the importance of promoting public awareness by selecting the word "kidney" of Middle English origin as immediately understood by patients in contrast to other terms such as "renal" and "nephrology."[5]

Limitations of the CKD Definition and Classification

By any criteria, the paradigm shift created by the 2002 KDOQI guideline for the definition and classification of CKD is a milestone in the evolution of nephrology, but was not without its limitations. Despite the effort exerted on developing the evidence base of the proposed classification, it was necessarily limited by the meager information then available. The guideline transformed the disease from a concern of nephrologists to one of importance to all clinicians, public health professionals, and clinical researchers. This broadening concept of kidney disease was, and to some degree remains, uncomfortable for nephrology, a clinical specialty focused on advanced disease and RRT. Thus, criticism of the definition and classification of CKD came mostly from nephrologists. These concerns included overdiagnosis of CKD supported by implausibly high prevalence, inaccurate methodology for eGFR determination and urinary studies, definition and classification independent of etiology, and labeling normal loss of kidney function with aging as a disease.[16,17] This controversy was an important derivative of the initial effort that provided the stimulus for new research and the accrual of new information necessary for guideline refinement.

Methodological issues associated with the initial definition of CKD were addressed in the following years and to some extent resolved. S[Cr] assays were standardized using isotope dilution mass spectroscopy reference measurement, the equation to calculate eGFR refined, and clinical laboratories integrated the reporting of eGFR in their results worldwide. The new

CKD Epidemiology Collaboration (CKD-EPI) creatinine equation of 2009 has proved more reliable in predicting morbidity and mortality outcomes of CKD.[18,19] Recently, serum cystatin C levels, in addition to creatinine levels, have been integrated into the formulas used for the estimation of GFR. The standardization and reporting of urinary albumin level is under investigation and awaits refinement.[19]

Overdiagnosis of CKD remains especially controversial, particularly in seniors. The reduction in quality-adjusted life years associated with a false-positive CKD diagnosis was considered by one interesting study that used Monte Carlo microsimulations in the transitions between six conditions: normal, false-positive CKD, true-positive or detected CKD, undetected CKD, chronic kidney failure, and death.[20] This study used the 2002 classification into stages and the eGFR by the Modification of Diet in Renal Disease (MDRD) Study equation. The assessment of the cost-effectiveness of eGFR reporting vs. S[Cr] reporting alone by the authors depends on the accuracy of the model. The assumption of one outpatient nephrology consultation for all detected and false-positive CKD may not be realistic. Nevertheless, the potential negative consequences of a patient being labeled with CKD should be addressed through ongoing investigation.

Apart from data on epidemiology and outcomes of CKD, the new evidence has revealed a strong graded and consistent relationship between the severity of the two hallmarks of CKD: increased albuminuria and reduced eGFR.[21,22] As a result the Kidney Disease: Improving Global Outcomes (KDIGO) group released a new guideline in 2012 for the staging of CKD that integrates albuminuria as a determinant of severity of the disease.[23] The new guideline maintains the definition of CKD as abnormalities of kidney structure or function, present for greater than 3 months, with implications for health of the individual, and refines the classification of CKD based on cause, eGFR, and albuminuria categories (CGA). The classification of CKD by the level of eGFR and albuminuria (the GA of CGA) and their impact on prognosis is shown in Figure 3.2.[23] Cause (C) is based on the presence and absence of systemic diseases and the location of the renal lesion (glomerulus, tubule, vasculature, cystic, genetic). Although albuminuria is now included in the staging of CKD, the evaluation of the individual patient with CKD should include other abnormalities in urinalysis that may be equally important and affect outcome of CKD, especially hematuria.[24]

The importance of considering the cause (the C of CGA) of CKD, now part of the staging, is highlighted in the conceptual model of CKD (Figure 3.1).[9] The dotted arrows in the figure reflect the potential for reversibility at each stage of CKD. This improvement may be part of the natural course of the cause of the kidney disease, but improvement may also be the result of early detection and proper treatment of individual cases. Thus, a patient

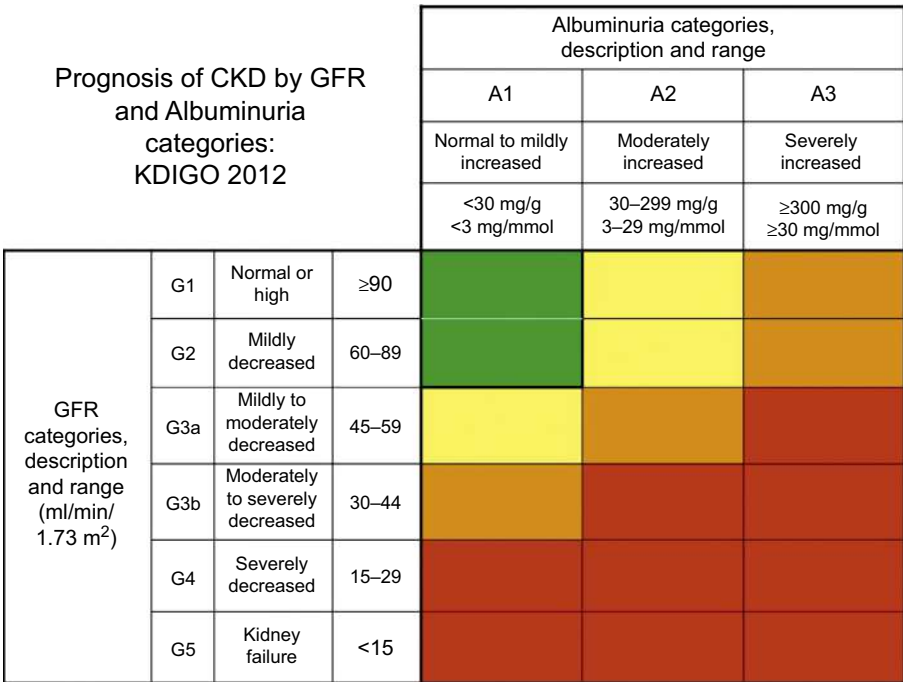

FIGURE 3.2 Staging and prognosis of chronic kidney disease (CKD) by glomerular filtration rate (GFR) and albuminuria. Green = low risk. If no other marker of kidney disease is present such as imaging or biopsy findings, then there is no CKD. Yellow = moderately increased risk. Orange = high risk. Red = very high risk. *Reproduced with permission from Reference 23.*

with severe hypertension and congestive heart failure, who presents with CKD and AKI requiring treatment with dialysis, can recover sufficient kidney function after control of the blood pressure and improvement of cardiac function to cease requiring dialysis, regressing to stage G3b or G4 CKD. The same argument can be made for all CKD patients whose kidney function is aggravated by poor management or that of the comorbid condition with which it overlaps, especially diabetes and hypertension. Improvement of kidney function with regression to an earlier stage is also achieved by proper therapy (for example, steroids, immunosuppression) in those with primary glomerular disease and the reduction of the magnitude of albuminuria with RAAS inhibitors. Finally, in those whose loss of kidney function progresses, it is essential to monitor and circumvent the complications of progressive CKD. The 2012 CKD CPG reemphasizes the importance of these complications, as well as the importance of their management and the need for early detection and intervention. The 2012 CKD CPG continues the trend of the original guidelines to shift the focus of care from exclusively nephrologists to primary care practitioners. A principal issue for clinicians is which population to test for CKD.

GENERAL POPULATION CKD SCREENING

There is insufficient evidence to support general population or mass screening for CKD, according to the US Preventive Services Task Force (USPSTF) and the American College of Physicians.[25,26] A fundamental cost-effectiveness study of CKD screening used a decision tree model to assess dipstick 1+proteinuria as the indication for therapy with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) in the general population.[27] The prevalence of CKD stages was based on National Health and Nutrition Examination Survey (NHANES) III, and transitions from each stage to ESRD or death were estimated based on the presence or absence of diabetes, hypertension, and proteinuria. Risks and costs of the screening included additional tests (such as ultrasound or kidney biopsy), physician visits, and adverse effects of interventions (ACEIs, ARBs, or kidney biopsies). The risk reductions for all-cause mortality and ESRD were conservatively estimated as 23% and 30%, respectively, based on previous publications. This widely cited US study concluded that mass screening for proteinuria was unfavorable and costs $282,818 per quality-adjusted-life-year (QALY), with an incremental cost of $616 and a gain of 0.0022 QALY per person.[27] The Centers for Disease Control and Prevention (CDC) CKD initiative built on some of the assumptions of this study, with a similar but more complex model, adding cardiovascular morbidity (angina, myocardial infarction, and stroke), and using the more sensitive albumin:creatinine ratio (ACR) $\geq$ 30 mg/g test as the indication for ACEI or ARB therapy.[28] The CDC study confirmed general population CKD screening is not cost-effective.

TARGETED SCREENING

Both CKD guidelines recommended targeted screening for CKD rather than mass screening. Clinical and sociodemographic factors for susceptibility to and initiation of CKD were described in the original 2002 KDOQI guidelines (Table 3.2).[5] The 2012 KDIGO CKD update recommends regular testing of high-risk groups—those with diabetes, hypertension, CVD, structural renal tract disease, multisystem diseases with potential kidney involvement such as systemic lupus erythematosus, a family history of kidney failure, hereditary kidney disease, the elderly, those receiving potentially nephrotoxic drugs or those opportunistically found to have hematuria or proteinuria. A practical list of the most common risk factors is diabetes, hypertension, age 60 years or older, CVD, family history of CKD, and those with racial and ethnic indications. In

TABLE 3.2 Potential Risk Factors for Susceptibility to and Initiation of Chronic Kidney Disease

Clinical Factors	Sociodemographic Factors
Diabetes	Older age
Hypertension	US ethnic minority status (African American, Hispanic, Asian or Pacific Islander, and American Indian)
Cardiovascular diseases	
Obesity	Exposure to certain chemical and environmental conditions
Autoimmune diseases	
Systemic infections	Low income/education

certain parts of the world, environmental exposures and nephrotoxins play a role. Herbal exposure or medicinal use results in aristolochic-acid nephropathy as a common regional cause of CKD in Asia and the Balkans.[29] Occupational heat exposure, water and solute loss in combination with nephrotoxin exposure is the leading hypothesis for the cause of Mesoamerican nephropathy.[30–32]

Targeted Screening: Diabetes, Hypertension, and Old Age

CKD risk conditions were assessed in a 1999–2004 NHANES population of over 15 thousand subjects with weighted logistic regression and a branching diagram for those under 60 years of age to evaluate eGFR <60 mL/min/1.73 m^2 and ACR >30 mg/g distribution.[33] The study revealed a prevalence of CKD of 39% for those aged over 60 years and older compared to 9.3% in those aged 20–59 years, supporting the importance of screening seniors. In individuals aged 20–59 years, CKD prevalence was greater for participants with diabetes (33.8%) than for those without diabetes (8.2%). Using hypertension in the decision tree detected CKD in more young participants with both diabetes and hypertension (43%) than for diabetic participants without hypertension (25.5%), while that of nondiabetic participants with hypertension yielded 15.2% vs. 6.8% for nondiabetics without hypertension. The CDC cost-effectiveness analysis also supported screening populations with diabetes and hypertension.[28] Hence, the recommendation is to target the population with diabetes, hypertension, and those 60 years and older for screening.

In a 1995–1997 cross-sectional survey of more than 65,000 Norwegian individuals assessed for risk factors and eGFR but not ACR, 3069 (4.7%) had an eGFR <60 mL/min/1.73 m^2, requiring 20.6 people (95% confidence interval (CI) 20.0–21.2) to be screened to identify one case.[34] Targeting diabetes, hypertension, and age greater than 55 years required screening 37.1% of the general population to detect 93.2% (95% CI 92.4%–94.0%) of individuals with CKD stages 3–5, with the number needed to screen 8.7 individuals (95% CI 8.5–9.0) to identify one case.[34] These conclusions of the Norwegian study are remarkably consistent with those of the NHANES analysis.

Targeted Screening: CVD

The interactions of CKD with CVD led the American Heart Association in collaboration with the National Kidney Foundation to recommend CKD screening of all patients with CVD.[35] However, in the NHANES study, the addition of CVD as a risk factor did not contribute significantly to the CKD screening yield of people with diabetes, hypertension, and age 60 and older.[33] In the Norwegian cross-sectional study, broadening the scope with CVD in addition to diabetes and hypertension increased identification of CKD from 44.2% to 57.5%. The alternative addition of age greater than 55 years improved the detection of CKD from 44.2% to 93.2%.[34] Thus, the prevalence of self-reported CVD in young individuals without diabetes and hypertension is probably too low (1.9% in the NHANES 1999–2004 population under age 60 years) to qualify CVD as an additional primary risk factor. Taken together, these studies suggest that if screening for CKD among the top three risk conditions (diabetes, hypertension, age 60 and older) is widely applied, screening of CVD patients without those conditions does not contribute significantly to the detection of kidney disease in the population.

Targeted Screening: Family History of CKD

Data on family history of CKD have not been collected in NHANES, and most of the available epidemiologic data derive from the subset of CKD patients treated with HD, making it difficult to assess the significance of this as a risk factor. Several regional US studies of ESRD patients have demonstrated a positive family history of ESRD as a significant risk factor for CKD, even after excluding etiologies with Mendelian inheritance.[36,37] Regional US ESRD data show that 22.8% (5901/25,883) of in-center HD patients report having a family history of ESRD.[37] There were positive associations for female gender, earlier age at ESRD onset, and a negative association with white race. Another study from this region showed that African Americans treated in HD units were 6 times more likely to have a family history of ESRD, yet they were less likely (37 vs. 50%) than individuals of other races to recognize the importance of family history as a CKD risk condition.[38] Although family history of CKD is clearly important in selected populations, it requires further study before it can be broadly adopted as a primary target group in screening for CKD.

Targeted Studies: Ethnic and Racial Minorities

Disparities in the prevalence of CKD affect African Americans, Hispanics, Asian-Pacific Islanders, and American Indians who experience a higher incidence of ESRD than whites. Although the reasons for these disparities are complex, the higher prevalence of type-2 diabetes and hypertension in these ethnic and racial groups are important contributors. Genetic factors may

also be contributors, particularly in African Americans in whom APOL-1 gene variants or gene−environment interactions play a role in susceptibility to CKD.[39] Therefore, targeting diabetes and hypertension in screening for CKD will substantially address the disparities observed in these vulnerable populations.

IDENTITY OF CKD IN PRIMARY CARE

There is little agreement among practitioners regarding a number of pivotal areas, including the definition of CKD (particularly for the elderly with eGFR of 45−60 mL/min/1.73 m^2 in the absence of albuminuria or stage G3a, A1),[16,17] the key elements of primary care management of stages 1−3 CKD, the indications for nephrology consultation,[40] and the scope of the respective roles and responsibilities of the primary care clinician and the specialist following consultation. In the absence of consensus in the therapeutic community, CKD has less of a clinical identity for detection and management than the longer-established chronic diseases such as diabetes and dyslipidemia. First, the distinction between making a diagnosis of CKD and needing to refer a patient to a nephrologist is underappreciated. Secondly, the majority of patients in a primary care practice will need to be managed without nephrology consultation. Lastly, one approach to defining the importance of detection and management of CKD in primary care is to focus on blood pressure control, diabetes management, and patient safety.

TABLE 3.3 Factors to Consider in the Implementation of Individualized Blood Pressure Targets in Chronic Kidney Disease Method of Blood Pressure Assessment (Office, Home, 24-hour Ambulatory)

Cardiovascular risk
Albuminuria
Age
Risk of adverse effects of low BP target (hemodynamic acute kidney injury, falls, syncope)
Orthostatic blood pressure (seniors, diabetic neuropathy)
Shared decision-making

Blood Pressure Control in CKD

Cardiovascular risk reduction is the major incremental benefit of the 2017 CPG recommendation for a lower blood pressure target of ≤130/80 mmHg,[41] based on SPRINT[42] and the standard glycemic arm of the ACCORD BP[43] trial results. Importantly, a target for each patient should be individualized with a suggested approach that incorporates the method of blood pressure measurement with cardiovascular benefit and side effects (Table 3.3). The SPRINT protocol included monthly visits during the titration phase to achieve the lower BP target, making more frequent visits at least initially a consideration for clinical implementation. Based on high level evidence, ACEIs or ARBs should be used for A3 level albuminuria and hypertension.[23,41] Figure 3.3[44] describes potential combinations for the first

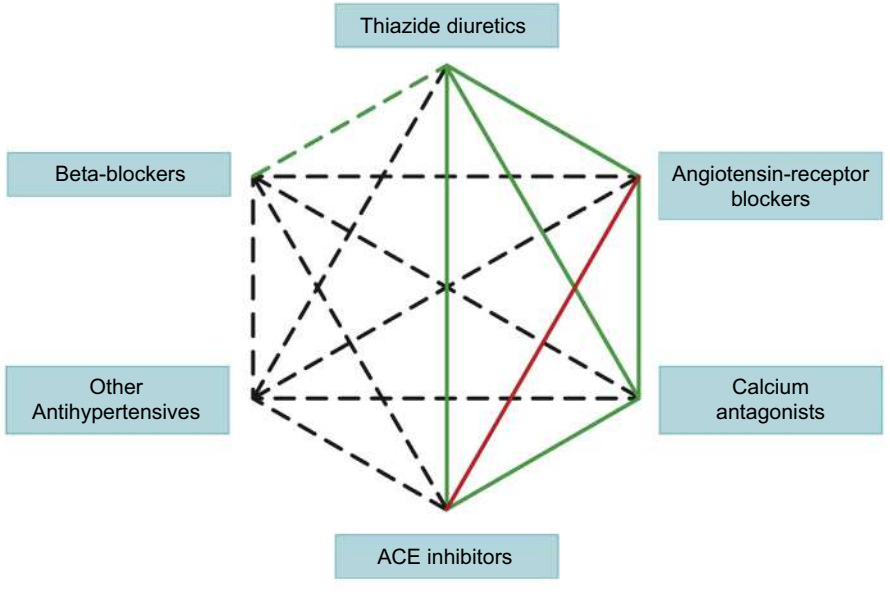

FIGURE 3.3 Possible combinations of classes of antihypertensive drugs. Green continuous lines: preferred combinations; green dashed line: useful combination (with some limitations); black dashed lines: possible but less well-tested combinations; red continuous line: not recommended combination. Dihydropyridine calcium antagonists should normally be combined with beta-blockers. *Reprinted with permission from Reference 44.*

three drugs, incorporating avoidance of dual ACEI and ARB therapy, based on safety signals for AKI and hyperkalemia in randomized trials. For resistant hypertension in CKD, mineralocorticiod receptor antagonists are recommended as fourth line drug therapy, based in part on the results of the PATHWAY-2 trial. The presence of obstructive sleep apnea and counseling regarding high dietary sodium intake as well as other lifestyle changes should be considered.[45] The achievement of an individualized BP target of less than 130/80 or 140/90 mm Hg could arguably be the single most important intervention to slow CKD progression and reduce both cardiovascular events and cardiovascular mortality.

Diabetes Management in CKD

Based on trial data, a hemoglobin A_{1c} (HbA_{1c}) target of approximately 7% is recommended in CKD, with a higher target for those with limited life expectancy, or an increased risk of developing hypoglycemia.[46] In addition to cardiovascular risk reduction, the benefits of glycemic control in CKD include reduced incident and progressive albuminuria and reduced loss of kidney function over time. Metformin is considered the first-line agent for type-2 diabetes but should be avoided at eGFR less than 30 mL/min/1.73 m^2, according to the FDA, because of the risk of development of lactic acidosis.[47] In addition, recent studies (EMPA-REG OUTCOME,[48] CANVAS Program,[49] and DECLARE[50] randomized trials) have demonstrated the antidiabetic drug class sodium-glucose co-transporter-2 (SGLT-2) inhibitors may play a unique role in the treatment of diabetes to slow loss of eGFR compared with placebo and reduce incidence and worsening of albuminuria. This drug class also has efficacy in reducing heart failure admissions, a complication that is enriched in populations with low levels of eGFR. Future investigations (CREDENCE & DAPA-CKD) and regulatory decisions are needed to address current FDA package inserts that restrict the use of these agents for lower levels of kidney function (eGFR <45 mL/min/1.73 m^2 for canagliflozin and empagliflozin and <60 mL/min/1.73 m^2 for dapagliflozin), and incorporate the risk of amputation and other side effects to more precisely define the population that will benefit. Lastly, the EMPA-Kidney study will test the efficacy of reducing CKD progression and cardiovascular mortality of empagliflozin in a randomized double-blind placebo-controlled trial of 5,000 people with CKD, with or without diabetes.[51]

Patient Safety in CKD

Patient safety hazards posed by CKD include drug prescription errors, contrast exposure, electrolyte disorders, inadequate CVD detection and management, and

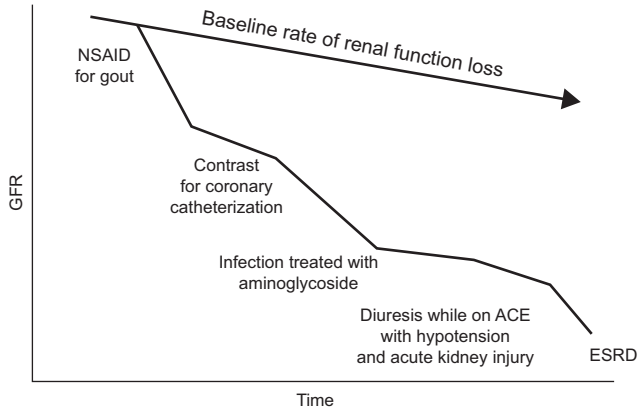

FIGURE 3.4 A theoretical patient with chronic kidney disease (CKD) is subject to several events that might be classified as preventable and related to patient safety. These events contribute to an accelerated rate of kidney function decay. Abbreviations: *ACE*, angiotensin-converting enzyme; *ESRD*, end-stage renal disease; *GFR*, glomerular filtration rate; *NSAID*, nonsteroidal antiinflammatory drug. *Reprinted with permission from Reference 52.*

therapeutic errors in managing effective arterial circulatory volume.[45,52–54] These hazards often result in hospitalization and AKI. Multiple insults leading to AKI are potentially preventable (Figure 3.4).[52] For example, arguably, intravenous therapy with either isotonic sodium chloride or sodium bicarbonate can reduce the risk of contrast-induced AKI in patients at risk, but acetylcysteine is of no benefit.[10,55] Medication dosing that considers the level of eGFR is the most actionable patient safety hazard, as many drugs are cleared by the kidneys.[23,52] Medications that require caution in prescribing include antihypertensive agents, analgesics (NSAIDs and opioids), antimicrobials, hypoglycemics, dyslipidemia therapy (statins and fibrates), chemotherapeutic agents (for example, cisplatin, melphelan, and methotrexate), anticoagulants (direct oral anticoagulants, low-molecular weight heparins, oral thrombin inhibitors, oral Factor Xa inhibitors, and warfarin), and others.[23,56] Vascular injury that limits options for subsequent HD access frequently occurs in the course of hospitalization of CKD patients and should be avoided.[57] Patient safety is a particularly important consideration in the elderly with CKD in whom comorbidities, frailty, and personal preferences may make conservative management a reasonable approach.

CLINICAL RESEARCH

Assessing the impact of the CKD guideline on clinical research is difficult to quantify, but a few of many potential examples follow. PubMed citations for the acronym CKD between 2001 and 2018, a crude surrogate marker of influence, have grown dramatically from 9 to 3,461,

respectively. Impressive progress has been made in what is perhaps the largest clinical research collaboration ever in nephrology, the CKD Prognosis Consortium.[21,22,58] International diagnosis codes incorporated the definition and classification of CKD into stages (585.X & N18.X), by the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM and ICD-10-CM),[59] presenting new opportunities for clinical research. Health services research can assess the impact of eGFR reporting and detection of CKD on care and outcomes.

Estimated GFR Reporting

Adoption of eGFR reporting worldwide resulted in an immediate form of clinician education regarding kidney function following every S[Cr] test, which in some cases included CKD guideline content. However, the impact of the CKD CPG is still in early phases of assessment. Clinical decision support is the implementation method of the future to bridge the gap between the evidence synthesized by CPGs and patient care delivered through the electronic health record in a cyclical process.[60]

Kagoma and colleagues evaluated the implementation of one of the key recommendations of the first CKD guideline[61]: to assess kidney function with eGFR in routine clinical practice, reserving 24-hour urine creatinine clearance collections for confirmatory testing.[5] The monthly prevalence of 24-hour urine collections in an adult population of more than 8 million patients in the province of Ontario, Canada, from 1999 to 2009 was used to investigate the impact of two major interventions: the CPG publication in February 2002 and the introduction of eGFR reporting in all outpatient laboratories in January 2006. The authors assumed a 3-month lag period following each of these events to assess variation based on previous publications.[62,63] Each eGFR value, based on the MDRD Study equation, was accompanied by one of five corresponding prompts relating the level of kidney function to CKD. For example, results between 30 and 60 mL/min/1.73 m^2 were followed by "consistent with moderate chronic kidney disease if result confirmed by repeat assessment, with persistence for 3 months or more."[61] This form of clinical decision support assists interpretation with direct incorporation into the clinical workflow for each laboratory result. The results from Canada's most highly populated province showed no significant change following the publication of the KDOQI CKD guideline, but a 23.5% reduction in 24-hour urine collections after eGFR reporting with prompts, from 44.6 to 34.1 per 100,000 population, which remained significant after adjustment for sex and age ($p < 0.0001$). The obvious benefits are improved patient convenience and increased accuracy of kidney function assessment for clinical practice, using eGFR rather than creatinine clearance. The estimated cost benefit was small, $5651 per month in reduced laboratory fees for 24-hour urine testing, based on a per-test cost of $10.35. The inability to distinguish the impact of eGFR reporting from the impact of the prompt is worth noting. An ongoing area of investigation is the assessment of the cost-effectiveness of CKD interventions using simulation models, observational data, and clinical trials.

Detection of CKD

Rather than assess the risks and benefits of screening, the important health services research question is whether or not primary care detection of CKD affects outcomes. There will never be a randomized trial of CKD screening, because withholding screening from a control population is neither feasible nor ethical. Preliminary regional data demonstrate that patients who have laboratory evidence of CKD that is detected by their primary care clinician are more likely to have evidence-based care (avoidance of unsafe medications, use of ACEIs or ARBs when indicated, and appropriate referral for nephrology) than individuals who have undiagnosed CKD.[64] An outpatient study by Wyatt et al. from the US Veterans Affairs Medical Center revealed small but significant improvements in CKD detection using administrative data collection for diagnosis codes before and after reporting (14.6–21.5%).[65] Although the comparison between detected and undetected CKD did not influence the achievement of target blood pressure (32.9–34.4%), the use of the appropriate CKD diagnostic code was significantly associated with urinary protein testing (39.8%–54.2%) and use of ACEIs or ARBs.[65]

Drug Prescription Practice and Patient Safety

Three of four studies demonstrated small but statistically significant increases in ACEI or ARB use following eGFR reporting.[63,65,66] The authors of the negative study speculated high baseline rates of these drugs might be a possible explanation for lack of differences.[63] A systematic review of drug prescribing practices that considered the level of kidney function using clinical decision support showed promise overall, with the limitation of heterogeneous design across studies.[67] A UK population study showed over 4000 fewer NSAID prescriptions following eGFR reporting (adjusted odds ratio 0.78). Furthermore, follow-up data confirmed that the 1511 individuals with eGFR <60 mL/min/1.73 m^2 experienced significant improvement in kidney function following withdrawal of NSAIDs.[68]

Nephrology Consultation

In the US, in 2016, late referral for nephrology services remains surprisingly common, as 35.4% of incident dialysis patients had little or no prior nephrology care before initiating dialysis, and only 36.8% received care from a nephrologist for at least 12 months before the start of RRT.[69] The effects of eGFR reporting on nephrology consultation may not be the best metric at this juncture in the absence of consensus,[40] despite comprehensive CPG recommendations (Table 3.4).[23] A recent systematic review of the impact of eGFR reporting with and without clinical decision support demonstrated an overall increase in nephrology consultations in the range of 13%–270% from 13 of 16 studies.[66] Most studies also showed a change in the distribution of patients, including more elderly and women, as would be expected on the basis of the variables of the eGFR equation. In the publications that provided data, there was a trend for a decrease in stages 1 and 2 consultations with increases in referrals in stages 3 to 5.[66] Studies were heterogeneous with regard to the predefined use of appropriate nephrology consultation indications. One study used discharge from nephrology care within one year of consultation as the definition of an inappropriate use of resources.[66] Two studies evaluated changes in the timing of referral relative to the onset of ESRD following reporting, but the assessment was complicated by the use of significantly different definitions of early and late consultation.[66]

These preliminary studies are encouraging regarding an overall trend for a benefit of detection of CKD and eGFR reporting following the guideline publication. Additional data are needed on the impact of eGFR reporting and CKD diagnosis on patient and public awareness of CKD and its risk factors and outcomes.[70] Evaluation of the impact of reporting will be essential for the refinement of methods of estimating GFR, such as the CKD-EPI creatinine equation, CKD-EPI cystatin C equation, and the CKD-EPI creatinine+cystatin C equation. Patient safety will be important to investigate further, but the metrics will need to be more precisely defined. What the impact of eGFR reporting is on the timing of dialysis initiation remains to be determined. Will there be an influence of reporting when enough time has elapsed to accrue adequate hard endpoints for cardiovascular events, onset of ESRD, and mortality? Future studies of eGFR reporting should further explore the impact of clinical decision support based on the level of kidney function.

TABLE 3.4 Recommended Referral to Specialist Kidney Care for People With Chronic Kidney Disease (CKD) in the Following Circumstances (Kidney Disease: Improving Global Outcomes Guideline Statement 5.1.1)

Acute kidney injury or abrupt sustained fall in glomerular filtration rate (GFR)
GFR <30 mL/min/1.73 m^2
Persistent albuminuria (albumin:creatinine ratio >300 mg/g)
Rapid progression is defined as a sustained decline in estimated GFR of more than 5 mL/min/1.73 m^2 per year (for other definitions of progressive CKD see guideline statement 2.1.3)
Urinary red cell casts, RBC >20 per HPF
CKD and hypertension refractory to treatment with 4 or more antihypertensive agents
Persistent abnormalities of serum potassium (S[K])
Recurrent or extensive nephrolithiasis
Hereditary kidney disease

CONCLUSION

The 2002 CKD guideline expanded the scope of kidney disease from a nephrology focus on advanced disease to additionally encompass earlier detection and management for primary clinicians. The first CKD CPG inspired clinical research activities and transformed the public health agenda. The 2012 evaluation and management of CKD guideline maintained the 2002 definition and further refined the classification. Preliminary data suggest benefits of eGFR reporting and detection of CKD by clinicians. Future studies will determine the importance of the guideline refinement on patient outcomes, particularly regarding albuminuria. The clinical case for the importance of CKD classification and terminology on outcomes is presented, but a financial case for return on investment of CKD interventions will be required to convince health system decision-makers to broadly implement CKD quality improvement and population health interventions.

QUESTIONS AND ANSWERS

Question 1

All of the following patients should have random or spot ACR testing at least annually, except?

A. 68-year-old woman with type-2 diabetes onset in 2010
B. 50-year-old man with uncomplicated essential hypertension since 2000
C. 52-year-old man with hypothyroidism and asthma
D. 65-year-old man whose mother required dialysis treatment at age 60
E. 70-year-old woman with osteoarthritis after cardiac catheterization revealing two-vessel coronary artery disease

Answer: C

Diabetes, hypertension, and age 60 years and older are the target conditions to test for CKD.[23,27,28,56]

Question 2

A 58-year-old man presents for initial outpatient visit. He has a long history of hypertension, but has not seen a physician in several years. He no longer takes any medication. On physical examination, BP 152/90 mm Hg, pulse 72 bpm. Physical examination is normal including cardiac lungs and absent peripheral edema. S[Cr] is 1.40 mg/dL. What is the best test for assessment of his kidney function?

A. S[Cr]
B. Cockcroft-Gault eGFR
C. CKD-EPI eGFR
D. 24-hour urine collection
E. Serum cystatin C

Answer: C

The CKD-EPI eGFR is the most accurate and least biased widely available assessment of kidney function for routine clinical practice.[23]

Question 3

A 55-year-old African-American woman with type-2 diabetes for 10 years presents for ambulatory care with BP 150/88 mm Hg, pulse 78 bpm, and body mass index 35 m^2. Physical examination reveals microaneurysms of the retina on fundoscopic examination, normal heart and lungs, obesity, +1 pedal edema, and decreased ankle reflexes.

Laboratory data:

S[K] 4.0 mEq/L
Total carbon dioxide 16 mEq/L
S[Cr] 2.75 mg/dL, CKD-EPI eGFR 22 mL/min/1.73 m^2
Hemoglobin 11.2 g/dL
Hemoglobin A1c 7.6%
ACR 450 mg/g

These test results are confirmed with repeat testing over a 4-month period. Current therapy includes labetalol 100 mg twice daily and metformin 500 mg twice daily. All of the following apply to this patient, except?

A. The patient has C = diabetic nephropathy, G4, A3 using the CGA staging of CKD
B. The patient should be referred for nephrology consultation
C. An ACE inhibitor or ARB should be added to the hypertension regime with S[K] and eGFR monitoring
D. Sodium bicarbonate 650 mg therapy should be initiated
E. Erythropoetin alpha 20,000 units subcutaneously weekly should be initiated

Answer: E

ESA therapy is only recommended after an initial investigation of anemia. In addition, the hemoglobin at which ESA should be initiated is less than 10 g/dL. See Reference 49. All the other answers apply to the patient.[23]

Question 4

For the patient described in Question 3, a patient safety approach to medication management that considers the level of kidney function includes all of the following, except?

A. Avoidance of nonsteroidal antiinflammatory drugs for analgesia
B. Discontinuation of metformin
C. Intravenous sodium chloride to reduce the risk of AKI following iodinated contrast media exposure for acute coronary syndrome
D. Avoidance of aspirin 81 mg daily for cardiovascular prophylaxis
E. Avoidance of sodium phosphate bowel preparations for routine colonoscopy surveillance

Answer: D

The correct answer is D. Routine daily aspirin prophylaxis for cardiovascular disease is not contraindicated in CKD. Nonsteroidal antiinflammatory (ibuprofen, naproxen) use should generally be avoided as it is a cause of AKI in CKD, especially when combined with diuretics or RAAS blockers (Answer A). Metformin risk of lactic acidosis contraindicates its use when the eGFR is less than 30 mL/min/1.73 m^2 (Answer B). For patients with eGFR between 30 to 60 mL/min/1.73 m^2, this biguanine should be used with caution. Intravenous sodium chloride administration is currently controversial

as a therapeutic maneuver in CKD patients receiving intravenous contrast (Answer C). Other considerations to reduce the risk of contrast-induced AKI include avoidance of high osmolar agents, use of the lowest possible contrast dose, and withdrawal of diuretics before and after the procedure. Sodium phosphate oral bowel preparations should be avoided, because these are associated with acute phosphate nephropathy in CKD and in diabetic patients with normal kidney function treated with RAAS blockers (Answer E). See References 23,52 and 56.

Question 5

All of the following adult patients with laboratory data and characteristics below should be referred for nephrology consultation, except?

A. Initial visit: eGFR 26 and 3 month visit: eGFR 28 (mL/min/1.73 m^2)
B. Initial visit: eGFR 55 and 3 months later eGFR 43 (mL/min/1.73 m^2)
C. Initial visit: ACR 450 and 3 months later: ACR 355 (mg/g) on both dates the eGFR >60 mL/min/1.73 m^2
D. Initial visit: eGFR >60 and 3 months later: eGFR >60 (mL/min/1.73 m^2) with personal history of autosomal dominant polycystic kidney disease
E. Initial visit: eGFR 42 and 3 months later: eGFR 44 (mL/min/1.73 m^2)

Answer: E

The correct answer is E. This patient has G3b CKD with no indication for nephrology referral. Answer B is incorrect as the eGFR trend reflects rapid progression of CKD, which is defined as a sustained decline of more than 5 mL/min/1.73 m^2 per year. Answers A and C are incorrect with low eGFR and severe albuminuria as indications for nephrology referral, respectively. Answer D is incorrect as a hereditary cause of CKD.

See Table 3.3 and Reference 23.

Question 6

Observational studies of early as compared with late nephrology referral have demonstrated which of the following?

A. Reduced 1-year mortality (11 vs. 29%, p value 0.028)
B. Reduced mean hospital days (13.5 vs. 25.3 days, p 0.0007)
C. Higher serum albumin at the initiation of dialysis or kidney transplantation (3.62 vs. 3.40 g/dL, p 0.0001)
D. Higher hematocrit at the initiation of dialysis or kidney transplantation (30.54 vs. 29.71%, p 0.013)
E. All of the above.

Answer: E

All of the above are associated with early as compared with late nephrology referral.[23]

Abstract

Glomerular filtration rate (GFR) is used to characterize kidney function. Its underlying determinants, nephron number and single nephron GFR, better characterize kidney function but are not easy to measure in patients. Using GFR to characterize chronic kidney disease (CKD) requires an understanding of its physiological variation, as well as its decline with healthy aging. The measurement of GFR is based on the urinary or plasma clearance of an ideal or near ideal exogenous marker such as inulin, iohexol, or iothalamate. This requires infrastructure, expense, and patient burden that are not feasible in most clinical settings. Endogenous circulating markers cleared primarily by glomerular filtration, particularly creatinine, are more practical and useful to detect level and loss of kidney function. Estimated GFR can improve the interpretation and application of endogenous markers of GFR. However, estimated GFR still reflects the biology of the underlying markers, which may be unrelated to kidney structure and function. There is not one GFR estimating equation that accurately estimates GFR in all clinical settings, optimally predicts CKD outcomes, and performs the same as measured GFR in its association with CKD risk factors and outcomes.

KIDNEY FUNCTION

The kidneys are essential to maintain homeostasis in the body. Kidneys have two main roles: eliminating catabolic-induced wastes and regulating the water-sodium equilibrium. In addition, the kidney has several endocrine roles, including erythropoiesis and maintenance of phosphorus–calcium balance. Other functions of the kidney include tubular reabsorption of nutrients and proteins, tubular secretion of metabolic wastes, and prevention of crystallization and stone formation in supersaturated urine. However, the term "kidney function" is often used to describe the glomerular filtration rate (GFR) alone because it is perceived to be the best global marker of kidney function. Chronic kidney disease (CKD) has primarily been defined and classified using GFR to define kidney function.

Glomerular Filtration Rate

The concept of GFR is best understood by first explaining the concept renal clearance.[1,2] The renal clearance of a plasma solute is defined as the volume of plasma cleared of this solute by the kidneys per unit time. Clearances are thus flow rates (mL/min). A solute marker with the following characteristics can be considered ideal for measurement of GFR: soluble in the plasma (not bound to protein), metabolically inert, freely filtered through the glomerular filtration barrier, neither secreted nor reabsorbed by the tubules, and only excreted by glomerular filtration.[2] Lower GFR is associated with metabolic complications of CKD (many of which reflect other functions of the kidney).[3] Lower GFR is also a risk factor for cardiovascular morbidity and mortality.[4,5] Clinical practice guidelines have used GFR (along with albuminuria) to define and stage CKD. In particular, CKD has been defined by a GFR less than 60 mL/min/1.73 m^2 (Table 4.1) with a normal GFR defined as 90 mL/min/1.73 m^2 or higher.[7]

Normal GFR levels have been thoroughly studied in healthy young adults. Homer W. Smith found a mean measured GFR of 127 mL/min/1.73 m^2 and 118 mL/min/1.73 m^2 for men and women, respectively.[8] Laurence G. Wesson found the values were 130 mL/min/1.73 m^2 and 120 mL/min/1.73 m^2 for men and women, respectively.[9] More contemporary studies have found somewhat lower mean GFR values in healthy young adults, i.e. around 100–110 mL/min/1.73 m^2.[10–14] Smith and Wesson observed a significant difference according to gender.[8,9] However, gender

TABLE 4.1 GFR Categories for CKD Classification According to the KDIGO Guidelines[6]

Term	GFR Category	GFR (mL/min/1.73 m^2)
Normal or high	G1	90 and higher
Mildly decreased	G2	60–89
Mildly to moderately decreased	G3a	45–59
Moderately to severely decreased	G3b	30–44
Severely decreased	G4	15–29
Kidney failure	G5	<15

CKD, chronic kidney disease; *GFR*, glomerular filtration rate.
In the absence of evidence of kidney damage, neither GFR category G1 nor G2 fulfill the criteria for CKD.

differences have been very small or not observed in more contemporary studies.[10–12] Normal GFR values do not significantly differ between healthy whites and African Americans.[11]

Physiological Variation in GFR

As with any physiological characteristic, distinguishing normal physiological variation in GFR from pathological disease states is critical.[15] There can be both between-individual and within-individual variations influenced by genetic and environmental factors, as well as variation due to assay error. Several studies have shown GFR variations of up to 10 mL/min following changes in dietary protein or sodium intake.[16,17] A small impact of exercise on GFR is also evident.[17,18] Diurnal variability with GFR in healthy subjects has also been described. Sirota et al. found lower GFR at night compared to the day.[19] Koopman et al. also found nocturnal variation in GFR.[20] The day-to-day variability of GFR (reflecting physiological variation and assay error) has been estimated to be between 4 and 10% in healthy subjects, and 5 and 15% in CKD patients, depending on the method used to measure GFR.[21–23]

Nephron Number and Single Nephron GFR

The underlying determinants of GFR are nephron number (number of nonsclerosed functioning glomeruli) and mean single nephron GFR. Factors that influence variation in nephron number and single nephron GFR have been studied in healthy adults (Table 4.2).[6] Some factors, such as age, associate with lower nephron number, but do not associate with single nephron GFR, resulting in a lower total GFR. Other factors, such as obesity, associate with higher single nephron GFR, but do not associate with nephron number, resulting in a higher total GFR. Importantly, some factors, such as family history of end-stage renal disease (ESRD), associate with both lower nephron number and higher single nephron GFR, such that no association with total GFR is evident. Nephron number is itself determined by nephron endowment (associated with factors such as family history of ESRD and height) minus any loss of nephrons (associated with factors such as age and nephrosclerosis on kidney biopsy).[24]

Determining nephron number and single nephron GFR in clinical practice is not easily accomplished. Nephron number can be determined from the volume of cortex in the kidney (determined from high-resolution kidney imaging with computed tomography) multiplied by the three-dimensional density of glomeruli in the kidney cortex (determined from stereological calculations applied to a kidney biopsy).[24] Single nephron GFR is calculated from total GFR divided by the nephron number.[6] Although these determinants of total GFR are not easily measured in CKD patients, we tend to assume that sustained reductions in GFR are due to reduction in nephron number while increases in

TABLE 4.2 Clinical Factors Associate Differently With Nephron Number and Single Nephron Glomerular Filtration Rate (GFR) (nL/min), but the Net Effect Determines How They Associate With Total GFR (mL/min) in Healthy Adults

Clinical Factor	Nephron Number	Single Nephron GFR	Total GFR
Age	↓	0	↓
Female	↓	0	↓
Obesity	0	↑	↑
Tall height	↑	↑	↑
Uric acid	↓	0	↓
Family history of ESRD	↓	↑	0

ESRD, end-stage renal disease.

GFR are due to increases in single nephron GFR. Enlarged glomeruli and tubules on a kidney biopsy are also reflective of glomeruli that are hyperfiltering (increased single nephron GFR).[6] Interstitial fibrosis in the cortex appears to restrict the ability of remaining glomeruli to enlarge and hyperfilter to compensate for the loss of nephrons.[25]

Age-Related Decline in GFR

GFR declines with normal adult aging.[8–12,26] Davies and Shock demonstrated a continuous decrease in GFR from a mean 123 mL/min/1.73 m^2 at age 20–29 years to a mean 65 mL/min/1.73 m^2 at age 80–89 years (about 10 mL/min per decade of age).[26] Other investigations have found a decline in GFR ranging from 6 to 12 mL/min/1.73 m^2 per decade of age.[10,27,28] There is some uncertainty regarding whether the decline in GFR is constant or accelerates with age. Some studies have shown that the decrease in GFR is relatively constant throughout adulthood,[10,12,29] while others find GFR decline begins[8–10,26,28] or accelerates[10,11] during middle age (approximately 40–59 years). These discrepancies likely reflect differences in how healthy adults are selected for study, particularly in the older age groups where comorbidities are common and difficult to exclude. These studies are cross-sectional, as there are no longitudinal studies following measured GFR in normal adults. A longitudinal study using urinary creatinine clearance found a decrease of 7.5 mL/min per decade of age. There was wide variation in this trend, and one-third actually had an increasing creatinine clearance. However, this analysis did not account for the substantial measurement error that occurs with urinary creatinine clearance or account for increasing creatinine clearance from diseases that cause hyperfiltration (e.g. early diabetes and obesity).[30]

Reference ranges for normal GFR values have been defined using potential kidney donors, though few subjects older than 70 years are studied. The lower reference value (fifth percentile) at 60 years was 64 and 60 mL/min/1.73 m^2 for men and women, respectively.[11] Creatinine-based estimated GFR underestimates GFR in healthy subjects, and the fifth percentile is below 60 mL/min/1.73 m^2 in women by age 50 years and in men by age 55 years[11,31,32] (Figure 4.1). Given the decline in GFR with age, it may be reasonable to expect that the value of the fifth percentile in healthy subjects older than 70 years could be well below 60 mL/min/1.73 m^2. Indeed, a study specifically targeting "healthy for their age" patients older than 70 years found that by age 90 years, the average mGFR was 60 mL/min/1.73 m^2.[10,33] A population-based study found that 48% of adults over age 70 years had a measured GFR <60 mL/min/1.73 m^2.[34]

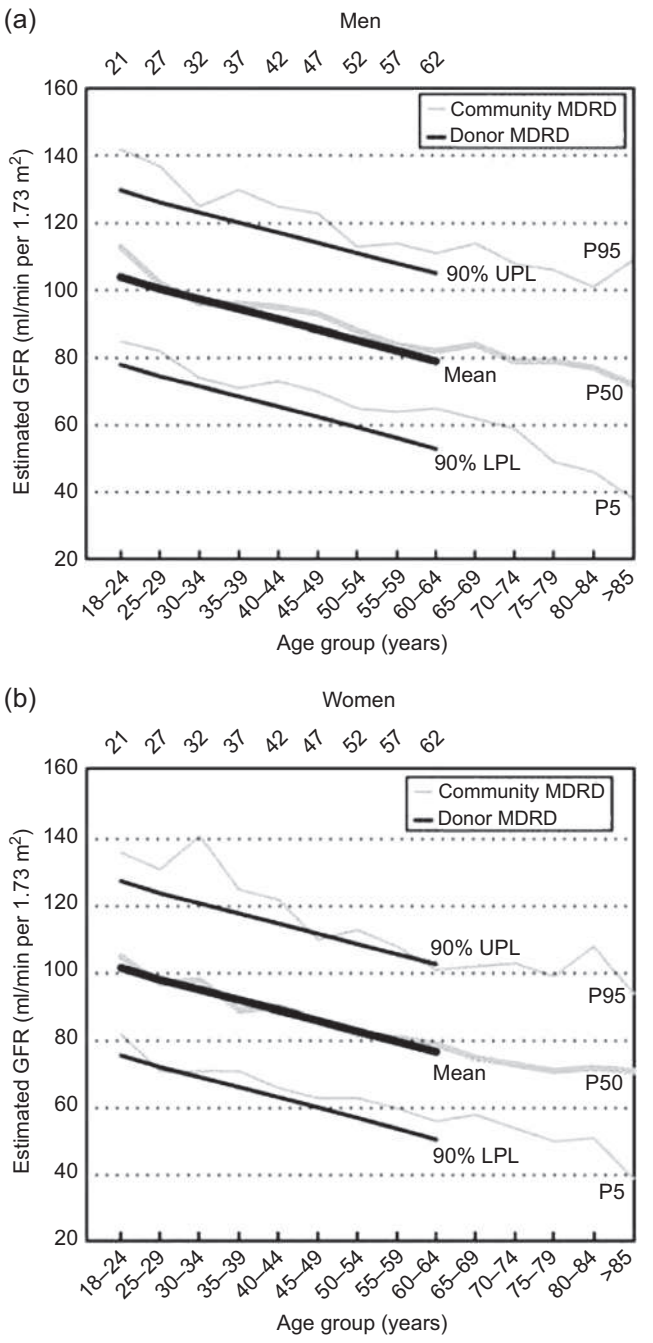

FIGURE 4.1 Comparison of estimated GFR in two different cohorts. Mean, 5th, and 95th percentiles for expected eGFR by MDRD equation in living kidney donors (Estimated MDRD—*black lines*) and eGFR by the MDRD equation in residents from the general community (Nijmegen MDRD—*gray lines*) among different age groups for (a) men and (b) women. *eGFR*, estimated glomerular filtration rate; *GFR*, glomerular filtration rate; *MDRD*, Modified Diet in Renal Disease. *Figure permission obtained from the Nature Publishing Group.*

The cause of this decline in GFR is due to a decline in nephron number without a compensatory increase in single nephron GFR or glomerular volume.[6,24,25] Whether nonrenal factors, such as decreased physiological

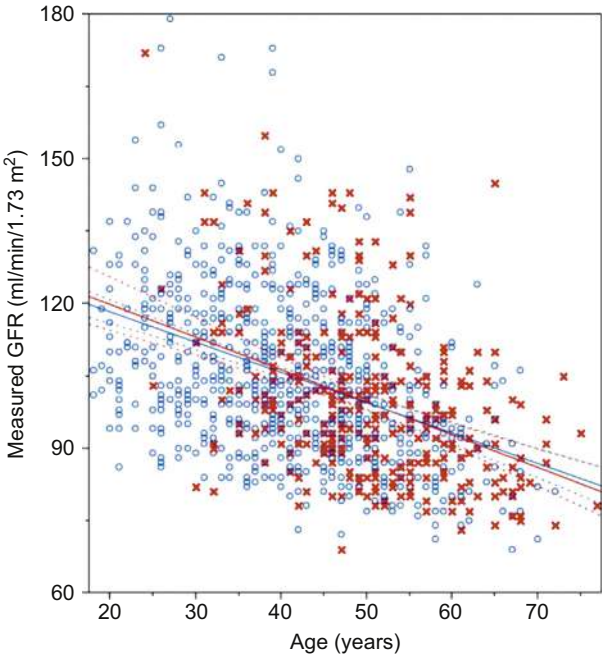

FIGURE 4.2 The relationship between GFR and age in persons with and without nephrosclerosis. The relationship between GFR and age in persons with nephrosclerosis is similar to that in persons without nephrosclerosis. *GFR*, glomerular filtration rate.

demand for GFR with less metabolic waste in the elderly, account for the lack of a compensatory increase in single nephron GFR with aging is unclear. A cause of age-related nephron loss is nephrosclerosis, which is only partially detected either by biopsy (globally sclerosed glomeruli atrophy and disappear) or by cortical volume on CT scan (tubular hypertrophy of remaining nephrons masks the nephron loss).[24] The age-related decline of GFR is not different in patients with more severe nephrosclerosis than expected for age on renal biopsy (Figure 4.2),[27] as there is a compensatory increase in single nephron GFR when nephrosclerosis exceeds that expected for age.[6]

DIRECT MEASUREMENT OF GFR

Exogenous Filtration Markers

Endogenous markers have biological activity that leads to variation in different physiological and pathological states. Thus, exogenous markers are needed to measure GFR. Inulin has been the most validated as an ideal marker. Inulin is a 5200 Da polymer of fructose, which is found in some plants (such as chicory and leek), which use it as energy source.[2] Inulin is freely filtered and not protein-bound.[2,35] The absence of both tubular reabsorption and secretion has been demonstrated in fish and dog models treated with tubular secretion inhibitors,[35,36] and further confirmed with tubular micropuncture studies in a rat model.[37] In humans, an intravenous injection of inulin is fully excreted in the urine, except for negligible amounts found in bile.[38] Because of these validation studies, inulin is an ideal marker for GFR measurement. Nevertheless, inulin is not readily available and is expensive, and assays are not easily standardized.[39] Other exogenous markers used to measure GFR have been generally validated against inulin clearance.

^{51}Cr-EDTA (Ethylenediaminetetra-acetic acid) is an alternative exogenous marker that shows good performance for GFR measurement compared to inulin.[40,41] While detected by radioactive decay, the quantity of ^{51}Cr-EDTA injected is relatively small, and the dose of radiation is very limited. Like ^{51}Cr-EDTA, ^{99}Tc-DTPA (Diethylenetriaminepenta-acetic acid) is an exogenous isotopic marker, but has a shorter half-life, making it less practical than ^{51}Cr-EDTA.[42] One advantage is that ^{99}Tc-DTPA clearance can be coupled with a nephrogram to demonstrate differential function between the two kidneys. However, physiological data to validate ^{99}Tc-DTPA are lacking, and performance may be suboptimal because ^{99}Tc-DTPA can bind to plasma proteins.[43] GFR can also be estimated with external counting using a gamma camera (the "Gates" method), but this method is not accurate enough to be considered a reference method for measuring GFR.[44]

Iothalamate is an iodinated contrast agent derived from tri-iodobenzoic acid. Iothalamate can be measured either by isotopic methods or by different analytical methods that do not require radiation. Many, but not all, studies have suggested iothalamate is secreted by renal tubules or has extrarenal clearance.[16,45–48] This marker is particularly important because iothalamate clearance has been used to develop most of the commonly used creatinine-based equations to estimate GFR. Iohexol is another iodinated contrast agent that can be used to measure GFR without requiring the nuclear medicine infrastructure needed for isotope based markers. Iohexol assays appear to have a low assay error.[49] Some studies showed acceptable performance for iohexol compared to inulin.[50,51] Most studies have shown plasma clearance of iohexol performs similar to other exogenous markers used to measure GFR.[52–55] Dried blood spot testing is possible with iohexol, which may make measured GFR more feasible in more settings.[56]

Methods based on fluorescein-isothiocyanate (FICT) may have the potential to make measured GFR a more convenient test. Inulin can be labeled with FICT,[57] and the clearance of this marker has been measured

transcutaneously[58,59] in rodent models. In humans, FICT conjugated with inulin has been assayed in plasma samples over a 3 h interval to measure GFR *via* its plasma clearance.[60]

Urinary and Plasma Clearance

GFR can be determined from two types of clearance methods. Urinary clearance uses timed urine and plasma samples, and plasma clearance uses only plasma samples. Ideally, for both methods the marker would be infused at a constant rate until a steady state plasma concentration has been achieved. Due to its high molecular weight and viscosity, this is the only way to administer inulin for GFR measurement. This is also often not practical with the time and expense constraints of clinical testing. For urinary clearance, some centers use a single subcutaneous injection of the marker, while others use constant intravenous infusions, but do not wait until steady state is achieved. Clearance is then calculated by the simple calculation: $U \times V/P$ (where U is the urine marker level, V is the urinary flow rate, and P is the plasma marker level).[2] Errors in urine collection, particularly from incomplete bladder emptying, are a limitation and a source of variability (imprecision) of urinary clearances. Averaging the clearance over multiple urine collections is used to decrease test error. Sonographic scanning to assess bladder emptying with bladder catheters as needed can also be helpful.[61]

Plasma clearance methodology has the advantage of not requiring urine collections, but it is more dependent on there being no extrarenal clearance of the marker. Like urinary clearances, a constant infusion is too time consuming to be practical, and a bolus infusion of the marker is given instead. After bolus intravenous injection, plasma concentration decreases in two stages: a rapid decrease that corresponds to the distribution of the marker throughout the extracellular space, and then a slower decrease which corresponds to the renal excretion of the marker by GFR (Figure 4.3).[40] The plasma clearance of the marker is then determined by the ratio of the injected dose and the area under the curve for the modeled rate of marker excretion. Plasma clearances are not accurate in patients with extracellular volume expansion, such as edema or ascites.[40,63] Moreover, the sample timing and the number of samples considered strongly influence the accuracy of the plasma clearance. In severe CKD, the longer the period before the last plasma sample, the more accurate the determination of plasma clearance.[40,64,65] Single sample methods appear to perform reasonably well compared to multiple plasma methods in patients who do not have severe CKD or obesity.[66] Several studies have compared simultaneous urinary and plasma clearances.[63–65] Plasma clearances tend to systematically overestimate urinary clearances because of the small amount of non-GFR clearance for all markers.

Clinical Indications for Measuring GFR

Guidelines have generally relegated the application of measured GFR in CKD as an alternative test in settings where serum creatinine concentration (S[Cr])–based estimated GFR is clearly inaccurate.[7] Studies comparing measured GFR and estimated GFR with clinical endpoint are few and generally limited to CKD

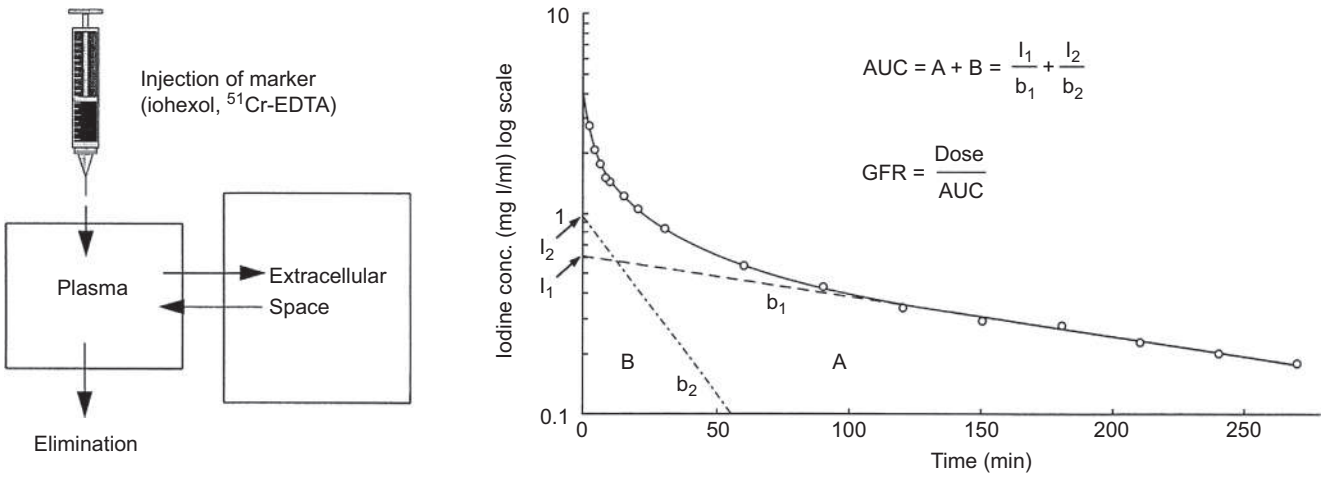

FIGURE 4.3 The two-compartment kinetic model for plasma clearance of iohexol.[62] The plasma concentration of iohexol as a function of time (t) based on all 16 measurements in the period 2–270 min after bolus injection of iohexol. The two-compartment model is mathematically described as the sum of two exponential functions. The elimination rate constants of the two compartments are *b1* and *b2* and the corresponding intercepts on the ordinate are I_1 and I_2 (mg I/mL). Plasma concentration of markers $= I_1\, e^{-b1t} + I_2\, e^{-b2t}$. *AUC*, area under the curve; *GFR*, glomerular filtration rate. *Figure permission obtained from Springer.*

populations. In CKD populations, measured GFR is not a better predictor of metabolic complications than estimated GFR.[3,67] There are generally two indications where measured GFR has been advocated. The first indication is when a very accurate GFR measurement is desired, such as for evaluation of potential living kidney donors or when administering a renally cleared medication with a narrow therapeutic window.[68] The second indication is in settings when estimated GFR is likely to be inaccurate, as discussed in the next section.

ENDOGENOUS FILTRATION MARKERS

Serum Creatinine

For almost a century S[Cr] has been the most widely used endogenous marker of GFR.[35] S[Cr] is assayed using either Jaffe or enzymatic methods, and many different assays are available. Over the past decade, most manufacturers have standardized their assays using reference materials traceable to the gold standard isotope dilution mass spectrometry (IDMS).[69,70] The IDMS traceability has reduced the bias observed between assays for both the Jaffe and enzymatic methods, although Jaffe assays continue to yield higher values than enzymatic ones.[71–73] Differences continue to exist largely due to both endogenous and exogenous interfering factors, which impact differentially on assays provided by different manufacturers. This appears to be less problematic with enzymatic methods that show improved precision over Jaffe methods.[72–74,70]

The two main biological limitations of using S[Cr] as a surrogate for GFR are the tubular secretion of creatinine[75,76] and the dependence of its circulating level on muscular mass.[75,77,78] Circulating creatinine is the catabolic end-product of creatine, which serves as an energy storage molecule for muscles. There is also some degree of extrarenal excretion of creatinine at very low GFR levels.[79] S[Cr] can also increase after ingestion of cooked animal protein.[80,81] S[Cr], like all endogenous filtration markers, has a reciprocal relationship with GFR (Figure 4.4).[75,82] Each doubling of S[Cr] represents an approximately 50% loss of GFR. The same increase in S[Cr] represents a smaller decline in GFR at low GFR levels compared to high GFR levels. This can be clinically useful since smaller changes in GFR become more clinically relevant as GFR declines to low levels.

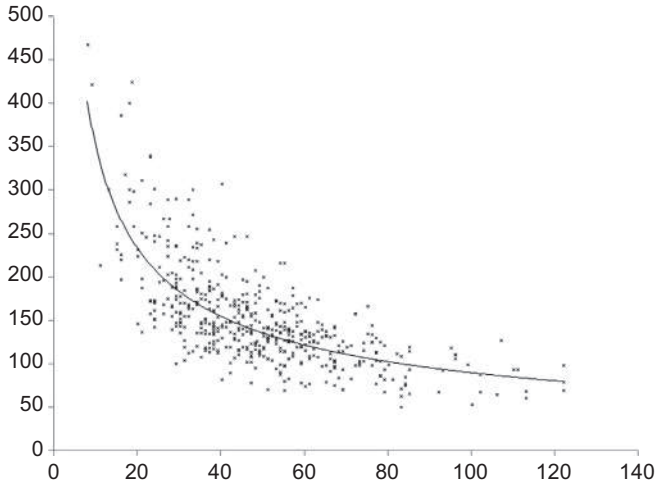

FIGURE 4.4 Relationship between GFR and serum creatinine concentration. *GFR*, glomerular filtration rate. *Figure permission obtained from Christophe Mariat, Saint Etienne, France.*

Urinary Creatinine Clearance

Urinary creatinine clearance, usually calculated from 24-h urine collections, is a relatively easy method to determine GFR, using the standard U x V/P clearance equation. Because of creatinine tubular secretion, creatinine clearance systematically overestimates measured GFR, particularly at low GFR levels.[75,76] Tubular secretion is also quite variable between patients and cannot be directly measured.[75,76] Administration of cimetidine has been used to block creatinine secretion and increase the accuracy of urinary creatinine clearance.[76,83] Perhaps the biggest limitations of creatinine clearance are the high intraindividual variation of creatinine excretion and inaccurate urine collection by patients.[75,78,84,85]

Cystatin C

Cystatin C (CysC) is a 13.3 kDa cysteine proteinase inhibitor[86] produced by nucleated cells.[87] CysC is freely filtered by the glomeruli and then reabsorbed by the proximal tubules, where it is catabolized.[88] A particular advantage of CysC over S[Cr] is that its concentration is less influenced by variations in muscle mass, age, and sex.[89–92] Many additional non-GFR determinants have been described including thyroid disorders, obesity, inflammation, viral load in HIV-infected patients, therapy with glucocorticoids, malignancy, and diabetes.[89,93–98] CysC can be measured by nephelometric, turbidimetric, and ELISA assays, although differences between these have been shown.[99,100] Assay drift over time has also been noted.[100–102] Certified reference material is now available,[103] although significant method-related bias exists between different assays.[104] CysC has emerged as the most prominent nontraditional GFR biomarker, and CysC is included in the diagnostic criteria for CKD in the KDIGO guidelines.[7] CysC has also been shown to be more strongly

associated with adverse nonrenal outcomes, such as death, compared to S[Cr]-based evaluations, even after accounting for mGFR in some cases.[105–108]

BTP

β trace protein (BTP) is a 109 amino acid glycoprotein with multiple isoforms due to variable posttranslational glycosylation. Originally identified in human cerebral spinal fluid,[109] BTP was recognized to be elevated in the serum of patients with CKD in 1997.[110] BTP is produced by numerous cell types, including endothelial, cardiac, CNS, bone, adipose, and kidney.[111] The origin of serum BTP remains uncertain.[111] The renal handling of BTP is also unclear and it seems unlikely given its molecular weight (26–29 kDa) that it is freely filtered. Unlike cysC and β_2-microglobulin (B_2M), BTP is not completely reabsorbed in the tubules. BTP is present in the urine in healthy people.[110]

There are at least two commercial assays (ELISA and nephelometric) used to measure BTP. There are no higher order reference methods or materials available and significant differences between the two assay types have been demonstrated.[112] Although not as well established as for S[Cr] and cysC, there are multiple non-GFR determinants of serum BTP concentration, including age, gender, weight, cardiovascular disease, inflammation, proteinuria, pregnancy and genetic factors.[92,111] This is not surprising given the biologic functions of BTP. BTP catalyzes the conversion of prostaglandin H2 (PGH2) to prostaglandin D2 (PGD2). PGD2 is involved in the inflammatory response, as well as in platelet aggregation, vasodilation, bone remodeling, sleep induction and nociception.[111] Most studies do not suggest BTP to be superior to S[Cr] or CysC as a diagnostic marker of GFR in CKD. BTP may however be a more sensitive marker of early GFR decline than S[Cr].[113–116] BTP has been shown to be a stronger predictor of all cause and cardiovascular mortality than S[Cr] and even, in some cases, than mGFR.[105,106] However, serious analytic impediments to the widespread use of BTP need to be addressed to integrate this interesting biomarker into clinical care.

B_2M

B_2M is a low molecular weight protein (11.8 kDa) expressed on the surface of all cell types.[117] B_2M is freely filtered and then is almost entirely reabsorbed and catabolized in the proximal tubules.[118] Serum B_2M concentrations can be elevated in conditions other than CKD including neoplastic, inflammatory, and infectious illnesses.[119] Systolic blood pressure, C-reative protein, age, gender, total cholesterol, smoking and urine protein excretion have also been shown to be associated with serum B_2M independently of GFR.[92,120] A variety of types of assays are commercially available to quantitate B_2M with differences between them identified.[121] Similarly to CysC and BTP, B_2M has been shown to be more strongly associated with certain adverse outcomes such as death than S[Cr].[105,122]

Nontargeted Metabolomics

There are numerous small molecules in the blood that are cleared by glomerular filtration. Rather than focusing on a specific endogenous filtration marker, a nontargeted metabolomic approach can be used to identify endogenous filtration markers. Various panels of renally cleared metabolites that in combination may improve the estimation of GFR have been identified.[123,124] However, development of such metabolic panels into useful and cost-effective tests for GFR assessment has not yet occurred.

ESTIMATION OF MEASURED GFR

The "Estimated GFR Construct"

Estimated GFR is a statistical model (equation) that estimates measured GFR using endogenous filtration markers and readily available surrogates (primarily age, sex, race, and weight) to model the non-GFR determinants of the marker. The best equation for estimated GFR has been a source of significant debate in the nephrology literature. So far, there have been primarily three different criteria used to evaluate and determine the "best" GFR-estimating equation: (1) Accuracy in estimating measured GFR, (2) Optimal discrimination of clinical outcomes, and (3) Similar association with CKD risk factors and outcomes to that seen with measured GFR. These criteria are often not in agreement regarding the best equation.[125] A major problem is that some markers such as CysC and BTP are actually better than GFR in predicting certain clinical outcomes.[108] Optimally predicting outcomes with kidney function markers is not the same as optimally determining how kidney function predicts outcomes.[126]

There are also specific issues that affect the performance of different equations in estimating measured GFR. GFR estimating equations are population specific. An equation developed using CKD patients will underestimate GFR in potential kidney donors, while an equation developed using potential kidney donors will overestimate GFR in CKD patients[82,127,128] (Figure 4.5). Equations can be developed for estimating GFR in mL/min or in mL/min/1.73 m^2. The former is

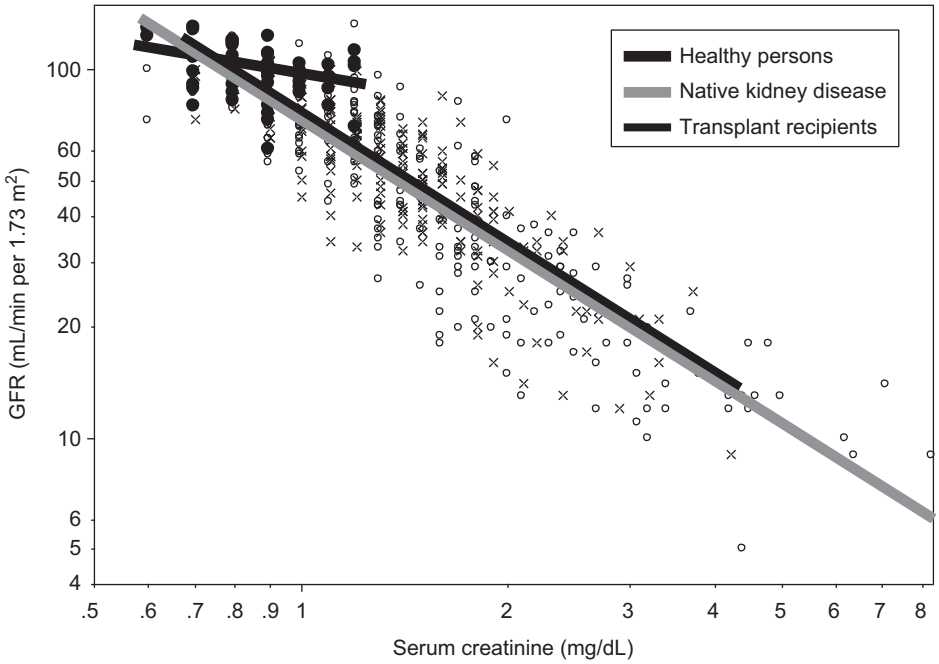

FIGURE 4.5 Relationship between serum creatinine and glomerular filtration rate (GFR) (measured by iothalamate) in healthy, native kidney disease and transplant recipients.[61] The *closed circles* represent healthy persons (n = 50). The *open circles* represent patients with native kidney disease only (n = 204). The *crosses* represent patients with solid organ transplants (n = 206). The regression lines (similar to GFR estimating equations) for all three patient groups (native kidney disease, transplant recipients, and healthy) are shown. *Figure permission obtained from the Nature Publishing Group.*

more relevant for determining drug doses, while the latter is more relevant for staging CKD. Endogenous filtration markers are inherently more correlated with GFR in mL/min/1.73 m^2 than GFR in mL/min. Indexing GFR to body surface area (1.73 m^2) is somewhat misleading in obese patients. The increase in GFR from the increase in single nephron GFR with obesity[129] is masked by the increase in body surface area in obesity.

Commonly used equations have been derived using standardized S[Cr] (Modified Diet in Renal Disease [MDRD] study and Chronic Kidney Disease Epidemiology [CKD-EPI] equations) or were derived in a manner that did not depend on S[Cr] standardization (Cockcroft-Gault equation) (Figure 4.6). Finally, there are numerous differences in GFR measurement protocols, including choice of exogenous markers, which can affect performance of any GFR estimating equation.[130]

Equations Used in Clinical Practice

Most current clinical practice guidelines recommend the S[Cr]-based CKD-EPI equation to estimate GFR in adults,[7] which has replaced the formerly recommended MDRD Study equation.[131] Both equations use the same variables (S[Cr], age, sex, black vs. nonblack race) to estimate measured GFR based on iothalamate clearance and give similar GFR estimates except in patients with lower S[Cr] levels. The S[Cr]-based CKD-EPI equation generally gives higher GFR estimates than the MDRD Study equation, because it was derived using about one-third low-risk patients (such as kidney donors) and two-thirds CKD patients, while the MDRD Study equation was derived using only CKD patients.[132,133] The CKD-EPI equation also models age with a linear function (MDRD Study equation used a logarithmic function), which leads to lower GFR estimates in the elderly.

The Cockcroft-Gault equation estimates urinary creatinine clearance rather than measured GFR.[134] It is imprecise relative to currently used S[Cr]-based equations[135] because it contains a weight variable, which is helpful in estimating GFR in mL/min. It is difficult to avoid anthropomorphic variables such as height and weight for equations that estimate GFR in mL/min instead of mL/min/1.73 m^2. The Cockcroft-Gault equation is still useful in clinical practice for dosing renally excreted drugs that have dosing guidelines based on estimated GFR with the Cockcroft-Gault equation.[136,137] More contemporary estimated GFR equations can substantially improve drug dosing over the Cockcroft-Gault equation once equation-specific dosing guidelines are developed.[138,139]

There are also equations based on cystatin C (with or without S[Cr]) including the CKD-EPI equations, the

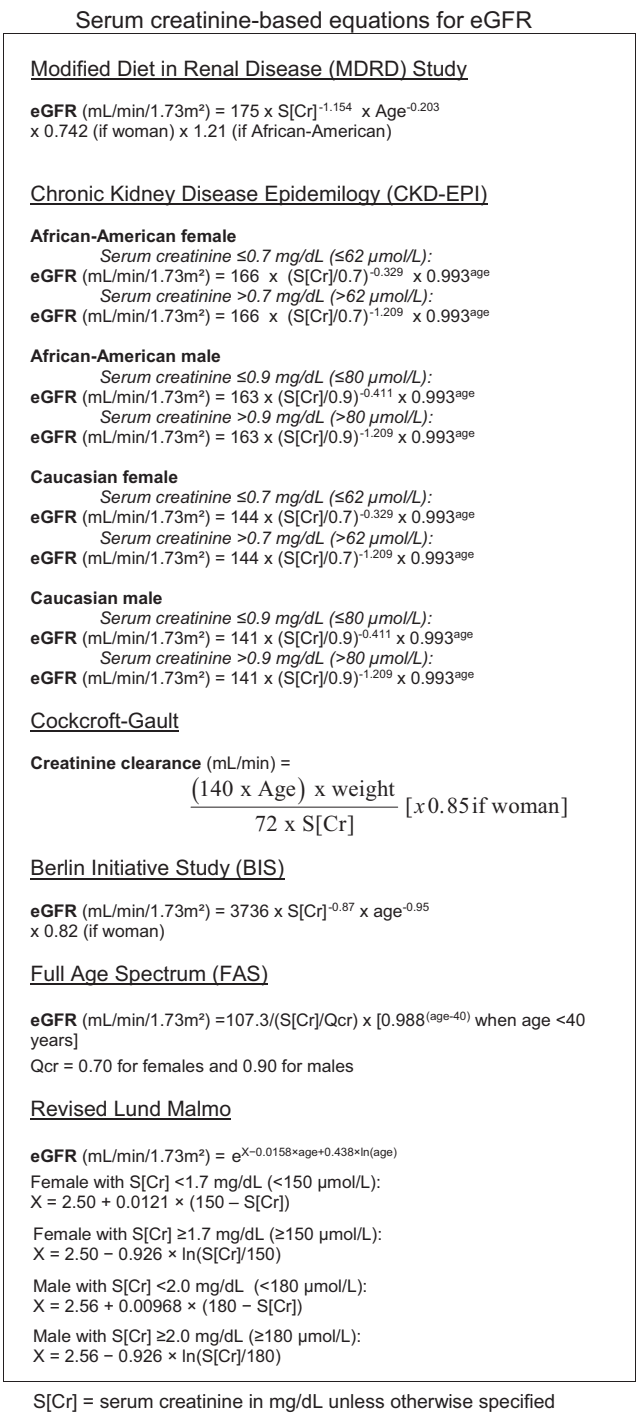

FIGURE 4.6 Creatinine-based equations to estimate glomerular filtration rate.

Full Age Spectrum (FAS) equations,[140] and the Caucasian, Asian, Pediatric, and Adult (CAPA) equation.[141] CysC-based equations perform similar to S[Cr]-based equations but combining S[Cr] and CysC improves the estimation of measured GFR, particularly in children and older adults. Interestingly, CysC has been shown to perform better than S[Cr] in predicting cardiovascular morbidity and mortality.[142–144] This does not necessarily make CysC or CysC-based estimated GFR a superior method for determining GFR, because better discrimination of outcomes can be due to the non-GFR determinants of CysC, such as inflammation and atherosclerosis.[145,146] In particular, S[Cr]-based estimated GFR is generally less biased in its associations with CKD risk factors and outcomes than CysC-based estimated GFR.[108,147,148] Several equations based on BTP or B_2M have also been proposed by different studies.[149–151] However, these equations have been developed from limited samples and have not shown an improvement in estimating GFR over S[Cr] and CysC-based equations in children or adults.[152–156]

All S[Cr]-based and adult-derived equations are inaccurate in children and adolescents.[157] In children, S[Cr] increases with age due to increases in muscle mass, while GFR also increases with age as kidneys grow in size. Reliability and standardization of endogenous filtration markers is particularly critical as their concentrations are lower in children than in adults.[158,159] The most popular equation in children remains the Schwartz equation (based on S[Cr] and height), especially the 2009 version, which has been developed with a standardized enzymatic IDMS-traceable assay, and validated against measured GFR by iohexol clearance.[160] CysC-based equations have also been developed.[161] CysC-based equations developed for use in children have been shown to be more accurate than S[Cr]-based equations.[162]

Ethnicity

Muscle mass and creatinine tubular secretion can differ by race or ethnicity.[163] This has been well described in assessing kidney function between white and African American patients.[75,95] The MDRD study equation was the first to include a race coefficient for African American *relative to* white subjects.[132] There is evidence that this race coefficient is less accurate and even inappropriate in low-risk populations.[164,165] Estimated GFR using the race coefficient leads to determination of a lower prevalence of CKD in African Americans than whites, despite the considerably higher risk of ESRD in African Americans. The African American coefficient may not be accurate in other black populations in Africa, Europe, Caribbean, or indigenous Australians.[165–168]

There are a variety of proposed race coefficients for the MDRD Study and CKD-EPI equations in Asian populations, but these studies lacked a white reference group. Thus, methodological differences between studies may explain these race coefficients.[169–171]

Older Adults

Older adults require special consideration in the context of GFR assessment. Older age leads to GFR decline from nephron loss in healthy adults,[24] and it is the strongest predictor of CKD.[27] The CKD-EPI equations were developed from a cohort that included a small proportion of patients older than 70 years. Both the CKD-EPI and the MDRD study equations overestimate measured GFR in older adults with CKD[34] (Figure 4.7). These results are explained by sarcopenia, which affects the relationship between S[Cr] and GFR and is not modeled correctly across the full adult age spectrum. Addition of CysC into estimating equations increases accuracy and precision for estimating measured GFR in older adults.[34,140,172] From a population-based sample of adults aged 70 years and older, the Berlin Initiative Study (BIS) developed two equations, one based on S[Cr] (BIS1) and the other based on both S[Cr] and CysC (BIS2).[34] While some external validation studies confirmed the improved accuracy of the BIS equation in older adults,[172–174] others did not.[175] The S[Cr] and CysC–based FAS equation, the CAPA equation, and the Revised Lund Malmo equations have also been shown to perform well in older adults.[140,172]

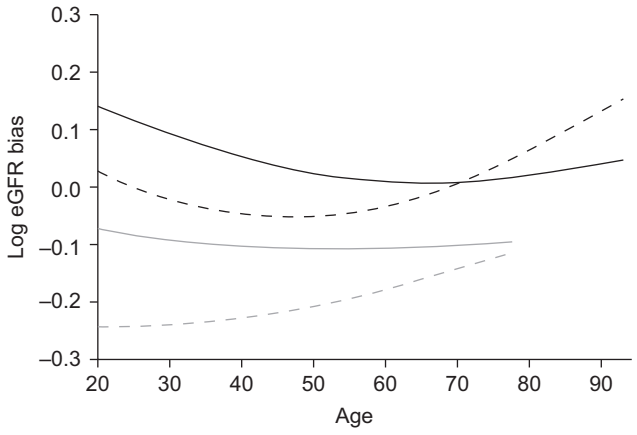

FIGURE 4.7 Bias between estimated and measured glomerular filtration by age (years) and population (healthy vs. chronic kidney disease [CKD]).[125] Mean bias calculated for log eGFR—log mGFR is depicted. The creatinine-based Chronic Kidney Disease Epidemiology (CKD-EPI) equation is represented by the solid smoother curves, and the Modified Diet in Renal Disease (MDRD) equation is represented by the dashed smoother curves. Native CKD and transplant recipients (n = 4558) are represented by the black curves, and the potential kidney donors and postnephrectomy kidney donors (n = 680) are represented by the gray curves. In CKD patients, the CKD-EPI equation tended to overestimate GFR more in younger adults, whereas the MDRD equation tended to overestimate GFR more in older adults, though both overestimate GFR in the very elderly. *GFR*, glomerular filtration rate. *Figure permission obtained from the American Society of Nephrology.*

Limitations of Estimated GFR

The MDRD and CKD-EPI equations were developed from cohorts that contained all or mostly CKD patients.[132,133,176] CKD patients have lower muscle mass than healthy subjects, leading to underestimation of GFR in low-risk populations, such as predonation or postdonation kidney donors.[127] Among hospitalized patients with muscle wasting, caution is needed with interpreting estimated GFR.[177,178] Other settings where creatinine generation is not well modeled by S[Cr]-based equations include obese,[179] anorectic,[180] critically ill,[177] and hyperfiltering patients.[181] As with any endogenous filtration marker, GFR-estimating equations are more accurate in the steady state than in acute kidney injury. GFR-estimating equations do not always correctly reflect the slopes of measured GFR.[181–184] Thus, in certain settings, such as dosing of nephrotoxic drugs or determining eligibility for kidney donation, direct measurement of GFR can be useful given the limitations of estimated GFR.[55]

CONCLUSIONS

Abnormal loss of kidney function identifies CKD, and kidney function is primarily determined using GFR. There are inherent problems with over-reliance on either measured GFR or estimated GFR to characterize kidney function. Other characterizations of kidney function are also useful to identify CKD, such as albuminuria despite the glomerular filtration barrier and tubular reabsorption. Future novel, practical tests that characterize additional aspects of kidney function may help better identify and classify CKD.

QUESTIONS AND ANSWERS

Question 1

A young 30-year-old white man is proposed as a living kidney donor for his daughter being treated with peritoneal dialysis (urological malformation). He is 190 cm high and weighs 90 kg. He is healthy, athletic, and frequently goes to a fitness center. Blood pressure is normal and urine analyses are normal. S[Cr] measured with a standardized assay is 1.4 mg/dL. Estimated GFR with the MDRD and CKD-EPI equations is 60 and 67 mL/min/1.73 m^2, respectively.

Which one of the following is true?

A. Donation must be refused because estimated GFR of the subject is too low for kidney donation
B. GFR must be measured by a reference method before potential donation
C. Donation is possible because the subject does not suffer from CKD according to its GFR level (>60 mL/min/1.73 m^2)
D. Cystatin C measurement in this subject would have no added value compared to S[Cr]

Answer: B

Measuring GFR by a reference method is recommended prior to living kidney donation. This would be especially recommended in an active person with high muscular mass. The increased S[Cr] levels could be due to a higher muscular mass, leading to an inaccurate decrease in GFR by the creatinine-based equations. Therefore, Answer A is incorrect. However, Answer C is also incorrect because his estimated GFR values are clearly abnormal for his age. Because Cystatin C concentration is less dependent on muscle mass, its measurement could be of interest. Elevated cystatin C is reflective of both GFR and non-GFR pathology that may preclude donation. Answer D is incorrect.

Question 2

A kidney recipient patient is admitted for pulmonary infection. He is 65 years old and his estimated GFR by the MDRD study equation is 40 mL/min/1.73 m^2. Because *Pneumocystis jirovecii* is suspected, the patient is treated by co-trimoxazole (trimethoprim/sulfamethoxazole) with doses adjusted for GFR level. Two days after starting the therapy, the estimated GFR significantly decreases to 30 mL/min/1.73 m^2.

Which one of the following is true?

A. Creatinine clearance must be measured to assess the potential effect of the therapy on GFR
B. In the absence of urine abnormalities and creatinine stabilization, the increase in S[Cr] is explained by the inhibition of the creatinine tubular secretion by sulfamides
C. In the absence of urine abnormalities and creatinine stabilization, the increase in S[Cr] is explained by the inhibition of the creatinine tubular secretion by trimethoprim
D. The dosage of co-trimoxazole must be decreased
E. Co-trimoxazole is not nephrotoxic and full doses should be given

Answer: C

Co-trimoxazole is a recommended and widely used antibiotic for the prevention and treatment of *Pneumocystis jirovecii* pneumonia and urinary tract infections. Co-trimoxazole combined trimethoprim and sulfamethoxazol (Sfx). Sfx may cause an abrupt increase in S[Cr] due to tubulointerstitial toxicity in high or incorrectly adjusted doses. Answer E is thus incorrect.

By inhibiting creatinine secretion, trimethoprim can lead to an elevation in S[Cr] and a decrease in creatinine clearance. Answer A is thus incorrect. This increase in S[Cr] is independent of any changes in GFR (Answer D is incorrect). This creatinine "elevation" impacts GFR estimation and will lead to the erroneous perception of a more severely impaired kidney function than there actually is. Answer C is the correct one. Trimethoprim induces a reversible and rapid (2–6 h after intake) increase in S[Cr]. Answer B is incorrect.

Question 3

A 75-year-old woman suffers from breast cancer. Oncologists recommend therapy by cisplatin. Except for the neoplasia, the patient is in good health and not treated by any therapy. Her body surface area is 1.7 m^2. Because the narrow therapeutic window, glomerular filtration rate was measured by iohexol plasma clearance at 50 mL/min. Urine analysis does not reveal proteinuria and renal sonography is normal.

Which one of the following is true?

A. Iohexol is not a reference method and GFR should be measured by iothalamate
B. Measuring GFR was not needed as both the MDRD and CKD-EPI equations are accurate enough in this setting
C. The patient's GFR is less than expected with normal aging.
D. Because the patient's GFR level is normal for her age, cisplatin dose adjustment for GFR is not needed.

E. The cisplatin dose should be adjusted to GFR because the subject is at risk for acute kidney injury.

Answer: E

Iohexol plasma clearance is an adequate reference method to measure GFR in the absence of edema. Therefore, there is no reason to measure GFR by another method and Answer A is incorrect. Estimating GFR by creatinine-based equations lacks precision in the elderly. Both the MDRD and the CKD-EPI equations tend to overestimate GFR. Answer B is thus incorrect. In the absence of other evidence for kidney damage, there is no reason to consider this level of GFR in an elderly subject as abnormal. Answer C is incorrect. However, senescence with a physiological decrease in GFR values make older subjects more sensitive to acute kidney injury. The dosage of cisplatin must thus be adapted. Answer D is incorrect and the correct Answer is E.

Question 4

A 60-year-old obese man with hypertension is found to have an eGFR of 50 mL/min/1.73 m^2 by cystatin C-based equation but an eGFR of 75 by a S[Cr]—based equation.

Which item about cystatin C is correct?

A. Cystatin C concentration is not influenced by obesity
B. Standardization of cystatin C measurement is not available
C. Equation only based on standardized cystatin C has been proven to be more accurate than creatinine-based equations in estimating measured GFR
D. Urinary clearance of cystatin C is a helpful confirmatory test for determining GFR
E. All items are false

Answer: E

Cystatin C is a cysteine proteinase inhibitor that is produced by nucleated cells and coded by a housekeeping gene. Cystatin C is freely filtered by the glomerulus and then reabsorbed by the proximal tubules, where it is fully catabolized. In the absence of tubular pathology, the level of cystatin C in the urine is thus very low. Answer D is incorrect. An advantage of cystatin C over S[Cr] is lesser dependence on muscular mass. However, other non-GFR determinants for cystatin C influence cystatin C. Obesity is one of these determinants and Answer A is incorrect. Moreover, in the general CKD population, there is no proof that the cystatin C-based equation performs better than the creatinine-based equations. Only equations combining cystatin C and creatinine seem to have slightly better precision. Answer C is incorrect. Cystatin C can be measured by nephelometric or turbidimetric assays but standardization is now available. Answer B is incorrect. The answer is E.

Question 5

A laboratory is reviewing how to report estimated GFR in patients whenever a S[Cr] is obtained. They are considering switching to the CKD-EPI equation instead of the MDRD study equation.

Which item about the creatinine-based equations is false?

A. The CKD-EPI equation is recommended by the KDIGO guidelines
B. Using the S[Cr]—based CKD-EPI equation leads to a lower prevalence of CKD in the general population than the MDRD Study equation
C. The CKD-EPI equation is more accurate to estimate GFR than the MDRD study equation in all patient settings.
D. An IDMS-traceable creatinine is needed to use either the MDRD Study or CKD-EPI equations

Answer: B

The CKD-EPI equation proposed by the CKD-EPI consortium in 2009 is now recommended by the international guidelines. Answer A is correct. Indeed, using this equation, instead of the MDRD, will lead to lower prevalence of stage 3 CKD in the general population because the MDRD equation systematically underestimates GFR in normal GFR ranges. Answer B is thus correct. An IDMS-traceable creatinine is needed to use these two equations and Answer D is correct. However, the performance of the CKD-EPI equation is not better than the MDRD equation to estimate GFR in CKD patients and even in subjects with GFR "around" 60 mL/min/1.73 m^2. Moreover, in subjects with abnormal or unusual muscular mass, both equations are similarly inaccurate. Answer C is thus incorrect.

Question 6

Which item about measured GFR is correct?

A. Measuring GFR with inulin is a convenient, inexpensive test with low patient burden.
B. GFR-estimating equations assume measured GFR is the gold standard method for determining GFR.
C. Measuring GFR with ^{51}Cr-EDTA and iohexol will give exactly the same results
D. Calculation of measured GFR by urinary clearances is usually higher than plasma clearances
E. Measured GFR is constant at night

Answer: B

Urinary clearance of inulin is still considered as the historical and "gold standard" reference method to measure GFR. However, inulin is not readily available and costly. Moreover, inulin can only be used with a constant infusion rate and repeated urinary clearances. Answer A is incorrect. According to these practical limitations, other markers such as ^{51}Cr-EDTA or iohexol are used with plasma clearances methodology. Even if both markers are considered as reference methods, GFR results will not be exactly the same and usually, differences of 5–10 mL/min/1.73 m^2 can be expected. Answer C is incorrect. Whatever the marker used, plasma clearances are not equivalent to urinary clearance. Because all GFR markers have a part of minimal extrarenal clearance, the plasma clearances results will be slightly but systematically higher than urinary clearances. Answer D is incorrect. Like any biological and physiological variable, GFR has within-individual variability, including nocturnal variation. Answer E is incorrect. Despite these limitations, measuring GFR is still helpful in certain populations and is used as the reference method when creatinine- or cystatin C-based equations are developed. Answer B is correct.

CHAPTER

Clinical Assessment and Management of Chronic Kidney Disease Across Its Stages

Ashte' K. Collins[a], *Mark E. Rosenberg*[b], *Paul L. Kimmel*[a]

[a]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States; [b]Division of Renal Diseases and Hypertension, University of Minnesota Medical School, Minneapolis, MN, United States

Abstract

Defining and staging chronic kidney disease (CKD) has been a major public health and clinical advance that has benefited patient care by primary care providers, as well as nephrologists and other specialists. Each stage of CKD confronts both the patient and provider with different problems and clinical issues, often predictable from the natural history of each CKD stage. Proper CKD management requires understanding the physical and biochemical abnormalities that one can expect to occur throughout the course of a person's kidney disease, which is usually progressive and irreversible. The classification and staging of CKD have advanced care and facilitated research. The major clinical manifestations of each CKD stage, and typical accompanying laboratory abnormalities, in addition to merely extent of change in glomerular filtration rate, dictate the stage-specific management of the CKD patient.

INTRODUCTION

The normal kidneys are the sentinels of body homeostasis. They preserve the "internal milieu" as a stable environment. Functions of the normal kidney include balancing ever-changing dietary intake of a plethora of substances with their excretion and controlling the internal and external distribution of water, sodium, potassium, and trace elements. Normal kidneys maintain acid–base balance and are involved in carbohydrate metabolism, the metabolism of exogenous substances, including licit and illicit drugs, as well as toxic agents. In addition, the kidneys are critical in maintaining bone mineral health, in part by the regulation of calcium, phosphate, and magnesium balance, and producing and responding to control hormones, cytokines, and growth factors involved in mineral metabolism. The kidneys regulate volume status and are involved in the maintenance of normal blood pressure, in part by producing and responding to vasoactive hormones and regulating the excretion of sodium and water.

Over the last century, clinicians and renal physiologists have struggled to determine an overarching, clinically useful measure of renal function. Consensus since the days of Homer Smith has settled on the glomerular filtration rate (GFR). Acute and chronic changes in the level of GFR, depending on their extent and temporal sequence, are often predictably associated with characteristic impairments of the multitude of tasks the kidney accomplishes. Many systemic illnesses involve the kidneys, leading to functional changes which may have dire consequences. When GFR is diminished, disruption in a host of normal physiologic functions occurs, sometimes affecting the function of distant organs or modifying the function of seemingly disparate processes. The care of patients with severe decrements in GFR may involve many health professionals with specific areas of expertise, in addition to primary care physicians.

The course of chronic kidney disease (CKD) is often characterized by inexorable progression, from asymptomatic, clinically inapparent disease or "benign" biochemical abnormalities to uremia with potentially life-threatening neurologic disorders, dysregulated potassium, calcium, phosphate, and acid–base metabolism, as well as abnormal control of blood pressure and plasma volume. Although many CKD patients do not experience progressive loss of GFR, or lose GFR relatively slowly, the pace of the progression of CKD may often be influenced by judicious management of blood

Chronic Renal Disease, Second Edition

pressure, dietary interventions, use of RAAS inhibitors, as tolerated, as well as identification and treatment of specific reversible causes of acute kidney injury (AKI). In the recent past, the scope of chronic, progressive renal disease was often categorized into four stages: loss of renal reserve, renal insufficiency, chronic renal failure, and end-stage renal disease (ESRD). This approach has been superseded by the CKD classification, a paradigm shift in public health and delivery of patient care by primary care providers, as well as nephrologists and other specialists. Nevertheless, each stage of CKD confronts both the patient and the physician, as well as other caregivers, with different problems and clinical issues, often predictable from the natural history of the underlying disorder.

OVERVIEW OF CKD

According to the Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline, CKD is defined as "abnormalities of kidney structure or function present for greater than 3 months with implications for health." Typical for any chronic disease, derangements in the normal functioning of the kidneys are responsible for the complications of CKD, which include clinical manifestations in a wide variety of other organ systems, including endocrine, cardiovascular, neurologic, gastrointestinal, musculoskeletal, and hematologic disorders. Proper CKD management requires an understanding of the physical and biochemical abnormalities that one can expect to occur throughout the course of a person's kidney disease, which is usually progressive and irreversible. This approach, previously guided by rough estimations of a person's kidney function as the patient progresses through the continuum of abnormal kidney function, is now more rigorously classified in the 2012 KDIGO guidelines (Figure 5.1).

Several goals are accomplished by this updated classification system, particularly regarding the relationship between certain kidney abnormalities and CKD outcomes. The current system expands on the actual risk of adverse outcomes stratified by GFR category. This classification provides a guide to assist primary care clinicians with timing and need for nephrologist referral by identifying high-risk patients. Second, the newest classification system not only stratifies CKD severity by GFR but also subclassifies CKD stage 3 into two groups, 3a (GFR 45–59 mL/min/1.73 m^2) and 3b (GFR 30–44 mL/min/1.73 m^2). This subclassification helps clinicians identify patients who are more likely to have biochemical and hematological abnormalities such as secondary hyperparathyroidism and anemia, which are more frequently encountered in CKD stage 3b. Furthermore, the new classification system indicates that not all CKD is equivalent. There are many more

Prognosis of CKD by GFR and albuminuria category

Prognosis of CKD by GFR and Albuminuria Categories: KDIGO 2012				Persistent albuminuria categories Description and range		
				A1 Normal to mildly increased	A2 Moderately increased	A3 Severely increased
				<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (ml/min/ 1.73 m^2) Description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60-89			
	G3a	Mildly to moderately decreased	45-59			
	G3b	Moderately to severely decreased	30-44			
	G4	Severely decreased	15-29			
	G5	Kidney failure	<15			

Green: low risk (if no other markers of kidney disease, no CKD);
Yellow: moderately increased risk; Orange: high risk; Red, very high risk.

FIGURE 5.1 Prognosis of chronic kidney disease (CKD) by glomerular filtration rate (GFR) and albuminuria category. *From Reference 13 with permission from National Kidney Foundation, Inc.*

patients with lower-stage CKD than the previous broader classification system identified, and the number of people with advanced CKD stages is much smaller. The fact that CKD stage 3 encompasses the fastest growing cohort of CKD patients in the US underscores the importance of classifying this group precisely. Third, the new system delineates the prognosis of CKD (see Figure 5.1) with respect to not only GFR categories but also albuminuria. For several years, albuminuria has been recognized as an independent risk factor for cardiovascular disease (CVD), CKD progression, AKI, and mortality, but it was not included in the previous KDIGO or Kidney Disease Outcomes Quality Initiative classifications. The inclusion of urinary albumin excretion as a factor in staging acknowledges its place as a risk factor for CVD as well as CKD progression and permits a more comprehensive prediction of CKD outcomes. Fourth, and critically, the new classification system calls for the inclusion of the cause of CKD, with emphasis on the presence of systemic disease and the specific anatomical abnormality present.

Estimating GFR

As the GFR categories in the new CKD classification system have become more complex, so have the methods for estimating GFR. Creatinine clearance was previously used as the primary clinical measure of GFR, the pre-eminent indicator of kidney dysfunction. Creatinine is a practical choice for estimating GFR because as a normal product of muscle metabolism, creatinine is produced in a relatively constant amount every day, is filtered as freely by the glomeruli as plasma water, and little creatinine is secreted or reabsorbed over the course of renal tubular transport. Because the vast majority of the constant daily production of creatinine is excreted every day in the urine, the serum creatinine concentration (S[Cr]) rises as the GFR falls. With every 50% decline in GFR, the corresponding S[Cr] should double, all other variables being unchanged. Were creatinine such an ideal indicator, it would be much easier to estimate GFR, but unfortunately S[Cr] is an imperfect filtration marker. Creatinine is secreted as well as filtered by the kidneys, and its production rate depends on patients' diet and muscle mass. The magnitude of creatinine production and its urinary excretion decrease with increasing age or muscle wasting, the latter often encountered in patients with advanced renal disease or systemic illnesses. The most serious error which stems from only following the level of S[Cr] as a marker of CKD is to grossly overestimate renal function in people with low weight or muscle mass, typically elderly women. Trimethoprim and cimetidine block maximal creatinine secretion by the renal tubules, leading to a decrease in creatinine clearance and a resultant increase in S[Cr], without affecting GFR.[1,2]

Several GFR estimation equations have been developed and validated to estimate GFR from S[Cr]. The Modification of Diet in Renal Disease (MDRD) equation has been in use since the early 2000s, replacing the Cockcroft-Gault equation on the strength of its broad applicability to the general population, as it adjusts for age, gender, and race. Despite its widespread use, the MDRD equation has certain deficiencies that limit its utility. The equation was developed in a population of patients exclusively with CKD. Therefore, its use in general populations presents inherent limitations. Although the MDRD equation is relatively accurate at lower GFRs, it tends to underestimate GFRs over 60 mL/min/1.73 m^2, especially in people without kidney disease. Due to this lack of accuracy, use of the MDRD estimating equation tends to overdiagnose stage 3 CKD. As the MDRD equation is S[Cr] based, it also loses accuracy in patients at the extremes of age and weight, as well as in malnourished patients.

The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) study equation was published in 2009. There have been several iterations of this equation, using either S[Cr], serum cystatin C concentration (S[Cys]), or both measures. Similar to the MDRD equation, the CKD-EPI equation also takes into account age, gender, and race, but the S[Cys]-based equations have the advantage of not being influenced by muscle mass, whereas the S[Cr]-based MDRD and CKD-EPI equations are. Cystatin C is a marker of GFR due to several properties. Cystatin C is produced by all nucleated cells, is freely filtered by the glomeruli, and undergoes tubular reabsorption with negligible urinary excretion. Diabetes mellitus, obesity, and inflammation are associated with elevated levels of S[Cys]. When the CKD-EPI and MDRD equations are compared, the CKD-EPI equation is more accurate than MDRD at GFRs greater than 60 mL/min/1.73 m^2, but the CKD-EPI equation is less likely than the MDRD equation to misclassify a patient with stage 3 CKD. When S[Cr] and S[Cys] are combined, the CKD-EPI equation becomes even more accurate, particularly in patients with measured creatinine clearances greater than 45 mL/min/1.73 m^2, those with decreased muscle mass, and those at extremes of age.[3–6]

Being able to estimate GFR accurately is important for identifying patients at high risk for CKD progression and complications, especially as most patients with CKD are asymptomatic. As a result, several organizations have proposed that CKD screening be done in high-risk populations, such as patients with diabetes and hypertension,[7,8] despite the fact that the American College of Physicians and the United States Preventive Services Task Force recommended against screening for CKD.[9–11] Although there are no RCTs demonstrating

a benefit from CKD screening, the slowly progressive nature of CKD suggests that a trial of screening would take several years and an enormous number of participants to demonstrate a benefit. Furthermore, the presence of biochemical, endocrine, and hematologic abnormalities early in the course of disease underscores the need for screening to identify and treat these early complications. In the early course of CKD (stages 1 and 2), elevations in S[Cr] and blood urea nitrogen can be detected, as well as the presence of albuminuria. In CKD stage 3 (GFR 30–59 mL/min/1.73 m^2), 1,25-dihydroxycholecalciferol (calcitriol) deficiency often becomes apparent, as do elevations in circulating parathyroid hormone (PTH) levels and blood pressure. Erythropoietin deficiency tends to occur in CKD stage 3b, manifesting as normocytic anemia.[1,12–14]

In CKD stage 4 (GFR 15–29 mL/min/1.73 m^2), these abnormalities become more pronounced, and there is also a markedly elevated risk of cardiovascular events, hospitalizations, and death. Metabolic acidosis often presents in CKD stage 4 due to retention of nitrogenous wastes, secondary to deficits in renal tubular proton secretion, and nutritional deficiencies become more prevalent as well.[13–15] Patients often have hyperphosphatemia and hypocalcemia, because GFR, renal tubular responses, and hormonal action are not capable of maintaining homeostasis. Controlling blood pressure becomes more challenging at this stage due to retention of sodium and water in the setting of low GFR, often requiring the administration of potent loop diuretics to achieve blood pressure goals.[14,16] There is recent evidence supporting the continued use of thiazide diuretics to establish volume homeostasis and control blood pressure in advanced CKD, though randomized controlled trials are needed.[16]

The vast majority of patients with CKD do not present with uremia, which is due to the retention of metabolic products, putative uremic toxins, fluid, acids, and electrolytes in the setting of CKD stage 5 (GFR <15 mL/min/1.73 m^2). The onset of uremia is variable across this level of GFR, and symptoms may differ among and between patients, even at the lowest levels of renal function. Uremic patients present with multiorgan dysfunction, manifesting as nausea, vomiting, weight loss, pruritus, complaints consistent with serositis such as pleuritic chest pain, and malaise, sleep disorders, mental lassitude, and inability to concentrate. On physical examination, classic neurologic signs can include asterixis, clonus, and neurocognitive defects. Volume overload or signs of pericardial disease may be present. Potassium metabolism is usually adequately compensated until the late CKD stages, but diabetic patients are more likely to develop hyperkalemia in CKD stage 3.[17–19] Treatment of uremia as well as refractory volume, electrolyte, and/or acid–base disorders usually calls for the initiation of RRT either using one of the several forms of dialysis or ideally renal transplantation (Table 5.1).

TABLE 5.1 Indications for Initiating End-Stage Renal Disease Therapy

Uremic symptoms
Hyperkalemia resistant to medical therapy
Metabolic acidosis resistant to medical therapy
Congestive heart failure
Uncontrollable hypertension
Pericarditis

Diagnostic Considerations

Identifying the cause of CKD has been included in the most recent KDIGO guideline. Ascertaining the cause of CKD with respect to the presence or absence of diabetes, hypertension, autoimmune disease, and human immunodeficiency virus infection as well as whether the abnormality is glomerular, tubulointerstitial, vascular, cystic or congenital is important because the locus of the abnormality often has prognostic and treatment implications. Detection of the nephrotic syndrome (conservatively based on the finding of urinary protein excretion greater than 3 g/24 hours) connotes the presence of an inflammatory or noninflammatory glomerular disease and leads to consideration of diseases such as diabetes mellitus (the most common cause of ESRD in the US), and less commonly systemic lupus erythematosus, dysproteinemias, viral infections, and rarely malignancies or drug-induced illnesses. Some patients with nephrotic syndrome have idiopathic kidney diseases, such as membranous nephropathy, focal segmental glomerulosclerosis, and minimal change disease.

The presence of dysmorphic red blood cells or red blood cell casts, hypertension, edema, subnephrotic proteinuria, and decreased GFR suggests the presence of an inflammatory glomerulonephritis, such as IgA nephropathy, lupus nephritis, membranoproliferative glomerulonephritis, Goodpasture's disease, vasculitis, postinfectious glomerulonephritis, cryoglobulinemia, fibrillary glomerulonephritis, or immunotactoid glomerulonephritis. Alternatively, patients with CKD with urinary protein excretion rates less than 3 g/24 hours often have hypertensive nephrosclerosis (the second most

common cause of ESRD in the US), renal vascular disease, chronic interstitial nephritis, or analgesic nephropathy. The presence or absence of chronic systemic hypertension and the findings on urinalysis add accuracy to these rough diagnostic guidelines. In many patients, a percutaneous kidney biopsy may be needed to determine the diagnosis.

Kidney ultrasonography is an important early step in the diagnosis of CKD, as it can rapidly detect increased renal cortical echogenicity, which often suggests the presence of interstitial fibrosis. Ultrasonography is noninvasive and relatively inexpensive and can also characterize kidney size, hydronephrosis, cysts, masses, stones, and vascular abnormalities in both native and transplanted kidneys.[20–22]

Treatment of CKD

While prevention of CKD is a primary, if difficult, goal to achieve, nephrologists are usually concerned with the care of patients who already have CKD. One can divide the management of CKD into two major areas: prevention of CKD progression and treatment of complications of CKD (Tables 5.2 and 5.3).

The first guiding principle in slowing the progression of CKD is exemplified by the Latin phrase *primum non nocere*, or "first, do no harm." The avoidance of treatments, medications, and procedures known to worsen renal function is paramount. Aminoglycoside antibiotics, nonsteroidal antiinflammatory drugs, and other nephrotoxic medications should be avoided in patients with CKD, especially because preexisting CKD is known to be a major risk factor for AKI. Furthermore, iodinated radiocontrast administration can also cause acute deterioration of renal function, sometimes requiring dialysis either temporarily or permanently. When the above interventions are deemed necessary, attenuation of the anticipated renal injury can be accomplished by early recognition of the risk of renal injury, volume expansion with isotonic saline or bicarbonate solutions, and perhaps use of low-osmolar contrast, and *N*-acetylcysteine administration, although the field is currently marked by controversy.[23–25] A recent landmark study, however, did not demonstrate differences between outcomes in patients undergoing procedures associated with administration of intravenous contrast treated with either bicarbonate or acetylcysteine.[26]

The second important principle in slowing the progression of CKD is the prompt recognition and treatment of reversible causes of AKI. AKI is a well-recognized risk factor for CKD progression, imparting an eight- to ninefold risk for subsequent CKD. The degree of renal injury during an AKI episode can be used to predict the likelihood of a person developing advanced CKD.[13,27,28] Furthermore, delayed recovery of renal function after an AKI episode is a strong predictor of incident CKD, even in patients with mild AKI.[29]

Additional factors may reversibly decrease renal function in patients with CKD (Table 5.4). CKD patients are particularly prone to AKI from volume depletion as they have diminished capacity to adapt to changes in renal blood flow from volume depletion. Specifically, patients with CKD have GFR-dependent changes in tubular responsiveness to volume stressors, providing a narrower range of concentrating and diluting capacity and sodium handling than normal subjects.[30,31] In times of stress or illness, diminished ability to concentrate

urine may lead to excess fluid losses. Patients with congestive heart failure and renal disease may have diminution of renal blood flow as cardiac function worsens. Local renal arteriolar prostaglandin production becomes important in maintaining GFR in the face of falling cardiac output, which is opposed by nonsteroidal antiinflammatory drug administration. Therapy directed at improving cardiac hemodynamics may in turn substantially improve renal function. Renal function in patients with nephrotic syndrome and cirrhosis is also more dependent on renal prostaglandin production, so optimizing the volume status in these patients is crucial to the maintenance of renal hemodynamics.[13,20]

Urinary tract obstruction (UTO) is an important cause of decline in GFR. Bilateral or unilateral UTO in CKD patients can often cause rapid diminution of renal function due to intense renal vasoconstriction, leading to a subsequent fall in GFR. UTO can sometimes be suggested by findings in the history (such as a history of prostatic disease or difficulty beginning the stream or by symptoms suggestive of gynecologic malignancy) or physical examination (such as identification of a suprapubic mass or dullness). UTO is usually associated with hydronephrosis on ultrasound or computed tomography (CT), but obstruction from renal lymphoma or retroperitoneal fibrosis may not present with hydronephrosis.[21,22,32]

Renal arterial disease can accelerate the progression of CKD. This diagnosis should be considered in patients with atherosclerotic vascular disease, suddenly worsening hypertension (especially when it was previously well controlled), abrupt decline of renal function after initiation of therapy with RAAS inhibitors, asymmetric kidney size, and/or flash pulmonary edema with normal left ventricular function. CT and magnetic resonance imaging studies are helpful in confirming the presence of renovascular disease. Statin therapy, RAAS blockade, antiplatelet therapy, and possibly renal artery stenting are the cornerstones of treating renal arterial disease.[33,34] Of note, in patients with renal vascular disease and either difficult to control systolic hypertension or CKD, there was no benefit of renal artery stenting combined with medical therapy compared with medical therapy alone on a combined cardiovascular and renal endpoint. This finding is consistent with other studies that failed to show a benefit of renal artery stenting on kidney function.[35–38]

SPECIFIC TREATMENT RECOMMENDATIONS

Adjustment of Drug Dosages

The treatment of CKD requires an understanding of the complex interplay between the etiology of the patient's CKD, severity of disease, comorbid conditions, CKD complications, and CVD risk management.[39] Prompt recognition and management of each of these issues is necessary to develop an individualized clinical action plan for CKD management (Table 5.5). Part of the clinical action plan should involve adjustments in drug prescription, especially because compromised kidney function can drastically alter the pharmacokinetics of many medications. Many CKD patients require individualized decreases in certain medication doses or extension of the administration intervals. Therapeutic drug monitoring may be required to assess for efficacy and toxicity. The increased bioavailability and diminished metabolism or clearance of certain medications in the setting of CKD are associated with increased mortality in CKD patients, and some medications are contraindicated in more advanced stages of CKD.[40,41]

Management of Hypertension

Regardless of the cause of CKD, strict blood pressure control has been thought to slow the progression of CKD.[39] CKD patients with poorly controlled blood pressure (systolic blood pressure greater than 150 mm Hg) are almost 10 times more likely to progress to ESRD than those with systolic blood pressure less than 130 mm Hg.[42] Decreased renal blood flow associated with vasoconstriction, renal cellular ischemia, or shear stress in the setting of hypertension as well as activation of hormones, growth factors, and cytokines may be important mediators of renal pathogenic processes, including renal fibrosis.[43] In previous reports of the Joint

TABLE 5.5 Stages of Chronic Kidney Disease: A Clinical Action Plan

Stage	Description	Glomerular Filtration Rate (GFR) (mL/min/1.73 m^2)	Action*
1	Kidney damage with normal or ↑ GFR	≥90	Diagnosis and treatment, treatment of comorbid conditions, slowing progression, CVD risk reduction
2	Kidney damage with mild ↓ GFR	60–89	Estimating and treating progression
3	Moderate ↓ GFR	30–59	Evaluating and treating complications
4	Severe ↓ GFR	15–29	Preparation for kidney replacement therapy
5	Kidney failure	<15 (or dialysis)	Replacement (if uremia present)

Chronic kidney disease is defined as either kidney damage or GFR<60 mL/min/1.73 m^2 for ≥3 months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies. Abbreviations: *CVD*, cardiovascular disease.
** Includes action from preceding stages.*

National Committee (JNC) guidelines for the management of hypertension in adults, the target blood pressure for all patients with CKD was less than 130/80 mm Hg.[44] However, this recommendation was based on a minimal evidence base largely composed of trials with inconclusive results.[45]

Recent evidence has served to provide a more specific framework which clinicians can use to treat hypertension in CKD patients. The African-American Study of Kidney Disease and Hypertension (AASK) RCT clearly demonstrated that in the subset of patients with higher levels of proteinuria (urine protein:creatinine ratio >0.22), achieving a blood pressure less than 130/80 mm Hg was associated with decreased risk of CKD progression.[46,47] However, in the MDRD, AASK, and REIN-2 trials, achieving a blood pressure target of less than 130/80 mm Hg did not slow CKD progression compared with a target of less than 140/90 mm Hg when all study patients with varying levels of proteinuria were analyzed together.[45] Based on these trial data, the JNC 8 guidelines released in 2013 recommend a target blood pressure of less than 140/90 mm Hg for all patients with CKD.[48] It is noteworthy that the benefits of blood pressure lowering to less than 130/80 mm Hg in patients with proteinuria were obtained by *post hoc* analysis of a subgroup.[48] These blood pressure treatment recommendations are consistent with those recommended by the KDIGO Blood Pressure Work Group.[49]

The SPRINT trial investigators randomized over 9000 nondiabetic patients over age 50 with increased CVD risk to an intensive systolic blood pressure target of less than 120 mm Hg vs. a standard target of less than 140 mm Hg. This randomized, controlled, open-label trial allowed for the use of any antihypertensive agent. Although the intensive treatment arm only achieved a mean systolic blood pressure of 121.4 mm Hg (vs. 136.2 mm Hg in the standard treatment group), there was a 25% lower risk of reaching the primary outcome in the intensive treatment group, leading to an early termination of the study after less than 4 years of intervention.[50] Over 2600 patients had CKD, which did not influence the primary outcome of myocardial infarction, stroke, heart failure, or death from cardiovascular causes. The prespecified kidney outcome was a composite of ≥50% decrease in estimated GFR (eGFR) from baseline or ESRD. While the number of events was low, there was no difference in the kidney outcome between the intensive and standard groups (HR 0.90, 95% CI 0.44–1.83).[51] This and other observations led to the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines updating their definition of hypertension to a blood pressure greater than 130/80 mm Hg, irrespective of CKD.[52] While the appropriate blood pressure goal to reduce progression of CKD is unknown, a target blood pressure of ≤130/80 mm Hg is reasonable given the benefits with regard to CVD risk reduction.[53] Of note there was a higher incidence of AKI, eGFR decline ≥30%, hypokalemia, hyponatremia, and hypotension in the intensive treated group in SPRINT.

Antihypertensive therapeutic regimens in CKD patients should include an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB), unless there are specific contraindications to their use. These medications have been shown in multiple trials to slow the progression of CKD and reduce urinary protein excretion, and they are now recommended in all CKD patients regardless of race or diabetes status.[48,49,54–56] The antiproteinuric benefits of ACEIs and ARBs are independent of their effects on systemic blood pressure.[46,47,54–56]

It has been postulated that combining ACEIs and ARBs in patients with CKD, particularly proteinuric CKD, may confer added renal protection and reduce cardiovascular events. Much of the enthusiasm for dual therapy was initially generated by the COOPERATE study, which was subsequently retracted.[57] In the Ongoing Telmisartan Alone and in Combination with

Ramipril Global Endpoint Trial (ONTARGET), patients with established atherosclerotic vascular disease or diabetes with end-organ damage were randomized to receive the ACEI ramipril, ARB telmisartan, or both drugs.[58] Combination therapy was associated with a higher occurrence of the composite primary renal outcome of dialysis, doubling of S[Cr] and death.

In another study, when the direct renin inhibitor aliskiren was combined with an ACEI or ARB in patients with type 2 diabetes mellitus with CKD and/or CVD, there was no cardiovascular or renal benefit observed compared with patients on monotherapy.[59] There was a higher incidence of hypotension and hyperkalemia in the combination therapy group. Fried and colleagues evaluated the effect of combination ACEI/ARB therapy in a study of Veterans with diabetic nephropathy, but they found no cardiovascular or renal benefit of the combination compared with monotherapy with losartan.[60] However, an increased risk of hyperkalemia and AKI was seen in the combination therapy group, further supporting the notion that ACEI/ARB combination therapy cannot be recommended for CKD patients.[48,52,60]

Diuretics are useful antihypertensives in CKD patients, particularly in those with volume overload. They are still recommended as first-line agents in patients with hypertension in general, but their efficacy in stage 4 CKD may be limited. There are observational data supporting their efficacy in advanced stages of CKD, as thiazide diuretics cause negative sodium balance and weight loss in stage 4 CKD.[16] However, loop diuretics are still the recommended diuretics in those patients with advanced CKD, as they can produce a dose-dependent diuresis in patients with late stages of CKD.[52,61,62]

Calcium channel blockers (CCBs) are commonly used for the treatment of hypertension, and their utility in reducing proteinuria is currently an area of great research interest. In particular, the use of nondihydropyridine CCBs, such as diltiazem, is associated with a reduction in urinary protein excretion in patients with renal disease.[63] On the other hand, there are only limited data to specifically recommend dihydropyridine CCBs as first line or monotherapy in CKD patients.[48] Combination therapy, using a CCB (amlodipine) with an ACEI (benazepril) was compared with combination therapy using benazepril with hydrochlorothiazide in the ACCOMPLISH trial. The trial was stopped early due to a significant cardiovascular benefit observed in the ACEI/CCB group compared with the ACEI/hydrochlorothiazide group.[64] Furthermore, in the renal outcomes follow-up study, patients in the benazepril/hydrochlorothiazide group had faster CKD progression and a higher incidence of ESRD.[65]

Cardiovascular Disease

CKD is independently associated with CVD and increased cardiovascular mortality. Stage 4 CKD patients are more than four times more likely to experience coronary heart disease than those with preserved renal function.[66,67] In this population-based study, the risk of CVD in patients with stages 1 and 2 CKD was actually higher than in patients with stage 3 CKD, likely related to albuminuria.[66] There is clear and consistent evidence linking albuminuria to heightened CVD risk, thus leading to the inclusion of albuminuria in the new KDIGO guidelines.[68–71] Furthermore, reduction of albuminuria in CKD patients has been associated with decreased CVD risk.[72] CKD patients often have many of the traditional risk factors for CVD, but they also have nontraditional risk factors such as inflammation, anemia, oxidative stress, endothelial dysfunction, increased sympathetic activity, abnormal calcium/phosphate metabolism, and hyperhomocysteinemia, all of which may enhance overall CVD risk.[67,73] Optimization of volume status, blood pressure control, and treatment of the nontraditional CVD risk factors may decrease the overall CVD burden in CKD patients.

Statins have been widely used to decrease CVD risk in CKD patients. In two meta-analyses, statins decreased all-cause and cardiovascular mortality and CVD events in nondialysis CKD patients, but this benefit was not evident in patients treated with dialysis.[74–77] In the SHARP trial, 6247 patients not on dialysis were randomized to simvastatin plus ezetimibe vs. placebo. After a median follow-up of 4.9 years, there was a significant reduction in major atherosclerotic events, although no effect was seen on the progression of CKD.[78] Based on this study, the KDIGO clinical practice guideline recommends statin therapy and LDL lowering to reduce risk of CVD in patients with CKD.[79]

Other Treatments

Dietary Protein Restriction

Dietary protein restriction has long been employed and recommended to slow the progression of CKD, but the evidence base remains controversial.[13] There have been several systematic reviews and meta-analyses to evaluate the effects of dietary protein restriction, with some of the earlier trials showing benefit in slowing CKD progression.[80,81] These results conflict with findings from the MDRD study, however. The MDRD study, now more than two decades ago, compared normal- to low-protein diets (1.3–0.58 g/kg/day) in patients with moderate CKD (eGFR 25–55 mL/min/1.73 m^2), and low-protein to very low-protein diets (0.58–0.28 g/kg/day) in patients with advanced CKD (eGFR

13–24 mL/min/1.73 m^2), finding no benefit in slowing CKD progression in either group.[82] Moreover, a long-term follow-up of this study concluded that the very low-protein diet patients were almost twice as likely to die during the follow-up period, perhaps related to protein malnutrition once patients reach ESRD. Measures of nutrition should be closely monitored in CKD patients on protein-restricted diets.[83] High-protein intake, greater than 1.3 g/kg/day, has been associated with increased incidence of cardiovascular events in CKD patients, and should be avoided.[84] A systematic review demonstrated that most dietary interventions have uncertain effects on cardiovascular events, CKD progression, and mortality in CKD patients, though increased fruit and vegetable intake, polyphenol enriched diets, and Mediterranean diets may improve blood pressure and LDL cholesterol.[85]

Sodium-Glucose Cotransporter 2 Inhibitors

An emerging area is the investigation of whether some glucose-lowering drugs have beneficial effects on diabetic nephropathy and cardiovascular outcomes above and beyond their effects on glucose control.

These drugs inhibit sodium and glucose transport in the S1 segment of the proximal tubule and consequently increase glucose and sodium excretion. In addition to effects on glycemic control, sodium-glucose cotransporter 2 (SGLT2) inhibitors lower BP, weight, and albuminuria and are associated with a decline in GFR.[86] In the first of these studies, Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPA-REG OUTCOME trial), the effects of empagliflozin was examined in 7020 adults with type 2 diabetes mellitus and established CVD with an eGFR of at least 30 mL/min/1.73 m^2.[87] Empagliflozin treatment over a median follow-up of 3.1 years reduced the risk of cardiovascular events defined as a composite of first occurrence of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke. The risk of the prespecified renal outcome of incident or worsening nephropathy (progression to macroalbuminuria, doubling of S[Cr] accompanied by an eGFR $\leq$45 mL/min/1.73 m^2, initiation of renal replacement therapy, or death from renal disease) and incident albumuniuria was also reduced by empagliflozin.[88] Interestingly, treatment with empagliflozin was associated with a decrease in eGFR that was reversible after stopping the study drug.

In the CANVAS Program, the SGLT2 inhibitor canagliflozin was studied in 10,142 type 2 diabetic subjects at high risk for CVD. Canagliflozin decreased the primary cardiovascular endpoint of death from cardiovascular cause, nonfatal myocardial infarction, or nonfatal stroke.[89] The renal outcomes were not statistically significant based on the "prespecified hypothesis testing sequence," with a possible benefit in progression of albuminuria and the composite of sustained 40% reduction in eGFR, the need for renal replacement therapy, or death from renal causes. There was an unexplained increased risk for amputation in the canagliflozin group. The use of SGLT2 inhibitors is not recommended when the eGFR is <30 mL/min/1.73 m^2.

These results demonstrating renal protective effects of SGLT2 inhibitors are promising but before they are widely used as renal protective agents studies are needed examining long-term kidney outcomes. In this regard, the Canagliflozin and Renal Endpoints in Diabetes with Established Nephropathy Clinical Evaluation trial (CREDENCE; ClinicalTrials.gov number NCT02065791) provides important information about renal outcomes.[86] This is a trial in 4400 patients with type 2 diabetes and urinary albumin:creatinine ratio (UACR) > 300 to 5000 mg/g and eGFR of 30 to < 90 mL/min/1.73 m^2 adding canagliflozin to standard care consisting of maximum labeled or tolerated dose of ACEI or ARB. The primary endpoint was a composite of time to dialysis or kidney transplantation, doubling of S[Cr], and renal or CV death. The relative risk of the primary outcome was 30% lower in the canaglifozin group than in the placebo group. The canaglifozin group also had a lower risk of cardiovascular death, myocardial infarction, or stroke. There were no differences in the rates of amputation or fracture. This exciting study provides strong data for a renal protective effect of canaglifozin.

The potential mechanism of the beneficial effects of SGLT2 inhibitors may be through decreasing hyperfiltration. By reducing proximal reabsorption of sodium, distal sodium delivery is increased activating tubular glomerular feedback leading to afferent arteriolar vasoconstriction and a reduction in hyperfiltration. This is a class effect and is reversible after stopping the drug. If true, then these drugs may also be effective in nondiabetic kidney disease, a hypothesis that is being tested in the Study to Evaluate the Effect of Dapagliflozin on Renal Outcomes and Cardiovascular Mortality in Patients With CKD (DAPA CKD) in which half the patients are diabetic and half are nondiabetic. The primary outcome is a composite of $\geq$50% sustained decline in eGFR, ESRD, or CV or kidney death (ClinicalTrials.gov NCT03036150).[86]

Targeting Uric Acid

Recent studies have examined the relationship between elevated uric acid levels and both renal and CVD events. It has been suggested that hyperuricemia is independently associated with increased incidence of CVD events, and that this association is strengthened in advanced CKD.[90–93] However, in light of recent studies suggesting only a marginal benefit in left ventricular mass index and endothelial function when

hyperuricemia is treated with allopurinol, there is insufficient evidence to either support or refute the use of uric acid lowering agents in CKD patients with hyperuricemia.[13,90–94]

Metabolic acidosis is an important complication and potential target of therapy in CKD patients. Metabolic acidosis initially ensues from impaired ammoniagenesis and diminished renal hydrogen ion excretion in the setting of low GFR, then progresses to retention of metabolic wastes as CKD progresses.[95,96] Metabolic acidosis can lead to myocardial depression, arrhythmias, insulin resistance, hyperventilation, muscle weakness, inflammation, and bone disease. Treatment of metabolic acidosis with oral alkali has been prospectively shown to slow progression of CKD.[97,98] KDIGO recommendations endorse treatment of metabolic acidosis with bicarbonate in CKD patients when serum bicarbonate concentration is less than 22 mmol/L.[13] However, an analysis of 3586 patients in the Chronic Renal Insufficiency Cohort demonstrated a higher risk of heart failure events and mortality when the serum bicarbonate is maintained above 26 mmol/L.[99]

Vitamin D

Vitamin D metabolism becomes impaired in CKD, primarily due to decreased conversion of 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D_3 by the kidneys.[100,101] It has been proposed that vitamin D supplementation can inhibit the RAAS and attenuate podocyte injury, and vitamin D supplementation has been associated with reduction in proteinuria.[102] De Zeeuw and colleagues showed in the VITAL study that high-dose paracalcitol supplementation was associated with a significant decline in proteinuria in patients with type 2 diabetes with CKD compared to placebo, but there was no significant slowing of CKD progression.[103] As more information is developed regarding circulating fibroblast growth factor-23 (FGF-23) and phosphate levels, and their interrelationships with CKD progression and mortality, the role of vitamin D supplementation in preserving residual renal function will become clearer.[104]

Serum Phosphate

As CKD progresses, deranged phosphate metabolism becomes apparent, even before serum phosphate (S[P]) levels begin to rise. Although overt hyperphosphatemia usually presents at or after CKD stage 3a, decreased tubular phosphate reabsorption as a result of increased levels of PTH and FGF-23 occurs as early as CKD stage 2.[12,105–107] These metabolic complications, in particular hyperphosphatemia, have been shown in multiple studies to be independently associated with higher mortality in CKD patients.[108,109] Furthermore, hyperphosphatemia in CKD is associated with increased risk of cardiovascular events, vascular and valvular calcification, fractures, and progression of CKD to ESRD.[110,111] Phosphate restriction to maintain S[P] levels within the normal range has been recommended for many years, most recently by KDIGO.[13,112,113] The beneficial effects of lowering S[P] on surrogate biochemical outcomes such as PTH levels, calcium × phosphate product, and FGF-23 levels have supported the use of phosphate binders in CKD patients.[113–116] Phosphate binders are widely employed in stages 3–5 CKD patients based on the premise that control of surrogate outcomes will lead to improved hard outcomes in this high-risk population. Unfortunately, when cardiovascular events and mortality are considered, there is insufficient evidence to support the use of either calcium-containing or non-calcium-containing phosphate binders in CKD patients, although it is clear that phosphate lowering is the first and most important step in controlling secondary hyperparathyroidism.[116–120]

Anemia

Anemia is a frequent complication of CKD and can be detected with 90% sensitivity at a measured GFR of 44 mL/min/1.73 m^2. The prevalence of anemia increases with advancing stages of CKD and is independently associated with increased risk of hospitalizations, mortality, and CKD progression.[121–124] Based on these observations, the most recent KDIGO guidelines recommend that hemoglobin concentrations be measured with increasing frequency with increasing severity of CKD. Furthermore, iron supplementation should be employed in anemic CKD patients with iron deficiency prior to prescribing erythropoiesis-stimulating agents (ESAs).[125] It was previously assumed that ESA therapy would not only correct the anemia but also slow the progression of CKD. However, the TREAT trial demonstrated no difference in CKD progression between patients randomized to darbepoetin or placebo with a target hemoglobin level of 13 g/dL.[126] The CREATE and CHOIR trials both demonstrated that treatment of anemia with ESAs to a target hemoglobin greater than 13–13.5 g/dL was associated with more rapid progression to ESRD than those with lower target hemoglobin levels.[127,128] Based on these trial data, KDIGO guidelines recommend that ESAs not be used to treat anemic CKD patients to a target hemoglobin above 11.5 g/dL.[125]

DELIVERY OF CKD CARE

The way we deliver care to CKD patients may also affect health outcomes. For example, multidisciplinary CKD programs (CKD clinics) are associated with better patient adherence to CKD guidelines, a higher incidence of fistula use at initiation of dialysis, and more outpatient dialysis starts (vs. emergency inpatient starts).[129] Also, early referral to a nephrologist is associated with improved outcomes once patients initiate dialysis. KDIGO recommends referral to a nephrologist when eGFR is less than 30 mL/min/1.73 m^2 and/or UACR is greater than 300 mg/g, with earlier referral recommended in specific cases.[13] Early referral has been associated with a number of beneficial effects including decreased mortality, reduced hospitalization days, and improvement in the appropriate use of fistulas and grafts as opposed to catheters at initiation of dialysis.

CONCLUSION

Defining and staging CKD has allowed the provider to take a systematic approach to CKD management. Each stage of CKD confronts both the patient and provider with different problems and clinical issues, often predictable from the natural history of each CKD stage. Proper CKD management requires an understanding of the physical and biochemical abnormalities that occur throughout the course of a patient's kidney disease, which is usually progressive and irreversible. The classification and staging of CKD has had a great effect on clinical care over the last decade. Major manifestations of biochemical abnormalities are predictable at each CKD stage. Stage-specific management of CKD is directed at avoiding additional kidney injury, adjusting and monitoring medications, slowing CKD progression, and managing the complications that arise at each stage.

Therapies to slow progression include blood pressure control with a target blood pressure less than 130/80 mm Hg. Preferential use of ACEI and ARBs, but not both together, should be a cornerstone of hypertension management in CKD patients. Reducing risk factors for CVD is an important component of management of the CKD patient, given the almost universal presence of this devastating complication. Guidelines are available for proper management of anemia and hyperphosphatemia. Other therapies for managing CKD are important at each stage, but evidence-based recommendations to change outcomes in CKD patients are largely lacking. Well-designed RCTs addressing such issues in patients with CKD are urgently needed to guide therapy for many of the complications of CKD. The care of the CKD patient must be individualized at present, as RCTs in this population have yielded variable success.

QUESTIONS AND ANSWERS

Question 1

Which ONE of the following is NOT TRUE regarding S[Cr] as a marker of kidney function?

A. S[Cr] level depends on diet and muscle mass
B. Creatinine production decreases with aging
C. S[Cr] underestimates renal function in people with low body weight
D. Creatinine secretion can be inhibited by drugs such as cimetidine

Answer: C

Answer C is incorrect as S[Cr] overestimates renal function in people with low body weight or with decreased muscle mass. The other statements about creatinine as a marker of kidney function are correct. The other drug that blocks creatinine secretion by renal tubules and therefore results in falsely elevated S[Cr] is trimethoprim.[1,2]

Question 2

Which ONE of the following is TRUE about the MDRD equation for estimating GFR?

A. It underestimates GFRs >60 mL/min/1.73 m^2
B. It leads to underestimation of the burden of stage 3 CKD
C. It is more accurate in older and malnourished patients
D. It should only be used in patients on a high-protein diet

Answer: A

Despite its widespread use, the MDRD equation has certain deficiencies that limit its utility. Although it is relatively accurate at lower GFRs, the MDRD equation tends to underestimate GFRs over 60 mL/min/1.73 m^2 especially in people without kidney disease. Therefore, **Answer A** is correct. Due to this lack of accuracy, use of the MDRD estimating equation tends to overdiagnose stage 3 CKD, making **Answer B** incorrect. Because the MDRD equation is S[Cr]-based, it also loses accuracy in patients at the extremes of age and weight, as well as in malnourished patients, making **Answer C** incorrect.[130] Although the equation was derived from patients enrolled in the MDRD study, the level of dietary protein intake has not been demonstrated to be a factor in the accuracy of the equation.

Question 3

A 55-year-old African-American woman has CKD secondary to diabetic nephropathy. Her GFR estimated by the CKD-EPI study equation using cystatin C is 38 mL/min/1.73 m^2.

Which ONE of the following is true regarding the use of cystatin as a marker of GFR in patients with CKD?

A. It can only be used in epidemiologic studies of CKD
B. It is less accurate than MDRD equation at GFRs greater than 60 mL/min/1.73 m^2
C. Cystatin C-based eGFR is a better predictor of death or ESRD compared to formulas that use creatinine
D. Estimating eGFR can be done with either S[Cr] or S[Cys] but not both

Answer: C

Cystatin C is a 120 amino acid protein that is synthesized and secreted at a nearly constant rate by almost all nucleated cells. It is freely filtered by the glomerulus and metabolized by the proximal tubule with negligible urinary excretion. Its advantage as a filtration marker is that it is not affected by muscle mass or chronic disease as is creatinine.

The use of cystatin C alone or in combination with S[Cr] improved the association between eGFR and the risks of death and ESRD in a meta-analysis of 11 general-population studies and 5 cohorts with CKD, making **Answer C** the correct answer.[118]

Answer A is incorrect as the CKD-EPI formulas were derived from large epidemiologic studies but can be used to estimate eGFR in individual patients.

Answer B is incorrect because any of the CKD-EPI equations are more accurate than the MDRD equation, which underestimates eGFR in those with levels >60 mL/min/1.73 m^2.

Answer D is incorrect as a CKD-EPI formula was developed and published in 2012 that uses both S[Cr] and cystatin C. This formula is more accurate than formulas using only one of these markers.[6]

Question 4

A 42-year-old African-American man with focal and segmental glomerulosclerosis has stage G3a CKD based on the 2012 staging system developed by KDIGO working group. His UACR is 750 mg/g placing him in the A3 albuminuria category.

Which ONE of the following is NOT TRUE regarding staging of his CKD?

A. Albuminuria is a risk factor for cardiovascular disease in CKD patients
B. Albuminuria is a risk factor for CKD progression
C. eGFR and albuminuria should be assessed at least annually in patients with CKD
D. Risk for CKD progression can be adequately assessed at the time of initial staging

Answer: D

Albuminuria is a risk factor for both CVD and CKD progression, therefore **Answers A and B** are true. KDIGO recommends GFR and albuminuria should be assessed at least annually in patients with CKD, and more frequently for those at higher risk of progression and/or where measurement will impact therapeutic decisions, therefore **Answer C** is true.[13] **Answer D** is not true and is the correct answer to this question. The confidence is assessing progression is increased with increasing number of S[Cr] measurements and duration of follow-up. It is important to realize that small fluctuations in GFR are common and not necessarily indicative of progression.

Question 5

A 58-year-old Hispanic woman with stage 3bA3 CKD secondary to diabetic nephropathy is seen in the outpatient clinic for management of CKD. Current S[Cr] is 3.7 mg/dL and eGFR using the abbreviated MDRD equation is 16 mL/min/1.73 m^2. A UACR is 3520 mg/g. Other medical problems include hypertension, currently treated with furosemide 40 mg orally twice daily and lisinopril 40 mg once daily. Her blood pressure is 155/95 mm Hg.

Which ONE of the following is true regarding management of her hypertension?

A. An ARB should be added to her antihypertensive regimen
B. Her blood pressure is adequately controlled on her current antihypertensive regimen
C. Hydrochlorothiazide should be added for better blood pressure control
D. Target BP is less than 130/80 mm Hg

Answer: D

Dual therapy with an ACEI and an ARB has not been effective in slowing progression of CKD and has been associated with significant complications such as hyperkalemia, hypotension, and AKI.[49–52] The current recommendations are not to use dual therapy, making **Answer A** incorrect. Although the exact target blood pressure in patients with CKD is unknown, most observational studies have demonstrated an association between level of blood pressure and clinical outcomes in CKD patients. Current clinical practice guidelines recommend BP <140/90 mm Hg, making **Answer B** incorrect. Hydrochlorothiazide is not the best agent to add, because in advanced CKD it is a relatively weak antihypertensive. Furthermore, in the ACCOMPLISH Study worse renal outcomes were seen in the ACEI/hydrochlorothiazide group compared with the ACEI/CCB group, therefore **Answer C** is incorrect.[57] Based on clinical practice guidelines, **Answer D** is the best choice.

Question 6

A 62-year-old man with known coronary artery disease and hypertension presented to the outpatient clinic for management of CKD secondary to membranous glomerulopathy. He has stable angina requiring 1 to 5 nitroglycerin tablets per week. His eGFR is 31 mL/min/1.73 m^2 and UACR is 920 mg/g (stage G3bA3 CKD). Other labs included a hemoglobin of 9.1 g/dL, transferrin saturation (TSAT) 21%, and ferritin 150 ng/mL.

Which ONE of the following is NOT TRUE regarding management of his anemia?

A. Hemoglobin concentration should be measured at least every three months in this patient
B. A trial of oral iron therapy should be initiated to try to correct the anemia
C. ESA therapy should be started targeting a hemoglobin concentration of 14 g/dL
D. ESA therapy should be started if there is no response to iron

Answer: C

Answer A is true. KDIGO clinical practice guidelines recommend measurement of hemoglobin concentration when clinically indicated and at least annually in patients with stage 3 CKD with anemia not being treated with an ESA.

Answer B is true. For CKD patients not treated with dialysis with anemia and not on iron or ESA therapy, KDIGO recommends a trial of oral iron therapy for 1–3 months if an increase in Hb concentration is desired, and TSAT is ≤30% and ferritin is ≤500 ng/mL. In this patient, an increase in hemoglobin is desired based on his stable but persistent angina. If oral iron is not effective, a trial of intravenous iron should be considered. Patients with CKD and anemia, if found to be iron deficient, need to have an evaluation for causes of blood loss.

When the hemoglobin concentration is less than 10 g/dL, the decision to initiate ESA therapy should be individualized. In this patient with angina, ESA therapy should be started to correct the anemia if there is no iron therapy. Therefore, **Answer D** is true. ESA should not be used to intentionally increase the hemoglobin concentration above 13 g/dL. In general, KDIGO recommends ESAs not be used to maintain Hb concentration above 11.5 g/dL in adult patients with CKD. Therefore, **Answer C** is not true and is the correct answer.[113]

CHAPTER

6

Epidemiology of Chronic Kidney Disease—Scope of the Problem

Mark Canney[a], *Peter Birks*[b], *Adeera Levin*[a]

[a]UBC Division of Nephrology and British Columbia Renal Agency, Vancouver, BC, Canada; [b]British Columbia Renal Agency, Vancouver, BC, Canada

Abstract

Chronic kidney disease (CKD) is defined as abnormalities of kidney structure or function that are present for at least 3 months. In epidemiological studies, CKD is usually defined by a glomerular filtration rate (GFR) <60 mL/min/1.73 m^2 and/or a urinary albumin:creatinine ratio ≥30 mg/g (≥3 mg/mmol). In these studies, the prevalence of CKD often exceeds 10%, increases markedly with age, and varies by race. Major risk factors for CKD include hypertension, diabetes, and vascular disease. In developing countries, infection and glomerulonephritis are important contributors. Although end-stage renal disease (ESRD) is the most commonly recognized outcome, CKD confers an increased risk for all-cause mortality, cardiovascular events, acute kidney injury, infection, hospitalizations, and frailty. Although our knowledge and understanding of the epidemiology of CKD has improved substantially over the past decade, significant gaps remain, most notably in the developing world.

INTRODUCTION

The purpose of this chapter is to describe the scope of the problem of chronic kidney disease (CKD) using the best available data and literature. We begin with some background regarding the CKD paradigm, starting with the harmonized definition of CKD in 2002, data generated since that seminal publication, and the refinement of definitions and classification systems outlined in 2012. Most of the information about the epidemiology of CKD is predicated on these definitions. This chapter describes the profound and consistent relationship of CKD with adverse outcomes, highlighting the importance of CKD as a public health priority. Although knowledge gaps remain, particularly in capturing the burden of CKD in developing countries and in our understanding of individual risks associated with CKD in different circumstances, accruing data from multiple sources confirms the global impact of CKD on health.

BACKGROUND

In 2002, the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) published a guideline on the definition, classification, and evaluation of CKD.[1,2] This represented a major paradigm shift for clinicians and researchers. The guideline recognized that patients with kidney disease were at risk of developing complications long before the need for renal replacement therapy and proposed that patients could be identified much earlier in the course of their disease using simple laboratory markers. Importantly, the classification system harmonized the nomenclature of kidney disease, thereby streamlining clinical care and facilitating collaborative research efforts. The publication has had a profound impact. It has stimulated discussion and debate, generated substantial research globally, and influenced public policy and laboratory practice.

It is of fundamental importance to recognize that the classification of CKD is built on risk of clinical outcomes. Multiple studies from different populations have consistently demonstrated higher risk of end-stage renal disease (ESRD), cardiovascular (CV), and all-cause mortality in individuals with a urine albumin:creatinine ratio (UACR) greater than 30 mg/g (3 mg/mmol) and/or estimated glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2, irrespective of the etiology or duration of kidney disease.[3] The international interest in understanding the epidemiology of CKD and improving the outcomes of people living with kidney

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00006-1

disease led to the revision and updating of the original NKF-KDOQI guideline by the international Kidney Disease: Improving Global Outcomes (KDIGO) group. The 2012 Clinical Practice Guideline on Evaluation and Management of CKD was informed by a decade of systematic research using common definitions, standardization of assays, and development of robust equations to estimate GFR.[4]

DEFINITION OF CKD

KDIGO defines CKD as abnormalities of kidney structure or function, present for at least 3 months, with implications for health. GFR has long been considered the best overall index of kidney function. The threshold to define CKD is a value less than 60 mL/min/1.73 m^2 body surface area. The categorization of GFR stage is described in Table 6.1. If GFR is ≥60 mL/min/1.73 m^2, CKD can be diagnosed by the presence of other markers of kidney damage including albuminuria, abnormal urinary sediment (such as hematuria or casts), renal tubular disorders, pathologic abnormalities such as tubulointerstitial diseases, and structural abnormalities detected by imaging (such as polycystic kidneys). The threshold of albuminuria to diagnose CKD is a UACR ≥30 mg/g (≥3 mg/mmol) (Table 6.2). KDIGO highlights the need to address three dimensions when describing CKD: cause, GFR category, and albuminuria category. Including cause of disease in the definition of CKD acknowledges potential differences in prognosis and therapy depending on the specific underlying etiology. The cross classification of GFR and albuminuria categories provides a color-coded stratification of risk for adverse outcomes (Figure 6.1). It is important to note that risk is high in the setting of significant albuminuria (>300 mg/g or >30 mg/mmol) even if GFR is preserved (>60 mL/min/1.73 m^2).

TABLE 6.1 GFR and ACR Categories in the KDIGO 2012 Classification GFR Categories

GFR Category	GFR (mL/min/1.73 m^2)	Descriptor
G1	≥90	Normal or high
G2	60–89	Mildly decreased*
G3a	45–59	Mildly to moderately decreased
G3b	30–44	Moderately to severely decreased
G4	15–29	Severely decreased
G5	<15	Kidney failure

Abbreviations: *ACR*, albumin:creatinine ratio; *CKD*, chronic kidney disease; *GFR*, glomerular filtration rate.
* *Relative to young adult level. In the absence of evidence of kidney damage, or structural abnormalities, neither GFR category G1 nor G2 fulfill the criteria for CKD.*

TABLE 6.2 ACR Categories

ACR Category	AER (mg/day)	ACR Equivalent (mg/mmol)	ACR Equivalent (mg/g)	Descriptor
A1	<30	<3	<30	Normal to mildly increased
A2	30–300	3–30	30–300	Moderately increased*
A3	>300	>30	>300	Severely increased**

Abbreviations: *ACR*, albumin:creatinine ratio; *AER*, albumin excretion rate; *CKD*, chronic kidney disease.
* *Relative to young adult level.*
** *Including nephrotic syndrome (albumin excretion usually >2200 mg/day [ACR >2220 mg/g; >220 mg/mmol]).*

The thresholds for GFR and albuminuria to classify the stage of CKD are based on large population studies examining prognosis. The CKD Prognosis Consortium (CKD-PC) was established in 2009 by KDIGO and sponsored by the US NKF.[5] CKD-PC is composed of investigators from around the world who share data from over 70 cohorts. Each participating study prepares a dataset with relevant variables according to a standardized coding framework. The data are sent to a coordinating center where they are pooled and meta-analyzed. CKD-PC investigators have consistently demonstrated that a GFR <60 mL/min/1.73 m^2 and an albumin:creatinine ratio (ACR) ≥30 mg/g (≥3 mg/mmol) are associated with increased risk of all-cause and CV mortality, CKD progression, and ESRD in the general population, high risk (for vascular disease), and kidney disease cohorts.[6–9]

Assessment of GFR

Although clearance of an exogenous filtration marker remains the gold standard for measuring GFR, the procedure is invasive, expensive, and time-consuming. A key factor in the rapid uptake of the CKD classification system was the availability of an equation to estimate GFR from an endogenous filtration marker such as creatinine. The first GFR estimating equation came from the Modification of Diet in Renal Disease (MDRD) study. The investigators used stepwise regression to generate a formula to predict measured GFR in 1628 participants from serum creatinine concentration (S[Cr]), demographic and clinical variables.[10] An updated, more parsimonious MDRD equation was published in 2006 which included just four variables: age, sex, race, and S[Cr] using a standardized assay.[11] The generalizability of the MDRD equation was hampered by the original study design. For example, included participants all had an underlying diagnosis of kidney disease, and the exclusion criteria included age >70 years and insulin-requiring diabetes mellitus.

Prognosis of CKD by GFR and Albuminuria Categories				Albuminuria categories Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30-299 mg/g 3-29 mg/mmol	≥300 mg/g ≥30 mg/mmol
GFR categories (mL/min/1.73m^2) Description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60-89			
	G3a	Mildly to moderately decreased	45-59			
	G3b	Moderately to severely decreased	30-44			
	G4	Severely decreased	15-29			
	G5	Kidney failure	<15			

Green: low risk (if no other markers of kidney disease, no CKD);
Yellow: moderately increased risk; Orange: high risk; Red, very high risk.

An alternative GFR estimating equation was published in 2009 by the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI).[12] The CKD-EPI equation was developed in a more diverse population than the MDRD cohort and included individuals with and without evidence of kidney disease. The equation was developed and internally validated in 8254 participants from 10 studies and externally validated in 3896 participants from 16 other studies. The CKD-EPI equation was shown to be as accurate as the four-variable MDRD equation at lower levels of GFR (<60 mL/min/1.73 m^2) and to demonstrate less bias than the MDRD formula at higher levels of GFR (≥60 mL/min/1.73 m^2). Where CKD-EPI has been modified for use in other racial and ethnic groups, and where validated country- or region-specific equations have been developed, those modified equations should provide valid estimates and can be used.[4] An important limitation of the CKD-EPI equation was the relatively small sample size for adults >70 years of age. This important gap has been addressed by the Berlin Initiative Study equations, which were specifically developed and validated in individuals over the age of 70.[13]

Despite the refinement of GFR estimating equations over time, they are still subject to the limitations of S[Cr] as a filtration marker, most notably large interindividual variability in creatinine generation due to differences in dietary protein intake and muscle mass.[14] The precision of GFR estimating equations remains limited at values of GFR >60 mL/min/1.73 m^2, suggesting that age, sex, and race do not account for all of the variation in non-GFR determinants of creatinine. The filtration marker that has gained most traction as an alternative to creatinine is cystatin C, a 13 kDa protein thought to be produced by all nucleated cells at a constant rate. Early studies demonstrated that cystatin C was a better predictor of measured GFR than creatinine.[15] An equation to estimate GFR from cystatin C was published by the CKD-EPI group in 2012.[16] While adjusting for non-GFR determinants of creatinine generation (age, sex, and race) significantly improved the correlation between S[Cr] and measured GFR, the same adjustments only minimally improved the correlation between cystatin C and measured GFR. For this reason, as well as higher cost and limited availability of assays, cystatin C struggled to enter clinical practice as a viable long-term alternative to S[Cr].[17] Where cystatin C has shown most promise is in risk stratification of CKD. A number of landmark studies have demonstrated that reclassification of estimated GFR (eGFR) stage using cystatin C can discriminate between high and low risk for important outcomes.[18,19] For this reason, cystatin C has entered KDIGO guidelines as a confirmatory test of CKD among individuals with GFR between 45 and 59 mL/min/1.73 m^2 without other evidence of kidney damage such as albuminuria. Cystatin C has strong associations with CV risk factors, independent of GFR, such as inflammation, smoking, and

obesity.[20–22] It is unclear if the improved risk discrimination of cystatin C relates entirely to its role as a marker of filtration or whether these non-GFR determinants of cystatin C also contribute to higher risk of adverse outcomes.

Assessment of ACR

To evaluate proteinuria, the measurement of urinary albumin, expressed as ACR, is recommended. By reporting the urinary albumin level in relation to urinary creatinine concentration, the ACR provides a standardized measure. Albumin is the most abundant protein excreted in the urine in most proteinuric kidney diseases (although urinary immunoglobulin loss characterizes monoclonal gammopathies affecting the kidney). ACR has greater sensitivity for detecting low-grade but clinically important albuminuria and is more precise at low but diagnostically important concentrations. Other measures of protein in the urine can be used, including total protein or qualitative measures (dipsticks), where circumstance does not permit use of the more expensive test of ACR.

PREVALENCE OF CKD

The standardized definitions of CKD have led to improved understanding of the burden of CKD in multiple populations. The remainder of this chapter reviews the prevalence of CKD in different regions around the world and by demographic subgroups, the outcomes associated with CKD that have underpinned the classification system, and recognized risk factors for CKD. Throughout the text, we discuss strengths and limitations of the current data available and highlight areas that require further study.

With the advent of GFR estimating equations and consensus definitions for CKD, there have been many studies evaluating the prevalence of CKD from around the world. A review published in the Lancet in 2013 provided CKD prevalence estimates from 18 countries.[23] The prevalence of GFR <60 mL/min/1.73 m^2, estimated by the MDRD or CKD-EPI equations, often exceeded 10%. The prevalence of proteinuria frequently exceeded 5%. In the US, robust prevalence data have been published from the 1988–1994 and 1999–2004 phases of the National Health and Nutrition Examination Survey (NHANES).[24] NHANES is a stratified, cluster probability sample that, coupled with the use of sampling weights, provides nationally representative prevalence estimates. CKD was defined using GFR estimated from S[Cr] (calibrated to a central reference standard) and persistent albuminuria. Overall, it was estimated that 13% of US adults had evidence of CKD. Of US adults with reduced GFR, the majority had mildly or moderately decreased GFR (30–59 mL/min/1.73 m^2), with only 0.35% having severely decreased GFR or kidney failure.

The European CKD Burden Consortium recently published prevalence data from various cohorts across Europe.[25] In addition to demonstrating overall high prevalence of CKD, the investigators observed considerable heterogeneity in included studies, for example, varying sample sizes and response rates, use or nonuse of a sampling frame, and lack of standardization of assays used to measure or cystatin C.[26] Notwithstanding these methodological differences, it is likely that there are population-specific factors that contribute to varying prevalence estimates. Therefore, it is important to accurately define the prevalence of CKD in well-characterized and representative samples to meaningfully compare prevalence estimates between different regions. Another limitation of most prevalence studies is the lack of a repeat assessment of GFR or ACR to confirm the chronic nature of the abnormality. Albumin excretion is subject to substantial intraindividual variation,[27] and both GFR and ACR can be affected by changes in body composition.[28] Use of a single GFR or ACR value to define the presence or absence of CKD can thus lead to substantial misclassification.[29]

CKD AND OUTCOMES

Although kidney failure is the most commonly recognized outcome for patients with kidney disease, CKD has also been strongly associated with an increased risk of several other important outcomes, most notably all-cause and CV mortality. CKD has thus been the focus of intensive research efforts to better understand the mechanisms driving poor outcomes in people with kidney disease.

CKD and All-Cause Mortality

CKD is associated with an increase in the absolute risk of all-cause mortality.[30] Life expectancy is reduced in the setting of either reduced GFR or increased ACR.[31,32] For example, individuals aged 30 years with evidence of severely increased ACR (≥300 mg/g) may have a shortening of life expectancy by as much as 18 years compared with their age-matched peers without albuminuria.[31] The CKD-PC pooled data on 1.2 million adults from general population cohorts and reported multivariable-adjusted hazard ratios (95% confidence interval (CI)) for all-cause mortality of 1.18 (1.05–1.32), 1.57 (1.39–1.78), and 3.14 (2.39–4.13) for GFR levels of 60, 30, and 15 mL/min/1·73 m^2, respectively, each vs. a reference GFR of 95 mL/min/1.73 m^2.[6] Results for GFR were nonlinear, tending

toward a U-shaped relationship, likely explained by low creatinine generation due to diminished muscle mass or malnutrition in the context of competing comorbid illness. In contrast, the association between ACR and mortality was linear. Hazard ratios (95% CI) were 1.20 (1.15–1.26), 1.63 (CI 1.50–1.77), and 2.22 (1.97–2.51) for ACR values of 10 mg/g, 30 mg/g, and 300 mg/g, respectively, each compared with an ACR of 5 mg/g. Although the interaction of GFR and ACR was not statistically significant, the highest risk of mortality was observed among those with a combination of low GFR and high ACR.

CKD and Cardiovascular Disease

Kidney disease has long been implicated as a risk factor for CV disease. Recent epidemiological studies have quantified this risk according to level of GFR and/or albuminuria. In a landmark study, Go and colleagues reported a graded increase in the risk of CV disease with diminishing GFR among patients in the Kaiser Permanente Northern California health system.[33] Leveraging data from >1.2 million individuals in the general population, the CKD-PC observed an increased risk for CV mortality associated with decreased GFR and increased albuminuria.[6] In this analysis, higher risk for CV mortality became evident at GFR values below 75 mL/min/1.73 m^2. There was no such threshold for ACR, indicating that even small increases in albuminuria are independently associated with CV mortality. The CKD-PC reported similar results for 266,975 individuals at high risk for CKD (history of hypertension, diabetes, or CV disease).[9] In this population, the risk of CV mortality started to increase below a GFR of 60 mL/min/1.73 m^2 and was statistically significant at a GFR of 45 mL/min/1.73 m^2 (HR 1.73, 95% CI 1.49–2.00). Again, ACR demonstrated a linear risk relationship with CV mortality with no evidence of a threshold effect.

The higher risk of CV disease among individuals with kidney disease is often attributed to shared risk factors such as diabetes and hypertension. This assumption was challenged in two meta-analyses that demonstrated that the relative risk of CV mortality according to either lower GFR or higher ACR was similar in participants with and without diabetes or hypertension.[34,35] Furthermore, the risk of myocardial infarction among people with CKD is comparable with the risk posed by diabetes mellitus, a recognized coronary heart disease equivalent. For example, in a population of nearly 1.3 million people without a prior myocardial infarction, the incidence rate (95% CI) for acute myocardial infarction was 5.4 (5.2–5.7) per 1000 patient years for people with diabetes and 6.9 (6.6–7.2) per 1000 patient years for people with CKD.[36] The incidence rate was twofold higher for CKD compared with diabetes when CKD was defined by stricter criteria: GFR <45 mL/min/1.73 m^2 with proteinuria. Similarly, CKD has been associated with a substantially higher risk of recurrent coronary events than established risk factors such as diabetes, metabolic syndrome, or cigarette smoking.[37] The totality of the data supports calls for CKD to be regarded as a coronary heart disease risk equivalent,[38] and for GFR and ACR to be included in CV risk prediction algorithms.[39]

CKD and Renal Outcomes

Both reduced GFR and increased ACR are strong risk factors for progression of kidney disease and the development of ESRD. Among general population and high-risk cohorts, the risk of renal outcomes appears to increase at GFR values below 75 mL/min/1.73 m^2 and to rise exponentially at lower GFR values.[8] Among CKD populations, a GFR threshold for increased risk is not as readily identified; however, each 15 mL/min/1.73 m^2 reduction in GFR (below a GFR of 45 mL/min/1.73 m^2) is associated with a sixfold increased risk of ESRD.[7] Similar to mortality outcomes, the risk relationship between ACR and ESRD is monotonic across the range of ACR.[8] The association between GFR or ACR and ESRD does not appear to vary by diabetes or hypertensive status, arguing against a clustering of risk factors driving ESRD risk.[34,35] These findings support the use of GFR and ACR to identify individuals at higher risk of kidney outcomes, including the development of kidney failure risk prediction tools for clinical practice.[40]

CKD and Other Outcomes

CKD has been examined as a risk factor for several other clinical outcomes. In keeping with the strong association between CKD and CV endpoints, CKD has been identified as an independent predictor of specific CV conditions such as atrial fibrillation, stroke, heart failure, and peripheral arterial disease.[41–45] In general, ACR appears to be a stronger predictor of outcome than GFR in these studies. CKD is also related to higher risk of infection, hospitalizations, fractures, and frailty.[33,46–49]

GLOBAL BURDEN OF CKD

Defining the Global Burden of Disease

The Global Burden of Disease (GBD) was initiated in 1992 as a collaborative effort between the World Bank and the World Health Organization (WHO). The purpose of this study was to address three primary goals:

(1) provide information on nonfatal health outcomes for debates on international health policy, (2) develop unbiased epidemiological assessments for major disorders, and (3) quantify the burden of disease with a measure that could be used for cost-effectiveness analysis.[50] The WHO first reported the GBD for 1990 using disability-adjusted life years (DALYs), which is a time-based measure that combines years of life lost due to morbidity and premature mortality.[51] Since the first report in 1990, there have been subsequent waves of the GBD study. Compared with prior GBD studies, the scope of the 2015 GBD study is expanded and includes over 300 diseases in 195 countries and territories from 1980 to 2015.[52]

In 1990, CKD was ranked 27th in the list of causes of total number of global deaths. CKD increased to the 12th leading cause of death by 2015. Mortality due to CKD rose between 2005 and 2015 by 32% to 1.2 million deaths worldwide, with an estimated annual death rate of 19.2 per 100,000. Since 1990, only deaths from complications of HIV infection have increased at a faster rate than deaths from CKD. Furthermore, the global burden of mortality associated with CKD may be substantially higher than reported in the GBD study. A study conducted in the US and Australia found that many deaths among people with diabetes and CKD did not mention CKD.[53] This study estimated that mortality from diabetes-related renal disease may be up to 9 times higher than the reported rate. The contribution of CKD to DALYs increased from 30th in 1990 to 20th in 2015.[54] In several world regions (high-income Asia Pacific, high-income North America, central Latin America, Southeast Asia, and Oceania), CKD was ranked in the top 10 for DALYs.[55]

CKD IN POPULATION SUBGROUPS

Like most chronic disease, CKD is not uniformly distributed in the population. Over the past decade, notable differences in the prevalence of CKD by demographic factors have been reported. We review differences in CKD prevalence and CKD-outcome associations by demographic factors, as well as the major risk factors for CKD.

Age

One of the most controversial aspects of the CKD classification system has been the apparently high burden of CKD among the general population of older adults. Several studies have demonstrated a steep age gradient in the prevalence of CKD. For example, in the NHANES 1999–2004 study, the prevalence of GFR <60 mL/min/1.73 m^2 increased from less than 1% among individuals aged 20–39 years to 38% among those over 70 years.[24] Similarly, the European CKD Burden Consortium reported prevalence estimates exceeding 40% among individuals aged ≥75 years.[25] Additionally, the prevalence of albuminuria increases with age. Using NHANES data, the prevalence of albuminuria (ACR >30 mg/g) was estimated at 5.8%, 11.4%, and 22.7% among US adults aged 20–49, 50–69, and ≥70 years, respectively.[56] In the Reasons for Geographic and Racial Differences in Stroke study, 25% of US adults aged ≥80 years had an ACR >30 mg/g.[57]

A number of arguments have been put forward to support an age-calibrated definition of CKD, built on the notion that decreased GFR or increased ACR in older people reflects "normal aging" rather than a disease.[58,59] It was postulated decades ago that GFR declines with advancing age. Contemporary population studies of apparently healthy adults have also demonstrated a gradual decline in estimated GFR with age.[60] An interesting population to study kidney aging are older individuals who donate a kidney. Living kidney donors are subject to a rigorous evaluation of their health status, including measurement of GFR and a kidney biopsy at the time of engraftment, providing a rich source of data regarding age-related structural and functional changes in the kidney. The prevalence of glomerulosclerosis, arteriosclerosis, interstitial fibrosis, and tubular atrophy, collectively termed nephrosclerosis, increases linearly with age.[61] This association is not explained by declines in GFR or risk factors for CKD, suggesting that these histological changes reflect a subclinical phenomenon of natural aging.[62,63] Critics of the CKD classification system also point to the discrepancy between high prevalence of the disease and comparatively low incidence of ESRD in older adults, often due to a competing risk of death from another cause.[64]

A meta-analysis of over two million participants specifically addressed the question of effect modification by age in the association between GFR and the risk of mortality or ESRD.[65] Among 33 general population and high risk of vascular disease cohorts, age was found to modify the relationship between GFR and mortality risk. Relative risks of mortality and ESRD were reduced at older age, whereas absolute risk differences were higher. Despite evidence of an interaction, GFR was independently associated with mortality and ESRD across all age categories. The increased risk of mortality generally became evident in the GFR range of 60–74 mL/min per 1.73 m^2, except in the oldest age group (>75 years) in whom the hazard ratio (with 80 mL/min per 1.73 m^2 as the reference) was statistically significant below a GFR of 56 mL/min per 1.73 m^2. In 13 CKD cohorts, the relationship between GFR and risks of ESRD and mortality did not vary substantially by age. Apart from hard outcomes, CKD has also been recognized as a contributing factor to the risk of more

proximal outcomes such as functional impairment,[66] an important patient-centered outcome for older adults.[67] Reduced GFR has been shown to be an independent predictor of poorer physical performance,[68,69] as well as a predictor of prevalent and incident frailty.[49] Even at older ages, reduced GFR is associated with a high prevalence of concurrent CKD complications such as anemia, acidosis, hyperphosphatemia, hyperparathyroidism, and hypertension.[70]

Gender

The prevalence of CKD and albuminuria appears to be higher in females. The 2016 USRDS annual report documented the prevalence of CKD in the US general population to be 13% in men and 16.5% in women.[71] In both sexes, reduced GFR and increased albuminuria are associated with higher risk of all-cause and CV mortality and ESRD. However, the slope of the risk relationship for mortality may be steeper in women.[72] Reasons for gender differences in CKD prevalence and outcomes are poorly understood.[73] Women have unique risk factors for kidney disease. Acute kidney injury (AKI), hypertension, preeclampsia, and diabetes during pregnancy are all risk factors for the development of CKD.[74,75] Furthermore, autoimmune diseases with a predilection for the kidney such as systemic lupus erythematosus, scleroderma, and rheumatoid arthritis are more common in women.[76] The potential contribution of autoimmune disease to the incidence and progression of CKD in women is an intriguing area that requires further study.[74]

Race and Ethnicity

Substantial differences have been identified in the incidence of ESRD by race or ethnicity.[77] Within the US, this takes the form of a higher incidence of ESRD among African American compared with Caucasian Americans. Around the globe, this has been investigated as differences between Asians, whites, and blacks.

Race and Ethnicity Differences in CKD in the US

According to the most recent data from USRDS, the prevalence of CKD is an estimated 16.9% in African Americans, 15.2% in Caucasians, 12.5% in Mexican Americans, 12.8% in other Hispanics, and 12.8% in other non-Hispanics. The prevalence of albuminuria is highest in African Americans (13.5%) and lowest in Caucasians (9.0%). The prevalence of ESRD is higher in African-American patients compared with other racial groups: 2.6-fold higher than Native Americans and Asians, and nearly fourfold higher than Caucasians.[71] Furthermore, analysis of NHANES data suggests that the prevalence of stages 3 and 4 CKD has stabilized in non-Hispanic whites, while it continues to rise in non-Hispanic African Americans.[78]

Genetic factors play a key role in the increased risk of CKD in African Americans. There has been increasing focus on the APOL1 gene encoding the protein apolipoprotein L1. APOL1 mutations (G1 and G2) are protective against the parasite *Trypanosoma brucei* that causes African sleeping sickness. Variants of this gene, found exclusively in individuals of recent African descent, are associated with increased risk of nondiabetic CKD, hypertensive nephropathy, and focal segmental glomerulosclerosis.[79,80] APOL1 variants also appear to increase the risk of CKD progression. In the CRIC study, participants with two copies of APOL1 risk variants were twice as likely to develop a composite renal outcome of 50% reduction in GFR or ESRD over a mean follow-up period of 9 years.[81]

Race and Ethnicity Differences in CKD Around the World

Latin America, Europe, East Asia, and the Middle East have the highest prevalence of CKD (approximately 12%), whereas South Asia (8%) and sub-Saharan African (7%) have lower prevalence estimates.[82] The incidence of ESRD also exhibits substantial regional variability, from more than 400 per million population (pmp) in Taiwan to less than 50 pmp in countries such as Russia and China.[23] It was previously estimated that >90% of all patients receiving treatment for ESRD reside in affluent countries with a large elderly population and good access to health care.[83] Using data from 25 population-based cohorts, the CKD-PC evaluated the prevalence of albuminuria and decreased GFR by race ethnicity and investigated differences in the association between these markers and clinical outcomes by race.[84] In this study, the prevalence of decreased GFR was higher among whites (16%) compared with blacks (9%) and Asians (5%). However, the prevalence of albuminuria was highest for blacks (17%) compared with whites (10%) and Asians (3%). In each race group, decreased GFR and albuminuria were associated with increased risk for all outcomes, with no evidence of effect modification by race.[84]

CKD IN THE DEVELOPING WORLD

Around 85% of the world's population live in low- and middle-income countries. Our current understanding of CKD epidemiology is predominately based on data from higher-income regions, leaving a major gap in our understanding of the scope of CKD in the developing world. The International Society of Nephrology

recently launched its "Closing the Gaps" initiative, aiming to define the current state of global kidney care and make recommendations for improvement. This initiative includes the Global Kidney Health Atlas project, a 130-country global survey seeking to characterize the current state of readiness, capacity, and ability to provide kidney health care in each country.[85] The information gathered will be invaluable to guide further initiatives to improve access to optimal care for kidney disease.

CKD prevalence is expected to grow rapidly in the developing world as rates of diabetes, hypertension, obesity, and metabolic syndrome increase.[86] Diabetic nephropathy is fast emerging as a major cause of kidney disease in the developing world. Another important contributor to CKD in these regions is the high burden of infectious diseases such as HIV, hepatitis B, malaria, and schistosomiasis that can affect the kidneys.[87] An estimated 37 million people are living with HIV worldwide. Several renal pathologic entities have been demonstrated in the HIV population including glomerular lesions such as HIV-associated nephropathy (HIVAN) and HIV-associated immune complex renal disease.[88] Early initiation of antiretroviral therapy is essential as it has been shown to reduce the risk and progression of HIV-related kidney disease.[89,90] While antiretroviral medications have dramatically reduced the risk of HIVAN, they are associated with chronic inflammation and metabolic syndrome, which are risk factors for CKD.[91] Additionally, as patients live longer with HIV infection, classic CKD risk factors such as diabetes and CV disease are becoming more common in this population.[92] CKD is associated with increased mortality and CV risk in HIV-infected patients.[93]

An emerging cause of kidney disease in low- and middle-income countries is CKD of unknown etiology (CKDu).[94] The condition was first described in plantation workers in Central and South America and is currently a leading cause of death and hospitalization in those regions.[95] Patients with CKDu do not have traditional renal risk factors such as hypertension or diabetes, suggesting the possibility of environmental factors in disease pathogenesis.[96,97] Air pollution, tobacco, pesticides, infections, heavy metals, high seasonal temperatures, and dehydration are all thought to be potential contributors.[98] The pathologic mechanism is thought to be predominately interstitial nephritis as the histological features in CKDu are interstitial inflammation and fibrosis, mononuclear cell infiltration, and tubular atrophy.[95,99] In Sri Lanka, the prevalence of CKDu was estimated at 12.9 % in males and 16.9% in females and accounts for nearly 4% of the national health care budget. In El Salvador, ESRD related to CKDu is the leading cause of in-hospital mortality.[98]

MAJOR RISK FACTORS FOR CKD

Capturing the scope of the problem of CKD lies in understanding its risk factors. Many risk factors for ESRD have also been identified to increase the risk of development of earlier stages of CKD. Several common risk factors associated with increased risk for CKD are also associated with increased risk for adverse outcomes among people with CKD.

Hypertension

Global age-standardized prevalence of hypertension in 2015 was an estimated 24.1% in men and 20.1% in women, overall equating to 1.13 billion adults.[100] Hypertension is considered both a cause and consequence of CKD. In the Framingham Heart Study, the presence of hypertension was associated with a 57% increased likelihood of incident CKD[101] The prevalence of hypertension increases with worsening kidney function and is nearly ubiquitous among patients starting renal replacement therapy. Among people with CKD, higher levels of systolic blood pressure in particular are associated with greater risk of progression to ESRD, as well as increased risk of coronary heart disease.[102–104] The optimal blood pressure target for people with CKD continues to be debated. In a prespecified subgroup analysis from the Systolic Blood Pressure Intervention Trial (SPRINT), targeting a systolic blood pressure of less than 120 mm Hg compared with 140 mm Hg was associated with reduced rates of major CV events and all-cause mortality among participants with CKD.[105] SPRINT excluded individuals with diabetes, advanced CKD, or proteinuria >1 g/day. Observational data suggest a J-shaped association between blood pressure and risk of death among CKD patients, a finding that could be confounded by the presence of underlying cardiac dysfunction in the CKD population.[106] An increasing body of literature has recognized the importance of blood pressure variability as a predictor of CV outcomes such as stroke, independent of mean or "usual" blood pressure values.[107,108] Recent data suggest that increased variability in visit-to-visit blood pressure is also a risk factor for adverse renal outcomes.[109,110]

Diabetes

The prevalence of diabetes mellitus is increasing around the globe. According to WHO 2016 data, 422 million people are living with diabetes (online reference http://www.who.int/diabetes/global-report/en/). Furthermore, impaired fasting glucose is even more prevalent (affecting more than 1 billion people

worldwide) and is associated with the development and progression of CKD.[111] According to the 2016 USRDS national report, 39% of individuals with diabetes have CKD.[71] Approximately 25% of people with CKD have diabetes, although it accounts for over 50% of ESRD cases in many countries.[56,77] Similar to hypertension, diabetes is a major risk factor for coronary heart disease, ESRD, and all-cause mortality among people with CKD.[112] Between 1990 and 2012, the number of global deaths attributed to diabetic kidney disease rose by 94%.[52]

Obesity

The global epidemic of obesity is well recognized. In 2015 worldwide, 107.7 million children and 603.7 million adults were obese.[113] Obesity is strongly related to CV disease and is also associated with an increased risk of CKD. In the Framingham Heart Study, each 4.2 kg/m^2 higher body mass index was associated with a 23% increased likelihood of incident CKD.[101] The amount of CKD attributable to obesity may be more substantial as this study adjusted for diabetes and systolic blood pressure, two major CKD risk factors that may be on the causal pathway between obesity and CKD. The mechanism of CKD in obesity is thought to be compensatory hyperfiltration and increased intraglomerular pressure.[114] Although wasting is common in more advanced CKD and obesity is protective against mortality among patients treated with maintenance dialysis, the association between obesity and outcomes in earlier stages of CKD is less clear.[115,116] When using BMI, obesity has not always been associated with CV or mortality outcomes in CKD.[117,118] However, waist circumference, which better captures abdominal adiposity, has been associated with an increased risk for all-cause mortality among patients with CKD.[118] Additionally, obese individuals often have hypertension, diabetes, and dyslipidemia, each of which are important risk factors for adverse outcomes among people with CKD. Therefore, intentional weight loss may be beneficial for preventing CKD and should be considered for overweight and obese patients with predialysis CKD.[119] The estimation of kidney function in obese patients can be problematic. Creatinine-based GFR estimating equations were not specifically derived or validated in obese patients. These formulas generally overestimate GFR in obese patients. Using cystatin C is also problematic as it is produced by adipose cells and therefore underestimates GFR.[120] CKD-EPI (creatinine) appears to the most accurate of the formulas in obese patients with GFR <60 $mL/min/1.73\,m^2$ compared with gold standard measurements of GFR.[121]

Acute Kidney Injury

AKI is defined as a transient reduction in kidney function, manifesting as decreased urine output or increased S[Cr], or both. Previous studies have demonstrated that severe AKI requiring hospitalization and short-term dialysis is associated with an increased risk of subsequent ESRD.[122] It is increasingly recognized that less severe forms of AKI can increase the risk of developing CKD, even if kidney function returns to baseline levels following the injury.[123,124] The speed of renal recovery following AKI may also be an important contributor to future CKD risk.[125] Reduced GFR and increased ACR are also strong predictors of AKI,[8] thus predisposing individuals with CKD to repeated insults which could in turn contribute to disease progression.[126] Additionally, AKI is associated with increased risk of mortality in hospitalized patients and an increased risk of CV disease including heart failure and myocardial infarction.[124,127]

CONCLUSION: SCOPE OF THE PROBLEM OF CKD

Epidemiologic data indicate the prevalence of CKD, whether defined by decreased GFR or the presence of albuminuria, is high in many regions of the world. Furthermore, the prevalence of major risk factors for CKD, including hypertension, diabetes, and obesity, is high and increasing with population aging, decline in mortality from communicable diseases, and adoption of sedentary lifestyles and a Westernized diet. Over the past 10 years, CKD has been identified as a major risk factor for CV disease, all-cause mortality, and ESRD. The risk for these adverse outcomes is higher in individuals with either reduced GFR or albuminuria, and highest if both parameters are present. Additionally, several studies have demonstrated that people with CKD have an excess risk for CV disease, exceeding that of other "high-risk" conditions such as diabetes mellitus. The emerging data regarding AKI as a predictor of CKD, as well as other adverse outcomes, emphasizes the importance of raising the awareness of kidney disease in the broader context of comorbid illness. The contribution of CKD to global mortality and disability rates has increased more than almost all other diseases over the past 20 years. Our understanding of CKD in the developing world, while improving, remains limited and has been identified as a key research priority. Although clearly challenging, public health efforts are needed to tackle the burden of CKD through greater awareness and earlier detection, better understanding of disease mechanisms, and improved access to care for all individuals.

QUESTIONS AND ANSWERS

Question 1

Which of the following is the recommended initial approach to identifying whether a patient has CKD?

A. A one-time S[Cr] measurement. Calculating eGFR should then be performed using the CKD-EPI equation
B. Serial assessments of S[Cr] (to calculate eGFR) and urinary albumin excretion, over a period of at least 3 months
C. S[Cr] should be used to calculate eGFR. If eGFR is <60 mL/min/1.73 m^2, then albuminuria should be assessed
D. Measure serial cystatin C and use this to calculate eGFR over a period of at least 3 months
E. Measure GFR using inulin clearance

Answer: B

KDIGO 2012 guidelines describe CKD as abnormalities in kidney structure or function, present for at least 3 months. A one-time measurement of S[Cr] may result in a false positive. Additionally, it is recommended that GFR be estimated using an equation (e.g. the CKD-EPI equation) rather than relying on elevated S[Cr]. Several equations have been developed including the MDRD and CKD-EPI formulas. GFR equations using creatinine have limitations such as differences in creatinine generation related to dietary protein intake and muscle mass. However, when adjusted for non-GFR determinants of creatinine generation (age, sex, race), the correlation between creatinine and measured GFR is significantly improved. Other tests such as cystatin C have shown promise as alternative filtration markers to creatinine, but their use has been hampered by cost and limited availability of assays. Clearance of exogenous filtration markers such as inulin remain the gold standard for measuring GFR, but this method is expensive, time-consuming, and not practical in most cases. eGFR alone cannot be used to define CKD; albuminuria also needs to be assessed. Many patients have albuminuria with preserved GFR.

Question 2

A patient has an eGFR of 45 mL/min/1.73 m^2 and a UACR of 30 mg/mmol. Which of the following is true?

A. This patient has an increased risk for ESRD
B. This patient has an increased risk for CV mortality
C. This patient has an increased risk for death
D. This patient has an increased risk for hospitalizations
E. All of the above are true

Answer: E

Data from several studies have demonstrated that reduced GFR and increased UACR are strongly associated with an increased risk of ESRD, CV, and all-cause mortality. CKD has also been identified as an independent predictor of other outcomes such as infection, hospitalization, and frailty. In general, ACR appears to be a stronger and more consistent predictor of adverse outcomes than GFR in these studies.

Question 3

Which of the following is true regarding CKD in patients of African descent?

A. The prevalence of albuminuria is lower than that of Caucasian patients
B. African Americans are more likely than other ethnicities in the US to have CKD, but are less likely to progress to ESRD
C. Genetic variants of the APOL1 gene found almost exclusively in people of African descent are associated with an increased risk of CKD
D. Focal segmental glomerulosclerosis is the most common cause of kidney failure in African Americans

Answer: C

There are significant ethnic differences in the prevalence of CKD both worldwide and in the US. African Americans are more likely than other ethnicities in the US to have CKD and albuminuria. African Americans with CKD are also more likely to progress to ESRD. The most common causes of CKD in African Americans are diabetic and hypertensive kidney disease. Genetic factors are largely responsible for the increased CKD risk and progression in patients of African descent. Mutations in the APOL1 gene are associated with hypertensive nephropathy and FSGS. These mutations are thought to be more common in African populations because they are protective against the parasite causing African sleeping sickness.

Question 4

Which of the following statements are true regarding CKD in the developing world?

A. The rise in CKD prevalence is being driven by increased rates of diabetes, obesity and hypertension
B. We have major gaps in our understanding of the prevalence of CKD because most of our

data regarding CKD comes from developed countries

C. CKDu is an increasingly recognized cause of CKD in agricultural communities

D. None are correct

E. All are correct

Answer: E

Although the majority of the world's population live in developing nations, our understanding of CKD epidemiology in these areas is limited because most data come from high-income countries. Historically the most common causes of CKD in the developing world were chronic glomerulonephritis and interstitial nephritis, related to the high incidence of infectious diseases such as HIV that can affect the kidneys. More recently the rapid rise in CKD prevalence in developing countries has been attributed to increasing rates of diabetes, obesity, hypertension and population aging. Furthermore, CKDu is increasingly being recognized as a major contributor to renal disease, especially in middle- and low-income agricultural communities. Patients with CKDu are missing traditional risk factors for CKD but share similar histologic findings, predominately chronic interstitial nephritis, which suggests the possibility of environments causes.

Question 5

Regarding AKI which of the following statements is false?

A. AKI rarely leads to end-stage kidney disease

B. AKI confers an increased risk of CKD, even if the kidney function returns to baseline levels

C. The speed of renal recovery following AKI may be an important contributor to future CKD risk

D. Prior CKD and albuminuria significantly increase the risk of AKI

E. AKI is associated with higher mortality, future cardiac disease, hypertension, and reduced quality of life

Answer: A

AKI is associated with an increased risk of CKD, ESRD, CV events, all-cause mortality, and reduced quality of life. More severe AKI, especially if requiring dialysis or hospitalization, is associated with higher risk of subsequent CKD and ESRD. Even seemingly mild AKI increases the risk of CKD.

CHAPTER

Gender Issues in Chronic Kidney Disease

Joel Neugarten[a], *Jane F. Reckelhoff*[b]

[a]Albert Einstein College of Medicine, Renal Division, Montefiore Medical Center, Bronx, NY, United States; [b]Women's Health Research Center, University of Mississippi Medical Center, Jackson, MS, United States

Abstract

Gender influences the incidence, prevalence, and progression of chronic kidney disease (CKD). In numerous experimental models of renal disease, progression is accelerated in male animals. Gender dimorphism in the course of renal disease is replicated by hormonal manipulation, suggesting that the actions of sex hormones, rather than structural differences between the sexes, are responsible for gender-related differences in renal disease progression. Sex hormones influence many of the processes known to mediate progressive renal injury including cell proliferation, mesangial matrix synthesis and degradation, generation of reactive oxygen species, and the expression of profibrotic proinflammatory cytokines, hormones, and vasoactive agents. In humans, the progression of CKD is arguably more rapid in men than in women, a finding which parallels observations in experimental animals. Translation of these observations into therapeutic interventions has not yet been realized, although selective estrogen receptor modulators, which lack the detrimental effects of estrogen on reproductive tissue, have shown renoprotective effects.

The Institute of Medicine has defined "sex" as those traits that are affected by sex chromosomal complement and the presence or absence of sex steroids.[1] The concept of "gender" is more complicated and is determined by a person's self-representation as "male" or "female" and society's response to this self-representation.[1] For discussions of studies in human subjects, the term "gender" will be used, whereas the term "sex" will be used to discuss animal studies. A series of seminal studies beginning the mid-1990s evaluated whether there were gender-related differences in the prevalence and progression of chronic kidney disease (CKD).[2–4] The finding that gender disparities did indeed exist gave rise to a myriad of studies in both humans and animals to evaluate the mechanisms that may be responsible for these sex/gender differences.

GENDER PROGRESSION OF CHRONIC KIDNEY DISEASE

In most experimental models, male animals show accelerated progression of renal disease.[4] Hormonal manipulation replicates the effects of gender on the course of experimental renal disease and suggests that female sex hormones may slow the progression of renal disease, whereas male hormones promote renal disease progression.[4] These observations also suggest that sex hormones themselves, rather than genetically determined structural differences, determine the greater susceptibility of the male kidney to progressive renal injury.

Unlike experimental models, studies describing the relationship between gender and renal disease progression in humans have yielded conflicting results. There have been no large well-designed prospective studies specifically evaluating the rate of decline of renal function in men compared with women. In this context, we performed a meta-analysis involving 11,345 subjects from 68 studies to determine the effect of gender on the progression of nondiabetic renal disease.[2] In individuals with autosomal dominant polycystic kidney disease, IgA nephropathy, membranous nephropathy, or CKD of unspecified etiology, progression was more rapid in men than in women. However, our meta-analysis was limited by the heterogeneity of study endpoints, failure to adequately account for confounding factors and lack of knowledge of menopausal status.

Among the studies evaluated in our meta-analysis was the Modification of Diet in Renal Disease study,[5] which included 840 participants, nearly 40% of whom were women, assigned to various dietary protein and blood pressure (BP) groups. As compared with men, the rate of deterioration of glomerular filtration rate

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00007-3

(GFR) was slower in women below the age of 55, but this difference was no longer significant after adjusting for differences in BP, urinary protein excretion, and HDL levels.

Similarly, Cattran and coworkers[6] reported a reduced rate of decline in kidney function and/or increased kidney survival in younger women with membranous nephropathy or focal and segmental glomerulosclerosis compared with men. The beneficial effect of female gender persisted after correction for BP and proteinuria. In contrast, these investigators failed to find any effect of gender on the progression of IgA nephropathy.

The Ramipril Efficacy in Nephropathy Study, a multicenter, randomized, double-blind, placebo-controlled trial performed in subjects with chronic nondiabetic, proteinuric renal disease, found that the rate of decline of GFR was faster in women compared with men in the placebo arm, whereas in the Ramipril-treated arm, progression was slower and the reduction in proteinuria greater in women.[7] Angiotensin-converting enzyme inhibitor (ACEI) therapy was uniformly renoprotective in women, regardless of angiotensin-converting enzyme (ACE) polymorphism, but in men ACEI therapy was renoprotective only in those with the DD genotype. The authors concluded that men with chronic proteinuric renal disease are at increased risk of progression of CKD due to their lesser response to ACEI therapy.

Numerous longitudinal studies have shown that the rate of decline in kidney function was more rapid in men than in woman.[4] Population-based, observational studies from the US, Europe, and Japan, including several mass screening studies, have identified male sex as a predictor of poor renal outcome.[8–14] Despite certain methodological limitations, these studies are consistent with observations in experimental animals showing a faster rate of progression of renal disease in males.

The Chronic Renal Insufficiency Cohort Study followed 3939 participants with a baseline estimated GFR (eGFR) of 20–70 mL/min/1.73 m^2 for a median period of 6.9 years and found that men were at higher risk of a 50% decline in eGFR ((HR 1.19, CI 1.06, 1.35), incident stage 5 CKD, incident end-stage renal disease (ESRD) (HR 1.39, CI 1.15, 1.69), and death (HR 1.79, CI 1.35, 2.27)) than women in fully adjusted models.[15] The rate of decline in eGFR was also greater in men than in women ($\Delta = 0.33$ mL/min/1.73 m^2/year), but this difference failed to achieve statistical significance in a fully adjusted model. Although menopausal status was not ascertained, the data failed to support a renoprotective role for estrogen, because sex-related differences in incident ESRD rates tended to be greater among older compared with younger subjects.

In contrast, other studies have concluded that there is no difference between men and women in the rate of progression of CKD, or that women progress at a faster rate than do men. Jafar and coworkers[16] performed a patient-level meta-analysis which evaluated 1650 nondiabetic subjects enrolled in 11 randomized studies evaluating the efficacy of ACEI therapy on the progression of renal disease over a mean duration of follow-up of 2.2 years. The authors concluded that after correction for differences in systolic BP and urinary protein excretion, women have a worse renal prognosis, showing a greater relative risk of doubling of serum creatinine (S[Cr]), renal replacement therapy (RRT), or death due to kidney disease compared with men. However, most of the female participants in these studies were postmenopausal, which may explain why these findings differ from those reported by our earlier meta-analysis.

The Chronic Kidney Disease Prognosis Consortium performed several patient-level meta-analyses, with varying degrees of patient overlap, which examined the role of gender in CKD progression.[17–20] Male gender was determined to be a risk factor for CKD progression in all but one of these studies. In the first of these patient-level meta-analyses, Nitsch et al.[17] studied more than 2 million subjects from 48 general population, high cardiovascular risk, and CKD cohorts. The primary endpoint was RRT or death due to kidney disease during a mean duration of follow-up of 2.3–24.9 years. The authors found that lower eGFR and albuminuria were associated with all-cause mortality and cardiovascular mortality, and that the risk was higher for men than women at all levels of eGFR and albumin:creatinine ratio (ACR). However, the slope of the risk relationship was steeper in women than in men in both the general population and the high cardiovascular risk cohorts. In all three cohorts, lower eGFR and higher ACR were associated with increased risk of developing ESRD, but the risk was similar between men and women. Results did not change when subjects less than 50 years of age were compared with those greater than 65 years of age. Despite the size of this meta-analysis and its robust methodology, the conclusion that gender has no impact on renal disease progression is subject to limitations imposed by competing mortality. Men are more likely to die a nonrenal death at any given level of eGFR or ACR, and the risks of both death and progression to ESRD increase at lower eGFR and higher ACR levels. Thus, the gender disparity in the risk of death disproportionately affects men at greatest risk for progression to ESRD and ultimately reduces the number of men at

risk for progression to ESRD. These factors limit the validity of conclusions about the role of gender in renal disease progression which derive from studies where ESRD is the sole outcome measure. Also relevant to interpretation of these data are results from a general population observational study performed by Japanese investigators which found that the cumulative incidence of ESRD did not differ between the sexes until four years after initial screening.[14] Very few of the general population and high cardiovascular risk cohorts studied by Nitsch et al.[17] were followed for more than three years, suggesting that a longer duration of follow-up may have been required to demonstrate sexual dimorphism in the progression to ESRD in these cohorts.

In a subsequent publication, the CKD Prognosis Consortium performed another patient-level meta-analysis of 731,357 subjects from CKD cohorts.[18] The primary outcome was RRT or renal transplantation with a median duration of follow-up of four years. Using a pooled eight-variable model, the risk of progression to RRT or renal transplantation was significantly greater in men than women (HR 1.34, CI 1.24, 1.44). However, a significant limitation of this study was the fact that nearly 435,000 subjects were derived from a Veterans Administration cohort severely deficient in women. Similar results, showing a worse renal prognosis in men, were obtained by these investigators when their analysis was restricted to patients with stages 4 and 5 CKD.[19] Grams et al.[20] studied over 5 million healthy subjects from 7 general population cohorts and found the risk of progression to ESRD was 50% greater in men than in women.

CKD, defined as an eGFR <60 mL/min/1.73 m^2, is more common in women than in men. Numerous population-based studies from across the globe have shown that the percent of women that suffer from CKD is greater than that of men in nearly every country studied and in all age groups except 20–29 years of age.[21–23] Data from the National Health and Nutrition Examination Survey (NHANES) of the civilian noninstitutional population of the US between 2005 and 2010 indicate that the prevalence of an eGFR less than 60 mL/min/1.723 m^2 is 7.7% in women vs. 5.6% in men and the prevalence of ACR >30 mg/g creatinine is 10.2% in women vs. 8.6% in men.[24] Similar results were obtained in later NHANES surveys.[25]

Any discussion of the relationship between sex and the prevalence and progression of CKD must first address the adequacy of the measures commonly used to quantify renal function in men relative to women. Glassock and Winearls[26] as well as numerous other investigators have suggested that CKD be defined according to sex-specific percentiles rankings that take into account sex-specific reductions in GFR associated with normal aging instead of using a single GFR threshold to define normality. They argue that a single threshold fails to adequately demarcate increased risk for adverse events across the gender and age spectrum, and that this practice leads to an overdiagnosis of CKD in women, especially in elderly women.

Similarly, numerous investigators have suggested that we use sex-specific cutoffs for urine albumin:creatinine ratio (UACR) to define the upper limit of normal in the healthy population.[27,28] Data from NHANES II collected between 1988 and 1994 showed that mean urinary albumin concentration was not different between men and women.[27] However, when UACR was used as the measure, the prevalence of microalbuminuria was greater in women than in men. This result is explained by the fact that men generally have a larger muscle mass and excrete more creatinine than do women. The NHANES II data were reanalyzed using sex-specific ACR cutoffs suggested by Warram et al.[28] (17 mg/g for men vs. 25 mg/g for women) which correspond to the 95th percentile values for healthy men and women. This reanalysis yielded identical albumin excretion rates, expressed as mcg/minute, in men and women. Thus, applying sex-specific ACR cutoff values to the NHANES II cohort leads to the conclusion that the prevalence of microalbuminuria is similar in men and women.

Additional concerns arise relating to the predictive performance of the MDRD and CKD-EPI equations to estimate GFR in men vs. women. The measure of interest is the difference in bias between men and women, where bias represents the difference between the actual and estimated GFR. Studies have generally yielded inconsistent results. Adding to the complexity in interpretation of available data are observations that differences in bias between men and women vary with age and baseline GFR. Moreover, interpretation of the data is limited by the small size of many of these studies. However, if our analysis is informed by study size, it is fair to conclude that the difference in bias between the sexes is small (weighted average of Δ bias for MDRD $= -1.42$ mL/min/1.73 m^2, n $= 8940$, range $= -5.1$ to $+7.77$; weighted average of Δ bias for CKD-EPI $= +1.93$ mL/min/1.73 m^2, n $= 8036$, range $= -2.7$ to $+10.8$ mL/min/1.73 m^2).[29]

GENDER AND THE TRANSITION TO ESRD

Despite the greater prevalence of CKD in women, ESRD registry data and cohort studies from around the world clearly establish that the incidence rate of ESRD is greater in men than in women.[30–34] The Dialysis Outcomes and Practice Pattern Study (DOPPS), an international prospective cohort study of dialysis practices in high-income countries, showed that, after

adjustment for the representation of each sex in the general population, the proportion of women in the incident dialysis population is less than men in every participating country.[35] The incidence rate of reported ESRD in the US, per million population, adjusted for age and race, is approximately 60% greater in men compared with women.[24] It is unlikely that the slightly higher eGFR at which men initiate RRT alone can account for this disparity in incidence rates (discussed below).[36–38]

Two explanations may account for the finding that women are less likely to initiate dialysis despite being more likely to suffer from CKD: (1) women with CKD progress more slowly to ESRD than men and/or (2) women start dialysis later than men and as a result are more likely to die in stage 5 CKD without ever being dialyzed. The DOPPS investigators propose that differences among countries in the age-adjusted proportion of women starting dialysis suggest that psychosocial and economic factors, rather than, or in addition to, biologic factors, are responsible for the fact that fewer women start dialysis than men. They speculate that women, especially those that are elderly and in poor health, are less likely to initiate dialysis than are men of similar circumstance.

This controversy raises several interrelated questions: (1) whether or not men and women have equal access to dialysis and (2) whether or not there exists a large pool of women with stage 5 CKD who are not being dialyzed and who have a high mortality.

Analysis of US Renal Data System (USRDS) data from 1995 to 2009 shows that women consistently initiate dialysis later than men at an adjusted eGFR that is 1 mL/min/1.73 m^2 lower than men and that this difference in eGFR between the sexes has not changed over the 15-year period studied.[37] Data from Europe parallel these observations.[38] Similarly, the DOPPS found that women initiate dialysis later than men at an eGFR 0.5 mL/min/1.73 m^2 lower than men and that this eGFR difference existed in all countries studied.[35] However, the differences in bias between the sexes for the MDRD and CKD-EPI equations used to estimate GFR are comparable or exceed the difference in eGFR observed between men and women at the start of dialysis. Thus, the difference in eGFR that exists between the sexes at the start of dialysis may merely reflect imprecision in the equations used to estimate GFR.

Multiple alternative explanations have been proposed to explain the observation that women start dialysis at a lower eGFR than men. These explanations focus on gender-related disparities in health care delivery. Although women are more likely to suffer from CKD than men, they are less aware of their CKD diagnosis, seek medical care later than men, are less likely to be given an ICD-10 diagnosis of CKD, are less likely to be referred to consult a nephrologist, and are underrepresented in CKD clinics.[35,39–41] In addition, at initiation of dialysis, women are less well educated and are more likely to be uninsured or unemployed.[36,39,40,42] All these factors may contribute to unequal access for women to RRT. However, in contrast to these observations, the USRDS has recently reported that the proportion of women receiving pre-ESRD care and the duration of such care is similar to that of men. However, the URSDS data pertain only to women who actually start dialysis and do not reflect the status of women who defer dialysis.[43]

In addition, it has been suggested that women, particularly elderly women, are more likely to choose conservative care rather than RRT.[41,44] Faruque et al.[45] followed 7901 patients with stage 5 CKD not on dialysis for a mean of 11 months. They confirmed that women were less likely to start dialysis than men, and that this disparity was most pronounced among the elderly where men were more than twice as likely to initiate dialysis. In another large study, women, particularly older women, were 50% more likely to choose conservative care.[41] However, many other studies of stage 5 CKD fail to show any significant difference between the sexes in the number of those with stage 5 CKD who elect conservative care. Interpretation of the data is limited by the small number of subjects in many of these studies.

The DOPPS investigators further suggest that later initiation of dialysis in women as compared with men leads to a large pool of women with stage 5 CKD and that a higher death rate among these women contributes to the higher incidence of men starting dialysis.[44,46,47] However, available data are inconclusive.

Go et al.[48] studied over 1 million patients enrolled in an integrated health care plan and found that the percentage of patients with an eGFGR <15 mL/min/1.73 m^2 who are not being dialyzed was slightly higher in women than in men. However, after adjustment for the proportion of men and women enrolled in the health plan, the opposite was true; among enrollees with an eGFR <15 mL/min/1.73 m^2, a greater percent of men than women were not being dialyzed. These data argue against the hypothesis that women are deprived of equal access to RRT. Similarly, the Stockholm Creatinine Measurements project which analyzed creatinine measurements in over 1 million adults found that stage 5 CKD without dialysis was more common in men than in women.[40] However, both these analyses were limited to individuals who have undergone S[Cr] measurements, and data from the USRDS suggest that women are less likely to undergo a S[Cr] measurement than are men. Using ESRD registry data and administrative codes for kidney disease on death certificates, Australian investigators concluded that women, especially

elderly women, are less likely to initiate dialysis than men.[41] In contrast, using a similar approach in a case-control study nested in NHANES, American investigators found no disparity in the provision of RRT based on sex.[49] However, both studies may be criticized for methodological flaws.

Turin has shown that the survival advantage enjoyed by women in the general population is attenuated as GFR declines and is lost when the GFR falls to 15–29 mL/min/1.73 m^2, where no significant difference is observed.[50] No data were reported regarding 5 CKD not on dialysis. Nevertheless, the survival advantage of women in earlier stages of CKD would tend to mask any renoprotective effect of female gender on the progression of renal disease where the outcome measure is ESRD. Men with progressive CKD are more likely to die before reaching dialysis than are women, reducing the population of men at risk to develop ESRD, which in turn would decrease the number of men starting dialysis. In contrast, the DOPPS investigators suggest that the relationship between the competing risks of death and dialysis in men vs. women with early CKD is reversed in stage 5 CKD.[44,46,47] They argue that women with stage 5 CKD are less likely to initiate RRT than men, have a higher mortality than men and are more likely to die without ever reaching dialysis. This in turn might contribute to the predominance of men in the incident dialysis population. However, available data are contradictory. Moreover, even if this hypothesis were true, it would not necessarily eliminate the impact of competing mortality in earlier stages of CKD on sex-stratified ESRD rates.

Faruque et al.[45] followed 7901 patients with stage 5 CKD not on dialysis for a mean of 11 months. They found that men, not women, with stage 5 CKD were more likely to die without initiating dialysis in adjusted analysis; however, this was not the case in unadjusted analysis. In a patient-level meta-analysis of 28 cohorts containing over 185,000 subjects with stage 4 or 5 CKD, Evans et al.[19] reported that in adjusted analyses male sex was associated with death without RRT. Several smaller studies that examine survival in late-stage CKD have yielded conflicting results.[51,52]

If women are more likely to suffer from stage 3 CKD then men and the progression of CKD is less rapid in women, this would lead to a higher proportion of men with advanced stages of CKD compared with early stages of CKD. This is precisely what was observed in the NHANES population.[53] Similarly, prevalence data from the National Health Examination Survey in Italy (n = 7652) and the Stockholm Creatinine Measurements project (n = 1,128,058) also found that the excess of women with CKD was attenuated in later stages of CKD as compared with stage 3 CKD.[40,54]

Although the age- and race-adjusted prevalence of ESRD on dialysis is greater in men than in women, women on dialysis show a modest survival advantage compared with men.[24,35] The prevalence of most primary, immune-mediated glomerular diseases is also greater in men.[4] Among patients with idiopathic membranous nephropathy, IgA nephropathy, and childhood minimal change disease, males outnumber females by 2–3 to 1.[4] Because most male animals exhibit reduced immune responsiveness and testosterone, administration is immunosuppressive, the mechanisms responsible for these gender disparities in immunologic-mediated renal diseases remain to be elucidated.[55]

GENDER AND DIABETIC CHRONIC KIDNEY DISEASE

Because ESRD due to diabetes makes up a substantial fraction of all incident and prevalent ESRD, the influence of gender on the development and progression of diabetic nephropathy merits separate consideration. Sexual dimorphism in the progression of diabetic nephropathy is even less well established than in nondiabetic CKD.

The impact of gender on the course of type 1 diabetic nephropathy in humans is controversial. Arguably, the preponderance of data support the conclusion that men with type I diabetes have a worse renal prognosis than do women despite the existence of contrary data. Numerous cross-sectional and longitudinal studies in individuals with type I diabetes show a greater prevalence of albuminuria, a greater risk of developing microalbuminuria, and a greater risk of progressing from micro- to macroalbuminuria in men compared with women.[56–58] In particular, a large study from Germany of 27,805 type I diabetics reported that male gender was associated with the development of microalbuminuria.[57] However, numerous other studies fail to demonstrate gender differences in the development and progression of albuminuria in type 1 diabetics.

Studies evaluating the effect of gender on the rate of decline of renal function in type 1 diabetics have also yielded conflicting results.[4,56,58–61] A retrospective analysis of the rate of decline of GFR in 59 normotensive type I diabetics with albuminuria showed more rapid progression in men.[61] In a prospective, observational study of 199 proteinuric type 1 diabetics, men had a significantly greater rate of decline in GFR than did women; however, this difference did not persist after adjustment for other progression factors.[60] In contrast, the Collaborative Captopril Study Group performed a prospective, double-blind, randomized placebo-controlled trial of the effect of captopril on the progression of nephropathy in type I diabetes (n = 409) and reported no effect of gender on renal disease progression.[59]

In evaluating these inconsistent data, lessons learned from several population-based longitudinal studies must be considered.[62–64] Finnish Diabetic Nephropathy Study investigators found no gender-related differences in the cumulative incidence of ESRD in patients diagnosed with type I diabetes before the age of 10.[62] In contrast, in those diagnosed after the age of 10, the cumulative incidence of ESRD was nearly twice as great in men. A gender-related difference in the risk of developing ESRD became significant only after a duration of diabetes exceeding 40 years. Other population-based studies from Sweden and the US confirm the observation that stratification by age at onset of diabetes and a lengthy follow-up period are required to demonstrate sexual dimorphism in the progression of nephropathy in type 1 diabetics.[63,64] Thus, differences among studies in the mean age of onset of diabetes, the intensity of metabolic control, and the duration of follow-up may make it more difficult to demonstrate sex differences in the progression of diabetic CKD. Adding to this complexity, sexual hormone synthesis and metabolism is dysregulated in both type 1 and type 2 diabetes mellitus.[65]

There is also limited and inconsistent data regarding the contribution of gender to the development and progression of nephropathy in type 2 diabetes.[56,58] Studies evaluating the effect of gender on the prevalence, incidence, and progression of albuminuria and on the rate of decline of renal function in type 2 diabetics have yielded conflicting results. In the placebo arm of the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan study, a multicenter, randomized, double-blind, placebo-controlled trial of the effect of Losartan on the progression of type II diabetes mellitus ($n = 1513$), male gender was found to be renoprotective by univariate but not by multivariate analysis.[66] However, most of the female subjects enrolled in this trial were postmenopausal, and interpretation of the data is confounded by gender differences in baseline characteristics; at baseline women had significantly more proteinuria and lower eGFR than did men. The Collaborative Study Group performed a multicenter, randomized, double-blind, placebo-controlled trial of the effects of Irbesartan on the progression of nephropathy in 1715 hypertensive type 2 diabetics.[67] The investigators found that albuminuria progressed more rapidly in women, and that women benefited less from irbesartan therapy than did men. Again, most female subjects in this trial were postmenopausal.

ESRD registry data show a similar pattern of sexual dimorphism among incident diabetic dialysis patients as has been observed in the general dialysis population. In 2010, the incident rate of reported diabetic ESRD in the US, adjusted for age and race, was nearly 25% greater in men than in women. Unadjusted UK registry data indicate an 80% greater incidence rate for diabetes-related ESRD in men than in women.[32] Similar data have been reported from Germany.[68] This male predominance persists into the postmenopausal age range in all these populations.[32,68] It should be noted, however, that registry data generally do not differentiate between types 1 and 2 diabetic nephropathy.

There is mounting evidence that sex hormone synthesis and metabolism is disturbed in diabetes mellitus.[65] However, data are conflicting as to the nature of this dysregulation. There are also data to suggest that aberrant sex hormone metabolism may influence the development and progression of diabetic nephropathy.[65] Maric et al.[65] examined the relationship between sex hormone levels and nephropathy in type 1 diabetes among male participants in the Finnish Diabetic Nephropathy Study. Uncomplicated type 1 diabetes was associated with a low serum testosterone level even after correction for multiple metabolic factors. Although sex hormone levels were not correlated with the development of microalbuminuria in a Cox regression model, reduced baseline testosterone levels predicted progression from micro- to macroalbuminuria. Higher testosterone levels and higher estrogen levels were each independent risk factors for progression from macroalbuminuria to ESRD.

FACTORS CONTRIBUTING TO GENDER DIFFERENCES IN RENAL DISEASE PROGRESSION

Numerous mechanisms have been suggested to explain the protective effect of female gender on the progression of renal disease including differences between the sexes in BP, renal structure, lifestyle factors, systemic and renal hemodynamics, and lipid metabolism, as well as direct effects of sex hormones on mesangial cell proliferation and matrix accumulation and the synthesis and release of cytokines, vasoactive agents, and growth factors (Table 7.1).

Lifestyle Factors

Lifestyle factors that influence CKD progression differ between men and women. Men are more likely to smoke, suffer from poorly controlled hypertension and hyperlipidemia, exhibit poor dietary habits, comply less with dietary restrictions, and ingest increased quantities of sodium, protein, calories, phosphorus, and potassium.[47] On the other hand, men with medical comorbidities are more likely to receive aggressive therapy.[69] Adding further complexity to this issue is the observation that risk factors may influence the rate of

progression of CKD differently in men and women. In this regard, several studies have identified a gender-specific risk pattern in the progression of CKD where, for example, smoking and hypertriglyceridemia accelerate CKD in men but not in women.[70–73]

Direct Effects of Sex Hormones on Cellular Biology

In a study that directly addresses the renoprotective role of estrogen, Kattah et al.[74] found that women who underwent bilateral oophorectomy before the age of 50 were at higher risk to develop CKD than women with intact ovaries.

Cell Proliferation and Mesangial Matrix Accumulation

Serum-stimulated mesangial cell proliferation is inhibited by physiologic concentrations of estrogen by a receptor-mediated mechanism.[4,75]

The accumulation of glomerular extracellular matrix reflects the balance between matrix synthesis and matrix degradation, both of which are influenced by sex hormones. Transforming growth factor-beta (TGF-beta) plays a central role in stimulating mesangial matrix synthesis and in promoting progressive renal injury. Although not a universal finding, circulating TGF-beta levels appear to be lower in women than in men.[76] In numerous animal models of renal disease, administration of estrogen decreases, whereas administration of testosterone increases glomerular and kidney expression of TGF-beta. Estradiol also decreases TGF-beta mRNA expression in cultured podocytes isolated from db/db diabetic mice.[77] In contrast, neither estrogen nor testosterone alters the expression of TGF-beta in cultured mesangial cells isolated from normal male rats nor does testosterone alter the expression of TGF-beta in podocytes isolated from female estrogen receptor knockout mice.[4,78] Many of the effects of estrogen on TGF-beta expression may be indirect. In this regard, estrogen suppresses and testosterone upregulates the synthesis and/or peripheral activity of two potent inducers of TGF-beta expression, angiotensin II and endothelin-1.[4]

The actions of TGF-beta depend, in part, on transcriptional effects mediated by cooperation between Smad proteins and the transcription factor Specificity Protein 1 (Sp1).[79] We have shown that activation of protein kinase CK2, a ubiquitous serine/threonine protein kinase involved in signal transduction and transcriptional regulation, mediates TGF-beta-simulated type IV collagen gene transcription by increasing the quantity of free Sp1 available to transactivate the collagen IV promoter.[79] Estradiol reversed TGF-beta stimulated type IV collagen gene transcription by preventing TGF-beta-induced activation of CK2[79] (Figure 7.1). We also demonstrated that TGF-beta induces mesangial cell apoptosis *via* upregulation of CK2 activity, which in turn leads to phosphorylation of p53 and initiation of an apoptotic cascade.[80] Again we showed that estrogen reverses this process by preventing TGF-beta-induced activation of CK2.

In transfected human embryonic kidney cells exposed to estrogen, estrogen receptor alpha forms a ternary complex with Smad2/Smad3 and the ubiquitin ligase Smurf. Formation of this complex enhances ubiquination and degradation of these Smad proteins.[81] These interactions inhibit the TGF-beta signaling cascade and explain the finding that estrogen decreased the expression of total and phosphorylated Smad2/3 in kidneys from diabetic rats.[46] In addition, estradiol reversed the increased expression of TGF-beta receptors types I and II in these diabetic animals[82] (Figure 7.1).

We have also shown that estradiol suppresses mesangial cell type I collagen gene transcription and protein synthesis *via* a mitogen-activated protein kinase/AP 1-mediated mechanism, stimulates mesangial cell metalloproteinase 2 activity *via* a mitiogen-activated protein kinase/AP 2-mediated mechanism,

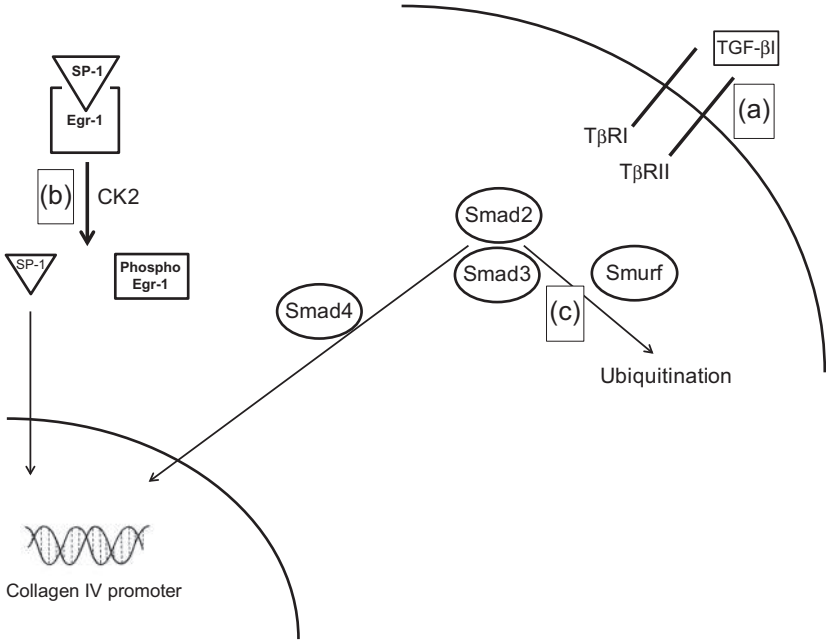

FIGURE 7.1 Interactions between estradiol and TFG-beta. (a) Estradiol downregulates TGF-beta R I and TGF-beta R II. (b) ER-alpha promotes formation of a complex between Smad2/Smad3 and Smurf leading to enhanced ubiquination. (c) Estradiol reverses TGF-beta-induced stimulation of CK2 enzyme activity which in turn limits the availability of free Sp1 to bind to the collagen IV promoter. Abbreviations used: *CK2*, protein kinase CK2; *ER*, estrogen receptor; *Smurf*, Smad ubiquitin regulatory factor; *Sp1*, specificity protein 1; *TGF-βR*, TGF-β receptor.

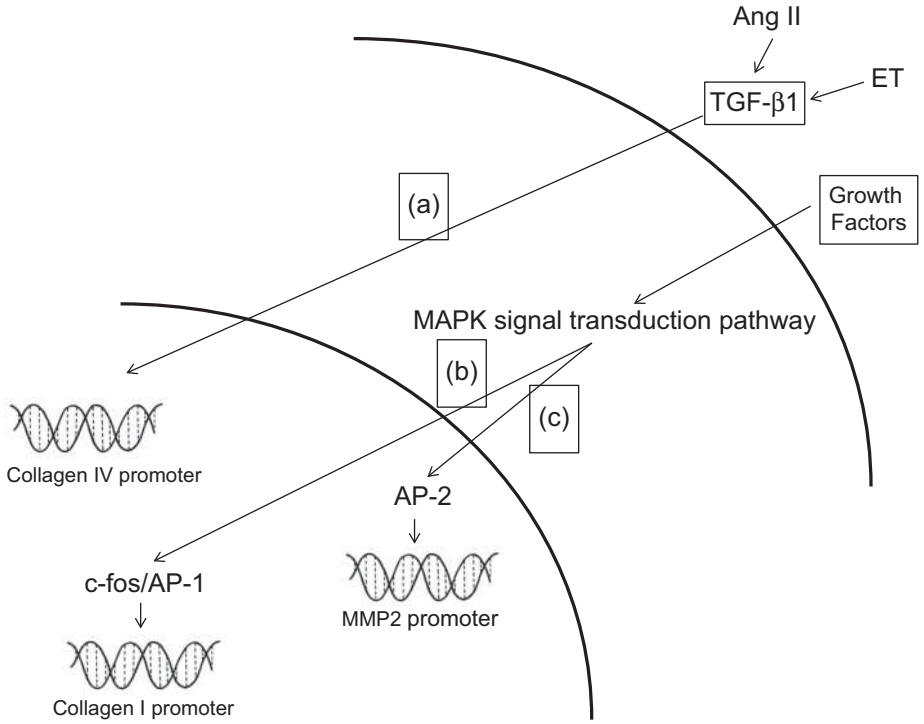

FIGURE 7.2 Estradiol alters the balance between mesangial matrix synthesis and degradation. (a) Estradiol inhibits AII-stimulated and ET-1-stimulated mesangial cell type IV collagen synthesis by interfering with the actions of TGF-beta on the collagen IV promoter. (b) Estradiol increases mesangial matrix degradation by stimulating MMP-2 synthesis *via* stimulation of the MAPK signal transduction pathway and upregulation of AP-2 activity. (c) Estradiol suppresses mesangial cell type I collagen synthesis by upregulating c-fos/AP-1 activity *via* stimulation of the MAPK signal transduction pathway. Abbreviations used: *Ang II*, angiotensin II; *AP*, activator protein; *ET*, endothelin; *MAPK*, mitogen-activated protein kinase; *MMP*, metalloproteinase; *TGF*, transforming growth factor.

and stimulates metalloproteinase 9 activity[83,84] (Figure 7.2). These actions shift the balance of matrix metabolism away from matrix accumulation and glomerulosclerosis.

Alb/TGF-beta mice overexpress TGF-beta and develop proteinuria and progressive renal injury. We have demonstrated that estradiol, by preventing CK2 activation, reverses the injurious effects of TGF-beta and ameliorates renal injury in this model.[85]

Nitric Oxide

Nitric oxide (NO) contributes to the development and progression of renal injury in numerous experimental models.[75,85–87] In cultured glomerular and vascular endothelial cells, physiological concentrations of estrogen cause a rapid release of NO *via* estrogen receptor α.[75,86] The promoter region of the endothelial nitric oxide synthase (eNOS) gene contains an estrogen responsive element, which may mediate estrogen-induced upregulation of eNOS mRNA and protein levels.[75,86] Estradiol also increases eNOS activity by increasing release of intracellular calcium.[75,86] In addition, estradiol increases local PGE_2 and prostacyclin levels, which in turn activate NO synthase.[75,86] As a consequence of these actions, female rats express higher levels of renal eNOS than males, an effect that is reversed by ovariectomy.[87] Although chronic NO inhibition in rats induces systolic hypertension in both sexes, only male rats develop proteinuria, which is prevented by orchiectomy.[88] Aging male rats show a greater reduction in renal NOS protein and enzyme activity as compared with females, which may contribute to greater age-dependent kidney damage in males.[89]

Reactive Oxygen Species

Enhanced generation of reactive oxygen species (ROS) has been shown to contribute to renal damage in experimental models of renal disease. Estrogen blunts the upregulation of nicotinamide adenosine dinucleotide phosphate oxidase activity induced by renal injury, which in turn suppresses the generation of superoxide anion, the major ROS produced by the kidney.[90] In contrast, testosterone increases oxidative stress either directly or indirectly. Testosterone inhibits antioxidant enzymes and amplifies the generation of ROS in response to numerous renal insults.[90] In several experimental models of hypertension, reversal of renal injury by estrogen and exacerbation of renal injury by testosterone is mediated by the ability of sex hormones to modulate ROS generation.[90]

Apoptosis

Testosterone induces podocyte apoptosis *in vivo* and *in vitro via* an androgen receptor-dependent mechanism which is independent of TGF-beta signaling.[78] Testosterone also promotes apoptosis of human proximal tubular cells by stimulating the c-Jun amino-terminal kinase signal transduction pathway associated with upregulation of Fas/Fas ligand and caspase-dependent apoptotic pathways.[91,92] In contrast, estrogen protects podocytes from apoptosis induced by testosterone, TGF-beta, TNF-alpha, and puromycin aminonucleoside *in vitro*.[78,93] This protective effect may be mediated by activation of the ERK or PI3K-AKT signal transduction pathways or by reduced generation of ROS.[78,93] In addition, we have shown that estrogen antagonizes TGF-beta-induced mesangial cell apoptosis by inhibiting activation of CK2 which in turn inhibits phosphorylation of p53.[80]

Kidney Structure and Renal Hemodynamics

Men tend to have larger kidneys than women. In addition, several studies in humans found that men have 10–15% more glomeruli than do women.[94] However, we previously suggested that body surface area (BSA), and not gender, is an independent determinant of kidney weight, glomerular size, and total glomerular volume.[95] As men are generally larger than women, these parameters also tend to be greater in men.

Munger and Baylis[96] suggested that an increased renal vascular resistance in female rats may protect their glomeruli from hyperfiltration-induced injury by blunting elevations in glomerular capillary pressure associated with renal insults. In this regard, female rats subjected to unilateral nephrectomy and fed a high-protein diet have lower glomerular capillary pressures and excrete less protein than similarly treated male rats.[4]

Early studies found a higher inulin clearance in healthy men than in healthy women.[97] However, with several notable exceptions, later studies have shown no difference in GFR between the sexes after correction for BSA.[4,98,99] Authors that reported a lower normalized GFR in women have suggested that these observed differences may merely reflect error introduced by indexing GFR by a constant BSA, which may fail to adequately correct for differences in kidney size or account for differences in physiologic demand between the sexes. In addition, neither testosterone nor estrogen directly affects GFR or renal blood flow in humans.[4]

Despite similar GFR, glomerular hemodynamic responses to vasoactive agents differ in men vs. women. Men respond to an infusion of AII by maintaining their GFR at the expense of an increased filtration fraction, suggesting an increase in glomerular capillary pressure.[100] In contrast, women showed a decrease in GFR and effective renal plasma flow (ERPF) without any change in filtration fraction, suggesting no increase in glomerular capillary pressure. As a result, men with CKD may be more likely to develop hyperfiltration

than women. Moreover, this gender dimorphism may contribute to renoprotection in females by blunting elevations in glomerular capillary pressure which in turn would reduce glomerular hemodynamic stress.

Studies of renal hemodynamic responses to angiotensin receptor blockade suggest that men may require higher doses of angiotensin receptor blockers (ARBs) than women and that the BP response to therapy may not adequately gauge renin-angiotensin system blockade.[101] Similarly, in Caucasian subjects with nondiabetic glomerular disease, ACEIs were more effective in reducing the rate of progression of CKD and led to a greater reduction in proteinuria in woman compared with men.[7] However, other investigators have reported the opposite. The Collaborative Study Group found that hypertensive women with diabetic nephropathy benefited less from ARB therapy than did men.[67] Moreover, a meta-analysis of efficacy studies in hypertensive cohorts concluded that ACEI and ARB therapy are more effective in reducing cardiovascular events in men than in women.[102] In addition, ACEI therapy of congestive heart failure has been reported to be more effective in reducing mortality in men than in women.[103,104] Whether gender differences in the response to ACEI/ARB therapy contributes to sexual dimorphism in the progression of CKD remains unclear.

Studies performed in normotensive, nonproteinuric type I diabetic adolescents found gender-related differences in the renal hemodynamic response to clamped euglycemia and clamped hyperglycemia.[105] During clamped euglycemia, males showed a higher ERPF and a lower renal vascular resistance than females. During clamped hyperglycemia, males did not exhibit any change in renal hemodynamics, whereas females showed a decrease in ERPF and increases in renal vascular resistance and filtration fraction, suggesting an increase in glomerular capillary pressure. It was suggested that these gender-related differences in the response of the renal microvasculature to hyperglycemia may explain the lack of a consistent protective effect of female gender on the course of nephropathy in type I diabetes.

Women with uncomplicated type 1 diabetes show exaggerated renal responses to cyclooxygenase 2 (COX-2) inhibition, characterized by decreased ERPF and increased filtration fraction, suggesting that women are more dependent on vasodilatory prostaglandins to maintain renal hemodynamics than are men.[106] COX-2 inhibition also eliminated gender-related differences in the response to angiotensin II (Ang II), indicating that vasodilatory prostaglandins may play a greater role in counteracting the effects of Ang II on the renal microvasculature of diabetic women compared with diabetic men.

In the rat, regional renal blood flow autoregulation is more efficient and papillary blood flow is lower in males.[4,75] A role for vasodilatory prostaglandins in mediating these effects is suggested by the finding that cyclooxygenase inhibitors abolish gender-related differences in regional renal blood flow autoregulatory capacity and in papillary blood flow rate.[4,75]

HYPERTENSION

The link between hypertension and renal insufficiency was recognized as early as the mid-1800s when Richard Bright noticed that individuals with renal disease also had hypertension.[107] The interaction between the kidney and hypertension sets up a vicious cycle in which renal injury causes hypertension, and hypertension causes further renal injury. Evidence that renal disease and hypertension are interconnected is shown by the many studies showing that the use of antihypertensive medications slows the progression of renal injury.[108] The mechanisms responsible for hypertension are multifactorial, and thus the mechanisms by which hypertension causes renal injury are also multifactorial. Similarly, the roles played by sex steroids in mediating gender differences in hypertension and renal injury have not been completely elucidated.[109,110]

Hypertension in all animal models studied is due to a hypertensive shift in the pressure-natriuresis relationship such that a higher BP is required to allow "normal" levels of sodium to be excreted. Reductions in GFR due to injury cause an increase in sodium reabsorption and hypertension.[109–112] Whether estrogens attenuate sodium reabsorption directly has not been determined to our knowledge. However, in studies in male rats, androgens increase proximal tubule sodium reabsorption directly *via* the androgen receptor, and this response is mediated by the RAS as blockade with AT1 receptor antagonists attenuated the response.[113] Thus, androgens could be prohypertensive.

In hypertensive animals, such as spontaneously hypertensive rats (SHRs), androgens promote hypertension and renal injury and castration of males attenuates the hypertension to level found in females.[114] Estrogens do not have a protective effect on hypertension in this model because ovariectomy does not increase BP in the females. With aging, androgens also promote increases in BP in Dahl salt-sensitive rats, castration attenuates the hypertension, but in females, ovariectomy promotes increases in BP.[114,115]

One mechanism by which hypertension is thought to occur is due to increases in ROS. Antioxidants reduce BP in male SHR but have no effect in females.[116] Prooxidants, such as molsidomine, increase BP in male SHR, but not females.[116] Because estradiol increases endothelial NO, and reductions in NO by interaction with superoxide are thought to contribute to the ROS-mediated increases BP, females were given L-NAME

and molsidomine in the hopes that blockade of NO synthesis would then cause BP to increase further with molsidomine. However, BP in females still did not respond.[116] Thus, the hypertension in female SHR is not controlled by ROS, whereas in males, the opposite is true. The role of oxidative stress in mediating hypertension in humans is not clear, however. No clinical trials to date have shown that antioxidant therapy alone decreases BP. However, this may be due to the fact that a competent NO system is necessary for antioxidants to be able to reduce BP.[117] Most hypertensive individuals have endothelial dysfunction and thus have reduced NO production, and antioxidants would not be effective in lowering their BPs. In addition, none of the studies to date have separated depressor response to antioxidants by gender. Thus, hypertensive men may benefit from antioxidant therapy and women may not, as in the animal studies. Thus, additional studies are needed to determine if there are gender differences in the depressor response to chronic antioxidant therapy.

Angiotensin II hypertension is also sex dependent. In rats given slow pressor doses of Ang II along with ACEIs to reduce the endogenous production of Ang II, the BP increases to higher levels in females than males.[118] Addition of high salt diet has no further effect to increase BP in females but causes a salt-dependent increase in the BP in males. In rats not given ACEIs, males exhibit a greater increase in BP than females. In contrast, male mice develop higher elevations in BP in response to Ang II than do females, regardless of whether they are given ACEIs.[119,120] Sex steroids affect the components of the RAS. Renal synthesis of angiotensinogen is increased with androgens,[121,122] and estrogens stimulate liver angiotensinogen synthesis but attenuate expression of AT1 receptors and ACE.[122,123] Estrogens also upregulate ACE2 to produce vasodilator Ang (1−7).[124]

Aging in both men and women is characterized by increases in BP,[125,126] and the prevalence of hypertension in postmenopausal women is higher than in men.[125,127−130] In the US, more than 75% of women over 60 years of age are hypertensive.[131,132] Nondipping of BP at night is associated with increased target organ damage (including renal injury) in both men and women.[133,134] However, there is evidence that nondipping in women, in general, is associated with greater target organ damage than in men,[133,134] and postmenopausal women are more likely than premenopausal women to exhibit nocturnal nondipping of BP.[134]

The mechanisms responsible for hypertension in aging hypertensive animal models also show sex differences. For example, in male SHR, albuminuria and glomerular sclerosis is present by 16 months of age.[135] In contrast, female SHR have little proteinuria or histologic evidence of glomerular or tubular injury despite the fact that their BP increases with aging to the same or higher levels than in age-matched males.[136] The mechanisms responsible for the hypertension in aging male SHR are mainly the RAS because AT1 receptor blockade, but not endothelin ETA receptor blockade, normalizes the BP old males and young females.[137,138] In old females, although blockade of the RAS, ETA receptor, 20-HETE synthesis, and renal denervation attenuate the hypertension, none of these maneuvers alone normalizes the BP. Combined administration of an AT1 receptor antagonist, an ETA receptor blocker, and a 20-HETE synthesis inhibitor reduces the BP toward normal levels but mean arterial pressure remains above 100 mm Hg.[139] These data suggest that more studies are necessary to determine the mechanisms responsible for hypertension in postmenopausal women to protect them from developing renal disease with aging. There is evidence that hypertension is not as well controlled in aging women as in aging men, despite the fact that women see their care providers more regularly than men and are typically more compliant in taking their medications.[140] The observations from animal studies suggest that the reason for the gender difference in BP control in aging individuals may be due to differences in mechanisms and further suggest that novel drug therapies may need to be developed to treat women.

THERAPEUTIC IMPLICATIONS

Several observational and three randomized, placebo-controlled studies have examined the effects of hormone replacement therapy and oral contraceptive therapy on renal function and proteinuria in diabetic and nondiabetic women. The results are contradictory and cannot be entirely explained by differences in estrogen dose, route of administration, or the nature of concomitantly administered progestins. Moreover, healthy user bias complicates interpretation of observations studies because women who take hormone therapy differ in relevant characteristics from those who do not take hormone therapy.

Jackson and coworkers have suggested that many of the beneficial effects of estradiol on cellular processes that influence real disease progression are mediated by nonestrogenic metabolites that lack feminizing properties, particularly catecholestradiols.[141] These agents inhibit mesangial cell proliferation and collagen synthesis *in vitro* and ameliorate oxidative stress and progressive renal injury in several models of experimental renal disease by estrogen receptor-independent mechanism. Whether these agents might exert a similar effect on progressive renal injury in humans without adverse effects on reproductive tissues has not been explored.

Selective estrogen receptor modulators (SERMs) are agents that mimic many of the beneficial effects of estrogen on bone and vascular tissue without reproducing estrogens deleterious effects on reproductive tissue. SERMs replicate the effects of estradiol on mesangial cell biology and are renoprotective in models of experimental renal injury.[142] The Raloxifene in Diabetic Nephropathy study, a double-blind, placebo-controlled trial in postmenopausal women with type 2 diabetes and evidence of renal involvement randomized to receive either Raloxifene or placebo for six months, reported that urinary protein excretion decreased in patients receiving Raloxifene but not in the placebo group.[143] We performed a *post hoc* analysis of the Multiple Outcomes of Raloxifene Evaluation trial, a multicenter, randomized, double-blind, placebo-controlled trial of Raloxifene vs. placebo on the risk of fractures in nondiabetic postmenopausal women, and found that women in the Raloxifene group had a slower rate of increase in S[Cr] and a significantly slower rate of decline in eGFR during three years of follow-up.[144]

CONCLUSION AND FUTURE DIRECTIONS

In experimental models of renal disease, there is a clear sexual dimorphism, with male animals showing a worse renal prognosis. However, in humans, a larger number of variables make the issue of gender and real disease progression more challenging. There have been no dedicated well-designed prospective studies evaluating the rate of decline in renal function in men vs. women. Individual studies that have taken gender into account when analyzing factors contributing to renal disease progression have often included small numbers of subjects with a short duration of follow-up. Although far from a universal finding, the predominance of data supports the conclusion that male gender is associated with accelerated progression of nondiabetic CKD. A similar case can be made for sexual dimorphism in the course of diabetic nephropathy; however, the evidence for this conclusion is even less robust.

Interpretation of data is confounded by uncertainty about the appropriate cutoff to define the normal range of GFR and ACR with respect to gender and age. This is especially relevant in cross-sectional studies examining the incidence and prevalence of CKD. Moreover, questions arise regarding the magnitude of differences between the sexes in the bias of equations used to estimate GFR. Inconsistent data may also reflect differences in the populations studied with respect to duration of follow-up, hormonal status, demographic features, disease-modifying therapy, lipid levels, and BP control, as well as differences in study methodology, most notably differences in outcome measures. In the case of diabetic nephropathy, inconsistent data may also reflect differences in the age of onset of diabetes and in the intensity of glycemic control. At present, insufficient data are available to adequately address these concerns. These issues merit serious consideration in any discussion of the relationship between gender and CKD.

We are not aware of any ongoing studies to investigate the effects of hormone replacement therapy, SERMs, or estradiol metabolites on the course of CKD in humans.[111] We speculate that a lack of enthusiasm to explore these novel therapeutic approaches arises from the dampening effect of the Woman's Health Initiative Study which raised concerns about the relationship between hormonal therapy and elevated risk of breast cancer and thromboembolic events.

QUESTIONS AND ANSWERS

Question 1

A 45-year-old woman with CKD presents to your office with nausea, vomiting, and anorexia. She is found to have an eGFR of 8 mL/min and is referred for initiation of chronic maintenance hemodialysis.

Which one of the following is true regarding the relationship between gender and CKD?

A. The incidence rate of ESRD is greater in men than in women
B. The prevalence of ESRD is greater in women than in men
C. The prevalence of stages 3–5 CKD not requiring dialysis in the US population is greater in men than in women
D. The prevalence of proteinuria in the US population is greater in men than women
E. Male gender confers a survival advantage in ESRD

Answer: A

The incidence rate of ESRD in the US is 60% greater in men compared with women.[24,30,32–34,38,145,146] B is incorrect. Both the incidence and prevalence of ESRD is greater in men than women. C and D are incorrect. Despite the fact that the prevalence of stages 3–5 CKD is greater in women than in men, the incidence of ESRD is greater in men. NHANES data indicate that the prevalence of an eGFR less than 60 mL/min/1.723 m^2 is 7.7% in women vs. 5.6% in men and the prevalence of ACR >30 mg/g creatinine is 10.2% in women vs. 8.6% in men.

Question 2

A 50-year-old woman with long-standing diabetes mellitus presents to your office for evaluation of hypertension, microalbuminuria, and an eGFR of 47 mL/min.

Which one of the following is true regarding the relationship between gender and diabetic nephropathy?

A. Sex hormone metabolism is dysregulated in diabetes mellitus
B. There is no gender disparity in the renal hemodynamic response to hyperglycemia
C. The incidence of diabetes-related ESRD is greater in women than in men
D. The prevalence of diabetes-related ESRD is greater in women than in men
E. Women initiate RRT at a higher GFR than do men

Answer: A

There is substantial evidence that sex hormone synthesis and metabolism is disturbed in diabetes mellitus. However, data are conflicting as to the nature of this dysregulation. B is incorrect. During clamped hyperglycemia, males do not exhibit any change in renal hemodynamics, whereas females show a decrease in ERPF and increases in renal vascular resistance and filtration fraction. C and D are incorrect. Both the incidence and prevalence of diabetes-related ESRD is greater in men than in women. The incident rate of diabetes-related ESRD in the US is 24% greater in men. E is incorrect. Women initiate renal replacement therapy at a lower GFR than do men both in Europe and the US.[24,32,38,65,68,105,147]

Question 3

Which one of the following is true regarding the effect of estrogen on the TGF-beta signaling cascade?

A. Estrogen reduces the bioavailability of the transcription factor SP1 to transactivate the type IV collagen gene promoter
B. Estrogen decreases ubiquitization and degradation of Smad2/3
C. Estrogen increases the density of TGF-beta receptors types I and II in experimental diabetes
D. Estrogen increases the synthesis and release of TGF-beta by mesangial cells and podocytes in experimental models of renal disease
E. Estrogen increases the expression of endothelin which in turn increases generation of TGF-beta

Answer: A

TGF-beta activates a serine/threonine protein kinase, protein kinase CK2, which leads to an increase in the quantity of free Sp1 available to transactivate the collagen IV promoter. Estradiol reverses TGF-beta stimulated type IV collagen gene transcription by preventing TGF-beta-induced activation of CK2. B is incorrect. Estrogen receptor alpha forms a ternary complex with Smad2/Smad3 and the ubiquitin ligase Smurf which in turn enhances ubiquitization and degradation of these Smad proteins and inhibits TGF-beta signal transduction. C is incorrect. Estradiol reverses the increased expression of TGF-beta receptors types I and II in experimental diabetes. D is incorrect. Estrogen decreases TGF-beta expression by mesangial cells and podocytes in numerous models of experimental renal disease. E is incorrect. Estrogen decreases and testosterone increases endothelin expression.[4,79,81,82]

Question 4

Which one of the following statements about the effects of sex hormones on mesangial cell and podocyte apoptosis is false?

A. Testosterone induces apoptosis in podocytes
B. Testosterone induces apoptosis in proximal tubule cells
C. Estrogen reverses TGF-beta-induced apoptosis in mesangial cells
D. Estrogen reverses podocyte apoptosis in an experimental model of renal disease induced by puromycin aminonucleoside
E. Testosterone reverses TGF-beta-induced podocyte apoptosis

Answer: E

Estrogen protects podocytes from apoptosis induced by testosterone, TGF-beta, TNF-alpha, and puromycin aminonucleoside. In addition, estrogen antagonizes TGF-beta-induced mesangial cell apoptosis. Testosterone induces podocyte apoptosis *in vivo* and *in vitro* and also promotes apoptosis of human proximal tubular cells.[80,91–93]

Question 5

Which one of the following is true regarding the effect of sex hormones on the generation of ROS?

A. Estrogen increases the generation of ROS
B. Estrogen upregulates NADPH oxidase
C. Interactions between testosterone and ROS mediate the renoprotective effects of testosterone
D. Testosterone upregulates cellular antioxidant defense systems
E. Interactions between sex hormones and the generation of ROS influence the course of several experimental models of hypertension

Answer: E

Enhanced generation of ROS has been shown to contribute to renal damage in experimental models of renal disease. In several experimental models of hypertension, reversal of renal injury by estrogen and exacerbation of injury by testosterone is mediated by the ability of sex hormones to modulate ROS generation. A and B are incorrect. Estrogen blunts the upregulation of nicotinamide adenosine dinucleotide phosphate oxidase activity induced by renal injury, which in turn suppresses the generation of superoxide anion, the major ROS produced by the kidney. C and D are incorrect. Testosterone increases oxidative stress and promotes renal injury. Testosterone inhibits antioxidant enzymes and amplifies the generation of ROS in response to renal insults.[90]

Question 6

A 60-year-old man with a history of long-standing hypertension presents for management of uncontrolled hypertension.

Which one of the following is true regarding the effect of gender on the renin-angiotensin axis and on the development and severity of hypertension?

A. The prevalence of hypertension is greater in premenopausal women compared with age-matched men
B. The prevalence of hypertension is greater in postmenopausal women compared with age-matched men
C. Estrogen reduces angiotensinogen levels
D. Estrogen increases the density of AT-1 receptors
E. The renal hemodynamic response to angiotensin II infusion is equivalent in men and women

Answer: B

The prevalence of hypertension is greater in postmenopausal women compared with age-matched men, but this relationship is reversed in premenopausal women. C and D are incorrect. Sex steroids affect the components of the renin-angiotensin system. Estrogens stimulate liver angiotensinogen synthesis but attenuate expression of AT1 receptors and ACE, whereas androgens increase renal synthesis of angiotensinogen. Estrogens also upregulate ACE2 to produce angiotensin (1–7), which has vasodilatory properties. E is incorrect. Men respond to an infusion of angiotensin II by maintaining their GFR at the expense of an increased filtration fraction. In contrast, women show a decrease in GFR and ERPF without any change in filtration fraction.[100,123,125,127–130]

Abstract

Chronic kidney disease (CKD) is a noncommunicable disease that is now well recognized as a major cause of premature morbidity and mortality. Racial/ethnic minorities have an increased prevalence of key risk factors such as diabetes mellitus and hypertension, as well as being 1.5–3 times more likely than their non-Hispanic White counterparts to reach end-stage renal disease (ESRD). While the term race represents a social/political construct, its association with health is complex. The term race is actually a misnomer as *Homo sapiens* is the only extant human species, so there is only one race. Thus, variations in groups of humans that share similar physical appearances, language, culture, and/or biology linked to ancestral geographic origins might more appropriately be classified as ethnicity. Understanding how the race/ethnicity interacts to influence CKD and ESRD risk, progression, and complications in the US is critical to advancing the care of all patients with kidney disease.

INTRODUCTION

We don't see things as they are, we see them as we are **Anais Nin (1903–1977)**

Chronic kidney disease (CKD) is epidemic in the US. CKD is a noncommunicable disease that is now well recognized as a major cause of premature morbidity and mortality.[1] Multiple aspects of CKD, ranging from the risk and development to progression and complications, differ by race/ethnicity and are among the starkest examples of health disparities in the US.[2,3] This is highlighted by racial/ethnic minorities having a nearly 2-fold higher incidence rate of diabetes mellitus (DM), the leading cause of CKD, as well as a 1.5- to 3-fold greater incidence of end-stage renal disease (ESRD) compared with their age-adjusted non-Hispanic White peers.[4,5] This chapter describes the current status of CKD and ESRD risk, complications, and care in the US and explores the social and biologic factors that interact to influence racial/ethnic differences in CKD/ESRD risk and outcomes.

HEALTHY PEOPLE 2020

The elimination of racial and ethnic disparities across all stages of CKD is widely recognized in nephrology as an important approach to understand and ultimately improve overall patient outcomes.[2,6–8] It is also one of the target areas for Healthy People 2020, our nation's blueprint for health.[9] The finding of increased rates of ESRD among racial/ethnic minorities Americans in the late 1970s and early 1980s[10–12] prompted the need to better understand the issues underlying both ESRD incidence and quality care for all groups of patients receiving renal replacement therapy (RRT).[13–16] A response to these early findings was the introduction of national ESRD performance measures and quality standards.[17,18] These national performance measures have led to a substantial improvement in the quality of care and a reduction in disparities for patients receiving RRT.[17,18] However, our work has just begun. In evaluating kidney disease-related racial/ethnic disparities, it is critical that we view this issue through two distinct lenses, one viewing race as a social construct and one as ancestral biological variants. Thus, outcomes for patients in varying settings with or at risk for CKD are influenced by the social determinants of health, juxtaposed with geo-evolutionary risk and resilience gene variants. Through this understanding, the nephrology community can move closer to creating more effective

Chronic Renal Disease, Second Edition

solutions to eliminate disparities and to use the lessons learned to improve outcomes for all patients.

DEFINING RACE AND ETHNICITY

The concept and use of the terms race and ethnicity are deeply integrated into our nation's social fabric. There is no generally agreed on definition for these terms, but it is clear that they carry complex nuances reflecting social position, political status, culture, economics, and history juxtaposed with differing frequencies of particular gene variants that reflect ancestral geographic origins.[19] Race and ethnicity can mean different things to different people, may have different implications in different settings, and a person's designation can change in a particular place and/or time. Historically, the use of the term race in the US derives from Carl Linnaeus, the father of modern taxonomy. Linnaeus designated four major "racial" groups by geographic region (Europe, Asia, Americas, and Africa), and then assigned each racial category select personality traits, skills, and abilities,[20] with the more desirable traits ascribed to White Europeans and the least desirable traits ascribed to Black Africans. This designation was viewed as an actual scientific fact and helped to establish the "scientific" foundation for racism.[21] By contrast, the actual science, including recent DNA analysis of different groups of people, confirmed that there are in fact no distinct populations within or that differ from modern *Homo sapiens*.[22] However, the US Census reporting still uses the original Linnaeus-based race categories—White, American Indian or Alaska Native, Asian, and Black or African American—with a fifth category added in 2000 for Native Hawaiian or other Pacific Islander.[23–25] The US Office of Management and Budget uses two major ethnic categories for each person: (1) not Hispanic or Latino and (2) Hispanic or Latino, regardless of race.[23,24] Clearly a decision to divide the world into two ethnic groups also has no scientific merit. These categories thus reflect not scientific differences among groups but the social, political, cultural, economic, and historical influences that provide access and opportunity in a society and its impact on multiple dimensions of being, including health.

A scientifically accurate view that humans are a single race is held by the Pan American Health Organization/World Health Organization, which does not use the term race and uses the term ethnicity to capture differences between groups of individuals that share common linguistic, cultural, and ancestral backgrounds.[26] Consistent with this, the terms "ethnicity" and "race" will be used as the combined term race/ethnicity in this chapter, not only recognizing that different races do not exist but different ethnic groups do but also acknowledging that the use of the term race persists in the US for categorizing people by governmental agencies, including health and educational systems.[26]

RACE/ETHNICITY AND HEALTH

Racial/ethnic minorities now comprise nearly 40% of the US population,[27] highlighting the importance of optimizing minority health to improve the overall health of our nation. However, given the political and social underpinnings of race and ethnicity in the US, and the persistence of structural racism, it is not surprising that minorities continue to suffer from worse health outcomes in most domains. This is because health outcomes stratified by race/ethnicity are strongly influenced by a group's social position/exclusion, marginalization, discrimination, and the associated socioecologic determinants of health such as residential segregation,[28] educational and income inequalities,[29–32] imbalance in community-level assets, access to care,[6] health care resources,[33–35] and exposure to environmental toxins.[7,36] Additional factors include health system barriers, unconscious provider biases, medical mistrust, patient beliefs and behaviors, and stereotype threat.[37–40] Stereotype threat is a more recently recognized concept in health care and refers to the fear of being judged by, and/or confirming through one's own actions, negative group stereotypes that operate within the domain of health care, such as inferior intelligence, lower social status, greater likelihood of engaging in risky behaviors, and less deserving of high quality care.[39] Despite the passing of civil rights legislation in the 1960s, the above issues are promulgated by judicial and institutional policies, practices, and beliefs that maintain many of the racialized precivil rights structural elements and thus perpetuate many of the persisting disparities by race/ethnicity and gender.

CKD PREVALENCE AND MAJOR CHRONIC KIDNEY DISEASE RISK FACTORS

Based on estimates from the National Health and Nutrition Examination Survey (NHANES), the overall prevalence of CKD in the US has slowly increased, and this increase is present in all racial/ethnic groups. The 1988-1994 NHANES compared with the 2011-2012 NHANES estimated prevalence of CKD stages 1–4 for

TABLE 8.1 Select Chronic Kidney Disease Risk Factors by Ethnicity

	Hispanic	Asian	Native American	Black/African American	White
Prevalence of age-adjusted diagnosed diabetes for adults aged 18 years or older, 2013–2015 (%)[46]	12.1	8	15.1	12.7	7.4
Age-adjusted prevalence of hypertension among adults aged 18 and over, 2015–2016 (%)[47,48]	27.8	25.0	26.4	40.3	27.8
Age-adjusted prevalence of controlled hypertension among adults with hypertension aged 18 and over, 2015–2016 (%)[47]	45	37.4	Not available	44.6	50.8
Prevalence of overweight/obese (age-adjusted) (%)[27]	69.9	42	70.5	72	64.1

TABLE 8.2 Select Socioeconomic Factors by Race/Ethnicity

Self-reported overall health status as fair or poor[27]	25.2	10.8	28.7	22.1	16.4
% Below federal poverty level[27]	16	9	22	20	8
Uninsured, nonelderly[27]	19	7	22	11	7
Graduation rate from public high school (%)[50]	79	91	72	76	88
No personal doctor or health care provider[27]	39	23	29.2	22.3	18

non-Hispanic Whites at 11.8 vs. 14.1%, non-Hispanic Blacks 13.7 vs. 17.3%, and for other 10.1 vs. 12.7%.[41] However, when the estimates were restricted to CKD stages 3 and 4, the authors found the rates for non-Hispanic Whites at 5.4 vs. 8.0%, non-Hispanic Blacks 3.7 vs. 6.2%, and for other 2.2 vs. 3.6%.[41] These findings suggest White patients with CKD are more likely to progress to stages 3 and 4 but appear less likely to progress to ESRD, especially because racial/ethnic minorities have a higher mortality rate among persons with CKD, especially those below 65 years of age.[42]

Diabetes and hypertension are the two leading causes of patients progressing to ESRD.[43] In addition, obesity/overweight is an emerging CKD risk factor as well as a noncommunicable public health epidemic, whereas albuminuria is an important CKD progression factor. Compared with their White peers, most racial/ethnic minorities have a higher prevalence of diabetes, hypertension, and obesity/overweight, as well as albuminuria (Table 8.1).[27,44,45]

SOCIAL DETERMINANTS OF HEALTH

The self-reported overall health status varies by race/ethnicity, with 20.5% of African Americans, 25.6% of Hispanics, 27% of Native Americans, 9% of Asians, and 15.7% of Whites reporting fair or poor health status.[27] This discrepancy is driven in part by many of the social determinants of health, which disproportionally affect minority and low-income populations adversely. Social determinants of health include factors such as access to providers/care, educational attainment, income, insurance, and community-level assets and deficits.[3,49] In general, compared with their White peers, racial/ethnic minorities are more likely to report having no personal doctor or health care provider, be below the federal poverty line, be uninsured, and have lower graduation rates at public high schools (Table 8.2).[27,50]

These adverse social characteristics are highly relevant for patients with CKD. An analysis of participants with or at risk for CKD in the National Kidney Foundation

Kidney Early Evaluation Program (KEEP) screening program found uninsured KEEP participants were 72% more likely to develop ESRD and 82% more likely to die than those with private insurance.[51] Similarly, Choi et al. found a nearly 20% higher adjusted relative risk of death for KEEP participants with CKD and less than high school education, compared with those with high school education or greater, followed over a mean follow-up period of 3.9 years.[31] A situation similar to limited educational attainment exists regarding low levels of literacy. An analysis of participants in the Chronic Renal Insufficiency Cohort study found 28% of African Americans and 5% of Whites had limited health literacy.[52] Limited health literacy in patients with CKD has been associated with increased hospitalizations, emergency department use, cardiovascular events, and mortality.[53] Cavanagh and colleagues found limited health literacy in dialysis patients was associated with a 54% higher risk for death and was more likely in be present in males, racial/ethnic minorities, and those with fewer years of education.[54] Thus, adverse social determinants of health have a major impact on CKD outcomesand they remain disproportionately prevalent in many racial/ethnic minority communities.

CKD QUALITY OF CARE

The Agency for Healthcare Research and Quality examined racial/ethnic differences in 182 national quality measures and reported areas where there was improvement, no difference or worsening. They found, compared with White patients, no difference or worsening in 87% of quality measures for Blacks, 78% for Hispanics, 87% for American Indian/Alaskan Natives, 76% for Native Hawaiian/Pacific Islanders, and 66% for Asians.[55] In addition, Blacks, Hispanics, and American Indian/Alaskan Natives had worsening in more than twice as many quality of care measures than they had improvement.[55] Details regarding improvement, no difference, or worsening of quality measures by race/ethnicity are provided in Table 8.3.

However, for CKD and major CKD-specific quality care metrics, there has been more substantial improvement noted by Healthy People 2020 (Table 8.4).[43,56] This includes a substantial increase in and reduced disparity over the last 10–12 years in the percent of racial/ethnic minorities diagnosed with DM who obtained an annual evaluation of urinary albumin, the percent of persons with DM and CKD who received a more comprehensive medical assessment and received recommendation regarding medical treatment with inhibitors of the renin angiotensin system, the percent of patients receiving care from a nephrologist at least 12 months prior to the start of RRT and others (Table 8.4). Because the number of patients receiving RRT has increased while the number of kidney transplants has remained flat, the percent of all patients receiving a kidney transplant has progressively fallen (Table 8.4).

Interestingly, despite an overall decline in the death rate for patients receiving dialysis treatments, the death rate for White dialysis patients remains above the Healthy People 2020 target level (Table 8.4). The reason for this observation is not clear, but a possible survival bias could lead to healthier minorities reaching dialysis or other resilience factors in the setting of chronic disease could account for the observed differences.[42,57–61]

ESRD TREATMENT MODALITIES

Despite a fairly similar prevalence of the early stages of CKD, and a lower prevalence of CKD stages 3 and 4, racial/ethnic minorities are 1.5–3 times more likely than their non-Hispanic White peers to progress to ESRD and require RRT.[4,5,41] In the US, the preferred options for RRT are kidney transplantation or home dialysis,[62] yet, racial/ethnic minorities are less likely to receive RRT with either a kidney transplant or home dialysis therapy.[63] These findings highlight the continuing need for efforts to achieve greater equity in the use of the preferred ESRD treatment options.

TABLE 8.3 Agency for Healthcare Research and Quality Racial/Ethnic Differences in 182 National Quality Measures Compared with Whites (Not all Measures Included all Groups, so Totals May Not = 182)

Change in Quality Metrics	Hispanic	Asian	American Indian/ Alaskan Natives	Black/African American	Native Hawaiian/ Pacific Islanders
Improved (n)	37	55	12	23	12
No difference (n)	66	76	50	82	24
Worsened (n)	65	32	31	77	14

ESRD QUALITY CARE METRICS

Ongoing quality improvement measures have eliminated individual-level racial/ethnic disparities for most metrics such as dialysis adequacy and anemia. Interestingly, disparities persist at the facility level, with lower levels of dialysis adequacy and higher rates of anemia reported in patients treated in dialysis facilities within neighborhoods with a higher proportion of African Americans.[64,65] These disparities persist even after controlling for neighborhood-level socioeconomic status and other factors in some,[64] but not all, studies.[65] Interestingly, when examining facility-level hemoglobin (Hb) targets by the percentage of African-Americans patients per facility, rather than by neighborhood, there was no difference in anemia-related quality measures.[65]

These findings reinforce the need to better understand and further explore the social determinants of health that drive facility/community-level outcomes to further advance efforts to achieve equity in treatment care at dialysis facilities, regardless of facility location or patient case mix.

IMPACT OF CHANGES IN ESRD REGULATORY PRACTICES ON RACIAL/ETHNIC DISPARITIES

Although there has been progressive improvement in quality care for racial/ethnic minorities over the last 25 years, concerns have been raised that these gains may have been negated by the implementation of the 2011 Medicare ESRD prospective payment system (PPS) and the simultaneous FDA-mandated manufacturer label changes to lower recommended Hb targets. Either of these could lead to more restricted erythrocyte-stimulating agent (ESA) use, increased rates of anemia, and subsequently worse outcomes.[66,67] Medicare ESRD PPS changes could also lead to poorer bone and mineral disorder (BMD) outcomes.[67] Anemia and BMDs are of particular concern, given the historically higher doses of ESA and vitamin D needed to maintain target Hb and parathyroid hormone (PTH) levels, respectively, in Blacks. A pre-post PPS analysis by Turenne and colleagues of over 7000 patients treated at 132 dialysis facilities from the Dialysis Outcomes and

Practice Patterns Study Practice Monitor found overall mean Hb levels fell from 11.5 to 11.0 g/dL and mean EPO dose declined from 20,506 to 14,777 U/week, with no meaningful differences by race/ethnicity.[68]

Similar to the potential impact of anemia management and outcomes, the PPS is likely to affect the dosing of vitamin D and related medications used to treat BMDs. The dose of vitamin D needed to maintain target PTH levels and the relationship between PTH levels, serum phosphate levels, and fibroblast growth factor 23, and bone fractures, bone histology, or mortality differs across racial/ethnic groups.[68–73] Following the implementation of 2011 Medicare ESRD PPS cost-saving measures, Turenne et al. found mean serum iPTH increased from 340 to 435 pg/mL, but these changes did not differ by race/ethnicity.[68]

In addition, Wang et al. examined cardiovascular outcomes following the PPS and ESA labeling changes in 2011 and found no overall difference before and after the changes among fee-for-service Medicare patients, with the exception of an 18% reduction in cardiovascular events that was observed in a secondary analysis of Black patients, suggesting the new policies had no adverse impact overall or by race/ethnicity, with a possible beneficial effect on Black patients.[74]

PRE-ESRD NEPHROLOGIST CARE AND VASCULAR ACCESS

Several markers of pre-ESRD care are linked to outcomes for patients receiving RRT, and the lack of or delay in establishing pre-ESRD care is associated with increased risk of death following transition to RRT.[75–77] Unfortunately, there has been little change over the last 15–20 years in the disparities related to pre-ESRD nephrology care.[75–79] Despite the introduction of the ESRD (and pre-ESRD) quality care initiatives in the early 1990s, Gillespie et al. reported in 2015 that more than 12 months of pre-ESRD care was less frequent in African Americans, Asians, Native Americans, and Hispanics.[76] These findings are reinforced by a report from Yan et al. who found a lower state-level probability of Blacks having received nephrologist care 12 months prior to dialysis, more so in younger Black patients.[80] The finding was attenuated for older Blacks, who were more likely to have had Medicare insurance coverage during the per-ESRD period, suggesting insurance has a major influence on racial disparities in the pre-ESRD period.[80]

Although the use of an arteriovenous fistula (AVF) at first hemodialysis treatment is associated with superior clinical outcomes, the use of an AVF at the first dialysis treatment remains a major area of racial/ethnic and gender disparities in dialysis care.[81,82] Analyzing a cohort of nearly 400,000 dialysis patients, Zarkowsky et al. found Hispanic and Black patients were less likely to initiate hemodialysis with an AVF than their non-Hispanic White peers, independent of insurance status, despite having fewer comorbidities and being younger.[83] Like pre-ESRD nephrologist visits, factors in addition to insurance, such as medical mistrust, health system barriers, health literacy, provider and patient biases, social determinants, and others that could account for these differences, require further investigation to create policies which might eliminate or diminish pre-ESRD disparities.[7,38,40,83,84]

SURVIVAL ON DIALYSIS

Despite higher rates of lower quality of ESRD care, observational data have consistently shown that racial/ethnic minorities receiving dialysis treatments have greater survival rates than their peer majority groups, even after adjusting for age, gender, and transplantation.[57–60,85–90] The observation that minority groups treated with dialysis have greater survival than their majority peers is not limited to the US.[86–88] In the US, Hispanics have a higher adjusted survival rate than non-Hispanics at every age, whereas the Black-White survival difference appears to vary by age, as there are significantly better survival rates for Blacks above 40 or 50 years of age compared with Whites, but younger Black and White patients have similar survival rates.[57,58,60] Asians also have a higher survival rates than Whites,[91] but due to fewer numbers of Asian ESRD patients, few comparative subgroup analyses have been feasible to date.

Community factors also influence dialysis outcomes. Facilities located in communities with higher proportions of Black patients (typically characterized by lower community SES and fewer health-related community assets) have poorer survival outcomes among both Black and non-Black patients.[35,64,65,92] These findings reinforce the notion that intertwined social and economic influences may have important implications for ESRD patient outcomes.

CONCLUSION

Social and to a lesser extent biological factors appear to contribute to the more frequent need for RRT for racial/ethnic minorities, where access to and quality of care, patient behaviors, control of medical risk factor conditions, and other factors combine with CKD risk alleles to influence CKD development and progression.[3,38] Once progression to ESRD has occurred, the impact of risk factors in different race/ethnic groups may vary substantially for different quality measures and

outcomes. The impact of longstanding racialized policies and practices on the social positioning of racial/ethnic groups, and associated barriers such as limited finances, inadequate health insurance, medical distrust, unconscious provider biases, that may result in differential clinical practice decision-making and related factors influencing patients' beliefs and behaviors together, may contribute to persistent disparities in the likelihood of receiving different care for CKD, pre-ESRD, and RRT.[2,6,7,29,33,84] Importantly, as the medical and health sciences professions identify health-related differences between racial groups, the lessons learned should not only prompt new biomedical advances including personalized medicine but also stimulate advocacy for social and health policy level changes that can promote equity while ensuring the highest quality of care within our health systems and dialysis facilities, to ultimately achieve health equity and improve outcomes for all patients.[93–95]

Ethnicity and Chronic Kidney Disease in Disadvantaged Populations—An International Perspective

Ricardo Correa-Rotter[a], *Guillermo García-García*[b], *Jonathan Chávez-Iñiguez*[b], *Juan C. Ramírez-Sandoval*[a]

[a]**Department of Nephrology and Mineral Metabolism, Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, México City, México;** [b]**Division of Nephrology, Hospital Civil de Guadalajara, University of Guadalajara Health Science Center, Guadalajara, Jalisco, México**

Abstract

Ethnicity is a powerful element that affects the incidence, prevalence, and course of chronic kidney disease (CKD) worldwide. Complex interactions of genetic, biologic, cultural, environmental, and socioeconomic factors are associated with CKD differences among countries, including several disadvantaged communities and ethnic minorities in developed countries. Conditions that predispose to CKD such as hypertension, diabetes mellitus, or obesity can be more prevalent in these communities, caused by differences in predisposing genetic backgrounds, prenatal and perinatal care, and experiences, including low birth weights, inadequate diets, infectious diseases, or exposure to toxins. End-stage renal disease incidence tends to rise in communities with social deprivation, and provision of renal replacement therapy depends mostly on extent of national health care expenditures and economic strength. Strategies to provide renal care for all including preventive care, early referral, timely dialysis initiation, and equalizing opportunities for kidney transplantation can be achieved through a concerted effort between nephrologists, governments, patients, charitable organizations, and industry.

BACKGROUND

Ethnic diversity is strongly associated with disparities in health status of millions of persons around the world and may explain differences in the rate of incidence, prevalence, morbidity, and mortality related to chronic kidney disease (CKD) between and within countries.[1] Dramatic increases in life expectancies and widespread declines of fertility and birth rates have been particularly marked in developing nations, increasing the incidence and prevalence of chronic diseases.[2] Obesity, diabetes mellitus (DM), hypertension, and CKD are the four major comorbidities leading to mortality disparities among disadvantaged populations.[3]

Epidemiologic and demographic transitions are not consistent among emerging nations.[4] While the trends described are happening rapidly in countries such as India, China, most of Southeast Asia, and Latin America, other regions of the world, such as sub-Saharan Africa or West Africa, are still plagued by devastating epidemics of communicable diseases. Nevertheless, even in those regions, dealing with tuberculosis, AIDS, viral hepatitis, and other infectious diseases, growing urban concentrations are also struggling with an increase in CKD that was not present decades before.[5,6]

In developed countries, the growth of ethnic minorities, in addition to the extent of racial diversity and mixture between ethnic groups, increases disparities related to the prevention, diagnosis, and treatment of CKD.[7] Socioeconomic status, education, and access to health care contribute to the differences in CKD risk among ethnic minorities, yet disparities persist even when these factors are controlled for in studies, suggesting that underlying biologic, genetic, or epigenetic effects may also be important factors related to outcome.[8]

Contemporary definitions of race and ethnicity are controversial, and occasionally indistinguishable, as

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00009-7

they may be viewed as a genetic inheritance or as a social construct.[9] In this chapter, ethnicity will be defined as a community whose shared heritage offers important characteristics in common between the members of a group, including physical appearance (the old concept of "race"), subjective identification, cultural tradition, common population history, religion, and language.[10]

In this context, inequities in CKD and end-stage renal disease (ESRD) incidence and treatment vary widely in developing countries and in ethnic minorities living in developed countries. Great variations in gross national product, standards of education, health care, and nutrition can be found in one specific region or even within a country itself. Therefore, it is not appropriate to generalize about epidemiologic and risk factors in disadvantaged communities. Nevertheless, some general aspects deserve to be highlighted.

In most of the world, increased CKD incidence and prevalence are strongly associated with lower socioeconomic status and belonging to certain ethnic groups. The interplay between these factors is complex, and it is not always possible to stratify them as single entities.[11] For example, low socioeconomic status is associated with duplication of the risk of CKD in both African Americans and White Americans, compared with individuals from higher socioeconomic status, yet the absolute risk is actually higher in African Americans than in Whites Americans, independent of whether African Americans have low or high socioeconomic status.[12] In a cohort with more than 22,000 subjects, in the REGARDS (Reasons for Geographic and Racial Differences in Stroke) cohort, lower income was strongly associated with albuminuria in African Americans compared with Whites.[13]

Lower household income may be associated with an inadequate diet.[14] The interpretation of dietary intake and its associations with CKD depends on the selected population and aspects of study design. For example, a restricted protein intake, which can be found in disadvantaged communities, is associated with lower risk of CKD.[15] In contrast, these same communities may be susceptible to adverse kidney outcomes because of other dietary factors, such as higher caloric intake,[16] salt consumption,[17] or high dietary protein intake, especially in African Americans with DM.[18]

Access to education is an important social factor that affects CKD in ethnic minority groups. In Netherlands, the Healthy Life in an Urban Setting cohort of more than 21,000 participants demonstrated that low- and mid-level education was associated with higher risk of CKD in ethnic minority groups, after adjustment for other confounders such as age or sex.[19]

Epigenetic interactions between environmental adversity and the genome, predominantly associated with malnutrition, could be a link between social factors related to ethnicity and subsequent development of CKD.[20] Low nephron number associated with low birth weight could explain, in part, differences in progressive renal injury observed in communities with lower socioeconomic status. Low birth weight in offsprings is a marker of an adaptation to a "thrifty phenotype" *in utero* in preparation for a world depleted of nutrients.[21] With exposure to high-calorie diets, maladaptive complications occur at a high frequency, ending in hypertension, DM, dyslipidemia, and obesity, as well as microalbuminuria and decreased estimated glomerular filtration rate (eGFR).[22] Poverty and deprivation during childhood are strong predictors of multiple adverse health outcomes during adulthood, such as cardiovascular disease (CVD) and type II DM.[23]

The presence of a predisposing genetic background for CKD may be associated with ethnicity. Some genetic variants such as APOL1, ELMO1, UMOD, ACTN4, and PROX1 are examples of risk factors for CKD linked to ethnic groups.[24,25]

Environmental exposure and gene interactions may be other relevant factors. Everett et al. reported that concentration of the pesticide DDT (dichlorodiphenyltrichloroethane) and its metabolites in the blood of Mexican Americans was associated with both diabetic nephropathy and DM without nephropathy.[26]

Patterns of unhealthy lifestyle behaviors differ among ethnic minorities and may modify the risk for CKD. For example, about one-third of Latin American smokers report a pattern of "intermittent smoking," which is higher compared with other ethnic groups. Nevertheless, intermittent smokers had an increased risk for CKD, similar to daily smokers.[27]

The prevalence of glomerular diseases in tropical countries is 2.5 times the rate in developed nations,[28] which could be related to the many endemic environmental, social, financial, and infectious causes which characterize regions but differ greatly between them. Noninfectious glomerulonephritides are greatly influenced by ethnicity. For example, lupus nephritis occurs more frequently in African, Caribbean, Asian, and Hispanic populations compared with White Europeans. Likewise, lupus nephritis is associated with a severe course in Asian and Hispanic individuals.[29]

DM and hypertension are the leading causes of CKD in developed and many developing countries. In contrast, infectious diseases continue to play an important role as causes of CKD and ESRD in low-income countries, probably in association with poor sanitation, inadequate supply and access to potable water, and high concentrations of disease-transmitting vectors.[30] Chronic glomerulonephritis and interstitial nephritis are currently the principal causes of CKD in the many underdeveloped nations, not only in sub-Saharan Africa but also in some Latin American and Southeast Asian nations, reflecting the high prevalence of bacterial, viral,

and parasitic infections. Several parasitic infections cause CKD through ureteral obstruction (such as schistosomiasis, in most of sub-Saharan Africa), interstitial nephritis (such as kala-azar [visceral leishmaniasis] in many African and Asian countries), glomerulonephritis associated with malaria and filariasis, in West Africa, and schistosomiasis, in Africa and Latin America.[31]

The incidence and prevalence of ESRD differ substantially across countries and regions (Figure 9.1a and b). More than 80% of all renal replacement therapy (RRT) is provided in affluent countries. In the US, the incidence rate of ESRD in ethnic minorities is 1.5–4.0 times more than its incidence in the White population, with African Americans suffering the highest rates.[32] Around the world, hemodialysis (HD) is the most prevalent mode of RRT employed, yet it may be inadequate in particular for patients living in remote nonurban areas, as happens in large parts of the developing world. In contrast, peritoneal dialysis (PD) is increasing in some countries, including China, the US, and Thailand, but has proportionally decreased in parts of Europe and in Japan.[33] The lower figures regarding RRT reported from emerging nations are largely due to patients not being accepted into dialysis or transplant programs, although where economies are growing, the numbers of patients being accepted are rising strikingly.

Projected worldwide population changes suggest that the potential number of cases of ESRD will increase disproportionately in developing countries, where the number of elderly people is increasing. This effect will be enhanced further if the trends of increasing hypertension and DM prevalence persist, competing causes of death such as stroke and CVDs are reduced, and access to treatment improves.[30]

The lack of renal registries in most developing nations hampers the publication of reliable statistics about the prevalence of ESRD. Information is mainly based on data obtained by questionnaires addressed to leading nephrologists, the dialysis industry, and from a few publications in local and international journals.[1]

AN INTERNATIONAL PERSPECTIVE REGARDING CKD

The Americas: Canada

The prevalence of CKD in Canada, determined primarily by eGFR, varies among ethnic groups. A screening program called the First Nations Community Based Screening to Improve Kidney Health and Prevent Dialysis project examined the prevalence of CKD among First Nations. They found a prevalence of 26% of CKD (defined as UACR $\geq$30 mg/g or eGFR <60 mL/min/1.73 m^2), a twofold higher prevalence of CKD in indigenous Canadians, and a prevalence of severely increased albuminuria that was fivefold higher in comparison with the general population.[34] Among Indigenous Canadian children, 11% had albumin:creatinine ratio >3 mg/mmol and 6% had an eGFR <90 mL/min/1.73 m^2.[35] Severe CKD (eGFR less than 30 mL/min/1.73 m^2) was almost twofold higher among First Nations people.[36] Zacharias et al. demonstrated that the prevalence and risk factors for albuminuria in a First Nation population is high and more prevalent in men.[37] Conley et al. studied a large community-based cohort of Caucasian, Chinese, and South Asian participants living in Alberta, to determine whether the prevalence of proteinuria varied across the three ethnic groups. While the prevalence of heavy proteinuria was higher in Chinese and South Asians compared with Caucasians regardless of eGFR (>60 mL/min/1.73 m^2 or <30 mL/min/1.73 m^2), these ethnicities experienced a decreased risk of death and similar risk of CKD.[38]

Samuel et al. demonstrated that the incidence of ESRD is higher among aboriginal (First Nations, Inuit, and Metis) children and young adults than among white children and young adults. They also showed congenital diseases were less common in aboriginal people, and glomerulonephritis was more common than in whites. An excess of glomerulonephritis, but not DM, was seen among aboriginal people aged 22–40 years. The converse was true (higher risk of DM, lower risk of glomerulonephritis) among aboriginal people aged 40 years and older.[39]

Canadian First Nations experience ESRD 2.5 to 4 times more frequently, and those with DM have 7 times the rate of diabetic ESRD compared with their non-First Nations counterparts.[40] Aboriginal Canadians (First Nations, Inuit, and Metis) are more likely to live farther from tertiary health care centers. PD may be appropriate for those who live in remote areas where there are no HD facilities.[41] Tonelli et al. evaluated the use of PD among three provinces with the highest proportion of aboriginal people.[42] After adjustment for age and comorbidity and comparison with white patients, aboriginal patients were significantly less likely to initiate therapy with PD compared with white patients and displayed a trend toward a higher risk for technique failure. This low PD use was independent of whether subjects lived remotely or in an urban location.

The Americas: Latin America

In Latin America, the prevalence and incidence of CKD has increased in all countries, yet with wide variations in rates between countries. Across the region, CKD stages 4 and 5 have increased from 119 patients per

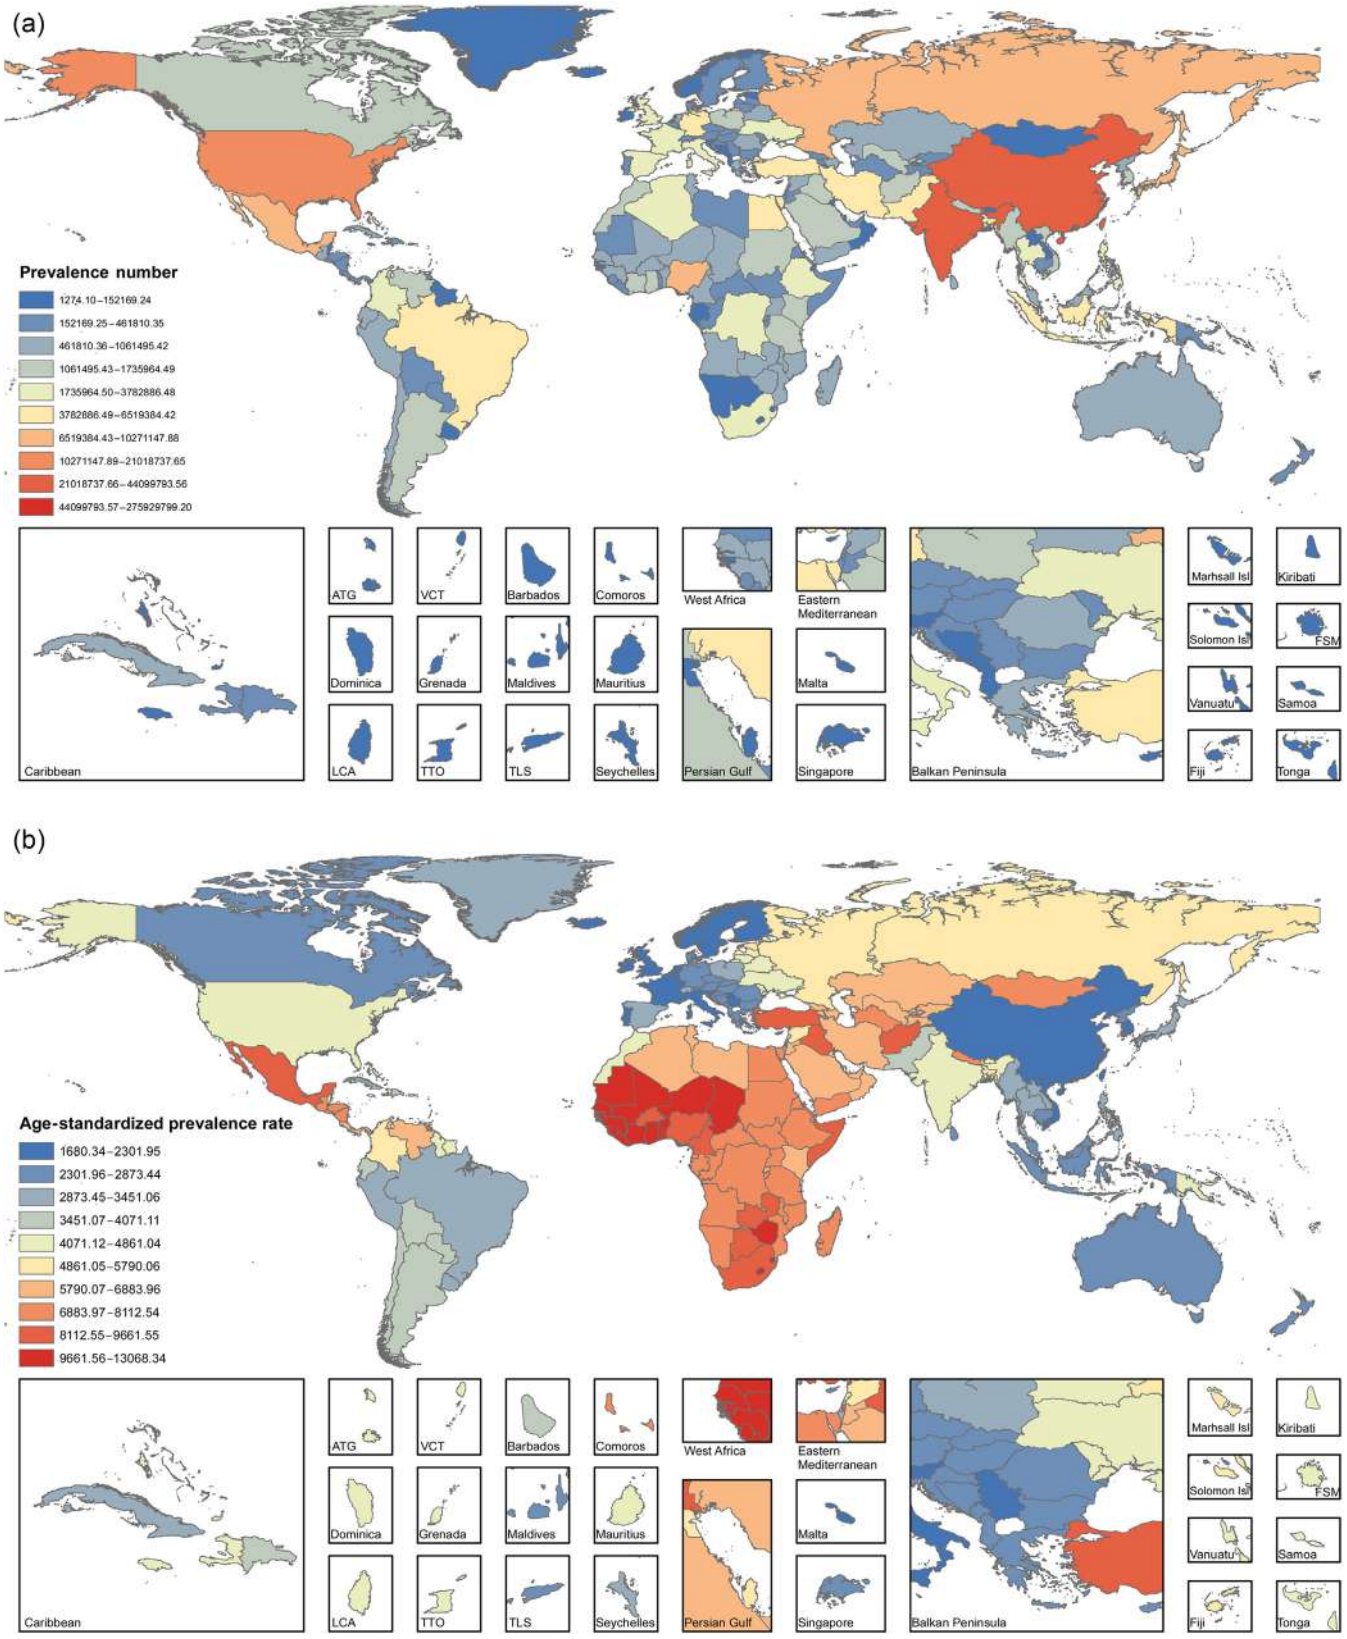

FIGURE 9.1 (a) Comparison of unadjusted end-stage renal disease (ESRD) prevalence number worldwide. Data from Japan are dialysis only. (b) Comparison of age-standardized ESRD prevalence rate worldwide. Data from Japan are dialysis only. *From U.S. Renal Data System. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2013.*

million population (pmp) in 1991 to 408 pmp in 2016. In 2016, the highest prevalence rates were reported in El Salvador (685 ppm), Mexico (628 ppm), Virgin Islands (627 ppm), and Honduras (416 ppm), with an increase in percentage rate from 1990 to 2016 of 106%, 94%, 122%, and 105.5%, respectively.[43]

An epidemic of DM has characterized the epidemiological transition in Latin America.[44] DM remains the leading cause of ESRD in Latin America, with the highest rates of DM as percentage of all cases of ESRD being in Puerto Rico (65%), Mexico (51%), Venezuela (42%), and Colombia (42%). The lowest rates are in Brazil (26%), Uruguay (22%), Costa Rica (20%), and Paraguay (15%).[45–47]

Several population-targeted approaches have been employed in Latin American nations to explore the prevalence of CKD. A methodology that evaluates population risks when confronted with a disease or injury, called the Global Burden of Disease, showed that in Mexico CKD-associated mortality had increased 108% from 1990 to 2015. DM is one of the main causes of CKD in Mexico and has largely increased mortality from 1990 to 2015, establishing itself as the third most common cause of death in that country.[48] Mexico City has the greatest CKD-related mortality and the greatest number of disability-adjusted life years.[49] A recent large prospective study in Mexico City showed that the greatest absolute excess risk of death associated with DM was from renal disease, primarily CKD.[50]

Glomerulonephritis, in particular secondary to bacterial and parasitic infections, remains a significant cause of ESRD in disadvantaged populations in some regions of Latin America. Herrera et al. showed that the incidence of ESRD in Venezuela's Goajiro Indians was 220 pmp, 1.7 times higher than the estimate for the country.[51] The authors suggested that a combination of high rates of poststreptococcal glomerulonephritis and low nephron number could be responsible.

In Bolivia, Perico et al. found urinary abnormalities in 30% of the subjects according to a screening performed in 14,082 healthy individuals.[52] In Peru, in a cross-sectional study involving 2968 high-risk individuals from 23 centers, the prevalence of microalbuminuria was 53.4%,[53] whereas the prevalence of CKD in the primary care setting was 18%.[54] A crosssectional study from the National Health Survey in Brazil found a prevalence of CKD of 1.4%, of which 7.4% had ESRD.[55] Environmental and socioeconomic factors may play a role in the development of glomerular disease in South America. For example, an outbreak of postinfectious glomerulonephritis in Brazil caused by contaminated nonpasteurized milk, led to the development of progressive nephropathy in some cases.[56]

An epidemic of CKD of unknown origin, named Mesoamerican nephropathy, is present in agricultural communities of the Pacific coast of Central America. This form of CKD is more frequent in young male individuals and has devastating consequences in some communities, in particular in El Salvador and Nicaragua.[57] Clinically and histologically, Mesoamerican nephropathy is a tubulointerstitial disease[57,58] that progresses to ESRD over a variable period of time. A number of possible causes have been proposed, yet it is most likely that it has a multifactorial etiology. Some of the causes that have been explored include recurrent dehydration-associated tubular injury in agricultural workers who labor under exhausting conditions in extremely hot and humid areas where recurrent dehydration and use of nonsteroidal drugs are common, environmental or agrochemical toxicities, and infectious causes, as well as others. A common element in all described cases is a state of economic and social deprivation of those affected.[57–59]

Asia

An epidemiological transition has been observed in the etiology of ESRD in the Middle East, with DM and hypertension as major causes. Together they are responsible for 52% of ESRD in this region. Other forms of glomerulonephritis, inherited nephropathies, and obstructive nephropathy occur, yet less frequently.[60]

In South Asia, chronic glomerulonephritis is the most common cause of CKD in Cambodia, Indonesia, Singapore, and Vietnam. Nephrolithiasis is the most common cause of CKD in Thailand.[61] Data from the Indian CKD registry show that DM is the commonest cause of CKD, followed by unknown cause and chronic glomerulonephritis. In Pakistan, the most common cause of CKD in children is obstructive uropathy (22%).[62]

China, the world's most populous country with more than 1.4 billion population, had a CKD prevalence of 10.8% (238 ppm). Nearly 120 million individuals were affected, according to a national survey from 2009 to 2010. Most CKD cases in this study had albuminuria >30 mg/g. Only 1.7% had an eGFR <60 mL/min/1.73 m^2, suggesting that later stages of CKD will increase in the future. In the general population, CKD was related to DM in 1.2% and glomerulonephritis in 0.9%. Approximately 21% of Chinese people with DM were diagnosed with CKD.[63]

Interracial/ethnic variations in CKD risk factors and prevalence have been evaluated in Singapore.[64] The prevalence of an eGFR <60 mL/min/1.73 m^2 or the presence of micro/macroalbuminuria in 4499 participants of Chinese, Malay, and Indian ethnicity, aged 24–95, that participated in the Singapore Prospective Study Program was determined. The age- and sex-standardized prevalence of CKD was 13% in the whole

population, 11% in Chinese, 19% in Malays, and 18% in Indians. The prevalence of major CKD risk factors such as DM, hypertension, overweight/obesity, and dyslipidemia was also higher in Malays and Indians. A population-based cross-sectional study in 10,033 Chinese, Malay, and Indian subjects found a higher risk of CKD and retinal emboli in Indian persons, independent of age, smoking, hypertension status, and other risk factors.[65] The association of these variables with CKD suggests the need to screen high-risk individuals for early detection and control of modifiable risk factors for CKD.

The prevalence of CKD is alarming in high-risk Asian communities. Among hypertensive individuals in rural Pakistan, rural Bangladesh, and Sri Lanka, CKD prevalence was 58%, 36%, and 17%, respectively.[66] A systematic review of prevalence in South Asia found an overall prevalence of CKD in Pakistan of 21%, in 17% in Bangladesh, in 10% in India, and 10% in Nepal. Nevertheless, the unusually high prevalence in Pakistan might be due to the higher minimum age requirement set as an inclusion criterion in Pakistani studies.[67]

In a cross-sectional screening study performed in Nepal, Mongolia, and China among 11,394 participants, decreased eGFR (less than 60 mL/min/1.73 m^2) was present in 7−14% of participants. Proteinuria (≥1+) on dipstick (2.4−10%), hypertension (26−36%), DM (3−8%), and obesity (>BMI 30 kg/m^2; 2−20%) were all common.[68]

In India, three population-based screening programs reported a low CKD prevalence, between 0.79 and 1.4%.[69,70] However, the Screening and Early Evaluation of Kidney Disease (SEEK) program of India reported a prevalence of 17.4% among 5623 participants. CKD was defined as the presence of proteinuria or abnormal urinary findings for more than 3 months with or without reduced eGFR, which was probably the reason for the high incidence.[71]

Africa

In Africa, the prevalence of CKD is uncertain due to poor methods of evaluation and the quality of data of studies. Prevalence is nevertheless estimated between 2% and 41%, yet in high risk groups, it ranges between 11−90% in patients with DM and 13−51% in patients with hypertension.[72] The overall prevalence of CKD in sub-Saharan Africa, obtained from 21 epidemiologic studies, was between 12% and 16%. No differences were observed between urban and rural areas.[73] The risk factors for CKD in sub-Saharan Africa were hypertension, DM, anemia, and history of tuberculosis or schistosomiasis. A single factor was found in 61% of individuals, two in 14% and 3 or more in 10% of all CKD cases. These findings support the hypothesis of a "double burden" of noncommunicable and communicable diseases as an important cause of CKD in Africa.[74]

HIV infection could be another factor related to the prevalence of CKD in regions of Africa. Patrice et al. found that the prevalence of CKD in HIV-infected patients was 44% in Northern Cameroon. Factors associated with CKD were age >35 years, longer duration of HIV infection, history of hepatitis B virus infection, and CD4 cell <200 cells/mL.[75] In 2017, Africa had the highest CKD prevalence in HIV-infected patients.[8] Rates were highest in West Africa (15%) and lowest in southern Africa (3%), compared with a worldwide prevalence of CKD in HIV-infected patients of 5%.[73]

In North Africa, demographic and epidemiological transitions have led to an increased incidence of DM and hypertension, but glomerulonephritis and interstitial nephropathies remain important causes of ESRD. The overall prevalence of CKD in North Africa was 484 ppm in 2016.[43] The reported annual incidence of ESRD ranges between 74 and 200 cases pmp. The pool of patients undergoing dialysis varies from 150 in Mauritania to more than 35,000 in Egypt. The prevalence of RRT ranges between 47 and 680 cases pmp and is highest in Tunisia and Egypt. Chronic glomerulonephritis represents 41% and 27% of the ESRD cases in Algeria and Sudan, respectively. The role of DM and hypertension is important in Egypt (14% and 37%), Morocco (18% and 10%), and Tunisia (14% and 20%). Interstitial nephritis remains an important cause of ESRD in Egypt and Tunisia, representing 17% and 13% of the burden of ESRD, respectively.[43,68] DM affects 9.4 million people in Africa. The estimated increase in DM in Africa is anticipated to be 12.7 million cases, an increase of 140%, by 2025. It is expected that the prevalence of diabetic nephropathy, currently estimated to be 6−16%, will increase dramatically.[73]

In sub-Saharan Africa, hypertension is a leading cause of CKD. Hypertension is the cause of 25% of the ESRD in Senegal, 30% in Nigeria, 46% in South Africa, and 49% in Ghana, especially in black patients. As in North Africa, glomerular diseases are a major cause of ESRD. With the introduction of the hepatitis B vaccine, the number of cases of membranous nephropathy associated with ESRD has declined, whereas the prevalence of HIV-associated nephropathy has increased.[76]

Australia, New Zealand, and South Pacific Islands

The number of Australian Aboriginal people with early CKD is hard to quantitate, yet risk factors, including hypertension and DM, are widespread in this population. DM is 2−5 times more common and

appears at an earlier age among indigenous people compared with the nonindigenous populations of New Zealand and Australia.[77] For all CKD parameters in Australia, rates among Indigenous people were strikingly correlated with increasing remoteness of residence, socioeconomic disadvantage, and female predominance.[78]

Albuminuria is common among indigenous populations of Oceania. Albuminuria ≥30 mg/mL was found in 41% of Nauruan adults.[79] Albuminuria ≥20 mg/mL was found in 26% of adults in one ethnic group in New Guinea.[80] Rates of microalbuminuria and overt albuminuria were 28−31% and 13−21% in two remote Aboriginal communities in Australia's Northern Territory.[81,82] There are great variations in biopsy rates and findings among Indigenous Australians, with high rates of segmental sclerosis and postinfectious glomerulonephritis. Glomerulomegaly was a prevalent finding in many biopsies.[83,84] The association of lower birth weight with CKD has been described in remote Australian community settings. Glomerulomegaly may represent compensatory hypertrophy in the presence of a low nephron number, related to low birth weight, with variable superimposition of postnatal effects. The increased risk of CKD in Australian Aboriginal adults is not established in childhood.[85]

An interesting finding was the prevalence of proteinuria of >100 mg/L in 63% of people without DM in the Australian Aboriginal community of Woorabinda.[86] This suggests that the dogma that most indigenous renal disease in this region is due to DM is not universally correct.

The incidence and prevalence of indigenous people starting RRT in Australia has significantly increased over the past 25 years, mainly due to diabetic nephropathy.[87] Stewart et al., using data from the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA), explored age- and sex-standardized incidence rates for RRT in four age groups of Maori, Pacific Islanders, and all other New Zealanders as well as Indigenous and nonindigenous Australians, from 1992 to 2001. The incidence of ESRD did not differ in those aged 0−14 years. The excess ESRD in Indigenous Australians was due principally not only to type II DM and glomerulonephritis but also to type I DM, hypertensive renal disease, and analgesic nephropathy. The excess in Maori and Pacific Island people was confined to those with type II DM, hypertensive renal disease, and glomerulonephritis.[77] For about two decades, starting in the 1980s, incidence of ESRD in indigenous people of Australia rose steadily, but by 2016 the incidence of RRT may be decreasing[78]

The age at which people develop ESRD is considerably younger among indigenous peoples in Oceania than among the mostly white nonindigenous people. The mean age at onset of RRT for nonindigenous people is 60 years, whereas Aboriginals are on average 48, Maoris 44, and Mariana Islanders 56 years old.[88]

ACCESS TO RENAL CARE

Ethnic disparities in access to health care and health outcomes are well documented worldwide. Gao et al.[89] identified 106,511 non-Aboriginal and 1182 Aboriginal Canadian patients with CKD (eGFR <60 mL/min/1.73 m^2) in Alberta, Canada. The authors compared outcomes, including preventable hospital admissions with appropriate outpatient care (ambulatory care−sensitive conditions) as well as use of specialist services. Aboriginal people were almost twice as likely as non-Aboriginal people to be hospitalized for an ambulatory care−sensitive condition. Aboriginal people with advanced CKD (eGFR <30 mL/min/1.73 m^2) were 43% less likely to visit a nephrologist. These results suggest potential inequities in care of patients with CKD and raise the possibility that aboriginal populations may have differential access to preventive and primary care, including opportunities to slow the rate of CKD progression.[90]

In Australia and New Zealand, the proportion of people receiving home HD and PD is lower among indigenous people compared with non-indigenous populations. Among those receiving dialysis at the end of 2007 in Australia, 33% of nonindigenous people received a home-based dialysis therapy, in contrast to 18% of Aboriginal people. In New Zealand, 62% of the non-indigenous proportion received home dialysis. The rate was 42% among Maori/Pacific Islanders.[91]

Similarly, the proportion of indigenous people receiving RRT with a functioning kidney transplant is lower among Aboriginal Australians (12% vs. 45% among non-indigenous Australians). Transplantation rates for Maori and Pacific people are approximately 25% of those of people of European origin. This is partly related to a reduced listing rate of about 50% compared with non-indigenous people, and a reduced transplantation rate of about 50% for Maori and Pacific Islanders. The causes of reduced listing are likely to be multifactorial, including increased obesity and co-comorbidities associated with DM, but other factors related to socioeconomic status and access to health care may also play a role.[92]

Caskey summarized the disparities in access to kidney transplantation in the United Kingdom. Compared with Caucasians, South Asians and Blacks were equally likely to reach the transplant waiting list, but significantly less likely to receive a transplant once listed. Living kidney donor transplantation was less likely for

those living in deprived areas and classified as South Asian or Black, respectively.[93]

Disparities in renal care are more evident in developing nations, and access to RRT is dependent mostly on health care expenditures and national economic strength. In Mexico, the fragmentation of the health care system has resulted in unequal access to RRT. Significant differences are observed between the insured and uninsured Mexican populations starting RRT. A prospective cohort study of 850 patients with ESRD in Mexico City found that lack of access to health insurance programs occurs in 88% of patients and was the most important risk factor for death.[94] In a report from the Mexican state of Jalisco,[95] the acceptance and prevalence rates of the insured population were significantly higher (327 pmp and 939 pmp, respectively) than patients without medical insurance (99 pmp and 166 pmp, respectively). The transplant rate also was different, at 72 pmp for those with health insurance and 7.5 pmp for those without insurance. In addition, uninsured Mexican patients with CKD have very advanced disease at the time of first nephrologic evaluation and have exceedingly high rates of mortality after dialysis initiation.[96] In Latin America, RRT prevalence and kidney transplantation rates correlate significantly with gross national income and health expenditures.[45]

In India and Pakistan, where total health care expenditures are 1.5% of the Gross National Income, less than 10% of all ESRD patients have access to RRT.[97] Less than 20% of all long-term dialysis patients receive PD. Among the factors identified as barriers to PD are the costs, risk of peritonitis, late referral, and selection bias for financial reasons.[62] Similar experiences have been reported in Africa,[68,76] the Middle East,[60] and Southeast Asia.[61] Transplantation in India and Pakistan is limited, has inadequate financial support, and lacks an organized deceased donor transplant program. Therefore, in these countries, the vast majority of grafts come from living donors.

The provision of renal care to all patients from developing nations, although a difficult task, is not impossible. A number of strategies have been proposed. These include the implementation of programs for prevention of kidney disease and establishment of measures to slow CKD progression. In addition, it would be desirable to be able to have universal coverage of RRT for all those that require it, with kidney transplantation as the ideal modality in all those who can receive a graft. Use of generic immunosuppressive drugs can make transplantation more affordable. PD has been considered a better choice of dialysis modality, as it may be more affordable and appropriate for patients living in areas where HD is not available.[98]

Access to kidney transplantation is the most serious disparity in ESRD, as it limits duration and quality of life in minority ethnic groups. In the US, the most important factors that drive racial disparities in transplantation for African Americans include poor access to timely donation, poor health insurance and a low rate of living donation, lack of education about kidney transplantation, and a lower rate of referrals, race-based bias, and poor communication, socioeconomic and environmental disparities, and genetic etiology and racial ancestry.[99] Living donation may be impaired by complex reasons related to ethnicity. For example, African Americans have a higher likelihood of ABO or crossmatch incompatibility with their intended recipients, a higher body mass index, and other medical conditions that may preclude donation.[100] Metabolic syndrome, DM, and overweight are frequent causes of rejection for living donation in Mexico.[101] A multinational study using data from Australia, New Zealand, and Canada found low rates of kidney transplantation among Aboriginal Canadians. Datasets were obtained from each country's ESRD registry. By the end of follow-up, 88,173 patients had received a renal transplant and 130,261 had died without receiving a transplant. Compared with white patients, the adjusted likelihood of receiving a transplant for Aboriginal patients was 77% lower in Australia, 66% lower in Canada, and 77% lower in New Zealand.[93] Although in Canada the likelihood of referral for kidney transplantation is similar for both Aboriginal and non-Aboriginal patients, the former are 54% less likely to be active on the transplant waiting list than non-Aboriginal patients and are more likely to be in the process of completing their transplant workup than on "hold" status on the waiting list, indicating that barriers that lead to reduced rates of transplantation appear to occur downstream from the referral step.[102]

Several potential barriers may prevent Aboriginal dialysis patients in Canada from successfully receiving a kidney transplant. These may include patient attitudes and preferences regarding transplantation, physician biases, residence in rural or remote geographic locations, differences in human leukocyte antigen pools, and lower selection from the waiting list. It is important to note that other global social determinants of health, such as poverty and lack of education, may also impact multiple levels of the transplantation process.

Rodrigue et al. proposed a transplant education program based on a house calls approach, designed to reduce racial disparities, which combines patient and group discussions with standardized educational materials.[103] This program increases the likelihood of receipt of a living donor kidney transplant in African-American patients compared with Whites.[104] Health policy can be shaped to immediately reduce ethnic disparities in transplantation. For example, the implementation of a

new American kidney allocation system in 2014 led to a substantial increase in the kidney transplantation rate for African Americans and Hispanics in the months following the policy change.[105]

New strategies to increase transplant evaluations in ethnic minorities have been successful. For example, the Kidney Transplant Fast Track protocol is an evaluation process to complete all pretransplant testing in one day to increase rates of kidney transplantation in vulnerable patients.[106]

End-of-life issues in ESRD patients, including access to palliative care, decisions about advanced life sustaining therapies, and advance care planning, are influenced by ethnicity.[107] African-American and Hispanic patients still remain less likely to discontinue dialysis or utilize hospice care compared with their White peers.[32] Eneanya et al. showed that African-American patients with stages 4 and 5 CKD are less likely to communicate end-of-life preferences and have less knowledge of hospice than their White counterparts, even after adjusting for factors such as age, education, and income. Interestingly, they found no racial differences in distrust of providers, or in spiritual/religious or cultural beliefs.[108] Latinos treated with HD in Denver, Colorado, prefer to avoid medications, favor family group decision-making, and want advance care planning conversations to occur at home with someone who is culturally and linguistically congruent.[109] The implementation of programs in minority ethnic groups to improve preparation for end-of-life decision-making and post-bereavement outcomes could be a successful approach. An advance care planning model of two sessions in HD patients was effective in improving preparation for end-of-life decision-making and post-bereavement outcomes in African Americans but not in Whites[110] The reasons for the ethnic differences reported in these studies are multiple and complex, including cultural differences, yet the observation has important implications for the design of care programs for diverse populations with CKD. Older Latinos with ESRD on dialysis were more trusting of their physicians when deciding on intensive procedures and deferred end-of-life care decision-making to their children compared with other groups.[111] These differences highlight the need for improved patient- and family-centered approaches in minority ethnic groups.

RELATION BETWEEN ETHNICITY AND CKD RISK

Differences in access to health care and other nonmedical factors may not explain worse kidney outcomes in some ethnicities. While there may be differences in health care system–related factors, intrinsic factors related to ethnicity may also play important roles in determining differences. Studies performed in the US have clearly shown that African-Americans progress from earlier stages of CKD to ESRD faster than Caucasians and are at higher risk for developing complications related to CKD such as cardiovascular diseased or reduced cognitive function[112] Van den Beukel et al. investigated whether progression of CKD in particular ethnic groups is also faster in a universal health care system.[113] Data from the PREdialysis PAtient REcord study (a multicenter follow-up study of patients with CKD who started predialysis care in the Netherlands between 1999 and 2011) show the risk of starting RRT within the first 15 months of follow-up was not different between Black and White individuals, whereas from 15 months onward Black populations had double the risk of requiring RRT. Decline of renal function was faster by 0.18 mL/min/1.73 m^2 per month in Blacks compared with Whites.

The higher risk of DM in certain ethnic groups modifies interpretations about ethnicitiy and CKD risk. In analyses from the Chronic Renal Insufficiency Cohort study, Hispanics had significantly higher rates of CKD progression, incident ESRD, and mean annual decline in eGFR compared with non-Hispanic Blacks. Nevertheless, when DM was excluded from the analysis, Hispanic ethnicity was associated with a lower risk of CKD progression and a lower risk of death compared with other ethnic groups.[114]

In Canada, quality of HD care appears to be similar in Aboriginal and non-Aboriginal patients. In a large Canadian population-based study of HD patients, no differences were observed in small solute clearance, anemia management, and use of a permanent access between groups. However, when compared with non-Aboriginal HD patients, Aboriginal patients were significantly less likely to achieve target levels for predialysis systolic blood pressure control and mineral metabolism goals.[115]

Similarly, Udayaraj et al. examined the associations between socieconomic status and ethnicity (White, Black, and South Asian) and the attainment of standards in 14,117 incident dialysis patients in the United Kingdom. Black individuals had lower attainment of appropriate hemoglobin and PTH standards, but better attainment of serum phosphate and calcium targets. South Asians experienced better or comparable outcomes for most standards except serum calcium concentration and PTH.[116] The authors concluded that these differences could be influenced by ethnicity-related biologic factors rather than inequity of care.

People of different ethnicities who become minorities in the country to which they are migrating may have

increased risk factors for CKD, especially after adopting new lifestyles. A population-based case-control study in the Netherlands showed a 22-fold higher risk of ESRD due to type 2 DM in Surinamese Indo-Asian immigrants compared with native Dutch individuals. After adjusting for age, the risk of ESRD was 38 times higher, as Indo-Asians were 14 years younger at onset of type 2 DM. This higher risk is explained by both an 8 times higher prevalence of DM in the Indo-Asian general population in The Hague and by a higher incidence rate of diabetic nephropathy for the Indo-Asian DM population.[117]

Other psychosocial factors related to ethnicity may be related to a higher risk of CKD. Perceived discrimination (general experience of discrimination, ethnicity-related or gender-related discrimination) has been linked to chronic psychosocial stress, to biological changes in neuroendocrine, autonomic and immune systems, and to hopelessness and low self-efficacy affecting the ability to self-manage one's health.[118] A prospective cohort study from 2004 to 2013 found perceived racial and gender discrimination were associated with modestly lower kidney function among African-Americans and white women.[119]

STRATEGIES TO MITIGATE KIDNEY-HEALTH DISPARITIES RELATED TO ETHNICITY

International initiatives, such as the Asian Renal Collaboration, including more than 20 epidemiologic studies from 7 Asian countries, have been proposed to obtain information about CKD prevalence and manifestations.[120] Increasing awareness of the effects of ethnicity may potentially lead to strategies to improve clinical outcomes in minorities with health disparities. Potential interventions to reduce inequities related to ethnicity include providing equal access to medical care and education, increasing access to clinical research in minority populations, instituting CKD awareness programs, improving communication skills of practitioners to modify treatment misconceptions, and identifying critical biomarkers for disease progression and drug responses in heterogeneous populations, as well as others.[121] The eradication of ethnic disparities among kidney disease patients is a highlighted target for Healthy People 2020, the US blueprint for health.[122] The National Institute of Health National Institute on Minority Health and Health Disparities launched a new precision medicine program to promote health equity and to advance the science of minority health and health disparities.[123]

The potential use of health information technologies to target certain ethnic minority groups may reduce inequalities, empower patients, and increase engagement in CKD management. For example, 67% of African Americans obtain health information from smartphones compared with 57% of White Americans.[124] Interventions through the Smartphone Medication Adherence Stops Hypertension program to decrease blood pressure were more effective than standard care in African Americans and Hispanics.[125]

The field of cross-cultural care involves strategies focused on the ability of physicians and organizations to understand and integrate models to provide quality health care to patients from diverse sociocultural backgrounds.[126] New innovative approaches that deliver community-based, culturally grounded interventions to vulnerable and key population ethnic subgroups have been implemented in clinical trials. These new strategies include an emotional health component and are delivered in community settings using a family-based model.[127]

Cultural competence in health care of patients with CKD includes addressing language barriers in the clinical encounter, learning the norms of specific cultures, and provision of care to immigrants, refugees, and other globally mobile populations.[128] From 2014 to 2015, Europe witnessed a huge rise in the number of refugees, increasing from 280,000 to more than a million.[129] Refugees represented 1.5% of the dialysis population according to a 2016 survey in Europe and North Africa.[130] Migration may change epidemiologic patterns in aging developed countries.[131] In the US, based on an estimated adjusted incidence rate of 500 ESRD cases per 100,000 population among all American Latinos, an estimated 11.1 million undocumented immigrants will be at risk of emergent dialysis, frequent hospitalization, blood transfusion, and complications.[132] In the region of Emilia-Romagna in Italy, cardiovascular, pulmonary, renal, and cerebrovascular diseases were significantly less frequent among migrants, a phenomenon that has been defined as the "healthy immigrant effect," although lower access of immigrants to health care may underlie these observations.[133]

A new program of research projects and infrastructure in Canada by the Canadian Institutes of Health Research had the vision that by 2020 every Canadian with or at high risk for CKD will receive the best recommended care, experience optimal outcomes, and have the opportunity to participate in studies with novel therapies, regardless of age, sex, gender, location, or ethnicity.[134] A public health campaign to increase kidney health awareness in Manitoba, Canada, increased overall awareness of the campaign from 7% to 25% and demonstrated that raising awareness of CKD is

possible with a public campaign based on a multifaceted approach.[135]

LIMITATIONS AND CONTROVERSIES

Clinical researchers frequently report race and ethnicity based on self-reporting, which is a major limitation to understanding the importance of sociologic compared with biologic factors.[136] It is important to interpret ethnicity categories as a social-political construct, not scientifically or genetically.[8] Therefore, health outcomes stratified by race and ethnicity are less likely a result of genetic inheritance and are more strongly influenced by socio-ecologic determinants of health such as discrimination, educational and income inequalities, imbalances in access to care, health care resources, and exposure to environmental toxins.[137] A multiplicity of alternatives on attempting to categorize ethnicity have been proposed, including clustering of populations based on genetic markers (single-nucleotide polymorphism or multiallelic microsatellite, for example) or reporting of ancestry instead of self-race by participants. For example, ancestry in African descent people (Africans, Caribbean, and African-American subgroups) is different in terms of the DM risk in complex ways, because Caribbean ancestry seem to have worse glycemic control and a higher rate of renal complications compared with African Americans. Those with direct African ancestry seem to also have a very high risk of DM, independent of body mass index.[138]

The precise mechanisms by which environmental factors interact with genetic determinants to affect CKD susceptibility are still unknown. One genetic approach is to calculate "the proportion of ancestry" of individuals across the genome to elucidate if genetic ancestry has a stronger association than social or environmental factors.[121] The risks and benefits of genetic testing, especially in minority ethnic groups, need to be considered from an individual and societal perspective. All health determinants are potentially stigmatizing, and people may inappropriately judge others as being sick because of "bad genes."[139] For example, APOL1 status may explain 70% of the excess prevalence of nondiabetic CKD in hypertensive people of African ancestry, yet individuals who undergo testing may have concerns about racial stereotyping, medical discrimination, and stigmatization.[140] These risks can be diminished with the use of a transdisciplinary team which includes patients, advocates, and genetic counselors to develop communication strategies and materials that are more appealing, understandable, and inspiring for diverse population.[141]

Despite efforts to achieve greater equity in kidney health, disparities have changed little over the last 20 years. In 2016, Mehrotra et al. showed that African Americans were still 60% less likely to be treated with home HD and 47% less likely to be treated with PD in comparison with Whites.[142]

Genetic variants associated with complex diseases, such as DM or CKD, constitute a major scientific challenge. Jun et al. performed a deep whole-genome analysis of large Mexican-American pedigrees to understand the role of rare-sequence variations in T2DM and concluded that rare expression quantitative trait loci explain a substantial, yet minor, portion of expression heritability.[143]

Ethnic differences may affect risk assessment and therapeutic approaches in clinical care. How clinically meaningful these may be is controversial. For example, normal hemoglobin A1c (Hb_{A1c}) concentrations are different among African Americans, Mexican Americans, and Whites, yet these differences do not influence the power of Hb_{A1c} as a diagnostic or prognostic tool in patients of different ethnic groups.[144] Biomarkers associated with increased risk of all-cause of mortality in ESRD, such as fibroblast growth factor-23, are not significantly modified by ethnicity.[145]

CONCLUSIONS

Factors related to lower socioeconomic status, racial heritage, and ethnicity interact in complex manners to modify the risk of developing CKD, especially in disadvantaged communities. Conditions that predispose to CKD such as hypertension, DM, or obesity can be more prevalent in these communities, due to differences in predisposing genetic background, prenatal and perinatal care, and experiences, including low birth weight, inadequate diets, infectious diseases, or exposure to toxins. ESRD incidence tends to rise in communities with social deprivation, and provision of RRT depends mostly on health care expenditures and national economic strength.

Strategies to provide renal care for all, such as prevention of kidney disease, early referral, timely dialysis initiation, and equalizing opportunities for kidney transplantation can be achieved through a concerted effort between nephrologists, governments, patients, charitable organizations, and industry.

QUESTIONS AND ANSWERS

Question 1

Which one of the following statements about the definition of ethnicity is most accepted?

A. Ethnicity is defined as the genetic, biologic, or epigenetic factors related to inheritance, which are not modified by environmental or cultural factors
B. Ethnicity is a system of categories based on physical characteristics such as skin color or hair type
C. Ethnicity is a category of people who identify with each other according to their country of birth
D. Ethnicity, or race, is an old term based on biological terms without scientific basis and must not be used anymore
E. Ethnicity is a group of people who share subjective identification, cultural tradition, common population history, physical appearance, religion, and language

Answer: E

Contemporary definitions of race and ethnicity are controversial, and occasionally indistinguishable, as they may be viewed as a genetic inheritance or as a social construct. The most accepted term of ethnicity emphasizes the social definition of the term. **The correct answer is E**, given that ethnicity is commonly accepted as a community whose shared heritage offers important characteristics in common between the members of a group, including physical appearance (the old concept of "race"), subjective identification, cultural tradition, common population history, religion, and language. The answers A and B are incorrect, given that these old definitions based on the biological terms of race are no longer recommended.

Question 2

A 29-year-old Latino man is referred to your clinic for evaluation of asymptomatic kidney disease which has been detected by routine laboratory examination. He noticed occasional intermittent weakness and muscle cramps, which he relates to his previous work, yet he has been asymptomatic for several months. On physical examination, height is 161 cm, weight is 57 kg, body mass index is 22 kg/m^2, blood pressure is 110/80 mm Hg, and pulse is 71 beats per minute. The remainder of his examination is unremarkable. The following laboratory values are obtained:

Serum electrolytes:
Hemoglobin 13 g/dL
S[Cr] 3.2 mg/dL (24.8 mL/min/1.73 m^2 by CKD-EPI); previous S[Cr] 3.2 mg/dL (3 months ago) and 3.1 mg/dL (5 months ago).
BUN 58 mg/dL
Serum electrolytes: S[Na] 138 mEq/L, S[K] 3.8 mEq/L,S[Cl] 97 mEq/L, S[HCO_3] 19 mEq/L
Urine protein:creatine ratio: 0.32 g/g Cr. Urinalysis: SG 1.010, negative leukocyte esterase negative, hemoglobin negative, protein 30 mg/dL.
Glycated hemoglobin 5.5%
Hepatitis panel and HIV negative.
Ultrasound examination of kidneys shows small kidneys with decreased cortical thickness. A kidney biopsy is deferred.

Which one of the following clinical data is the most valuable to guide a diagnosis of kidney disease in this case?

A. The patient's mother has a diagnosis of diabetic nephropathy and his father has hypertension
B. The patient smoked five cigarettes per day, for 3 years, and consumed 20 g of alcohol every weekend for 2 years
C. The patient worked as sugarcane cutter in Nicaragua for 9 years
D. Antinuclear antibody titer is 1:80 (nucleolar pattern); normal C3 and C4
E. Tuberculin skin test 15 mm, positive interferon-gamma release

Answer: C

The clinical presentation is of a healthy young man who has asymptomatic, moderately advanced CKD. The ultrasonographic characteristics of kidneys preclude performance of a biopsy. **The correct answer is C** as the history of agricultural work in Central America, in the absence of any clear etiology, suggests a high probability of Mesoamerican nephropathy. Tubular atrophy and fibrosis coupled with widespread chronic glomerular changes are changes observed on biopsies. The diagnosis is suspected in Central American agricultural workers who perform physically demanding work for long hours in conditions of heat exposure. Even though family history of diabetes and hypertension increases the risk for these conditions in first degree relatives, especially in ethnic groups living in the same environment, these clinical data are of less relevance compared with the past work exposure (option A is incorrect). Likewise, the patient has latent tuberculosis (option E) and tobacco exposure (option B), yet these are insufficient elements to suspect or diagnose CKD. Symptoms of intermittent weakness and muscle cramps are nonspecific and not consistent with a diagnosis of lupus, especially with negative serology (option D).

Question 3

Which of the following statements about the relationship between ethnicity and kidney disease is true?

A. Ethnicity assessment is based on genetic markers more than self-reporting in the majority of clinical studies
B. One of the main objectives of ethnicity studies is to find harmful genes for different races to stratify diagnostic and prognostic clinical tools
C. In general, biochemical values such as electrolytes, glycosylated hemoglobin, parathyroid hormone, or hemoglobin values are radically different among populations of different ethnic origins
D. Health outcomes related to ethnicity are more influenced by socio-ecologic determinants than by genetic inheritance
E. To achieve better clinical outcomes taking into account ethnicity, assessment of race (for example, Black, White, Latino, and Asian) by clinical observers is more useful compared with other alternatives, for example, reporting of ancestry

Answer: D

There are a multiplicity of limitations and controversies regarding the relationship between ethnicity and health. **The correct answer is D**, as health outcomes stratified by ethnicity are less likely a result of genetic inheritance and are strongly influenced by socio-ecologic determinants of health, such as discrimination, educational and income inequalities, imbalances in access to care, availability of health care resources, and exposure to environmental toxins. Answer A is incorrect, as the majority of ethnicity assessments in clinical studies are based on self-report by participants and genetic markers are not well validated. One of the risks of genetic testing, especially in minority ethnic groups, is inappropriately judging a group of people as being sick due to "bad genes." Genetic variants associated with complex diseases explain only a minority of risk factors associated with CKD, most of which are more completely explained by social and environmental exposures, making Answer B incorrect. Answer C is incorrect, considering the majority of biochemical laboratories are not significantly modified by ethnicity, although there are exceptions such as the value of S[Cr] or hemoglobin. Answer E is incorrect, given that ethnicity classification according to physical features, such as skin color and hair texture, is subject to biases and discrimination. A multiplicity of alternatives attempting to categorize ethnicity have been proposed, such as self-questionnaires, clustering patients on genetic marker, or reporting ancestry, yet it is not clear which is best to achieve better clinical outcomes.

Question 4

An 84-year-old Latino man with type 2 DM, with ESRD treated with HD, undergoes follow-up evaluation following a recent diagnosis of metastatic pancreatic cancer. Three months after the diagnosis of cancer, the patient has been hospitalized three times due to episodes of heart failure, venous thromboembolism, and disabling pain. Decisions about suspending HD will be discussed with the patient.

Which one of the following should be taken in account before a decision is made?

A. In general, Latinos prefer to avoid family group decision-making as they make their decisions individually
B. End-of-life attitudes and expectations are similar between white patients and minority ethnic groups
C. Whenever possible, it would be desirable to choose a doctor who is culturally and linguistically similar
D. Latinos treated with HD are less likely to communicate and trust their doctors differently, compared with members of other minority groups
E. Latino groups are more likely to stop HD based on religious beliefs

Answer: C

Understanding and integrating cultural values and preferences into supportive or palliative care improves quality patient-centered care. A one-size-fits-all approach to palliative care perpetuates disparities. **The correct answer is C**, given that Latinos treated with HD favor family group decision-making and want advance care planning conversations to occur at home with someone who is culturally and linguistically congruent. Latinos describe unique cultural preferences, such as avoidance of medications for symptom alleviation and a preference to have family group decision-making and communication of advance care planning, making Answer A incorrect.[109] Option B is incorrect, given that end-of-life issues in HD patients, including decisions about stopping HD, are greatly influenced by ethnicity. New evidence highlights that older Latinos treated with HD are more trusting of their physicians and defer end-of-life care decision-making to their children.

Question 5

Which of the following statements about risk factors related to ethnicity is true?

A. In most of the world, high socioeconomic status is associated with more obesity, hypertension, diabetes, and CKD, compared with low socioeconomic status

B. Tropical countries have at least twice the risk for glomerular diseases in comparison with developed countries
C. Around the world, the most prevalent mode of renal therapy replacement therapy is PD
D. Severe caloric restriction during pregnancy and low birth weight in offspring of ethnic minorities are associated with hematuria or nephritic syndrome in adulthood
E. In the next decades, the potential number of patients with ESRD in developing countries will decrease as a consequence of control and prevention of infectious diseases

Answer: B

Tropical regions, the regions of the Earth flanking the equator, comprise mostly of emerging nations with similarities in terms of risks of kidney diseases. Tropical infections increase the risk of AKI and diverse glomerulonephridites. It has been estimated that there is an increased risk for glomerulonephritis in emerging compared with developed regions of the world. **Answer B is correct**. The interplay between socioeconomic status and CKD is complex, yet evidence suggests that low socioeconomic status is linked to the risk of CKD in multiple cohorts, probably associated with inadequate diet, lesser access to education and health services, and epigenetic interactions related to environmental adversity, so option A is incorrect. Although PD is prevalent in some countries such as China or Mexico, the most prevalent mode of renal therapy replacement around the world is HD; option C is incorrect. Severe caloric restriction during pregnancy and low birth weight are risk factors associated with low nephron mass, microalbuminuria, and low eGFR, yet unassociated with hematuria or nephritic syndrome in adulthood, so option D is incorrect. The projected worldwide population changes suggest that the number of cases of ESRD will increase disproportionately in developing countries, explained by an increase in elderly people. This effect will be enhanced further if the trends of increasing hypertension and DM prevalence persist, competing causes of death such as stroke and CVDs are reduced, and access to treatment improves.

Question 6

Which of the following statements is true?

A. Type 2 DM is the leading cause of ESRD in Latin America
B. Canadian First Nations experience ESRD related to hepatitis B virus and glomerulonephritis more frequently compared with non-First Nations
C. In South Asia, DM is the most common cause of CKD
D. In North Africa, HIV infection is the most common cause of CKD compared with other regions
E. In Oceania, Indigenous people develop ESRD late compared with nonindigenous people

Answer: A

An epidemic of DM has characterized the epidemiological transition in Latin America. DM remains the leading cause of ESRD in Latin America, with the highest rates of DM as percentage of all cases of ESRD being in Puerto Rico (65%), Mexico (51%), Venezuela (42%), and Colombia (42%). **Answer A is correct**. Canadian First Nations experience ESRD 2.5 to 4 times more frequently compared with their non-First Nations counterparts, and those with DM have seven times the rate of diabetic ESRD. Therefore, Answer B is incorrect. Option C is incorrect, given that chronic glomerulonephritis is the most common cause of CKD in South Asia (Cambodia, Indonesia, Singapore, and Vietnam), except in Thailand, where nephrolithiasis is the most common cause of CKD. Although Africa had the highest CKD prevalence in HIV-infected patients, rates are highest in West and sub-Saharan Africa. Therefore, option D is incorrect. The age at which people develop ESRD is considerably younger among indigenous peoples in Oceania than among the mostly white nonindigenous people. Therefore, Answer E is not correct.

CHAPTER

10

Ethnicity and Chronic Kidney Disease in Japan

Hiroko Kanno[a], *Yoshihiko Kanno*[b]

[a]Tokyo Women's Medical University, Tokyo, Japan; [b]Tokyo Medical University, Tokyo, Japan

Abstract

Japan is one of the higher-income countries in Asia, composed of people of almost a single race. Chronic kidney disease prevalence is about 12% in the general population, similar to that seen in other Asian countries. The most common primary kidney disease is immunoglobulin A nephropathy (IgAN). High rates of participation in health checks in school, the workplace, and in the community might increase disease detection of incidental findings of hematuria/proteinuria, rather than due to specific genetic factors. In Japan, tonsillectomy with corticosteroid therapy has become a major choice in treatment of IgAN. Over 90% of end-stage renal disease patients are treated with hemodialysis, with a high survival rate. However, aging is a major factor in dialysis outcomes, due to many aging complications such as sarcopenia, frailty, dementia, and social isolation.

INTRODUCTION

The population of Japan is approximately 125 million, including mostly people of Japanese ethnicity. There are about 70,000 Ryukyuan and 16,000 Ainu members of minority groups. The physical characteristics of the people in Japan are similar to those of other Asians, but the genetic characteristics may differ and polymorphisms related to kidney disease have not been determined.[1,2] Lifestyles and personalities also differ somewhat from those of other Asians.

The common characteristics that reflect the so-called Japanese personality and character include choosing obligations to the community over individual rights, exhibiting politeness and respect in interpersonal relationships, belief in order and stability, tidiness, a strong work ethic, punctuality, attention to keeping promises, and avoidance of religious conflict and terrorism. The effects of these characteristics on health care in Japan are uncertain. Race and beliefs are more related to the prognosis of cardiac failure in low-income patients, compared with economic conditions.[3] In chronic kidney disease (CKD), for which long-term management is important, Japanese lifestyle and character may be critical in disease management.

The Japanese diet is referred to as Washoku (Figure 10.1). "Washoku; traditional dietary cultures of the Japanese" was registered on the Intangible Cultural Heritage UNESCO list in 2013. Although Washoku has not been defined, traditional Japanese dietary patterns include many foods from vegetable sources (fruits, vegetables, grains, corn, beans, and seeds), low to moderate intake of fish and meat, and low intake of lean meat.

FIGURE 10.1 Traditional Japanese food "Washoku." Daily menu for lunch or dinner. Simmered black cod and konjac starch noodle with soy sauce (bottom); simmered daikon radish and boiled shrimp with sweet miso sauce (right); white rice (left); and small salad of corn and asparagus (top). *Photograph is transferred with permission from Kanno Y, editor.* Safety meal for patients receiving renal replacement therapy. *Tokyo: Kagawa Nutrition University Publishing Division; 2016.*

Chronic Renal Disease, Second Edition

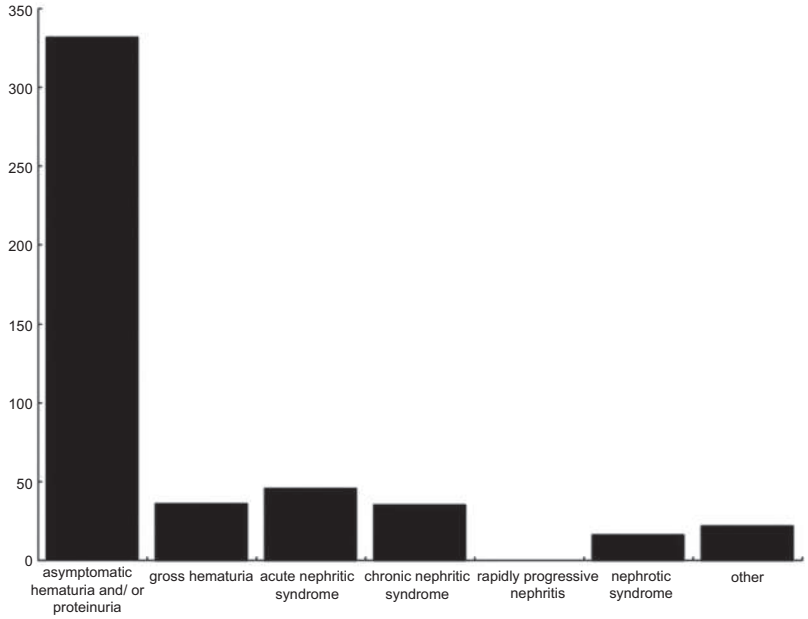

FIGURE 10.2 Clinical manifestation of immunoglobulin A nephropathy (IgAN) among 487 patients. Approximately 68.2% of the patients with IgAN were discovered by asymptomatic proteinuria and/or hematuria by a urinalysis screening program held in Japan. *From reference 6.*

Therefore, the diet can be thought of as an "oriental" Mediterranean diet.

The large amount of salt used as a preservative and for seasoning (in miso and shoyu) is a problem. In a study performed in the 1950s, salt intake was found to be 27 g/day, contributing to a high incidence of stroke.[4] This has now been decreased to about 10 g/day through a public awareness campaign and improvement of food conservation techniques without use of salt. Washoku has a beneficial lipid profile[5] and has traditional protein restriction. Thus, the diet may have long-term renal protective effects if salt use is reduced.

There are racial differences in primary renal diseases that lead to end-stage renal disease (ESRD) and in the incidence and prevalence of cardiovascular disease (CVD). To reduce the number of patients with ESRD and CVD, an effective screening method for CKD is required. In Japan, screening with the urine dipstick test for proteinuria has been used since 1972 for every child and worker, and since 1983 for every resident over 40 years old. Japanese kidney disease management is performed in the context of the Japanese people overall having a strong interest in health, easy access to medical facilities, and relatively low medical expenses. Housewives and the elderly account for about 50% of the population, and dipstick urinalysis is performed for all of them at health checks, contributing to early detection of kidney disease.

There are several reasons for continuing the CKD screening program. First, the rate of proteinuria is high in the Japanese population, and especially in those with neither hypertension nor diabetes. Most of these subjects are asymptomatic, and the only sign of renal disease is urinary abnormalities. Second, the prevalence and incidence of glomerulonephritis, especially immunoglobulin A nephropathy (IgAN), are high in Japanese and Asian people, and urinalysis is the only method for early detection of chronic glomerulonephritis. Third, the 10-year survival of patients with ESRD due to glomerulonephritis is approximately twice that of those with ESRD due to diabetes and nephrosclerosis. Proteinuria is the best predictor of reduced renal function, and the urine dipstick test for proteinuria is less expensive than other tests (Figure 10.2). Therefore, universal screening with this test may be an effective strategy for detecting hematuria and proteinuria and reducing the prevalence of ESRD in Japanese and Asian populations.[6]

EPIDEMIOLOGY

The prevalence of CKD in the adult Japanese population is higher than that in other high-income East Asian countries, such as Hong Kong and Taiwan[7] (Table 10.1). A study by the Japanese Society of Nephrology (JSN) in 2005 estimated that 19.1 million patients had stage 3 CKD in the Japanese adult population of 103.2 million in 2004, with prevalences of 1.4%, 3.6%, 10.8%, 15.9%, 31.8%, 44.0%, and 59.1% at ages 20–29, 30–39, 40–49, 50–59, 60–69, 70–79, and 80–89 years, respectively. About 200,000 patients were predicted to have CKD stages 4 and 5. The prevalence of hypertension, diabetes,

TABLE 10.1 Chronic Kidney Disease Epidemics in North and East Asia

Parameters	Chinese Mainland	Japan	Mongolia	South Korea	Taiwan
Prevalence of CKD,[1] %	10.80	12.90	13.90	13.7[a]	11.90

CKD, chronic kidney disease; *ESRD*, end-stage renal disease; *pmp*, per million population.
[a]*The data were based on survey of urban population.*
[b]*The incidence of treated ESRD of China is much higher in big cities (e.g. 107.3 pmp/yr in Beijing and 82.9 pmp/yr in Shanghai).*
[c]*The prevalence of ESRD of China is much higher in big cities (e.g. 524.6 pmp in Beijing and 544.7 pmp in Shanghai).*

and proteinuria increased as the estimated GFR (eGFR) decreased. The prevalence of concurrent CKD was significantly higher in patients with hypertension and diabetes than in the general population, when CKD was defined as an eGFR of <40 mL/min/1.73 m^2 instead of <60 mL/min/1.73 m^2.[8]

There are several theories regarding the high prevalence of CKD in the Japanese population. Greater than 20% of the Japanese population is aged $\geq$60 years. This percentage is much higher than in other countries. With increased average age, the prevalence of CKD becomes higher. Second, Asian populations, including Japanese people, may have a lower normal GFR than Caucasian populations in the US. The average kidney size of Japanese people is smaller (longest axis of 10 cm) than in Caucasians (11 cm). Inulin clearance in healthy Japanese controls in their 20s is about 83 ± 9 mL/min/1.73 m^2 while fasting and 121 ± 16 mL/min/1.73 m^2 after excess protein intake.[9] The average GFR is similar, at 81.4 ± 19.4 mL/min/1.73 m^2, in healthy organ donors in India ($n = 610$, average age 35 years).[10] In contrast, Davis and Shock[11] found that the US population has a higher average GFR of 122.8 ± 16.4 mL/min/1.73 m^2. In another report in a Caucasian population, GFRs were 130 and 120 mL/min/1.73 m^2 in young men and women, respectively. The difference in kidney size may affect the normal GFR in different ethnic groups, but the reason for the differences in normal GFR levels between Asian and Caucasian ethnic groups is not well understood.

The prevalence of diabetic nephropathy is increasing in Japan concurrent with the change from a traditional Japanese to a western lifestyle. The prevalence of overweight subjects increased from 30.3% in 1983 to 36.1% in 1993, while the prevalence of hypertension significantly decreased.[12] The impact of obesity and complications of diabetes mellitus (DM) may be different among races and ethnicities.[13] Public information on the risk of DM and its complications is especially important in Asian countries, because Asians have more fat than non-Asians, even with the same BMI.[14] Knowledge of predictors of DM/ESRD is crucial as a first step toward prevention, and international initiatives on the management of CKD and ESRD have recently been organized to address this issue.[12]

In the town of Hisayama-cho in Kyushu, all residents have undergone screening since the 1960s. All health data from Hisayama-cho have been collected and analyzed at Kyushu University as the Hisayama study, which is a community-based cohort study with the goal of evaluating the effects of lifestyle changes on CVDs in Japan.[15–17] In the series of reports on the Hisayama study, Nagata et al. assessed trends in the prevalence of CKD and risk factors over the last three decades.[18] The prevalence of CKD increased significantly over time in men (13.8% [95% confidence interval (95% CI), 11.4–16.2%] in 1974, 15.9% [95% CI, 13.6–18.2%] in 1988, and 22.1% [95% CI, 19.6–24.6%] in 2002; $p < 0.001$ for trend), but not in women (14.3% [95% CI, 12.2–16.4%], 12.6% [95% CI, 10.9–14.3%], and

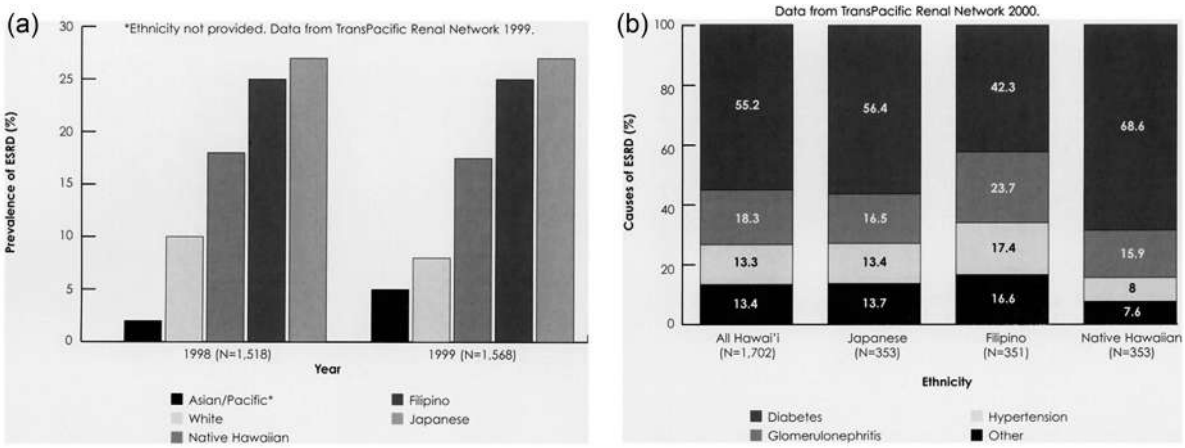

FIGURE 10.3 (a) Prevalence of end-stage renal disease (ESRD) in Hawaii in 1998 and 1999. Japanese show the highest prevalence among five ethnic groups. (b) Causes of ESRD in Hawaii in 2000 by ethnicity. The prevalence of glomerulonephritis in Japanese is lower than other ethnic groups. *From reference 20.*

15.3% [95% CI, 13.4–17.2%]; $p = 0.97$ for trend). The prevalence of CKD stages 3–5 (eGFR <60 mL/min/1.73 m^2) increased over the three decades in both sexes. Despite the widespread use of antihypertensive agents, only 27.0% of men and 47.5% of women with CKD had blood pressure <130/80 mm Hg. The prevalence of metabolic disorders including DM, hypercholesterolemia, and obesity increased over the three decades in both sexes. In the general Japanese population, the prevalence of CKD has also increased significantly in men, but not in women, over the last three decades, but there are regional variations. Thus, the demographics of participants differed in the 1993 and 2003 general screenings in Okinawa, but the prevalence of CKD seemed to be similar or at least did not increase substantially from 1993 to 2003.[19]

Mau et al. compared the prevalence of CKD in Japanese people living in Hawaii with other races.[20] As shown in Figure 10.3, of 1568 patients in Hawaii diagnosed with ESRD in 1999, 88.2% of those on dialysis were of Asian or Pacific Islander ancestry, with the major ethnic groups being Japanese (26.7%), Filipino (24.7%), and Native Hawaiian (17.0%).

In addition to common Japanese views on disease and society, additional ideas that influenced health and well-being were identified: the importance and hierarchy of the family; bachi, which means "curse"; and shikata ga nai, which means "it cannot be helped." Thus, several common themes prevail in the health beliefs and attitudes of Hawaii's ethnically diverse populations. For example, both Asian and Pacific Islander populations have strong ties to family and community, and wellness is achieved through balance or harmony of physical being and nature. They seem to share a sense of fatalism toward their health status, and they value interpersonal relationships, including the patient–physician relationship.

Role of the Japanese Society of Nephrology

The JSN was established in 1959, and now has over 10,000 members. The JSN conducts a range of activities to promote the practice and study of nephrology. These include holding regular meetings as a forum for diffusion of information, publishing journals (Clinical and Experimental Nephrology, CEN Case Reports, Japanese Journal of Nephrology), coordinating clinical research, developing national guidelines, establishing systems for CKD management, and promoting cooperation with related national and international societies. In 2007, the Committee for Standardization of Renal Pathological Diagnosis and the Working Group for the Renal Biopsy Database of the JSN started the first nationwide, web-based, and prospective registry system, the Japan Renal Biopsy Registry (J-RBR), to record pathological, clinical, and laboratory data for renal biopsies. The J-RBR contains data regarding more than 20,000 patients, including age, gender, laboratory data, and clinical and pathological diagnoses, recorded until the end of 2013.

The JSN analyzed clinical and pathological data collected from 818 patients at 18 centers in 2007 and from 1582 patients at 23 centers in 2008. In 2007, the most common clinical diagnosis was chronic nephritic syndrome (47.4%), followed by nephrotic syndrome (16.8%), and renal transplantation (11.2%). Similar rates were found in 2008. For native kidneys, the most common pathological diagnosis was IgAN in 2007 (32.9%) and 2008 (30.2%). Among primary glomerular diseases (except IgAN), membranous nephropathy (MN) was most common in 2007 (31.4%) and 2008 (25.7%).[21]

Ethnic differences in the eGFR equation may affect the epidemiological prevalence of CKD. An equation from the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) provides a more accurate eGFR than that from the Modification of Diet in Renal Disease (MDRD) Study, although both include a two-level variable for race (Black and White, and other). Because creatinine generation differs among ethnic groups, a multilevel ethnic variable should allow more accurate estimates across all groups. Stevens et al. developed an equation to calculate eGFR that includes a four-level race variable (Black; Asian; Native American and Hispanic; White and other) using a database of 8254 patients pooled from 10 studies. This equation was then validated in 4014 patients using 17 additional studies from the US and Europe (validation database), and in 1022 patients from China (675), Japan (248), and South Africa (99). In the validation database, the two-level race equation had minimal bias in the Black, Native American and Hispanic, and White and other cohorts. The four-level ethnicity equation significantly improved bias in Asians in the validation dataset and in Chinese, but both equations had a large bias in Japanese and South African patients. Thus, heterogeneity in performance among ethnic and geographic groups precludes use of the four-level race equation.

The CKD-EPI two-level race equation can be used in the US and Europe across a wide range of ethnicities.[22] Because there was a significant discrepancy between measured inulin clearance and eGFR using the 1.0 × MDRD and the Cockcroft Gault equations, it has been suggested that an original eGFR equation is required for Japanese patients.

The MDRD equation modified with the Japanese coefficient (0.881 × MDRD) determined for Japanese CKD patients yielded a lower mean difference and higher accuracy for GFR estimation. In particular, in patients with inulin clearance of 30−59 mL/min/1.73 m^2, the mean difference was significantly smaller with the 0.881 × MDRD equation than with the 1.0 × MDRD equation (1.9 vs. 7.9 mL/min/1.73 m^2; $p < 0.01$). The accuracy was significantly higher, with 60% vs. 39% of the points deviating within 15%, and 97% vs. 87% of points within 50% (both $p < 0.01$). Validation with a different dataset showed that the correlation between eGFR and inulin clearance was better with the 0.881 × MDRD equation than with the 1.0 × MDRD equation. In participants with inulin clearance <60 mL/min/1.73 m^2, the accuracy was significantly higher, with 85% vs. 69% of the points deviating within 50% ($p < 0.01$). The mean difference was also significantly smaller ($p < 0.01$). However, GFR values calculated by the 0.881 × MDRD equation still underestimated inulin clearance in the range >60 mL/min/1.73 m^2.[23]

The final equation for Japanese patients was developed based on a national study directed by the JSN. This was a diagnostic test study using a prospective cross-sectional design, with new equations developed in 413 participants and validated in an additional 350 participants. eGFR was determined with the modified isotope dilution mass spectrometry (IDMS)-traceable four-variable MDRD equation, using the previous Japanese Society of Nephrology Chronic Kidney Disease Initiative (JSN-CKDI) coefficient of 0.741 (equation 1), the previous JSN-CKDI equation (equation 2), and new equations derived in the development dataset: a modified MDRD equation using a new Japanese coefficient (equation 3), and a three-variable Japanese equation (equation 4). Performance of equations was assessed based on bias (eGFR—mGFR), accuracy (percentage of estimates within 15% or 30% of mGFR), root mean squared error, and correlation coefficient. In the development dataset, the new Japanese coefficient was 0.808 (95% CI, 0.728−0.829) for the IDMS-MDRD equation (equation 3), and the three-variable Japanese equation (equation 4) was eGFR (mL/min/1.73 m^2) = 194 × S [Cr]$^{-1.094}$ × Age$^{-0.287}$ × 0.739 (if female). In the validation dataset, bias was −1.3 ± 19.4 vs. −5.9 ± 19.0 mL/min/1.73 m^2 ($p = 0.002$), and accuracy within 30% of mGFR was 73% vs. 72% ($p = 0.6$) for equation 3 vs. equation 1 and −2.1 ± 19.0 vs. −7.9 ± 18.7 mL/min/1.73 m^2 ($p < 0.001$) and 75% vs. 73% ($p = 0.06$) for equation 4 vs. equation 2 ($p = 0.06$). Therefore, equation 4 is more accurate for the Japanese population than the previous equation and is now used as the standard.[24]

CKD PROGRESSION

Umesawa et al. examined 135,007 participants who completed an annual health checkup in 1993−1996 in Ibaraki Prefecture, Japan, and were initially free of CKD (defined as stage 3, 4, or 5 CKD or proteinuria [2+ or 3+] by dipstick evaluation). During follow-up, 7500 and 8964 cases of CKD developed in the northern and southern regions, respectively. Older age, proteinuria (1+), higher systolic blood pressure, medication for hypertension, and current smoking were associated with increased risk for CKD in both sexes. Higher eGFR and daily alcohol intake were associated with lower risk.[25] Despite Japan being a relatively small country, regional variation in CKD progression was found. The incidence of ESRD increased by about 3 times in Japan during the study period, from 81.3 per million (1 m) in 1982 to 237.6/m in 1998. Significant regional differences have been found in the mean (SEM) annual ESRD incidence ($p < 0.01$) and in the rate of increase of ESRD ($p<0.01$) across Japan. Koshinetsu (140 ± 11

per 1 million and 9.1 ± 0.6 per 1 million/year) and Hokuriku (141 ± 12 per 1 million and 9.7 ± 0.5/million/year) were the areas with the lowest incidence and rate of increase. Okinawa (188 ± 17/million/year and 13.4 ± 0.6/million/year) and Kyushu (179 ± 15/million/year and 12.0 ± 0.6/million/year) had the highest incidence and rate of increase.[26]

IGA NEPHROPATHY AND TONSILLECTOMY

O'Shaughnessy reported a large-scale study comparing glomerular disease frequencies across regions and race/ethnicity, using 42,603 diagnosed cases of glomerular disease (median age 47 years, 52% male, 57% White) from 29 laboratories in four continents. Those in Asia were from Japan and Thailand. IgAN (39.5%) and lupus nephritis (16.8%) predominated in Asia (mostly Japan), more than in other regions (22.1% in Europe, 11.8% in US/Canada, and 6.1% in Latin America).[27] In the national renal biopsy database, IgAN was also the most frequent pathological diagnosis.[28] Effects of expression and inhibition of salivary secretory IgA on negative emotions, health, and mood states have been examined in Japanese undergraduates with mild depression.[29] For this frequent glomerulopathy, the JSN has disease-specific original guidelines.[30] In Japan, the major treatment modalities for adult IgAN are renin–angiotensin–aldosterone system (RAAS) blockers, corticosteroids, nonsteroidal immunosuppressive agents, antiplatelet agents, n-3 fatty acids (fish oil), and tonsillectomy with corticosteroid pulse therapy (TSP).

Use of tonsillectomy differs from the international consensus and has a low recommendation grade (C1) in the JSN guidelines: "Tonsillectomy (with corticosteroids) may improve urinary findings in patients with IgAN and slow the progression of renal dysfunction. This may also be considered as a treatment option." Several studies are described in the guidelines as evidence for this treatment. In a retrospective cohort study, Hotta et al. found that TSP normalized urinary findings, which are predictors of renal failure.[31] Additionally, in a nonrandomized comparative study, Komatsu et al. found a higher normalization rate of urinary findings with TSP compared with steroid pulse (SP) therapy alone.[32] However, the level of evidence is regarded as insufficient because these studies were not designed as RCTs. However, at a JSN meeting in 2011, the Ministry of Health, Labor and Welfare Progressive Renal Dysfunction Research Group stated that TSP was more effective than SP therapy alone in reducing urinary protein in RCTs.[33]

After this announcement, Hoshino et al. followed 1127 biopsy-proven IgAN patients with CKD who were treated with TSP (n = 209), SP therapy (n = 103), oral corticosteroids (OS) only (n = 300), or RAAS inhibitors (RAASis) alone (n = 515). The hazard ratios (HRs) for ESRD or death, renal survival, and proteinuria level were analyzed. With TSP as the reference, the overall HRs for SP therapy, OS, and RAASi were 1.33 (0.44–4.04), 3.56 (1.45–8.71), and 3.64 (1.48–8.96), respectively. The respective HRs were 2.99 (0.71–12.54), 5.04 (1.44–17.67), and 7.23 (1.98–26.40) for patients with proteinuria ≥1.0 g/gCr and 0.42 (0.04–4.89), 3.24 (0.79–13.30), and 2.05 (0.52–8.05) for those with proteinuria <1.0 g/gCr. They concluded that TSP may decrease the risk of ESRD more than other therapies for IgAN patients with CKD with eGFR ≥60 mL/min/1.73 m^2 and proteinuria ≥1.0 g/gCr, while outcomes are similar to SP therapy in those with CKD stage 3 or proteinuria <1.0 g/gCr.[34]

In a network meta-analysis of IgAN with proteinuria >1 g/day, a total of 21 RCTs with 1822 participants were included for comparison of seven interventions. The rank of the most effective treatments to induce clinical remission was RAASi plus urokinase, TSP, and RAASi plus steroids, with the surface under the cumulative ranking area (SUCRA) of 0.912, 0.710, and 0.583, respectively. For prevention of ESRD or doubling of S[Cr], RAASi plus steroids (SUCRA 0.012) were most effective, followed by RAASi alone (SUCRA 0.282) and steroids alone (SUCRA 0.494), leaving mycophenolate mofetil as the least effective (SUCRA 0.644).[35] To establish more substantial evidence, the superiority of TSP requires further investigation.

RENAL REPLACEMENT THERAPY IN JAPAN

The annual survey of the Japanese Society for Dialysis Therapy Renal Data Registry was conducted for 4380 dialysis facilities at the end of 2015. 4321 facilities (98.7%) responded. This survey has been carried out since 1968. Initially, the purpose was to ensure the presence of dialysis units nationwide, and not for research. In 1968, there were only 215 patients and 48 consoles. The number of chronic dialysis patients in Japan continues to increase every year and reached 324,986 at the end of 2015 (Figure 10.4). The mean age of these patients was 67.9 years. At the end of 2015, the prevalence was 2592 patients/m population.

Diabetic nephropathy was the most common primary disease among prevalent dialysis patients (38.4%), followed by chronic glomerulonephritis (29.8%) and nephrosclerosis (9.5%). The rates of diabetic nephropathy and nephrosclerosis have been increasing yearly, while chronic glomerulonephritis has been declining. The number of incident dialysis patients in 2015 was

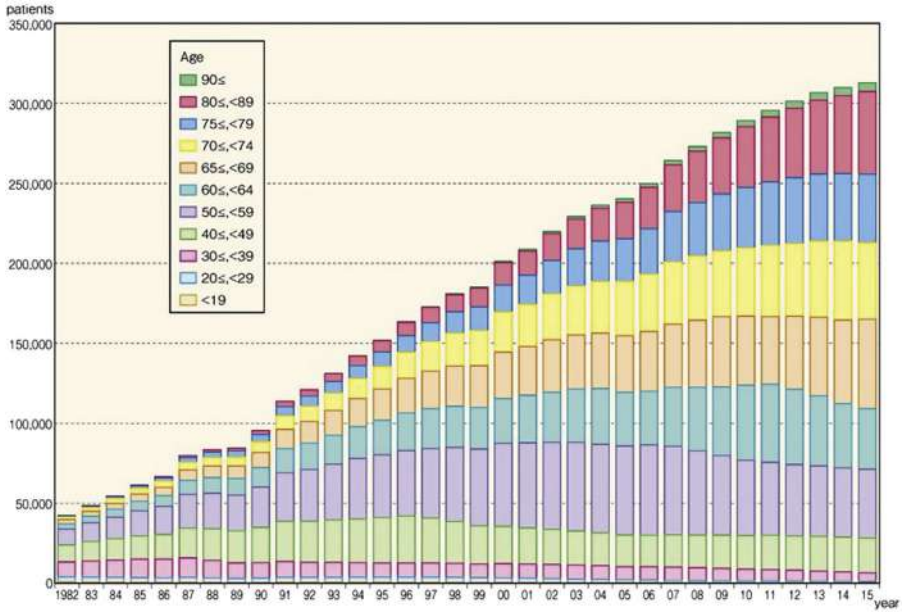

FIGURE 10.4 Prevalent dialysis patient distribution by age, 1982–2015. *From reference 36.*

39,462. This number has remained stable since 2008. The average age was 69.2 years, and diabetic nephropathy (43.7%) was the most common cause of incident dialysis. Cases caused by diabetes have not changed in number for the last several years. A total of 31,608 dialysis patients died in 2015, yielding a crude mortality of 9.6%. The number of peritoneal dialysis (PD) patients was 9322 in 2015, with a slight increase from 2014.[36]

In 2015, there were 71,270 dialysis patients aged <60 years, 141,634 aged 60–74, and 100,308 aged ≥75 years. Males were more frequent in all age categories, but as age increased, the percentage of females also increased. Women accounted for 40.8% of elderly dialysis patients. Elderly patients had the shortest dialysis period of 5.71 years, with 54.8% having received dialysis for <5 years and 80.3% for <10 years. Nephrosclerosis (16.6%) was the more common primary kidney disease among elderly dialysis patients than in other age groups. The rates of diabetic nephropathy (34.3%) and chronic glomerulonephritis (26.5%) were lower than in other age groups. The rates of myocardial infarction, cerebral infarction, and proximal femur fracture were high in the medical histories of elderly dialysis patients. No differences were found for cerebral hemorrhage or limb amputation.

Figure 10.5 shows the overall survival of hemodialysis patients. Despite progress in technology and medicine, the 5-year survival rate remains about 60%. This may partly be because patients who originally had expected survival of less than 5 years (i.e. those aged >90 years or with multiple complications) have started dialysis recently.

Itoh et al. established a scoring system for prediction of 15-year survival in 622 Japanese dialysis patients. In this system, age ≥65 years, diabetic nephropathy, hypotension, pre-HD cardiothoracic ratio ≥50%, pre-HD BNP ≥250 pg/mL, and pre-HD abnormal findings on electrocardiograms were prognostic risk factors.[37]

On March 11, 2011, the Great East Japan Earthquake highlighted the vulnerability of chronic dialysis patients to disasters. Of 4205 facilities, 314 could not offer daily dialysis sessions for various reasons that depended on seismic intensity (Figure 10.6). To minimize negative effects on patients treated with chronic maintenance dialysis in future large-scale disasters, it will be important to promote self-help for dialysis facilities and to develop mutual assistance systems within local communities. The effects of the 2011 earthquake showed that each facility requires comprehensive disaster management, including vibration control of large machinery, use of flexible tubes, securing patient beds, and flexible use of bedside consoles. Local governments should plan for support of chronic dialysis therapy in their areas and assign roles among themselves for dealing with a large number of patients with acute kidney injury during long-term disruption of lifelines, including electricity, water supply, and fuel.[38]

A characteristic of Renal Replacement Therapy in Japan is the variation in therapy selection. About 300,000 of 320,000 ESRD patients receive HD, while

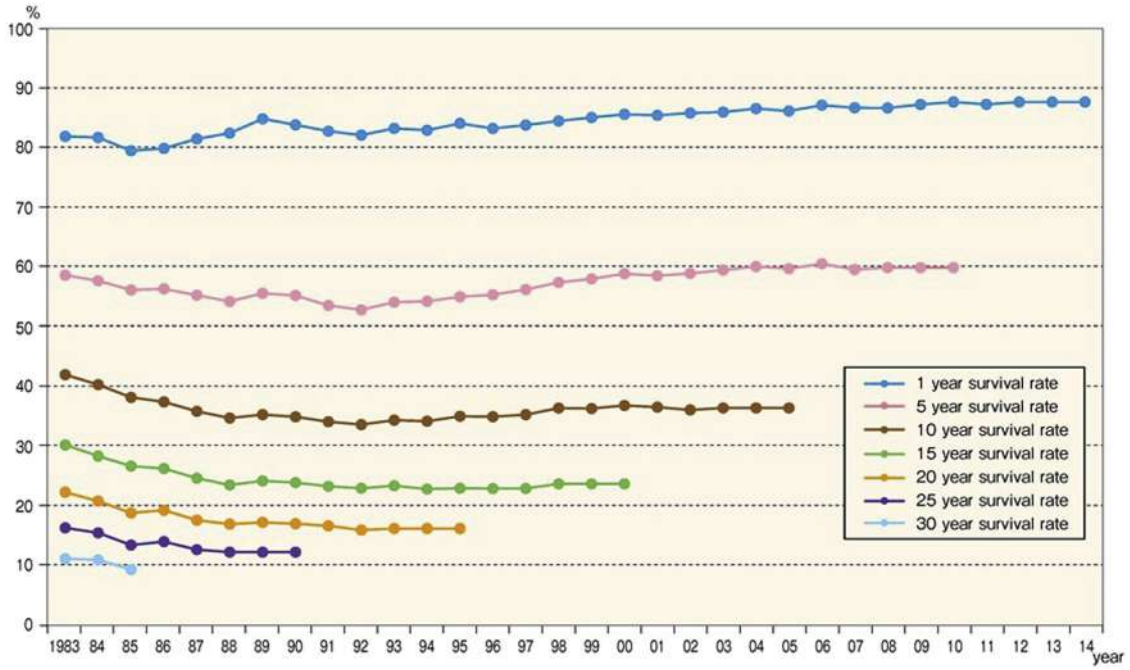

FIGURE 10.5 1-, 5-, 10-, 15-, 20-, 25-, and 30-year survival rate in Japanese dialysis patients from 1983 to 2014. *From reference 36.*

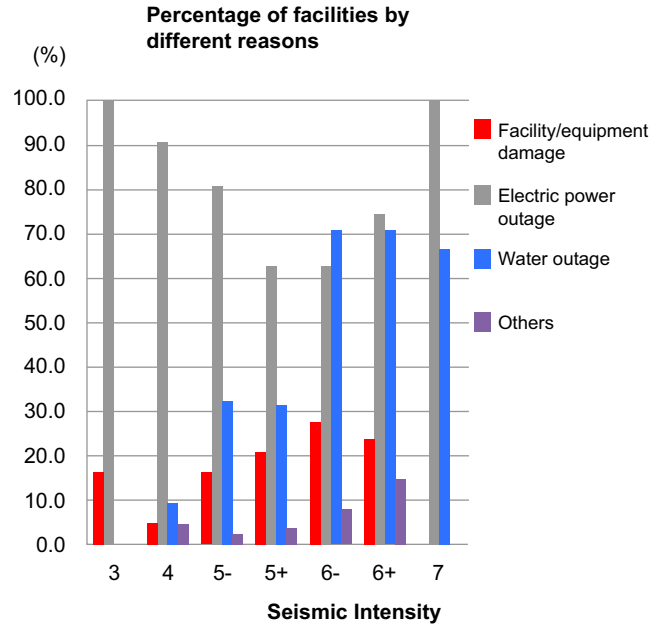

FIGURE 10.6 Reasons for interruption of dialysis services related to seismic intensity showing the percentage of different reasons. The most common reason for interruption was power outage. Some facilities that were hit by an earthquake of moderate intensity (3 or 4) also experienced interruption due to facility damage. *From reference 38.*

fewer patients receive PD and renal transplantation. The first deceased and living donor kidney transplants were performed in Japan in 1956 and 1964, respectively. More transplants were performed after the introduction of cyclosporine in 1983, and the number has gradually increased, with 1661 transplants performed in 2015. In addition, outcomes have improved year by year. The indications for transplantation have also expanded in various ways, including recipient and donor age, primary diseases, ABO-incompatible and highly sensitized cases, and preemptive transplantation.[39]

CONCLUSION

As observed in other countries, CKD has become one of the most important diseases in Japan over the last decade. Countermeasures have been started through the combined efforts of the government and the JSN. Etiological causes of ESRD used to be chronic glomerulonephritis, mainly IgAN, but have now been replaced by diabetic nephropathy. Nephrosclerosis associated with aging is expected to increase in the future. As these diseases lack fundamental treatment, patients, families and physicians need to manage the lifestyle implications of CKD and ESRD.

QUESTIONS AND ANSWERS

Question 1

Which nations have a lower CKD prevalence compared with Japan?

A. South Korea
B. Mexico
C. US
D. China
E. Germany

Answer: D

As shown in Table 10.1, CKD prevalence in China (10.8%) is lower than in Japan (12.9%). The prevalence of CKD is higher in the US, Mexico, and Germany.

Question 2

Which is the most frequent primary glomerulonephritis in Japan?

A. MN
B. Lupus nephritis
C. IgAN
D. FSGS
E. Minimal change disease

Answer: C

As in other Asian countries, IgAN is the most common primary glomerulonephritis in Japan. However, as a cause of ESRD, diabetic kidney disease and hypertensive glomerulosclerosis are more common than primary glomerulonephritis.

Question 3

Which element is heavily used in Washoku?

A. Oil
B. Salt
C. Sugar
D. Protein
E. Dairy products

Answer: B

Washoku is approved as low-protein, low oil healthy food worldwide, but its problem is salt-rich seasoning. Salt is a major factor in the high prevalence of stroke in Japan, prompting the Japanese Ministry of Health, Labour and Welfare to work on lowering the worked salt intake of Japanese people.

Question 4

What is the mean age of patients receiving dialysis therapy in Japan?

A. 48 years old
B. 56 years old
C. 62 years old
D. 68 years old
E. 72 years old

Answer: D

The number of chronic dialysis patients in Japan reached 324,986 at the end of 2015. The mean age of these patients was 67.9 years and for incident patients 69.2 years. Both of these ages have increased yearly.

Question 5

What did Japanese dialysis facilities learn about disaster management from the 2011 earthquake?

A. Vibration control of large machinery
B. Flexible use of bedside consoles
C. Securing patient beds
D. Use of flexible tubes
E. All of the above

Answer: E

Of 4205 facilities in Japan, 314 could not offer daily dialysis sessions mainly because of electric power and water shortages. In each facility, vibration control of large machinery, use of flexible tubes, securing patient beds, and flexible use of bedside consoles have been improved since the earthquake.

Ethnicity and Chronic Kidney Disease in Africa

Dwomoa Adu[a], *Akinlolu O. Ojo*[b]

[a]Honorary Senior Research Fellow and Consultant Nephrologist, School of Medicine and Dentistry, University of Ghana, Accra, Ghana; [b]Associate Vice President for Clinical Research and Global Health Initiatives, University of Arizona Health Sciences, Tucson, AZ, United States

Abstract

The estimated prevalence of chronic kidney disease (CKD) in adults in sub-Saharan Africa (SSA) is 13.9%. The major causes of CKD in Africa are hypertension, diabetes mellitus, glomerulonephritis, and HIV infection. These diseases occur on a background of a high prevalence of Apolipoprotein L1 (*APOL1*) gene variants G1 and G2, which are common in Africans, presumably having evolved to provide protection against Trypanosomiasis some 10,000 years ago. The prevalence of CKD in individuals in Africa with hypertension ranges from 15 to 48%, in individuals with diabetes mellitus from 14.1 to 32.6% and in individuals with HIV infection from 5.6 to 27.3%. Up to 33% of patients with end-stage renal disease (ESRD) in Africa have glomerulonephritis. Other major causes of CKD in Africa are *Schistosoma mansoni* (*S. mansoni*) and *Schistosoma haematobium* (*S. haematobium*) infection and sickle cell disease. The major causes of CKD in children in Africa are glomerulonephritis and congenital abnormalities of the kidneys and urinary tract. In SSA there is a startling gap between the estimated incidence of ESRD due to diabetes and hypertension of 239 per million population and patients receiving renal replacement therapy of 1.5%.

INTRODUCTION

Africa is geographically and ethnically diverse and has a population of over one billion people. Africans face a growing burden of chronic kidney disease (CKD), which is driven by several factors. First, there is a demographic transition in which populations in Africa are aging with a corresponding increase in the prevalence of obesity, diabetes, and hypertension. Second, this is occurring in populations in which infections such as human immunodeficiency virus (HIV) and schistosomiasis, which increase the risk of CKD, are common. Third, many African populations have a genetic susceptibility to CKD driven by allelic variants in the gene encoding Apolipoprotein L1 (*APOL1*), which evolved to provide protection against Trypanosomiasis some 10,000 years ago.[1,2] These APOL1 variants are also associated with an increased risk of HIV-associated nephropathy (HIVAN), hypertensive CKD, focal and segmental glomerulosclerosis (FSGS), sickle cell nephropathy, and lupus.[3–5] The prevalence of CKD in sub-Saharan Africa (SSA) is estimated to be 13.9%.[6] The Global Burden of Disease study reported that individuals in low sociodemographic index countries (SDI) such as SSA had a greater percentage of subjects with CKD at an earlier age (adolescents and young adulthood) compared with high SDI countries.[7] Our data from SSA confirm this, as Africans succumb to end-stage renal disease (ESRD) 20–30 years earlier than the median age of onset of ESRD among Europeans.[8] The major causes of CKD in Africa are HIV infection, hypertension, glomerulonephritis, and diabetes mellitus. Renal replacement therapy (RRT) is either unavailable or unaffordable, making the development of ESRD a death sentence for many. In addition predialysis CKD extracts an enormous toll in premature mortality, cardiovascular comorbidities, and health care expenditures.[9] CKD imposes severe human suffering on the African continent as well as a huge economic burden.

PREVALENCE OF CKD IN SSA

Africa has a population of 1.2 billion people with 969.2 million in SSA and 225.1 million in Northern Africa.[10] Africa is facing a double burden of disease in which infections such as HIV, schistosomiasis, and hepatitis B (HBV) and C (HCV) viruses are still common. At the same time, Africa is facing an increasing burden of noncommunicable diseases (NCD) such as obesity, hypertension, and diabetes, all of which are risk factors

Chronic Renal Disease, Second Edition

for CKD. CKD appears to be common in SSA, but until recently there were very little data on prevalence. A recent systematic review and meta-analysis of 21 medium- and high-quality studies reported that the prevalence of CKD in SSA was 13.9% (95% CI: 12.2–15.7)[6] (Table 11.1). Other systematic reviews, pooled analyses, and meta-analyses from Africa have come to broadly similar conclusions. In the meta-analysis of Kaze et al.[11] the overall prevalence of CKD (stages 1–5) was 15.8% (95% CI: 12.1–19.9). For CKD stages 3–5 it was 4.6% (95% CI: 3.3–6.1). These rates of CKD are comparable to that of 13.1% (95% CI 12.0–14.1%) in the US.[12] The study of Abd El-Hafeez et al. reported the pooled prevalence of CKD to be a little lower than in the studies described above at 10.1% (95% CI: 9.8–10.5%).[13] The prevalence of CKD was also higher in West/Central Africa at 16.5% than in North Africa where the prevalence was lower.[13] The study of Kaze et al. provided similar conclusions.[11] All the studies report significant heterogeneity in the prevalence of CKD in Africa. This is to be expected as African populations differ at many levels, including genetic ancestry and the prevalence of hypertension, diabetes mellitus, and HIV infection. In a study in Ghana we reported that the prevalence of CKD in 2424 individuals aged 25–70 years was 13.3% (95% CI 11.6–13.4).[14] By contrast in a study from Tanzania the prevalence of CKD was 7.0% (95% CI 3.8–12.3).[15] There may be a genetic cause for this difference, because in Tanzania the APOL1 renal risk variant frequency of 11–17%[16] is less than half of that of the 41% found in Ghana.[2,17] CKD is thus a major NCD in Africa. Patients with CKD are at increased risk of developing ESRD, as well as cardiovascular disease and death.[18]

CAUSES OF CKD IN AFRICA

The major causes of CKD in Africa are hypertension, diabetes mellitus, glomerulonephritis, and HIV infection, and these occur on a background of a high prevalence of *APOL1* variants, which increase the risk of CKD.

Apolipoprotein L1 Nephropathy in Sub-Saharan Africa

Studies showing variable susceptibilities in African populations to HIVAN had postulated the existence of an "African renal susceptibility gene" prior to the established association between risk variants on chromosome 22 and CKD in people of African ancestry.[19] APOL1 G1 and G2 variants have been identified as potentially causative and progression factors in people of African descent, and possible mechanisms by which these renal risk variants lead to the development and progression of CKD of various etiologies are beginning to be defined.[1,2] The variability in the population frequencies in the heterozygous, homozygous, and compound homozygous states of *APOL1* G1 and G2 alleles in various African populations are shown in Figure 11.1 and Table 11.2. The highest frequencies of the G1 and G2 variants have been observed among the Yoruba and Igbo tribes in Southern Nigeria, with East Africans generally having the lowest frequencies.[17] The heterozygote *APOL1* G1 and G2 variant proteins are most effective as trypanolytic factors for the *Trypanosoma brucei rhodesiense* (*T. b. rhodesiense*).[1] A recent study showed the *APOL1* G2 variant leads to strong protection against *T. b. rhodesiense* infection in Uganda, while the G1 variant did not.[20] The association between *APOL1* variants and *Trypanosoma brucei gambiense* (*T. b. gambiense*) infection is also complex, in that individuals carrying the G1 and G2 variant were not protected from developing *T. b. gambiense* infections. However individuals carrying the G1 variant were more likely to have asymptomatic latent infections, whereas individuals with the G2 variant had severe active infection.[20] This study provides some explanation for why the highest allele frequencies of G1 variants are found in West Africa, where the *T. b. gambiense* is endemic, but do not explain why the highest frequencies of the G2 variants are also found in West Africa. The discrepancy in the trypanosomal distributions and the G1 and G2 variants allele frequencies may be due to more recent evolution of the G2 variant and possible evolution of the G1 variant in response to other intracellular or extracellular pathogens. Studies are ongoing to determine more precisely the explanations for the discrepancies between the patterns of trypanosomal species endemicity and the *APOL1* risk variants geographic allele distributions.

Genetic epidemiologic studies of *APOL1* nephropathy have been undertaken in only a few thousand individuals in African populations, in contrast to large numbers of studies in people of African descent in the US, Brazil, and Western Europe.[21] Most studies consistently show that (1) the presence of *APOL1* renal risk variants (G1/G1, G2/G2, or G1/G2) confers highest susceptibility to HIVAN with odds ratio as high as 89;[5] (2) in addition to HIVAN, *APOL1* risk variants increase susceptibility to CKD due to sickle cell disease,[22] systemic lupus erythematosus,[23] FSGS,[24] and hypertension-associated kidney disease[1], but not to diabetic nephropathy; and (3) homozygous or compound homozygous *APOL1* renal risk variants may be progression factors for most forms of CKD that have been studied, including diabetic nephropathy.[25] The Human Heredity and Health in Africa (H3Africa) Consortium funded by the National Institutes of Health (NIH) and the Wellcome Trust are conducting studies in large populations in

SSA to more precisely characterize the variability in susceptibility to CKD among geographic and ethnic populations and elucidate the etiologies of the CKD for which the *APOL1* risk variants confer increased risk of causality and progression.[8,26]

The prevalence of *APOL1* risk alleles in West Africa is twice as high as in African Americans, and this would be expected to be associated with an increased prevalence of CKD. Although this appears to be the case, confirmatory studies are required. The high prevalence of CKD in East and South Africa that have a lower frequency of *APOL1* risk alleles suggests the presence of other "African susceptibility genes" and/or other environmental factors contributing to the high burden of CKD in SSA.[27]

In African Americans, an estimated 11% of individuals with two *APOL1* risk alleles have a lifetime risk of developing CKD, but studies in SSA have yet to determine what fraction of the population with *APOL1* risk alleles will develop kidney disease. The higher overall prevalence of CKD in SSA would also suggest that the attributable risk of *APOL1* renal risk variants would be much higher than that in African Americans. The average age of onset of CKD in SSA (where measurable, as only 1–2% have access to maintenance dialysis or kidney transplantation) is about one and one-half decade earlier than the average age of onset of ESRD in African Americans (45 years vs. 61 years).[8] Whether CKD is initiated at an earlier age in general, or whether ApoL1 risk renal variants independently confer more accelerated progression, or interact with other progression factors to accelerate the progression of CKD in SSA, have not be determined. These questions are being addressed in ongoing cohort studies of ApoL1 nephropathy in SSA.

Specific Causes of CKD in Africa

Hypertension

Across the World Health Organization (WHO) regions, the highest prevalence of hypertension is found in Africa, with an age-adjusted prevalence in individuals over 18 years of 27.4% (95% CI: 24.5–30.4).[28] The prevalence rates of hypertension differ substantially across Africa. Rates in the AWI-Gen study ranged from 15.1% in Burkina Faso to 54.1% in South Africa.[29] A meta-analysis of hypertension studies from Africa came to broadly similar conclusions, with the prevalence of hypertension rising from 16% at the age of 30 years–44% at 60 years.[30] This high prevalence of hypertension was confirmed in a recent systematic review.[31]

Hypertension is a recognized risk factor leading to CKD. In Africa, the prevalence of CKD in people with hypertension was reported as 18.8% (medium-quality studies) and 14.8% (high-quality studies).[6] (Table 11.3) In the study of Kaze et al.[11] the prevalence of CKD in people with hypertension in Africa was 35.6% (95% CI: 27.9–43.7). In a pooled study the prevalence of CKD in patients with hypertension was similar at 34.5% (95% CI: 34.04–36.0).[13] In a study of 712 adults from Ghana with hypertension, the median age was 59 years (range 19–90), the median duration of hypertension was

4 years, and the prevalence of CKD was 46.9% (95% CI: 43.2–50.7).[32] Hypertension is thus common in Africa and contributes substantially to the risk of CKD.

Diabetes Mellitus

The prevalence of diabetes mellitus has increased from 3.1% in 1980 to 7.1% in 2014 in the African region of the WHO.[33] Over 90% of people with diabetes in SSA, as elsewhere, have type 2 diabetes mellitus.[34,35] The true burden of CKD in people with diabetes is unknown, as there are few reliable data at the population level, and the definitions of CKD have been variable and imprecise. The increased prevalence of type 2 diabetes in SSA will be a major driver of CKD. Studies of the prevalence of proteinuria and CKD in patients with diabetes in Africa are hampered by small sample sizes, variable quality, and a wide variation in prevalence rates. Several meta-analyses and pooled studies have reported the prevalence of diabetic nephropathy in people with CKD (Table 11.3). In the study of Stanifer et al.[6] the prevalence of CKD in people with diabetes mellitus was 14.1% (in medium-quality studies) and 19.8% (high-quality studies). Kaze et al.[11] reported a prevalence of CKD in diabetes of 32.6% (95% CI: 0.3–82.3%). Abd El-Hafeez et al.[13] found a prevalence of CKD in diabetes of 24.7% (95% CI: 23.6–25.7) in their pooled study. A further systematic review of 32 studies from Africa reported that 34.7% of people with diabetes mellitus had ESRD after 5 years and that 18.4% died at 20 years.[36] Despite the variability of these studies, they all report a high prevalence of CKD in people with diabetes. Studies are needed to define the prevalence of CKD in people with diabetes mellitus in Africa and to establish optimal methods of reducing this, including using blockers of the renin angiotensin aldosterone system.

HIV and CKD

Prevalence of HIV in Africa

Over 25 million people in SSA have HIV infection,[37] and this is associated with a high prevalence of CKD. The highest prevalence of HIV-associated renal disease is found in SSA. The adult (age 15–49 years) prevalence of HIV infection ranges from 1.9% in West and Central Africa, to 6.8% in East and Southern Africa, to 18.8% in South Africa and 22.8% in Botswana.[37] The reasons for this are due first to the high prevalence of HIV infection. Secondly, populations in SSA have a genetic predisposition to HIVAN. South Africans with two copies of the risk alleles (G1 and G2) of *APOL1* have a significantly higher risk of developing HIVAN (OR: 89.1; 95% CI: 17.8–811.72) compared to individuals without these risk variants.[5] This is higher than in African Americans (OR of 29.2; 95% CI: 13.1–68.5).[24] By contrast, Ethiopians with HIV infection who lack *APOL1* risk variants do not develop HIVAN.[38] The HIV epidemic in SSA may soon lead to an additional epidemic of CKD as a significant cause of morbidity and mortality.

Prevalence of CKD in HIV

The prevalence of CKD in people with HIV infection ranges widely, from 5.6 (95% CI: 5.4–5.8),[13] to 7.0% (95% CI 2.8–12.9%),[39] and 11.9% (medium-quality studies)[6] and 27.3% (95% CI: 17.0–38.9).[11] In Ethiopia the absence of HIVAN in subjects with HIV can be explained by the lack of APOL1 variants in this population (Table 11.3).[38]

HIV Renal Disease in Africa (Table 11.4)

The causes of kidney disease in people with HIV infection include HIVAN, FSGS, immune complex kidney disease, and kidney injury from nephrotoxicity from antiretroviral drugs and coexistent HBV or HCV infection.[40,41] The two major histological lesions in HIV-infected individuals in Africa are HIVAN and HIV immune complex kidney disease (HIVICK) (Table 11.4). Han et al.[42] studied 615 patients with HIV infection in South Africa. Of these 38 (6%) had proteinuria. Thirty of their patients had a renal biopsy. Twenty-five (83%) showed HIVAN with collapsing FSGS (Figure 11.2). Two had membranoproliferative glomerulonephritis (7%), three interstitial nephritis (10%), and four patients had coexistent HIVAN and membranous nephropathy. Of these four patients, two had HBV surface antigenaemia.

In another study from South Africa, Gerntholtz et al.[43] reported that of 99 patients with HIV infection who had a renal biopsy, 27 (27%) had HIVAN with an FSGS pattern of glomerular damage with or without a collapsing pattern, and 21 (21%) had HIVICK. They also described subepithelial deposits with a basement membrane reaction giving a "ball in cup" appearance in the HIVICK biopsies. Other lesions seen were membranous nephropathy, postinfectious glomerulonephritis, mesangial proliferative glomerulonephritis, and IgA nephropathy. In a large study of 192 renal biopsies in patients with HIV infection from South Africa, of whom 172 (89.6%) were of black African ancestry, Wearne et al.[44] reported that the most common histological feature was HIVAN in 110 biopsies (57.3%), followed by a mixed HIVAN and HIVICK pattern in 42 (21.9%) biopsies, and HIVICK alone in 16 (8.4%) biopsies. They also reported a "fetal" variant of FSGS that showed a dense mesangial core with absent capillary loops.

Studies in South African children also showed a prevalence of HIVAN of 26.5% and HIVICK of 10.2%.[45] Other studies from Africa have reported smaller numbers of HIV-infected patients who have had a renal biopsy. In a report from the Democratic Republic of the Congo, 6 out of 32 renal biopsies (19%) showed HIVAN.[46] By contrast two studies from Nigeria showed that 70% of patients with HIV infection who had a renal biopsy had HIVAN.[47,48] Finally a report from Kenya showed a striking absence of HIVAN in the renal biopsies in 27 combined antiretroviral treatment (cART) naïve subjects with HIV infection and persistent microalbuminuria.[49] The most common histological lesion was acute interstitial nephritis in 41% of the patients. It is difficult to explain the absence of HIVAN in this Kenyan study.

In patients with HIV-associated renal disease, adverse prognostic factors were proteinuria, the presence of microcysts (Figure 11.3), the fetal variant, and

interstitial fibrosis. The prognosis is poor in untreated patients with HIVAN. In the study of Wearne et al. the 50% survival without treatment was 4.47 months.[44] The prognosis improved as did renal survival with cART. In addition to an improvement in renal function, the use of cART was accompanied by improvement in renal histology.[50]

Tenofovir Nephrotoxicity

Tenofovir disoproxil fumarate (TDF) is a nucleotide analogue reverse transcriptase inhibitor, which is effective in the treatment of HIV and HBV infections. TDF enters proximal tubular cells through basolateral organic anion transporters and is excreted into the lumen through multidrug resistance associated protein (MRP4) but not MRP2. TDF is associated with the development of proximal tubular injury, occasionally leading to Fanconi syndrome characterized by phosphaturia, glycosuria, amino aciduria, proteinuria, and bicarbonate wasting and rarely to acute kidney injury.[51] In addition, TDF is associated with increased risk of developing CKD, although the size of this effect is unclear. A systematic review and meta-analysis reported that patients treated with TDF showed a small but significant difference in glomerular filtration rate (GFR) of 3.9 mL/min (95% CI: 2.1−5.7) using the Cockroft-Gault formula compared with patients not on TDF.[52] None of the studies analyzed were from Africa, although most included black participants. In a large study from Zambia, of 62,230 adults with HIV infection, 38,716 were started on cART containing TDF. Patients with normal or mild renal impairment at the start of TDF were more likely to develop moderate (OR: 3.11 95% CI: 2.52−3.87) or severe (OR: 2.43 95% CI: 1.8−3.28) decrease in eGFR compared with patients not on TDF. Among patients with moderate or severe renal dysfunction, however, renal function improved regardless of the type of cART therapy.[53] One study in Nigeria of 5273 patients with HIV infection found the risk of CKD (eGFR <60 mL/min/1.73 m^2) at 48 weeks in patients on TDF was 4.6%, compared to 2.3% in the TDF unexposed group (OR: 2.0; 95% CI: 1.58−2.89).[54] The study of De Waal et al. from South Africa reported a small decline in eGFR (-2.3 mL/min/1.73 m^2 (95% CI: -2.5 to -2.1)) in participants on TDF who had a CKD-EPI eGFR >90 mL/min/1.73 m^2 but improvement in patients with initial renal impairment.[55] A study from Uganda showed no differences in renal function of participants whether or not they were on TDF.[56] Our anecdotal experience is that TDF is an important cause of CKD and that this effect merits further study. Recently an analogue of TDF, tenofovir alafenamide has been introduced, which is reported to be less nephrotoxic.[57]

CKD in Children

The major causes of CKD in children in Africa are glomerulonephritis and congenital abnormalities of the kidneys and urinary tract (CAKUT) (Table 11.5). Studies from West and South Africa showed a higher prevalence of glomerulonephritis (53−77%)[58−60] than studies from Sudan[61] and Egypt,[62] where the prevalence ranged from 15.3 to 25.4%. CAKUT were the next most common cause of CKD in children in Africa, ranging from 9.8 to 28.9%.

Low Birth Weight and CKD

Low birth weight (LBW) is common in SSA with an incidence of around 15%.[63] LBW is associated with an increased risk of adult hypertension, impaired glucose tolerance, and CKD compared to those with normal birth weight.[64,65] LBW is thus likely to be an important contributor to hypertension and CKD in later life in SSA. Future studies should focus on translational research that combines investigation with measures to reduce the impact of LBW on public health.

Glomerulonephritis

Glomerulonephritis is an important cause of ESRD in Africa.[66,67] In most cases the diagnosis of glomerulonephritis is presumed in patients who present with late-stage renal failure with kidneys that are too small to biopsy safely. In an autopsy study we showed histologically proven glomerular disease, mostly FSGS, in 33 of 78 (42.3%) patients with ESRD.[66] A recent systematic review of renal biopsy studies from Africa showed a high prevalence of glomerular diseases that may lead to CKD (such as FSGS, mesangiocapillary glomerulonephritis, HBV-associated glomerulonephritis, and lupus nephritis).[68] Because of selection issues, the prevalence of HIV-associated glomerular disease was low in the study, but this has been reported to be increasing in South Africa.[69] Similarly in children in Africa, FSGS (26.3%), membranoproliferative glomerulonephritis (16.8%), proliferative glomerulonephritis (27.0%), and membranous nephropathy (4.5%) are now major causes of the nephrotic syndrome in childhood, as are HBV, HIV infection, and sickle cell disease, and these may lead to CKD.[70] One striking feature of contemporary renal histology from African children is the lack of *Plasmodium malariae*−associated nephropathy (Quartan malarial nephropathy),[71] which was a prominent cause of the nephrotic syndrome in the 1950s and 1960s.[72,73]

Schistosomiasis

Schistosoma haematobium (*S. haematobium*) and *Schistosoma mansoni* (*S. mansoni*) are parasitic flukes that are found in tropical areas where there are large areas of water. Both are common in Africa and may lead to CKD.

FIGURE 11.4 Bladder calculus and bladder wall calcification in a patient with *Schistosoma haematobium* infection. Bladder calculus ——→. Calcified bladder wall ·····→.

Schistosoma haematobium

S. haematobium is common in many African countries, with a prevalence of 22.4 ± 9.8% in 43 countries.[74] The disease is caused by parasite eggs that are deposited in the blood vessels surrounding the genitourinary tract, leading to inflammation and scarring. The clinical presentation is hematuria and dysuria. The inflammatory reaction to severe urogenital schistosomiasis leads to chronic fibrosis of the urinary tract with hydroureter and hydronephrosis.[75–77] Other features include bladder calcification and stones (Figure 11.4). These urological complications lead to CKD in a significant proportion of patients. The WHO estimates 112 million individuals in SSA have *S. haematobium* infection and that an estimated 150,000 infected individuals die from kidney failure each year.[78] This makes *S. haematobium* infection a major and as yet poorly studied cause of CKD in Africa. In the long-term, chronic infection can lead to squamous cell carcinoma of the bladder.[75,79]

Schistosoma mansoni

S. mansoni infects an estimated 54 million people in Africa.[78] The disease is caused by parasite eggs that are deposited in the blood vessels of the gastrointestinal tract, leading to inflammation and scarring. Some people with *S. mansoni* infection develop hepatosplenic disease with periportal fibrosis. *S. mansoni*–associated glomerular disease is found in 5–6% of infected patients. It more commonly occurs in 10–15% of patients with hepatosplenic disease.[80] The clinical presentation varies from asymptomatic proteinuria to ESRD. Common histological glomerular lesions are mesangioproliferative glomerulonephritis, diffuse proliferative glomerulonephritis, mesangiocapillary glomerulonephritis, FSGS, and amyloidosis.[80] Treatment of both *S. mansoni* and *S. haematobium* is with praziquantel or oxamniquine.

Sickle Cell Nephropathy

Sickle cell disease is a major public health burden in SSA. It is estimated that in 2010, 200,000–300,000 children were born with this disorder.[81] Early renal manifestations of sickle cell disease are hyposthenuria, renal tubular acidosis, and defects in potassium excretion.[82] For those children who survive, renal disease is a common complication, which starts in childhood with hyperfiltration and microalbuminuria, and can progress in adult life to CKD. In a study of 2582 patients with sickle cell disease from four SSA countries (Cameroon, Cote d'Ivoire, Mali, and Senegal) albuminuria was reported in 33.7% (95% CI: 31.6–35.8) of patients with Hb SS and $S\beta^0$ and 16.4% (95% CI: 13.6–19.2) of patients with Hb SC and $S\beta^+$ phenotypes.[83] The prevalence of albuminuria increased with age (27% for children aged less than 10 years and 48% for patients aged over 40 years). Hyperfiltration was more common in younger individuals and individuals with Hb SS and $S\beta^0$ compared with Hb SC and $S\beta^+$ phenotypes. Risk factors for albuminuria were age, female sex, and high lactic dehydrogenase and low hemoglobin (negative correlation). Other studies from SSA show rates of microalbuminuria of 18.5–28.0%,[84–86] which increases with age.[87,88] In addition eGFR decreases with age.[87,88] The renal lesions seen on biopsy in patients with sickle cell disease are FSGS, membranoproliferative glomerulonephritis, and glomerular hypertrophy with or without mesangial hypercellularity and thrombotic microangiopathy.[89] Biopsy studies from Africa also report membranoproliferative glomerulonephritis and FSGS.[71,90] Albuminuria in sickle cell disease reduces with treatment with angiotensin-converting inhibitors or angiotensin II-receptor blockade. It is possible that these agents, by reducing intraglomerular pressures, might reduce the rate at which renal function declines.[91,92]

CKD and Sickle Cell Disease

There are relatively few data on the prevalence of CKD in adults in SSA. This is in part because of the high childhood mortality in children with sickle cell disease in Africa, where an estimated 50–80% die before adulthood. In a study of 413 sickle cell disease patients

from Cameroon, *APOL1* renal risk variants were significantly associated with microalbuminuria, and there was a borderline association with GFR,[93] as had been reported from the US[22,94] and Europe.[95]

Sickle Cell Trait and CKD

Sickle cell trait is associated with hyposthenuria, hematuria, and renal papillary necrosis.[96] There is contradictory evidence regarding whether sickle cell trait (Hb AS) is associated with a risk of developing CKD. Three US studies reported an increased risk of ESRD[97,98] or CKD[98,99] in people with sickle cell trait. In another study from the US, however, there was no association between sickle cell trait and diabetic or nondiabetic ESRD.[100] Studies from Africa did not show an increased risk of CKD in people with sickle cell trait. In a study of 359 people from the Democratic Republic of Congo, sickle cell trait was found in 21% of subjects with CKD and 18% of those without CKD ($p > 0.05$).[101] In an unpublished study from Ghana of 244 subjects, 17.1% of healthy controls had sickle cell trait compared with 14.0% of cases with CKD ($p = 0.24$).[102] Further studies are required to determine the risk of CKD in people with sickle cell trait.

Traditional Herbal Remedies and CKD

There are temporal associations between the use of traditional herbal remedies and the development of AKI that make a causative association plausible. In one prospective study in South Africa, 76% of 103 patients who had taken herbal remedies had renal dysfunction.[103] Although many of our patients with CKD have taken herbal remedies, it is harder to implicate these agents as a cause of CKD.[104] Most users of traditional herbal remedies do not disclose this to their medical attendants.[105] The best known example of herbal remedies causing CKD is the use of Chinese herbal remedies containing aristolochic acid, which are associated with the development of urothelial cancers. Aristolochic acid has also been implicated as the cause of Balkan endemic nephropathy.[106]

Chronic Kidney Disease of Uncertain Aetiology

Chronic kidney disease of uncertain etiology (CKDu) describes a disorder in which CKD is not due to disorders such as diabetes, hypertension, glomerulonephritis, or HIV infection. CKDu is found in tropical countries (mostly in Central America and Sri Lanka) and is more common in young men in agricultural communities working in high ambient temperatures and with exposure to agrochemicals.[107,108] There are only a few reports of CKDu from Africa. A study from El-Minya in Egypt reported that 27% of patients with ESRD had CKDu.[109] In a follow-up case control study from the same area, patients with CKDu were significantly more likely to be living in rural areas, drinking unsafe water, exposed to pesticides, and more likely to use herbal remedies and have a family history of CKD compared with controls.[110] A study from Tunisia reported an association between exposure to ochratoxin and CKD, but the kidney disease was not well characterized.[111] A study of sugarcane plantation workers in Cameroon found a low prevalence of CKD of 2.4%.[112] Further studies are required to determine the prevalence of CKDu in Africa.

Lupus Nephritis

Lupus nephritis remains an important cause of renal failure and death in Africa. Most reports come from Northern African countries. The clinical presentation and treatment differs little from that elsewhere, except most patients are likely to be treated with prednisolone and cyclophosphamide.[113]

Hepatitis B

There is high prevalence of HBV infection in Africa, averaging 8.8%.[114] The association between HBV infection and glomerular disease has been widely reported from Africa.[115] It is perhaps less widely appreciated that HBV infection is associated with a small but significant increase in the rate of CKD, with a hazard rate of 1.13 (95% CI: 1.03–1.21) in Korea.[116] However other meta-analyses have reported contradictory results, showing no association between HBV infection and CKD,[117] while another study showed an association.[118] There are no comparable studies from Africa. Appropriately designed studies would determine whether HBV infection leads to the development of CKD. The widespread HBV vaccination programmes in Africa should lead to a reduction in kidney disease from this cause.

Hepatitis C

Meta-analysis shows that HCV seropositivity is associated with an increased risk of CKD, with a hazard ratio of 1.54 (95% CI: 1.26–1.87).[119] Although the prevalence of HCV is high in parts of Africa, there are no studies to assess the effect on development of CKD.

Tuberculosis

Renal disease is an important extrapulmonary complication of tuberculosis and one that is likely to become more prominent with the increase in the prevalence of tuberculosis in Africa as a consequence of HIV infection. Tuberculosis can involve the renal parenchyma with caseating and cavitation lesions, leading in an advanced stage to autonephrectomy. The ureters and bladder are also often affected with ulcerating lesions leading to scarring and obstruction.[120] Other lesions include interstitial nephritis (sometimes with granulomatous inflammation) and renal amyloid as a

TABLE 11.6 Causes of End-Stage Renal Disease in Africa

Others	4.6		18		10.0		5.1

consequence of extrarenal tuberculosis. Coexistence of tuberculosis and interstitial nephritis with HIVAN has been reported.[44] In one study from Tanzania, a history of tuberculosis was associated with an increased risk of CKD, OR 3.75 (95% CI: 1.66–8.18; p = 0.001).[121]

Incident Renal Disease in ESRD

Because of a lack of renal registries there are few data on the prevalence, causes, and treatment of ESRD in Africa.[122] The clinical impression that ESRD is common is in keeping with reports that the proportion of medical admissions in Ghana with CKD has risen from 5% in 1999[123] to 17% in 2016.[8] In Ghana an autopsy study of 94,309 deaths reported that the mortality rate from renal disease doubled from 5.0% in 1994–2009 to 10.8% in 2010–2013.[124] The reasons for the apparent increase in the prevalence and mortality rate from renal disease are not known. The major causes of ESRD show regional differences in Africa, but in all regions the major causes of ESRD are hypertension (10–42.7%), glomerulonephritis (9–43.7%), and diabetes mellitus (3.7–15.25%)[109,125–130] (Table 11.6).

Treatment of ESRD

In SSA there is a startling gap between the estimated incidence of ESRD due to diabetes and hypertension of 239 per million population and patients receiving RRT of 1.5%.[131] A systematic review reported that 84% of patients in SSA who needed dialysis did not receive this therapy.[132] In a pooled study 96% and 95% of adults and children, respectively, who needed but could not access dialysis did not survive.[133] Of those who had dialysis, 84% of adults discontinued dialysis and died.

CONCLUSION

CKD is a leading public health problem in Africa with an estimated prevalence of 13.9%. The major causes of CKD in Africa are hypertension and diabetes, which are both increasing in prevalence. Other causes of CKD in Africa include glomerulonephritis, infections with HIV, *S. mansoni*, *S. haematobium*, and possibly HBV. In addition sickle cell anemia, which is common in SSA, increases the risk of CKD. These etiological causes of CKD occur in a population with a high prevalence of *APOL1* G1 and G2 variants, which also increase the risk of CKD. Less than 1.5% of patients projected to develop ESRD in SSA have access to RRT, meaning that most patients die untreated.

QUESTIONS AND ANSWERS

Question 1

Increased susceptibility to CKD due *APOL1* renal risk variants has been demonstrated in patients with the following disease conditions except?

A. Sickle cell disease
B. HIV-associated nephropathy
C. Diabetic nephropathy
D. Systemic lupus erythematosus
E. Hypertension-associated kidney disease

Answer: C

APOL1 variants are associated with an increased risk of HIVAN, hypertensive CKD, focal segmental glomerulosclerosis, sickle cell nephropathy, and lupus with ESRD but not with diabetic nephropathy.

Question 2

Schistosoma mansoni infection can cause all the following glomerular histological lesions except

A. Mesangioproliferative glomerulonephritis
B. Diffuse proliferative glomerulonephritis
C. Focal segmental glomerulosclerosis
D. Amyloidosis
E. Thin basement membrane disease

Answer: E

The histological glomerular lesions associated with *Schistosoma mansoni* infection are mesangioproliferative glomerulonephritis, diffuse proliferative glomerulonephritis, mesangiocapillary glomerulonephritis, focal segmental glomerulosclerosis and amyloidosis.

Question 3

Which of the following statements is true about hypertension and CKD in Africa?

A. Across the WHO regions, the highest prevalence of hypertension is found in Africa with an age-adjusted prevalence in individuals over 18 years of 27.4% (95% CI: 24.5−30.4)
B. The prevalence rates of hypertension are similar all over Africa
C. Hypertension is not a recognized risk factor of CKD in Africa
D. The prevalence of CKD in Africans with hypertension has been reported to be 5%
E. The prevalence of hypertension in Africa decreases with increasing age

Answer: A

Question 4

A 60-year-old man with HIV infection who is not treated with antiretroviral medications presented with impaired kidney function and proteinuria. The most likely cause of his renal insufficiency is:

A. Collapsing focal segmental glomerulosclerosis
B. Mesangiocapillary glomerulonephritis
C. Contrast-induced nephropathy
D. Minimal change disease
E. Urolithiasis

Answer: A

The causes of kidney disease in individuals with HIV infection include HIV-associated nephropathy, collapsing focal segmental glomerulosclerosis, HIV-associated immune complex renal disease, and kidney injury from nephrotoxicity from antiretroviral drugs. The risk of HIV-associated renal diseases is reduced in patients treated with antiretroviral drugs.

Question 5

Which of the following is false regarding Tenofovir nephrotoxicity?

A. Tenofovir alafenamide is more nephrotoxic than tenofovir disoproxyl fumarate
B. Tenofovir nephrotoxicity may present as Fanconi's syndrome
C. Tenofovir disoproxil fumarate enters proximal tubular cells through basolateral organic anion transporters and is excreted into the lumen through multidrug resistance associated protein (MRP4) but not MRP2
D. Tenofovir may cause acute kidney injury
E. Tenofovir is associated with increased risk of developing CKD although the size of this effect is unclear

Answer: A

Tenofovir disoproxyl fumarate is more nephrotoxic than tenofovir alafenamide.

Question 6

Which of the following is a risk factor for albuminuria in patients with sickle cell disease in Sub-Saharan Africa?

A. Female sex
B. High hemoglobin level
C. Sequestration crises
D. West African origin
E. Frequent blood transfusions

Answer: A

In a study of 2582 patients with sickle cell disease from four SSA countries, risk factors for albuminuria were increasing age, female sex, high lactic dehydrogenase, and low hemoglobin concentration.

CHAPTER

Ethnicity and Chronic Kidney Disease in China

Bixia Gao[a], *Jinwei Wang*[a], *Luxia Zhang*[a], *Shougang Zhuang*[b]

[a]Renal Division, Department of Medicine, Peking University First Hospital; Peking University Institute of Nephrology, Beijing, China; [b]Department of Nephrology, Shanghai East Hospital, Tongji University School of Medicine, Shanghai, China

Abstract

Chronic kidney disease (CKD) has been recognized as a major public health issue worldwide. China is the most populous country in the world, thus, the impact of CKD on public health and socioeconomics are profound both in China and worldwide. In the past decade, booming trends in diabetes, hypertension, and obesity, coupled with an aging population, will exacerbate the burden of CKD unless effective control and prevention strategies are implemented. Changes in environmental and behavioral factors, as well as reforms in health care systems, all have profound effects on the spectrum, prognosis, and treatment of patients with CKD in China. The prevalence, incidence, and spectrum of CKD, as well as the comorbidities, treatment, and prognosis of patients with CKD in China, have changed enormously.

SCOPE OF THE PROBLEM/PUBLIC HEALTH IMPLICATIONS

China is the most populous country in the world. After rapid economic growth for nearly four decades, China is now the second largest economy in the world. Abundant food supply and a sedentary lifestyle exert great influence on disease patterns among the Chinese population. The prevalence of obesity, hypertension, diabetes, metabolic syndrome, and the related cardiovascular and kidney diseases has increased greatly since China initiated its economic reforms in the late 1970s.[1] A survey conducted in 2009–2010 with a nationally representative population showed the prevalence of chronic kidney disease (CKD), in China to be 10.8%.[2] The figure is equivalent to the level of 10%–16% among other major developed and developing countries.[3] The prevalence of CKD stages in China were 5.7%, 3.4%, 1.6%, and 0.1% for stage 1 through 4, respectively.[2] The corresponding rates in Japan were 0.6%, 1.7%, 10.4%, and 0.2%, respectively,[4] and in the US were 1.8%, 3.2%, 7.7%, and 0.35%, respectively.[5] A larger proportion of patients with CKD in China were in early stages. The prevalence of hypertension and diabetes has continuously increased in recent decades in China.[6,7] It may take several years for patients with hypertension and/or diabetes to exhibit kidney disease, and they may progress to renal functional decline after decades. Hence, although the majority of patients with CKD in China are in early stages, more patients are expected to progress to late stages in the future, similar to the situation seen in developed countries.

In addition, there is a different spectrum of epidemiology of CKD between rural and urban areas and across levels of per capita GDP in China. According to the study by Zhang et al.[2] the prevalence of albuminuria was higher in rural than that in urban areas (10.1% vs. 7.0%). Conversely, the prevalence of eGFR less than 60 mL/min/1.73 m^2 was higher in urban than in rural areas (2.3% vs. 1.6%). Further stratification by per capita GDP showed different patterns in rural and urban areas. In rural areas, the prevalence of albuminuria increased through higher levels of per capita GDP, while that of eGFR less than 60 mL/min/1.73 m^2 remained stable. However, in urban areas, both the prevalence of albuminuria and eGFR less than 60 mL/min/1.73 m^2 decreased through per capita GDP levels.[2] The pattern of epidemiology of CKD in China indicates there is a unique opportunity to prevent advanced disease, given low stages accounted for the majority of patients. Lifestyle changes associated with economic growth could exert an adverse effect on the burden of CKD, as seen in rural areas of China. However, we propose that improvement in health literacy and health care access may effectively curb the epidemic of CKD, as seen in urban areas of China, where economic and social

https://doi.org/10.1016/B978-0-12-815876-0.00012-7

development is substantially superior to that in rural areas.

Routinely collected medical record data may provide a unique opportunity for estimating the disease burden of CKD according to etiology, treatment, comorbidity, mortality, and costs.[8] Based on a hospital discharge record database (Hospital Quality Monitoring System, HQMS), which covers nearly half of tertiary hospitals in China, Zhang and colleagues made a comprehensive annual report regarding CKD in China.[9] The proportion of patients with CKD varied from 3% in Shanghai to 7.2% in Guangxi (Figure 12.1). Taken together, there were nearly 1.8 million hospitalizations due to a main claim of CKD in fiscal year 2013, which accounted for only 1.6% of the total estimated number of CKD patients (10.8% of the total adult population, equivalent to 113.8 million patients with CKD). However, the average cost of 9.5 thousand yuan per each hospitalization due to CKD (a total estimate of 17.5 billion yuan) has generated a huge burden for the health care system. If the comorbidities of cardiovascular disease (CVD) were considered, the economic burden of CKD would be even higher.

In addition, the current incidence and prevalence of end-stage renal disease (ESRD) is still low in China, with an estimated incidence of 15.4 cases per million population (pmp), and an estimated prevalence of 237.3 cases pmp in 2012.[10] However, in some developed regions/countries such as Taiwan and Japan, where genetic characteristics of the population are similar to those in China, the corresponding rates were more than 10 times higher than those in China.[11,12] Patients with ESRD need costly renal replacement therapy to maintain life. Thus, the economic burden in China may be even greater if there are not effective measures to control CKD.

PATHOPHYSIOLOGY

There is currently not a nation-wide registry for kidney disease in China. To know the spectrum of CKD, we reviewed the best available evidence based on large-scale renal biopsy series and a national database for hospitalized patients, where CKD was identified through ICD codes. In an analysis of 13,519 renal

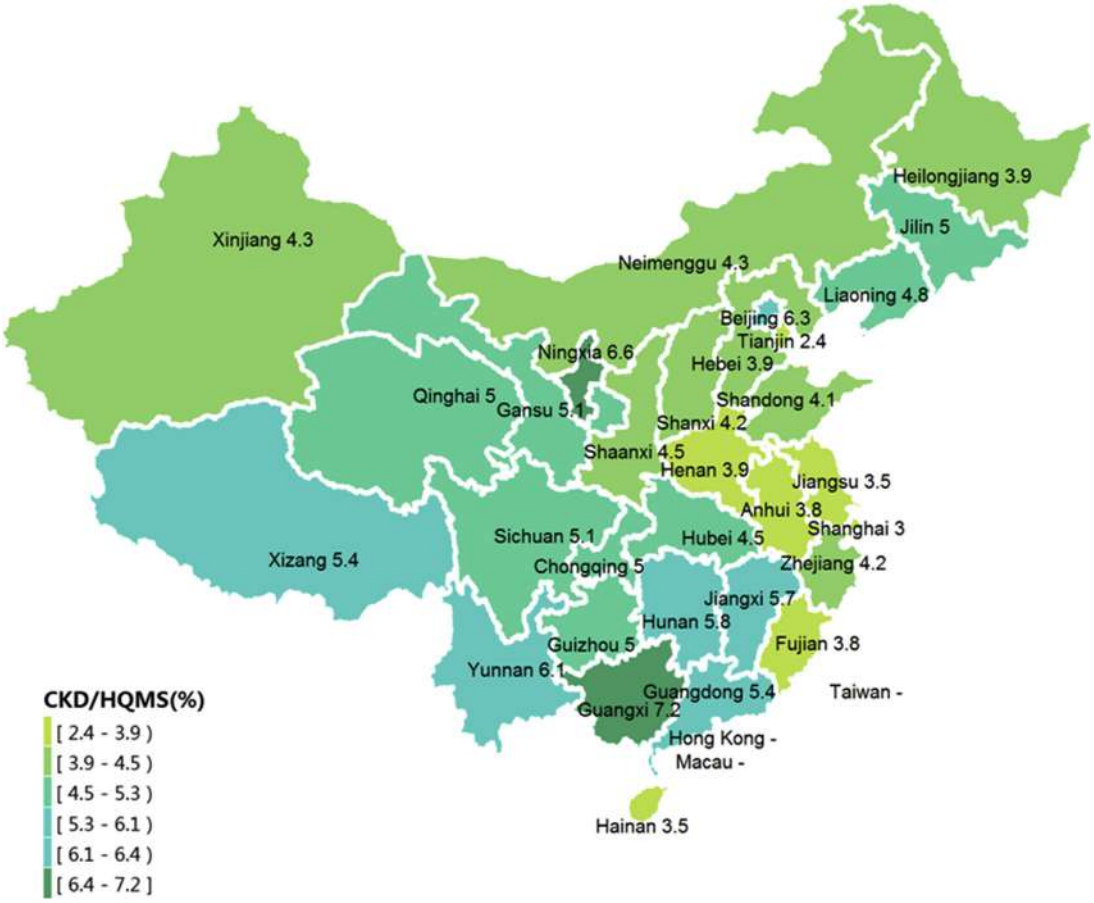

FIGURE 12.1 Geographic distribution of residence of patients with chronic kidney disease. *Adapted from Zhang L, Wang H, Long J, et al. China Kidney Disease Network (CK-NET) 2014 annual data report.* Am J Kidney Dis *2017;**69**(6S2):S1—147. Copyright (2016), with permission from Elsevier.*

biopsies accumulated from 1979 to 2002 in a central clinical center located in southeast China, Li et al. systematically evaluated pathologic types of kidney disease. Primary glomerulopathy was the most prevalent type of kidney disease, accounting for 68.6% of total cases.[13] IgA nephropathy (IgAN) was the most common type of primary glomerulopathy, accounting for 45.3% of cases. Non-IgA diffuse mesangial proliferative lesion comprised 25.6% and idiopathic membranous nephropathy (MN) 9.9% of cases.[13] The pattern was different from that reported in Western countries, where MN and minimal change disease (MCD) are typically more prevalent. Another renal biopsy series (2004–2014) of 71,151 patients conducted in 938 hospitals in 282 cities across China replicated the findings. IgAN was the most prevalent type of glomerulopathy (37.4%), while MN and MCD were also common (28.0% and 22.2% of primary glomerulopathies, respectively), similar[14] to reports in Western countries. MCD was the most prevalent type among children (20.4% in all primary and secondary glomerulopathies in the 0–14 age group). IgAN was most prevalent among young to middle-aged patients (36.0% of all primary and secondary glomerulopathies in the 15–39 age group). MN was the most prevalent type among middle-aged and elderly patients (31.9% in the 40–64 age group and 45.0% in the 65 and above age group).

Although biopsy series provide valid diagnoses for different types of kidney disease, results may be biased in reflecting the spectrum of CKD because patients undergoing renal biopsy may be more likely to have obvious clinical syndromes. In the cited nation-wide renal biopsy series, 45.4% of patients undergoing renal biopsy had nephrotic syndrome and 40.4% of patients had urinary abnormalities as indications for biopsy.[14] Thus, the burden of metabolic diseases related to kidney disease may be underestimated. For example, diabetic nephropathy only accounted for 1.7% of the total glomerulopathies, listed after lupus glomerulopathy (7.4%), purpuric glomerulopathy (3.4%), and thin basement membrane nephropathy (2.0%).[14] However, according to the annual data report of kidney disease based on HQMS in fiscal year 2013, although primary glomerulonephritis is the most common pathologic type of CKD, accounting for 17.6% of CKD, diabetic nephropathy, and CKD with hypertension occupied a prominent position compared with reports based on renal biopsies. There was nearly an equivalent proportion of primary glomerular disease attributed to diabetic nephropathy (17.4% of all CKD) and CKD related to hypertension (14.4%) (Figure 12.2).

Patients with glomerulonephritis were younger than those with diabetic nephropathy, with a median age of 48 (interquartile range [IQR]: 35–61) years vs. 63 (IQR: 53–72) years. Among the 18–44 year old group, glomerulonephritis was the most common type of CKD (23.3% in men and 19.2% in women). In the 45–64 year old group and the ≥65 year old group, diabetic nephropathy was predominant (28.0% in men and 18.4% in women in the 45–64 year group; 23.3% in men and 20.7% in women in the ≥65 year group).

There was geographical variation in the pathologic types of CKD in China. The proportion of glomerulonephritis was higher in provinces located in north China, while the proportion of obstructive nephropathy was higher in those located in south China.[9]

According to the annual data report of kidney disease, IgAN, MN, and MCD were the most common

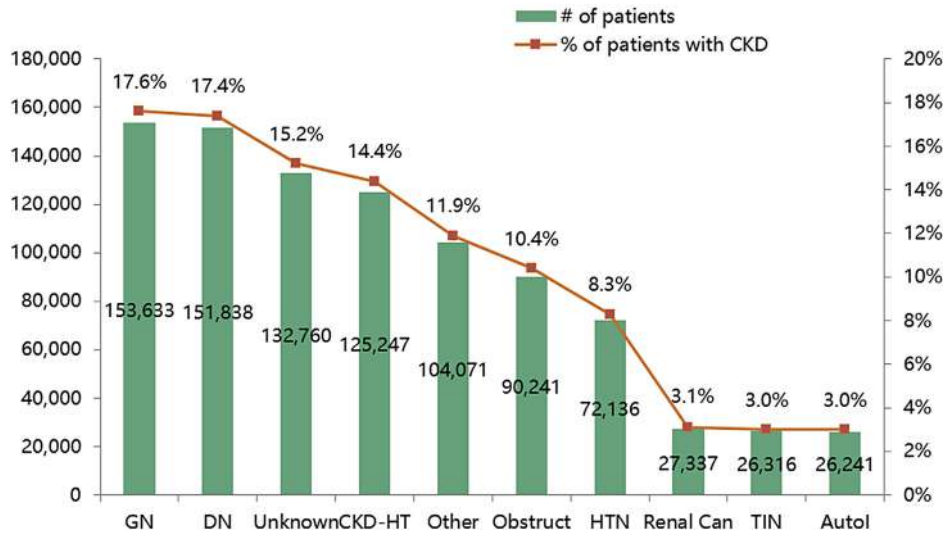

FIGURE 12.2 Patients with chronic kidney disease (CKD), stratified by cause. *Adapted from Zhang L, Wang H, Long J, et al. China Kidney Disease Network (CK-NET) 2014 annual data report.* Am J Kidney Dis *2017;**69**(6S2):S1–147. Copyright (2016), with permission from Elsevier.*

types of primary glomerulonephritis among hospitalized patients, accounting for 10.3%, 8.5%, and 1.9% of all patients, respectively, and 43.8%, 35.9%, and 8.1% of patients with pathological diagnoses, respectively.[9] The most common types were consistent with those reported in renal biopsy series.

Over time, the spectrum of primary glomerulonephritis has changed significantly in China. Li et al. conducted a study using the same HQMS data; however, they included all 0.3 million patients with primary glomerulonephritis from 2010 through 2015. They found the percentage of MN as primary glomerulonephritis doubled from 4.6% in 2010 to 8.8% in 2015, while that of IgAN decreased from 19.0% in 2010 to 10.6% in 2015. In places in north and northeast China, the proportion of MN already exceeded that of IgAN since 2014 and became the predominant type of primary glomerulonephritis (Figure 12.3). The authors also reported a disproportionate increase of the proportion of MN in urban and rural areas. In urban areas, the proportion of MN increased from 5.0% in 2010 to 11.4% in 2015, while there was only a slight increase from 6.1% to 7.4% in the same period observed in rural areas. By linking the air pollution database, they detected an association between the concentration of atmospheric particulate matter with a diameter of less than 2.5 micrometers (PM2.5) and the frequency of MN, as well as a disproportionately high frequency of MN in some minorities, especially the Zhuang, who live in south China.[15]

During the past decades, the prevalence of diabetes mellitus has increased dramatically from less than 1.0% in 1980 to 11.6% in 2010 in China.[7,16] This trend of increased prevalence of diabetes will surely exert an influence on the etiology of CKD in the future. Before Zhang and colleagues used the national database of hospitalized patients to address the problem, some findings from local disease registries demonstrated the impact of diabetes. For example, Gan and colleagues reported that the leading cause of incident ESRD has changed from chronic glomerulonephritis to diabetes since 2010 in the Beijing-based hemodialysis registry, although chronic glomerulonephritis remained the most important cause of prevalent ESRD.[17] Besides using one year data to present the epidemiologic characteristics of kidney disease, Zhang et al. used serial data from hospitalized patients from 2010 to 2015 to compare the prevalence of CKD with diabetes and glomerulonephritis in China.[18] The percentage of CKD with diabetes and that with glomerulonephritis were 0.82% and 1.01%, respectively, in 2010. However, the percentage of CKD with diabetes surpassed that of CKD with glomerulonephritis from 2011. The percentage gap between the two types continued to increase afterward. The corresponding percentages were 1.10% and 0.75%, respectively, in 2015.[18] However, the pattern in urban and rural areas was different. In urban areas, percentage of CKD with diabetes was higher than in rural areas from 2010 through 2015. In rural areas, the percentage of CKD

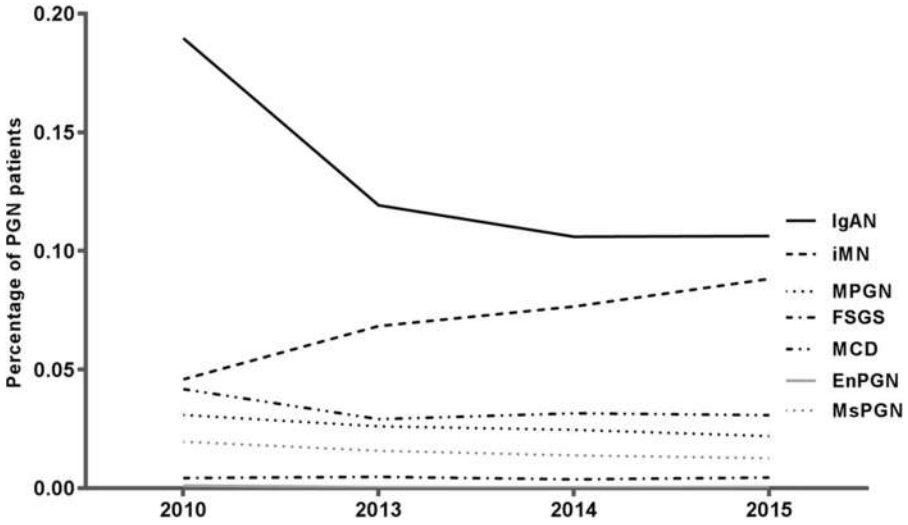

FIGURE 12.3 The changing pathology of primary glomerular disease in China. The figure shows the changing percentage of different primary pathological types among patients over time. The percentage of iMN increased almost twofold, while the percentage of IgAN decreased. *EnPGN*, endocapillary proliferative glomerulonephritis; *FSGS*, focal segmental glomerulosclerosis; *IgAN*, IgA nephropathy; *iMN*, idiopathic membranous nephropathy; *MCD*, minimal change disease; *MPGN*, membranoproliferative glomerulonephritis; *MsPGN*, non-IgA mesangioproliferative glomerulonephritis; *PGN*, Primary glomerular nephropathy. *Adapted from Li J, Cui Z, Long J, et al. Primary glomerular nephropathy among hospitalized patients in a national database in China.* Nephrol Dial Transplant, *2018. https://doi.org/10.1093/ndt/gfy022. FIGURE 12.4 Trends in CKD related to glomerulonephritis among hospitalized patients in China. The percentages shown were calculated among hospitalized patients each year. The number of hospitalized patients for each year (numbers at risk) was obtained from the Hospital Quality Monitoring System, a mandatory patient-level national database for hospital accreditation, under the authority of the National Health and Family Planning Commission of the People's Republic of China. *Adapted from Zhang L, Long J, Jiang W, et al. Trends in chronic kidney disease in China.* N Engl J Med *2016;**375**(9):905–6. Copyright (2016), with permission from Massachusetts Medical Society.*

with diabetes increased gradually but was still less than the percentage of glomerulonephritis during the same period[18] (Figure 12.4). The crossover of the etiologies of CKD among patients treated with dialysis has been observed in other countries/regions of Asia as well.[19,20]

DIAGNOSIS

Prevalence of CKD

Previous regional cross-sectional studies from economically developed cities in China, including Beijing, Shanghai, and Guangdong, reported the prevalence of CKD was 11.8%–13.0%.[21–23] However, those studies used different sampling methods, screening procedures, and diagnostic criteria. In 2012, a national survey used a multistage, stratified sampling approach to obtain a representative sample of the adult population in China.[2] In this survey, CKD was defined by the presence of eGFR lower than 60 mL/min/1.73 m^2 and/or urinary albumin:creatinine ratio higher than 30 mg/g creatinine. A total of 47,204 participants were included. The prevalence of CKD was 10.8% [95% confidence interval (CI) 10.2%–11.3%],[2] comparable to that reported in developed countries.[5] Based on the huge population of China, the number of CKD patients was estimated as up to 119.5 million. Thus, the impact of CKD on public health and socioeconomics are profound.

Despite the high prevalence, the awareness of CKD in the Chinese population is extremely low. For example, one prospective cohort study containing 462,293 adult participants in Taiwan in 1994 reported that prevalence of CKD was 11.93%, but only 3.54% of participants were aware of their disorder.[24] In 2011, another study in Taiwan enrolled 6001 subjects and reported the awareness rates were 8.0% for individuals with stage 3 CKD, 25.0% for those with stage 4 CKD, and 71.4% for those with stage 5 CKD.[25] In 2010, the national CKD survey in China revealed that the adjusted awareness rate of the predialysis CKD population was 12.5%[2] and only 38.2% in those with stages 4–5 CKD. The awareness of CKD is closely related to the management and prognosis of the CKD population, thus, educating patients with CKD to be aware of their kidney disease is a first step in CKD care in China.

Epidemiologic Characteristics of CKD

The distribution of CKD stages is different between China and the US. Individuals in China are at relatively early stage of CKD. For example, the prevalence of CKD stages 3–5 is lower in China (1.7%, 95% CI 1.5%–1.9%),[2] compared with 8.2% in the US[5] Further, the majority of participants had CKD due to albuminuria (prevalence of 9.4%)[2] compared with 5.0% in the US.[5] Previous studies reported that diabetic kidney disease (DKD) in Asian populations is more likely to present as albuminuria.

In the Microalbuminuria in Patients with Diabetes study, the prevalence of microalbuminuria and macroalbuminuria in type 2 diabetic Asian patients with 6.9 years duration of diabetes was 38% and 18%, respectively.[26] In contrast, in the United Kingdom Prospective Diabetes Study, the prevalence of microalbuminuria and macroalbuminuria 10 years after diagnosis of diabetes was 24.9% and 5.3%, respectively.[27] Ethnic differences in CKD patterns need to be further investigated.

Other issues regarding the characteristics of CKD in China are regional differences and socioeconomic disparities. The prevalence of albuminuria among rural residents is higher than those among urban residents (10.1% vs. 7.0%), especially for those from economically improving rural areas (14.8%).[2] In addition, the north and southwest have relatively higher prevalence rates of CKD, 16.9% (95% CI 15.1%–18.7%) and 18.3% (95% CI 16.4%–20.1%), respectively.[2] A cohort study in Taiwan enrolled 56,977 CKD participants and found that in those with low socioeconomic status, the prevalence of CKD was nearly three times higher than that in the high socioeconomic group (19.87% vs. 7.33%).[24] This difference was most substantial for participants with stage 3–5 disease, for whom low socioeconomic status was between four and eight times higher.[24] Reasons for this difference are not fully understood and might be due to multiple factors, including the differences in environment and behavioral factors across different regions, economic, social, or educational disadvantage, access to and uptake of care, lower achievement of treatment goals, lower screening rates, and suboptimal early treatment of complications.

Major Risk Factors of CKD

In the last decades, the lifestyle changes that accompanied the economic boom in China, as well as the surging prevalence of obesity, diabetes, and hypertension have led to a change in the spectrum of CKD in China. Despite glomerulonephritis as the leading cause of CKD and ESRD in China, DKD and hypertensive nephropathy constitute the major proportion of CKD in the elderly CKD population.[28] A recent analysis based on the HQMS dataset reported that DKD has become the leading cause of CKD in the hospitalized population.[18] Over the past two decades, the prevalence of hypertension has doubled. A nation-wide survey of hypertension in 1991 examined 950,356 residents aged ≥15 years and suggested the overall prevalence of hypertension among those residents was 11.26%.[29] Ten years later, the results of the International Collaborative Study of Cardiovascular Disease in Asia[30] suggested 27.2% of the Chinese adult population aged 35–74 years had hypertension. A more recent national survey from Wang et al.[31] reported that the prevalence of hypertension among the adult population in China was 29.6%. Using data from the China Health and Nutrition Survey, Mi et al. analyzed the trend of overweight and obesity from 1993 to 2009 in China. The prevalence of overweight (BMI 25–27.49 kg/m) increased from 8.0% to 17.1% among men and from 10.7% to 14.4% among women. The prevalence of obesity (BMI>27.5 kg/m^2) increased from 2.9% to 11.4% among men and from 5.0% to 10.1% among women. Without effective control, the increasing trend of these metabolic disorders will result in an even greater burden of CKD in the future. Thus, the primary prevention focuses on these high-risk populations and integration of surveillance of CKD in the management of the population with hypertension and diabetes at a national level should be recommended.

In addition to these metabolic risk factors, Chinese herbs containing nephrotoxic agents were identified as an important risk factor for CKD in China. A longitudinal study from Taiwan indicated that regular users of Chinese herbal medicines had a 20% increased risk of developing CKD.[24] A recent study using a national-representative sample in China indicated that long-term intake of herbs containing aristolochic acid (AA) was independently associated with eGFR <60 mL/min/1.7 m^s and albuminuria, with odds ratio of 1.83 (95% CI 1.22–2.74) and 1.39 (95% CI, 1.03–1.87), respectively.[32] Longitudinal studies from Taiwan revealed use of AA containing herbs, especially >60 g of Mu Tong or Fangchi from herbal supplements, is associated with increased risk of developing kidney failure.[33] In addition to the increased risk of developing CKD, the AA-containing herbs were found to be associated with urothelial malignancy, even several years after their discontinuation.[34] Despite the Food and Drug Administration's warnings concerning the safety of botanical remedies containing AA, these herbs are still sold *via* the Internet.

Environmental pollution–associated CKD has become an issue of global concern.[35] Hou et al. analyzed data from an 11-year (2004–2014) national renal biopsy series including 71,151 patients from 938 hospitals in 282 cities across China. During the study period, the level of PM2.5 exposure varied from 6 $\mu g/m^3$ to 114 $\mu g/m^3$ (mean 52.6 $\mu g/m^3$) among the 282 cities. The prevalence of MN increased from 12% to 24% during the decade, while the prevalence of other major glomerular diseases remained relatively stable.[14] Each 10 $\mu g/m^3$ increase in PM2.5 concentration was associated with 14% higher odds for MN (odds ratio, 1.14; 95% CI 1.10–1.18) in regions with PM2.5 concentration >70 $\mu g/m^3$.[14] Similarly, a longitudinal study of over 2 million US veterans with no previous history of kidney disease found that long-term exposure to PM2.5,

PM10, nitrogen dioxide, and carbon monoxide was associated with an increased risk of incident CKD, CKD progression, and development of ESRD.[36] The pathogenic mechanisms underlying the association between air pollution and kidney injury remain to be completely elucidated. In addition to air pollution, heavy metals polluting the drinking water and food have been considered another major threat to human health. Studies have revealed the nephrotoxicity of some heavy metals, such as mercury,[37] cadmium,[38] and lead.[38,39] China produces the largest number of major pollutants in the world, which cause serious air pollution. In addition, approximately 10% of farmland soil and 14% of grain production in China is estimated to be contaminated with heavy metals through irrigation and the use of fertilizers.[40] Thus, the management of environmental pollution in China is urgent. Further studies are needed to elucidate the causal relationships between exposure to environment pollutants and the development of kidney disease, as well as pathogenic mechanisms of environmental nephrotoxins.

PREVALENCE AND INCIDENCE OF ESRD IN CHINA

In 2010, the prevalence of CKD was 10.8%, and ESRD accounted for 0.03% of the general population in China.[2] Glomerulonephritis remained the leading cause of ESRD, followed by diabetes and hypertension. The estimated prevalence of ESRD in China is about 200–250 cases pmp.[41] The cost of treatment for a patient with ESRD in China is approximately US $13,850–$15,380 per year,[42] which puts a large economic burden on individuals and health care resources.

The Dialysis and Transplantation Registration Group of the Chinese Society of Nephrology release of an annual data report on dialysis and transplantation in China began in 2001.[43] However, the response rate of regions other than Beijing and Shanghai was lower than 50%, and the status of kidney transplantation was not mentioned in the report. Thus, the burden of ESRD in China was largely underestimated. In 2008, the Chinese Society of Blood Purification distributed a survey to each provincial Society for Blood Purification in mainland China, to collect information on dialysis facilities.[44] Among 31 provinces/regions in mainland China, 27 participated in the survey and further distributed the survey to each local dialysis facility. Based on this survey, the point prevalence of dialysis and annual incidence of treated ESRD in 2008 were estimated to be 71.9 pmp and 36.1 pmp, respectively.[44] In April 2010, with an endorsement from the Ministry of Health of China, the Chinese Society of Nephrology launched the first nation-wide, web-based, prospective renal data registration platform, the Chinese National Renal Data System (CNRDS), to collect structured demographic, clinical, and laboratory data on dialysis patients, as well as to establish a kidney disease database for researchers and policymakers.[10] According to a presentation regarding data analyses of that system at the annual conference of Chinese Society of Nephrology, the prevalence of maintenance HD in China increased substantially to 237.3 pmp in 2012, while the incidence remained stable (estimated at 15.4 pmp).

Besides these national registries, some regional registries in economically developed cities also release their local dialysis reports. For example, in 2011, the Beijing Hemodialysis Quality Control and Improvement Center (BJHDQCIC) and Shanghai Hemodialysis Quality Control Center reported that the prevalence and incidence of maintenance hemodialysis were 524.6 and 107.3 pmp in Beijing, and 544.7 and 82.9 pmp in Shanghai.[45,46] In Taiwan, the prevalence of patients with ESRD treated with dialysis reached 2584 PMP in 2010, while a rate of 1106 pmp was reported in Hong Kong.[47] The prevalence reported among these economically developed cities are substantially higher than national levels, reflecting disparities of medical resources across China.

TREATMENT AND PROGNOSIS

Use of Renin–Angiotensin–Aldosterone System Blockade

Inhibition of the renin–angiotensin–aldosterone system (RAAS) with an angiotensin-converting enzyme inhibitor (ACEI) or an angiotensin II receptor blocker (ARB) is a well-evidenced strategy for delaying the progression of CKD, particularly in those with mild to moderate renal insufficiency (serum creatinine concentration (S[Cr]) <3 mg/dL).[48,49] In China, national data on use of RAAS blockers in the CKD population are lacking. One prospective cohort in Hong Kong included 4421 type 2 diabetic outpatients between 1995 and 2000 and revealed that the percentage of use of RAAS blockers was 68.7% in stage 3 CKD participants, and 53.5% in stage 4 CKD participants.[50] In comparison, the Chronic Renal Insufficiency Cohort (CRIC) study, a national prospective CKD cohort in the US, reported that the percent use of RAAS blockers among stage 1–4 CKD patients was 74%.[51]

The renoprotective effect of RAAS blockade in advanced CKD has always be a topic of concern. A few high-quality studies have shown potential benefits of these drugs among the advanced CKD population.

One randomized, double-blind study enrolled 244 nondiabetic CKD patients with S[Cr] of 3.1−5.0 mg/dL. These patients were randomly assigned to receive 20 mg of benazepril per day (112 patients) or placebo (112 patients) and then followed up for a mean of 3.4 years.[52] Compared with placebo, benazepril was associated with a 43% reduction in the risk of the primary endpoint (defined as composite of a doubling of the S[Cr] level, ESRD, or death), independent of the control of BP.[52] The overall incidence of major adverse events (such as hyperkalemia) in the benazepril and placebo subgroups was similar.[52] Recently, a large prospective cohort in Taiwan showed that stage 5 predialysis CKD patients (S[Cr] >6 mg/dL) who received therapy with ACEIs/ARBs exhibited moderately reduced incidence of dialysis without increasing the risk of death.[53] The analysis of this study came from the NHI Research Database, which contains health care utilization data for more than 95% of the hospitals in Taiwan and 99% of the entire 23 million persons enrolled in the NHI program.[53] Overall, a total of 28,497 hypertensive adult patients with predialysis stage 5 CKD were included. 49.5% participants had at least one prescription for an ACEI/ARB. In a median follow-up of 7 months, 20,152 patients (70.7%) required long-term dialysis and 5696 (20.0%) died before progression to ESRD requiring dialysis. Use of ACEIs/ARBs was associated with a lower risk for long-term dialysis (HR, 0.94 [95% CI, 0.91−0.97]) and the composite outcome of long-term dialysis or death (0.94 [0.92−0.97]).[53]

Hypertension, Anemia, CKD-MBD, CVD, and Mortality in CKD

CKD has become an increasing public health issue. Complications of CKD include increased all-cause and cardiovascular mortality, kidney-disease progression, acute kidney injury, cognitive decline, anemia, mineral and bone disorders (MBDs), and fractures.[3] Despite it being a public health problem, studies on CKD complications are relatively limited in China. Most of the epidemiologic features of CKD complications come from regional, small sample studies. The Chinese Cohort Study of Chronic Kidney Disease (C-STRIDE) is the first national prospective CKD cohort in China, which started in 2011 with 39 clinical centers in different geographic regions of China.[54] It aims to provide a comprehensive understanding of the CKD population in China, including CKD complications and treatment, comorbidities, health resource utilization, cognitive function, and quality of life, as well as exploring associations between these factors and CKD progression and other adverse consequences. It has enrolled about 3000 Chinese predialysis CKD patients and provides data representing the Chinese CKD population.

Hypertension is a common comorbidity in patients with CKD, and it is also an important determinant of CKD development and progression. The C-STRIDE enrolled 2873 predialysis CKD participants. The prevalence of hypertension in predialysis CKD patients is 78.4%,[55] lower than that reported in the CRIC study in the US (85.7%).[51] Based on the subgroup analysis of C-STRIDE, the awareness, treatment, and control rates (defined as BP <140/90 mm Hg) of hypertension among 2251 hypertensive CKD subjects were 80.7%, 95.6%, and 57.1%, respectively,[55] worse than that reported in the CRIC study. The CRIC study reported the awareness and treatment rates of hypertension were 98.9% and 98.3% (67.1% and 46.1% had hypertension controlled to <140/90 and <130/80 mm Hg, respectively). Over 50% of study subjects were prescribed two or more antihypertensive medications. Only 7% were prescribed diuretics.[55] Compared with another national survey between 2004 and 2005, despite minimal change in the awareness of hypertension in the CKD population, the treatment and control rates significantly improved (95.6% vs. 85.9% and 57.1% vs. 30.0%, respectively) over the past decades.[6]

Anemia is another frequent complication in patients with advanced CKD, and it is associated with poor quality of life, impaired cognition, and increased all-cause mortality.[56] A multicenter survey of 2420 predialysis patients with CKD from 25 hospitals in Shanghai reported that the prevalence of anemia was 51.5%. Prevalence increased with advancing CKD stage (from 22.4% in CKD stage 1%−90.2% in CKD stage 5).[57] The overall awareness and treatment rates were 67.5% and 44.9%, respectively. Further, 22.7% patients initiated treatment of anemia when hemoglobin (Hb) was less than 7 g/dL. The target-achieving rate (Hb at 11−12 g/dL) was only 8.2%. Among patients receiving dialysis, the target-achieving rate was also significantly worse in China than in developed countries. Results of the Dialysis Outcomes and Practice Patterns Study[58] reported the status of anemia in 11,041 HD patients from 12 countries. The target-achieving rate was 73% in the US, but only 21.3% in China.[59]

MBD in patients with CKD is associated with increased morbidity and mortality. However, MBD is suboptimal among Chinese CKD patients. In the C-STRIDE, the proportions of predialysis CKD patients with hyperphosphatemia were 2.6%, 2.9%, 6.8%, and 27.1% in CKD Stages 3a, 3b, 4, and 5, respectively. Moreover, 71.6% of patients with hyperphosphatemia did not receive any phosphate binder.[60] Another cross-sectional study of 2074 dialysis patients from 28 hospitals in China (1711 HD and 363 peritoneal dialysis [PD]) revealed that only 38.5%, 39.6%, and 26.6% of

participants were within the optimal level of S[P], corrected S[Ca], and iPTH recommended by the Kidney Disease Outcomes Quality Initiative (K/DOQI) guideline. In comparison, results from the DOPPS reported that percentages of optimal S[P], S[Ca], and iPTH were 49.8%, 50.4%, and 31.4%, respectively.[61]

CKD entails excess risk of CVD and mortality, even at early stages. One large prospective cohort in Taiwan enrolled 56,977 CKD individuals and followed them for a median duration of 7.5 years. 5987 CKD died. Participants with CKD had 83% higher risk of all-cause mortality (HR 1·83 [1·73–1·93]) than those without.[24] Another prospective study of 4421 type 2 diabetic patients revealed that all-cause mortality rate increased from 1.2% (95% CI 0.8–1.7) to 18.3% (9.1–27.5) as renal function deteriorated from stage 1 (eGFR 90 mL/min/1.73 m^2) to stage 4 (15–29 mL/min/1.73 m^2). Despite limited data being available about CVD burden in individuals with CKD in China, a few studies provide some useful information. Among 3168 CKD stage 1–4 participants in C-STRIDE, the prevalence of CVD was 9.8%, much higher than the overall percentage of 1.4% in the general Chinese population.[62] Cerebrovascular disease was most common subtype, accounting for 69.1% of CVD population, followed by myocardial infarction (20.6%) and congestive heart failure (9.0%).[62] Using HQMS data, the pattern of CVDS is quite different from outpatients with CKD in the C-STRIDE. In hospitalized CKD patients the prevalence of CVD (defined by ICD-10 coding) was 27.8% in 2014. Coronary heart disease was most common, followed by congestive heart failure and stroke.

Treatment and Prognosis of Dialysis Patients

For the past decades, the Chinese government has paid increasing attention to the treatment available for patients with ESRD, as uremia is one of eight major serious diseases covered by National Social Medical Insurance. Recently, with the advancement of health care system reforms in China, basic medical insurance now covers 95% of urban and rural residents, and a high-reimbursement policy for catastrophic diseases including ESRD has been established. Despite this, there are still disparities between ESRD care in China and Western countries.

Due to limited medical and economic resources, particularly in the countryside and remote areas, the proportion of individuals with ESRD who are treated with dialysis in China is only about 20%.[63] Both national registries reported the majority of Chinese ESRD patients received HD, accounting for 89.5% in 1999 and 89.1% in 2012, respectively.[43] In Shanghai in 2012,[45] 77.5% of patients receiving dialysis therapy were on HD, slightly lower than national levels. HD in China still faces many challenges. Almost all HD centers are located at hospitals in urban areas. The development of HD services in various regions remains uneven. Dialysis equipment, as well as the professional skills of medical staff, needs to be improved in remote and rural locations. Currently, more than 90% of dialysis equipment and 80% of HD consumables in China are imported. Accelerating the research and development of blood purification products in China is crucial to reducing the cost of dialysis and providing treatment to more Chinese ERSRD patients. According to the annual data report from BJHDQCIC, the annual mortality rate was approximately 7.0%–9.2% from 2007 to 2013. This was lower than that reported by USRDS, which was approximately 15%. In 2009, the mortality rate for prevalent White, African American, and Asian American maintenance HD patients in the US and for Chinese HD patients in mainland China was 236.3, 156.7, 147.9, and 77.3 per 1000 patient-years, respectively.[64] The annual mortality rate was decreasing in the US but was increasing in mainland China. The low mortality rate in mainland China might be partly attributed to the fact that all dialysis facilities were hospital-based and doctors were always present during hemodialysis sessions, or to factors related to patient selection.

Compared with HD, PD has minimal requirements for equipment support and electricity, which is important for patients in rural and remote areas. The annual cost of PD is comparatively lower than hemodialysis ($15,034 US dollars vs. $16,625 US dollars for hemodialysis).[47] PD has grown at a rate of 30% annually recently,[63] but most of the centers are located in big cities. Currently, approximately 1024 hospitals offer PD to more than 40,000 ESRD patients throughout the nation, accounting for 20% of the total patients with ESRD receiving dialysis in China. However, 90% of PD solutions used in China are imported. Therefore, to increase the affordability and accessibility to renal replacement therapy (especially for patients in rural areas), the Chinese government is planning to support the local manufacture of PD solutions. However, lack of training, education, and quality control systems for PD in rural or remote areas are still major constraints to the diffusion of treatment. Renji Hospital in Shanghai reported patient survival rates at 1, 2, 3, and 5 years of 90%, 79%, 71%, and 64% (similar to the results of Canadian PD centers) death censored technique survival rates of 97%, 93%, 90%, and 88%, respectively; and incidence of peritonitis of 0.198 per patient-year.[65]

Kidney transplantation is one alternative choice for patients with ESRD. Kidney transplantation began in

China in the 1960s. Since September 1, 2013, it became mandatory to allocate organs through the China Organ Transplant Response System (COTRS), a national open and transparent organ allocation computer system. Recently, the Work Group of CK-NET provided information about the kidney transplantation waiting list using a dataset from the China COTRS.[9] From September 1, 2013, through August 31, 2014, there were 19,354 candidates on the waiting list, with male preponderance (67.8%). Nearly two-thirds of candidates were of age 18–45 years. Altogether, 4285 candidates were removed from the waiting list during the time period. Of these, 90.1% received a kidney transplant. The median waiting time was 10.3 (interquartile range, 4.7–17.2) months.[9]

CONCLUSIONS

CKD is an important public health issue with escalating affects on the health care system in China. The management of CKD and its complications in China is currently suboptimal. Despite the majority of the CKD population in China being at relatively early stages, the industrialization and urbanization, and the increase in metabolic disorders could result in a greater burden of CKD in the near future. More research on Chinese CKD is needed to promote the best quality health outcomes. Prevention, treatment, and control strategies should be developed and implemented according to local levels of economic development and resources.

QUESTIONS AND ANSWERS

Question 1

Which of the following describes the current prevalence of CKD among the general population in China?

A. <5%
B. 5%–9.9%
C. 10%–14.9%
D. 15%–19.9%
E. ≥20%

Answer: C

According to the latest national survey of CKD conducted in China, the prevalence of CKD among adults in China is 10.8%.[2]

Question 2

Which of the following choices correctly describe the epidemiology of CKD in China?

A. Reduced eGFR (<60 mL/min/1.73 m^2) accounted for the majority of prevalence of CKD
B. Albuminuria accounted for the majority of prevalence of CKD
C. Both prevalence of eGFR <60 mL/min/1.73 m^2 and albuminuria were higher in rural than in urban areas
D. Both prevalence of eGFR <60 mL/min/1.73 m^2 and albuminuria were higher in urban than in rural areas
E. Prevalence of eGFR <60 mL/min/1.73 m^2 was higher in urban than in rural, while prevalence of albuminuria was higher in rural than in urban

Answers: B and E

According to the latest conducted national survey of CKD in China, prevalence of CKD stratified by stage was 5.7% for stage 1, 3.4% for stage 2, 1.6% for stage 3, and 0.1% for stage 4. Albuminuria without an eGFR <60 mL/min/1.73 m^2 accounted for the majority of patients. In addition, the prevalence of albuminuria was higher in rural than in urban areas (10.1% vs. 7.0%). Conversely, the prevalence of eGFR <60 mL/min/1.73 m^2 was higher in urban than in rural areas (2.3% vs. 1.6%).[2]

Question 3

What are the top three major subtypes of primary glomerular nephropathy in China according to the latest evidence from both renal biopsy registry and hospital databases?

A. IgAN
B. Idiopathic membranous nephropathy
C. Membranoproliferative glomerulonephritis
D. Focal segmental glomerulosclerosis
E. MCD

Answers: A, B, and E

According to both the nation-wide renal biopsy registry and the database for hospitalized patients, IgAN, idiopathic membranous nephropathy, and MCD are the top three major primary glomerulopathies in China.[14,15] The proportion of IgAN has decreased through the years but is still the leading cause of primary glomerulopathy. The proportion of idiopathic membranous nephropathy has increased through the years (Figure 12.3).

Question 4

Which of the following statements best describe the change in causes of CKD and ESRD in China recently?

A. Glomerulonephritis is increasing, and diabetes is decreasing
B. Glomerulonephritis is decreasing, whereas diabetes is increasing
C. Both glomerulonephritis and diabetes are increasing
D. The current pattern for causes of CKD is different in rural and urban areas of China

Answer: B and D

Explanations: The percentage of CKD due to diabetes and that due to glomerulonephritis was 0.82% and 1.01%, respectively, in 2010. However, the percentage of CKD due to diabetes surpassed that of CKD due to glomerulonephritis since 2011. The current pattern for causes of CKD is different in rural and urban areas of China.

Question 5

Which of the following is not true regarding CKD in China?

A. Compared with the US, individuals in China are at relatively early stages of CKD
B. Individuals of low socioeconomic status present with higher risk of developing CKD
C. Long-term intake of herbs containing aristolochic acid is independently associated with CKD and urothelial malignancy
D. Environmental pollution–associated CKD has become an issue of global concern, especially in China
E. CKD complications are well controlled in China

Answer: E

Answers A through D are true. Complications of CKD include increased all-cause and cardiovascular mortality, kidney-disease progression, acute kidney

injury, cognitive decline, anemia, mineral and bone disorders, and fractures. Both national and regional studies indicate the management of CKD and its complications are suboptimal.

Question 6

Which of the following is not true regarding the ESRD population in China?

A. The proportion of individuals with ESRD who are treated with dialysis in China is about 20%
B. Hemodialysis is the major treatment modality of ESRD in China
C. Currently, greater than 90% of dialysis equipment and 80% of HD consumables in China are imported
D. Kidney transplantation is the major renal replacement therapy for patients with ESRD in China
E. In China, the annual cost of peritoneal dialysis is comparatively lower than that of hemodialysis

Answer: D

The proportion of individuals with ESRD who are treated with dialysis in China is about 20%. Both national registries indicate the majority of patients receive HD. Currently, greater than 90% of dialysis equipment and 80% of HD consumables in China are imported. Compared with HD, PD has the advantage of minimal requirements for equipment support and electricity. Furthermore, the annual cost of peritoneal dialysis is comparatively lower than hemodialysis ($15,034 US dollars vs. $16,625 US dollars).

CHAPTER

13

Poverty and Chronic Kidney Disease

Jenna M. Norton, Paul Eggers

National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD, United States

Abstract

Once considered diseases of affluence, many chronic conditions—including chronic kidney disease (CKD)—are now recognized as diseases of social disadvantage. Risk for CKD and end-stage renal disease (ESRD) is increased among individuals of low socioeconomic status. This increased risk is mediated by negative social determinants of health—such as poor access to healthy foods, unsafe communities, poor health literacy and numeracy, limited access to transportation, lack of paid sick leave, lack of health insurance, poor housing quality and stability and limited social support, among others. These negative social determinants create barriers to health-promoting lifestyles and behaviors, reduce access to healthcare, increase risk for environmental exposures, elevate stress and allostatic load, and contribute to harmful developmental programming and epigenetic changes. These mechanisms contribute to poor kidney outcomes directly and indirectly, through increased risk of causal (e.g. diabetes, hypertension, HIV) and complicating (e.g. depression) diseases.

SCOPE OF THE PROBLEM AND PUBLIC HEALTH IMPLICATIONS

Chronic diseases were once widely considered "diseases of affluence," an unfortunate side effect of lifestyles enabled by the wealth of Western societies. Evidence generated in recent decades suggests the opposite: many chronic diseases are in fact diseases of poverty and social disadvantage. In the early 1980s, the seminal Whitehall study demonstrated that mortality from coronary heart disease was elevated in those with low compared to high employment grade among 17,530 male civil servants in London tracked over 10 years.[1] Since then, disparities along socioeconomic lines have been identified in several chronic diseases.[2]

Chronic kidney disease (CKD) is no exception. Recent systematic reviews demonstrate significant associations between low socioeconomic status (SES), defined in different ways, and increased incidence and prevalence of CKD and end-stage renal disease (ESRD). A 2015 review and meta-analysis of 35 studies, including more than 3.6 million participants and 800,000 cases of CKD, found low SES is associated with prevalence of CKD—defined by presence of either reduced estimated glomerular filtration rate (eGFR), elevated urine albumin levels, or both—and incidence of ESRD.[3] A 2018 review and meta-analysis of 43 studies across multiple countries found incidence and progression of CKD were each associated with lower income, occupation level, and overall SES but not with lower education, while elevated prevalence of CKD was associated with lower income, education, and overall SES but not with occupation.[4] The effect of income on CKD prevalence was greater in the US compared to Europe, Asia, and Latin America,[4] which may reflect differences across these regions in social programs, insurance systems, health care practice, cultures, lifestyles, or other potentially moderating factors.

Associations between area poverty and negative kidney outcomes have been mixed, perhaps due to differences in the size of the areas studied and the resulting differences in variability of wealth and resources within those areas, as well as the so-called "ecological fallacy," the attribution to individuals of characteristics found at group levels. In an analysis of 23,314 Reasons for Geographic and Racial Differences in Stroke (REGARDS) participants, incidence of ESRD was not associated with county level poverty after adjusting for age, sex, race, education, and income.[5] County level assessment may, however, have masked within county variation in wealth. In 4735 Cardiovascular Health Study participants aged 65 and older, living in a census tract within the lowest, compared to highest, SES quartile was associated with 50% greater risk of progressive CKD over four years, after adjusting for age, gender, study site, baseline serum creatinine concentration

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00013-9

(S[Cr]), lifestyle risk factors, diabetes, hypertension, and individual SES,[6] suggesting community poverty may increase risk independently from individual poverty.

Additionally, in an analysis of linked US Renal Data System (USRDS) and Census data for nearly 1.4 million incident ESRD patients, those living in a high poverty zip code had a 23% higher incidence of ESRD compared to patients in low poverty zip codes, after adjustment for age, sex, race/ethnicity, and time period.[7] In 14,086 individuals from the ARIC study with baseline eGFR >60 mL/min/1.73 m^2, higher zip code level deprivation was associated with increased incidence of both CKD and ESRD in a dose–response manner, after adjusting for age, sex, race, and baseline eGFR. The association was attenuated but remained significant for incident ESRD (but not CKD) after adjusting for smoking status, alcohol intake, physical activity, BMI, hypertension, diabetes, total cholesterol, HDL cholesterol, and lipid-lowering medication use, suggesting that these factors may be on the causal pathway for both CKD and ESRD, but that—at least for ESRD—these factors do not fully explain the association.[8] Higher area level deprivation was also associated with faster rates of eGFR decline in crude, covariate-, and fully adjusted models.[8]

Mortality is also elevated in individuals with CKD of low compared to high SES. In a prospective analysis of 2761 participants with CKD from the REGARDS study, participants with baseline income of less than $20,000 a year had a higher hazard of all-cause mortality than those with higher incomes.[9] Living in a higher, vs. lower, income area was associated with increased survival among 589,036 ESRD patients in an analysis of merged USRDS and Census data.[10] Among 1794 incident dialysis recipients in an Irish tertiary center, those from the lowest SES quartile based on a spatial index of deprivation had lower survival compared to those in the highest quartile after adjusting for age, gender, and dialysis modality.[11] In 10,392 White ESRD patients from the UK Renal Registry, living in an area of high social deprivation (measured by area unemployment, home and car ownership, and overcrowding) was associated with poorer survival after adjustment for age, gender, and cause of renal failure.[12]

Inequities in wealth along racial and ethnic lines likely interact with biologic and clinical factors, contributing to racial disparities in CKD.[13] Compared to White Americans, ESRD incidence in 2015 was 8.4 times higher among Native Hawaiians/Pacific Islanders, 3.0 times greater in Black Americans, and 1.2 times greater in American Indians/Alaska Natives.[14] Compared to non-Hispanic Americans, incidence of ESRD in 2015 was 1.3 times greater for Hispanic Americans.[14] In analyses of data of 11,027 ESRD patients from the USRDS and Census, Black ESRD patients residing in low-SES neighborhoods had greater mortality than their White counterparts, after adjusting for baseline demographics, clinical characteristics, rural residence, and access to care factors, but the disparity was significantly attenuated in higher SES neighborhoods—suggesting poverty accounts for some, but not all, of the disparity between Black and White patients.[15] Similar conclusions were reached in an analysis of a 5% Medicare random sample including nearly 1.2 million patients with and without CKD, which found the higher sex-and-age–adjusted mortality in Black compared to White beneficiaries was fully attenuated when controlling for "buy-in" status—a proxy for poverty—suggesting the greater mortality in Black compared to White beneficiaries is accounted for by the greater poverty in Black compared to White beneficiaries.[16]

POTENTIAL MECHANISMS OF POOR KIDNEY OUTCOMES DUE TO POVERTY—SOCIAL DETERMINANTS OF HEALTH

Two models of the interplay between contextual factors and health outcomes may help to conceptualize the mechanisms of poor kidney outcomes due to poverty.[17,18] First, McLeroy's adaptation of the social ecological model to health promotion[19] (Figure 13.1) facilitates a comprehensive perspective of the potential mechanisms along the pathway from poverty to poor kidney outcomes, providing a framework to consider factors across public policy, community, organizational, interpersonal and individual domains. More importantly, this model reminds us that individual health factors are not independent of the other domains but rather are subject to the interpersonal, organizational, community, and public policy context in which a given individual exists. For example, behaviors relating to physical activity may depend on an individual's interest in physical activity, the patterns of physical activity among that individual's social circles, the presence or absence of wellness policies at the person's workplace, and the availability of sidewalks in her or his community, which in turn depend on local infrastructure policies.

Second, the World Health Organization defines these contextual factors—the "conditions in which people are born, grow, live, work, and age"[20]—as the social determinants of health. Poverty contributes to a complex set of negative social determinants that combine and interact with clinical and biological factors, producing poor health outcomes, including CKD.[13] Social determinants of health may include availability of safe places for physical activity, housing quality and safety, access to grocery stores or other sources of healthful food, level of support from social networks, availability of paid leave for seeking medical care, health insurance coverage status, access to transportation, proximity to health care centers, and health literacy level, among

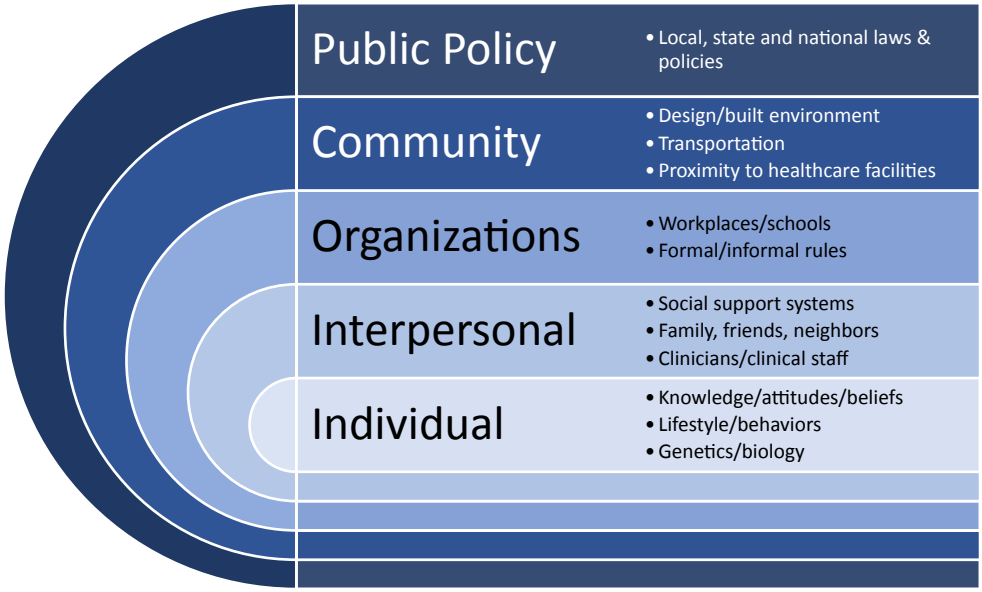

FIGURE 13.1 **Social ecological model of health promotion.** McLeroy's Social Ecological Model of Health Promotion provides a framework to consider the influence of interacting factors across public policy, community, organizational, interpersonal, and individual domains on health outcomes and behaviors. *Source: McLeroy et al. (1988).*

other factors. These social determinants act as facilitators or barriers that affect each individual's ability to engage in health-promoting behaviors and activities, likelihood of exposure to disease-causing pollutants, and level of stress and capacity for coping with stressors (Figure 13.2). In addition, social determinants may have lifelong or even multigenerational effects, through processes of developmental programming or by engendering epigenetic changes. In turn, poor health contributes to job loss and loss of insurance in a vicious cycle of poverty and disease (Figure 13.3).

Poverty, Clinical Risk Factors, and Complications

The increased prevalence of the two leading causes of ESRD—diabetes and hypertension—in low SES groups is well known.[21,22] Research suggests that socioeconomic disparities in these conditions contribute to similar disparities in CKD. Indeed, controlling for diabetes and hypertension attenuated the association between SES and CKD in an analysis of 5,799 participants who had valid S[Cr] values in the Health Survey for England, a random, nationally representative study.[23] Similarly, an analysis by Vart et al. of potentially modifiable factors mediating the relationship between SES and CKD in 9,823 NHANES participants found comorbid factors, including diabetes, hypertension, obesity, and hypercholesterolemia, accounted for 32% of the SES–CKD association.[24] The association between area deprivation and poorer survival in ESRD patients from the UK Renal Registry was attenuated after adjusting for baseline comorbidity, including vascular disease, smoking,

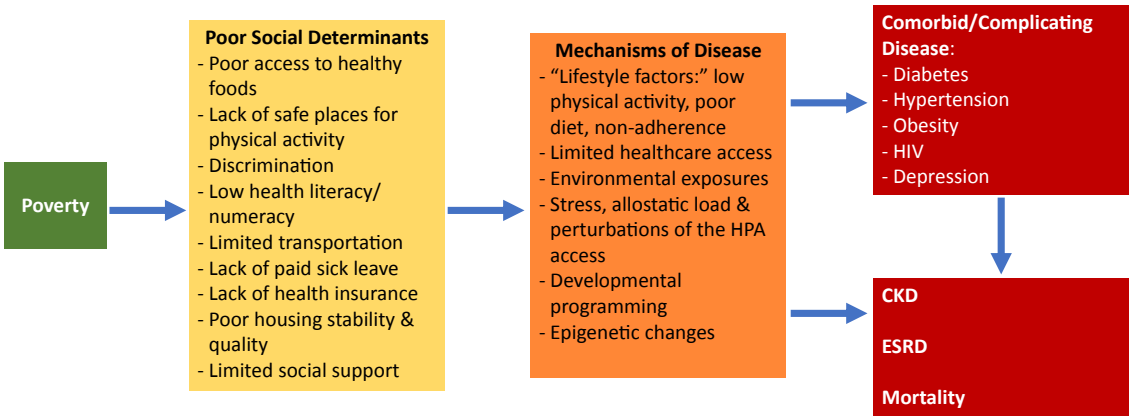

FIGURE 13.2 **Pathway from poverty to poor kidney outcomes: a conceptual model.** Poverty contributes to a cadre of negative social determinants of health, which act as barriers to healthy lifestyles and behaviors, reduce health care access, increase environmental exposures, elevate stress and allostatic load, and contribute to harmful developmental programming and epigenetic changes. Such mechanisms of disease contribute to poor kidney outcomes directly and indirectly, through increased risk of causal comorbid and complicating diseases.

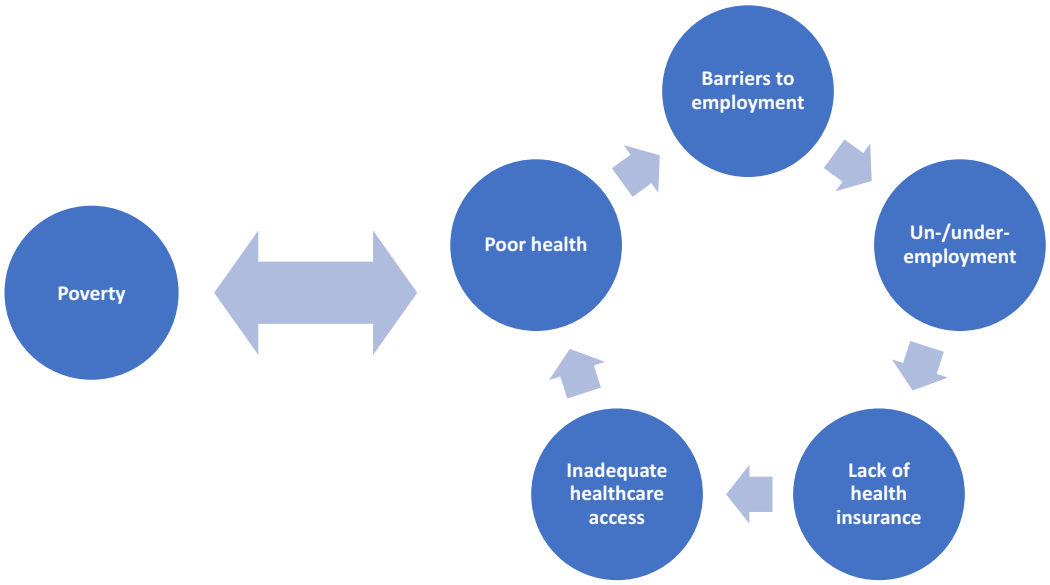

FIGURE 13.3 **The cycle of poverty, disease, and job loss.** Poverty increases risk for poor health, which creates barriers to acquiring and maintaining employment and leads to under- or unemployment. Without full time employment, many individuals lose health insurance, resulting in inadequate access to healthcare, which exacerbates poor health and poverty.

malignancy, COPD, diabetes, and liver disease, suggesting these conditions may be on the causal pathway between disadvantage and mortality in ESRD.[12]

Poverty appears to also raise the likelihood of complications in both CKD and ESRD patients. In a 2016 systematic review of 58 studies assessing cardiovascular outcomes in 8.9 million people with prevalent CKD or ESRD from 10 countries, low education and income were associated with increased cardiovascular events and all-cause mortality.[17] Similarly, an analysis of 9270 adults with moderate to severe CKD from the Study of Heart and Renal Protection randomized controlled trial found increased risk of poor vascular outcomes with decreasing education level, and two-fold higher all-cause mortality in participants with no formal education compared to those with a tertiary education.[18]

Comorbidities associated with poverty in CKD extend beyond cardiovascular diseases. In NHANES participants with CKD, prevalence of disability was higher for those with low (compared to high) income and education.[25] In a cohort study of 2171 peritoneal dialysis (PD) patients from 7 US dialysis centers, high-income patients had a significantly lower risk of peritonitis than low-income patients, after matching for age, hemoglobin, albumin, PD center, and regional SES, though no association was found for education.[26] A large study of 2032 PD patients recruited from 114 dialysis centers in Brazil, however, did demonstrate an association between low education and peritonitis in PD patients.[27] Low education levels have also been associated with increased likelihood of graft failure in kidney transplant recipients.[28]

Depression is a less well studied, but potentially contributing factor to disparities in kidney outcomes along lines of wealth and poverty. Rates of depression are elevated among those with lower SES, both in the general and in CKD populations. A 2003 meta-analysis of 56 studies on SES and depression concluded that prevalence of depression is increased in low-SES groups.[29] A 2018 systematic review and meta-analysis of 12 studies showed greater risk of depression in populations with higher- vs. lower-income inequality, with several studies reporting greater impacts in low-income populations.[30] In a sample of 2500 NHANES participants with CKD, depression was more likely in those with less than high school education compared to those who graduated high school, and in those with an annual income less than $20,000/year compared to those with incomes at or above $20,00/year.[31]

Depression might exacerbate kidney outcomes by modifying immunologic and stress responses, decreasing nutritional status, and creating a barrier for adherence to medical regimens and self-management practices.[32] In a nationally representative prospective cohort of 933,211 US Veterans with diabetes, depression—ascertained by ICD-9 code or prescription of antidepressant medication—was associated with a 20% increased risk of incident CKD and a 25% increased risk of all-cause mortality.[33] However, several cross-sectional studies have shown no association between depression and the prevalence of CKD.[34–37] A systematic review of 22 prospective studies comprising 12,063

cases of depression in CKD (including nondialysis dependent, dialysis, and transplant patients) found that depression consistently was associated with increased risk of all-cause death in people with CKD to a greater degree than in the general population.[38] Since this review, the association has been replicated in additional populations.[39–43] Depression among people with CKD has also been associated with incidence of ESRD,[44] increased morbidity,[45] and more frequent hospitalizations.[46]

Lifestyle and CKD in the Context of Poverty

Negative health behaviors—such as poor diet, low physical activity, smoking, and drug and alcohol abuse—are generally more common among low-income groups. These factors likely contribute to the pathway from poverty to CKD. In the Vart et al. analysis of factors mediating the relationship between SES and CKD among NHANES participants, health behaviors—including physical activity, smoking, and alcohol intake—accounted for 20% of the SES–CKD association. Neither fruit and vegetable intake, nor sedentary time was found to mediate the relationship.[24] Yet, in a cross-sectional study of 2058 community-dwelling adults in Baltimore, poor adherence to Dietary Approaches to Stop Hypertension nutrient intake targets was associated with prevalence of CKD among individuals with low, but not high, SES,[47] suggesting dietary patterns may have greater impact on CKD for individuals living in poverty.

However, targeting such behaviors as a root, rather than intermediary, cause of disease in low-income groups is likely an ineffective strategy. As McLeroy cautions with regard to health promotion activities that emphasize individuals' behaviors, "…use of terms like 'lifestyle' and 'health behavior' may focus attention on changing individuals, rather than changing the social and physical environment which serves to maintain and reinforce unhealthy behaviors".[19] The community in which an individual lives determines to a great degree the health behavior promoting resources she or he can access. Compared to high-income areas, low-income communities have fewer walkable areas, safe places for physical activity, and sources of healthy food,[48–52] but a higher density of fast food restaurants and convenience stores.[53]

Resources that enable healthy food choices are particularly relevant in CKD, given the complexity of dietary recommendations for the disease.[54] Low availability of fresh fruits and vegetables in high-poverty areas may contribute to increased acid load, which has been associated with reduced eGFR,[55] increased albuminuria,[55] and progression of CKD to ESRD.[56] Among adults in the NHANES sample, those living in a food desert—compared to those not living in a food desert—had lower levels of serum carotenoids—a biomarker of fruit and vegetable intake—and higher systolic blood pressure, though not higher odds of CKD.[57] In a cross-sectional analysis of 9126 NHANES participants, lack of reliable access to sufficient amounts of affordable, nutritious foods—or "food insecurity"—was associated with greater odds of CKD for individuals with hypertension or diabetes.[58] In a separate study of 1486 NHANES participants with low income and CKD, food insecurity was associated with an increased incidence of ESRD, identified through the USRDS, over a median of 14.2 years.[59]

Phosphate content of food is another potential factor on the pathway from poverty to CKD. High serum phosphate (S[P]) levels are associated with mortality in individuals with CKD,[60] yet manufacturers are not currently required to list phosphate content on food labels, and therefore, consumables may contain undisclosed amounts of phosphorus.[61] This may pose a particular challenge for individuals in high-poverty areas, where processed foods—which are often high in phosphate content—are widely available. The Chronic Renal Insufficiency Cohort Study participants with the lowest incomes had higher S[P] than participants with the highest incomes.[62]

Poverty and Capacity to Access and Engage in Health Care

Poverty generates numerous barriers to accessing health care. In a systematic review of 24 studies in the nondialysis CKD population and 34 studies in the ESRD population, including 8.9 million participants from 10 countries, dialysis recipients with low education, no health insurance, low occupational level, or no home ownership were significantly less likely to access cardiovascular health care. People with non–dialysis-dependent CKD with low health insurance and no home ownership were significantly less likely to access cardiovascular and nephrology health services than their more advantaged counterparts.[17] It is perhaps not surprising then that adult kidney transplantation recipients, identified through the Scientific Registry of Transplant Recipients, who received insurance through Medicaid were listed with more severe organ failure and shorter transplant wait times and had lower post-transplantation survival compared to privately insured individuals.[63] An analysis of USRDS data for 669,206 hemodialysis patients who initiated treatment between 2007 and 2012, those with dual eligibility for Medicare and Medicaid—a proxy measure for poverty—were significantly less likely to initiate dialysis with an arteriovenous fistula, the preferred method of vascular access in dialysis, suggesting delayed access to

nephrology care.[64] Similarly, in a retrospective cohort of more than 700,000 dialysis patients, dual Medicare/Medicaid eligibility, higher area poverty by zip code, Black race, and Hispanic ethnicity were each associated with lower likelihood of pre-ESRD nephrology care in adjusted models.[65]

Reduced health insurance coverage is a widely recognized barrier to health care access, with well documented consequences. In 903 NHANES participants aged 18–64 with albuminuria, lack of insurance and coverage through public insurance were each associated with increased all-cause mortality compared to having private insurance.[66] Among 86,588 participants of the Kidney Early Evaluation Program, lack of health insurance was associated with increased risk of ESRD incidence and death, after adjusting for age, race, ethnicity, education level, and smoking status.[67]

Although health insurance coverage is often used as a proxy for health care access, an individual's ability to access health care must be considered from a broader perspective. Andersen's Behavioral Model of Health Services Use posits that health care access is a function of individual and contextual factors that predispose (e.g. demographics, education, community composition, cultural norms), enable (e.g. income, insurance status, transportation access, proximity to care), and generate real or perceived need for (e.g. functional status, or injuries related to occupation or crime) an individual to use health care.[68,69] Andersen's model ensures a comprehensive view of health care access, encouraging looking beyond health insurance for potential barriers that may limit access to care, including costs of care after coverage, limited transportation to and from medical appointments, lack of paid leave from work or child care, poor health literacy or numeracy, and limited availability of social support systems.

A diverse sample of publicly insured adults enrolled in Minnesota Health Care Programs reported barriers to care despite insurance coverage, which included inability to cover cost, transportation problems, incompatible clinic hours, and lack of child care.[70] Similar barriers—including transportation difficulties, economic challenges, and lack of time off from work—were cited by predominantly low income, African American "safety net" CKD patients receiving primary care at two facilities in Buffalo, NY.[71] In addition, studies in the United Kingdom, Denmark, and Australia found that low SES is associated with CKD prevalence, incidence of ESRD, and reduced dialysis survival despite availability of universal health care coverage—suggesting presence of health insurance alone is not sufficient to mitigate the effects of poverty on CKD.[12,23,72–75] Further, in the Medicare population, low income is associated with lower use of services—despite equal insurance coverage.[76]

Health literacy and health numeracy are defined, respectively, as the degree to which individuals have the capacity to "obtain, process, and understand basic information and services"[77] and "access, process, interpret, communicate, and act on numerical, quantitative, biostatistical, and probabilistic health information".[78] Both are necessary to make effective health decisions and are major contributors to an individual's ability to access and use health care resources. Poor health literacy is more common among individuals who have limited education, lack insurance, or are insured through Medicaid or Medicare, compared to their high education or privately insured counterparts.[79] Poor health literacy and numeracy, along with the related lack of plain language information on CKD, have been cited as major barriers to successful patient education and self-management.[80]

Poor health literacy is associated with lower levels of CKD knowledge,[81] reduced kidney function,[82,83] poor self-management capacity,[84] and lower rates of kidney transplantation.[85] In individuals with ESRD, low health literacy increases risk for poor blood pressure control,[86] reduced self-management ability,[87,88] more frequent hospitalizations,[88] and greater mortality risk.[89] In incident dialysis, incident transplant, and transplant wait-listed patients in the United Kingdom, poor health literacy was associated with low SES, and patients with low health literacy were less likely to be placed on the transplantation waiting list or to receive preemptive or live donor transplantation.[90] Limited health numeracy has been associated with similar barriers to kidney transplantation. In a prospective cohort of 187 late-stage CKD or ESRD patients, higher health numeracy was significantly associated with receipt of a transplant or active waiting list status.[91]

Poverty may also represent a barrier to accessing health information *via* digital channels. In a study of more than 2,000 individuals seen in four nephrology clinics affiliated with an academic medical center, electronic health record (EHR) portal users were more likely to be non-Black, to be married, to have private insurance, and to have higher neighborhood median household income.[92] Such disparities in access to health data may contribute to disparities in outcomes by posing a barrier to self-management.

The association of poverty with smaller, less-robust social support systems may also interfere with ability to access and engage in health care. In a cross-sectional analysis of 410 African American and Hispanic/Latina women in Texas, neighborhood disadvantage—measured by six indices including low-wage jobs, joblessness, percent of professionals and managers, percent high school graduates, female headed households, and poverty—was associated with reduced peer social support.[93] In a cross-sectional analysis of a cohort

of 4814 middle-aged, urban-dwelling adults in Germany, low (vs. higher) income and education were each associated with poor social support.[94]

Social support—which includes emotional (e.g. empathy), informational (e.g. advice), and instrumental (e.g. transportation to health appointments) support from family, friends, neighbors, community members, and health care providers, among others—may facilitate access to health care and engagement in self-management through monetary support, transportation, advice on how and where to access care, reinforcement of positive health behaviors, and company at medical appointments. A lack of social support was associated with delaying needed medical care, after adjusting for demographics, SES, comorbidities and access to care, among 18,980 Minnesota and Tennessee residents in a cross-sectional analysis of data from the Behavioral Risk Factor Surveillance System.[95] A higher level of social support was associated with improved self-management in a cross-sectional sample of 410 patients with various stages of CKD drawn from nephrology clinics in Taiwan.[84] In dialysis recipients, higher levels of social support are associated with improved dietary, fluid[96] and medication[97] adherence and self-management.[98] A systematic review of 37 studies on factors associated with nonadherence in kidney transplant recipients concluded low social support was associated with poorer adherence.[99]

Social support may be particularly instrumental in management of depression in kidney disease, as it appears to buffer against the disease. Depression is more likely with lower levels of social support in patients with ESRD[100,101] and is more likely in transplant recipients with perceptions of negative social support.[102] Social support also mediated the relationship between depression and quality of life in ESRD patients.[103]

Level of social support appears to be a major determinant of negative health outcomes—though the mechanisms of this association likely extend beyond health care access and engagement to include elevated perception of quality of life,[104,105] improved immune function,[106] and increased ability to cope with stress.[32,107] In a prospective cohort study of 6916 middle-aged adults with nonalbuminuric diabetes followed for 5.5 years, small social network size was associated with incident CKD and mortality,[108] with a population-attributable fraction of 6.28% for mortality.[109] In a cross-sectional study of 382 adults with CKD in Sri Lanka, low social support—defined as support from less than 13 people—and poor satisfaction with social support were each associated with psychological distress.[110] In dialysis recipients, lower levels of social support have been associated with increased hospitalizations,[104,111] elevated mortality,[112,113] reduced patient satisfaction,[104] and poorer psychological[114] and general well-being.[115]

Stress and Allostatic Load

Increased stress has been widely theorized as a mechanism through which poverty increases risk of developing poor health outcomes. Poverty and associated negative social determinants may impede allostasis—the ability to maintain physiologic homeostasis in response to physical and psychological demands of stress through appropriately matched physiologic responses in the endocrine, cardiovascular, metabolic, immune, and autonomic systems.[116] In addition these factors may increase allostatic load—repeated stress responses or heightened and/or sustained activity of systems to maintain allostasis resulting from (1) frequent stress, (2) inability to adapt to repeated stress, (3) inability to shut off stress response, and (4) an unbalance allostatic response requiring compensatory responses from other systems.[117,118] Elevated stress and allostatic load may lead to increased sympathetic nervous system activity, perturbations of the hypothalamic–pituitary–adrenal axis, and altered inflammatory cytokine and endothelin-A levels, which might affect outcomes, related to kidney disease.[32]

In addition, stress may contribute to poor health outcomes by increasing risk for negative health behaviors. In a cross-sectional study of 1010 socioeconomically disadvantaged patients attending a publicly funded sexually transmitted disease clinic, an association between low SES and poor health was mediated by perceived stress, and perceived stress fully accounted for a relationship between SES and health-compromising behaviors, suggesting a causal pathway from low SES to stress to health-compromising behavior to poor perceived health.[119]

A 2009 systematic review of 26 studies assessing the relationship between SES and markers of stress or allostatic load in various populations identified inconsistent findings regarding the relationship between SES and stress, concluding that existing evidence of an association was weak.[120] Inconsistent findings may be due to variation in methods and timing for measurement of stress (e.g. biomarkers vs. self-report, weekday vs. weekend assessments, diurnal vs. life-course variation) and SES (e.g. income vs. education vs. occupation) or differences in study populations.[120]

However, since that 2009 review, the body of evidence has greatly expanded. In 1693 individuals from a cross-sectional substudy of the Midlife in the US Study (MIDUS), individuals with only high school education or who were non-White were more likely to have less healthy, or "flatter" cortisol rhythms measured at four

time points over four days, compared to college graduates and White individuals, respectively.[121] A cross-sectional substudy of more than 900 participants from the Multi-Ethnic Study of Atherosclerosis (MESA), which included a racially and ethnically diverse cohort of adults without cardiovascular disease at baseline, found higher income–wealth index score, but not education, was consistently associated with lower cortisol, epinephrine, norepinephrine, and dopamine after adjustment for age, gender, race/ethnicity, medications, education, psychosocial factors, BMI, smoking, and alcohol use.[122] The association was modified by race, with a greater level of effect for non-Hispanic Black compared to non-Hispanic White and Hispanic Americans.[122]

A longitudinal analysis of 6135 participants from the MESA examining the relationship between childhood and adult SES—measured by parental and adult education level, respectively—and a composite measure of allostatic load based on metabolic and cardiovascular variables found high adult education was associated with slower progression of allostatic load, but the relationship was only significant for those with lower baseline allostatic load, suggesting the association may vary with accumulation of risk.[123] In a prospective study of 3080 young adults followed since birth through the Cebu Longitudinal Health and Nutrition Survey, lower SES—measured by income, education and assets—was associated with less healthy cortisol profiles. The association was greater with chronically low SES and as compared to low SES during individual time periods.[124] A prospective, community-based study of 999 adults in Scotland found lower social class over the 20-year study period was associated with elevated levels of a composite measure of allostatic load, based on cardiovascular, metabolic, and inflammatory markers at final follow up. The association was attenuated only partly—by 24%—when adjusting for health-damaging behaviors, including smoking, alcohol consumption, diet, and physical activity.[125]

Stress may pose a particular problem in individuals with CKD, where downregulation of the stress response may be impeded due to reduced ability to clear and metabolize stress hormones by the kidneys, leading to a heightened or prolonged stress response consistent with elevated allostatic load.[32] In adults with CKD, stress has been associated with reduced quality of life,[126] which is in turn associated with poor outcomes in kidney disease.[127] Increasing serum cortisol levels have been associated with decreasing eGFR and increasing creatinine and cystatin C in people with CKD[128,129]; however, due to the cross-sectional nature of these studies, one cannot determine whether stress contributes to decrements in GFR, worsening CKD leads to increased stress, or both. A randomized, nonblinded trial of mindfulness-based stress reduction in people with diabetes and albuminuria showed decreased UACR and blood pressure in the intervention vs. control group at one year. Differences, however, were not detected at 2- and 3-year follow up.[130]

Environmental Exposures and CKD

Greater risk of exposure to environmental contaminants may be one mechanism of increased risk for kidney damage in individuals living in high-poverty areas. Relative to their high-income counterparts, low-income communities have more toxic waste sites,[131] poorer air quality,[132,133] elevated crime rates,[134] and poorer quality of housing, including contamination with lead, molds, and other toxins.[135] Growing evidence demonstrates an association between development of CKD and low-level environmental exposure to lead, cadmium, and mercury, and such exposures are hypothesized to contribute to the epidemic of CKD of unknown origin affecting low-income agricultural communities in India, Egypt, and Latin America.[136,137]

Developmental Programming

Developmental programming, defined in the *Prenatal Antecedents of Chronic Kidney Disease* chapter of this text as "the ability of the normal developing organism to undergo durable changes in response to environmental conditions without changes in DNA sequence," may contribute to the increased risk of poor renal outcomes seen among those living in poverty. Maternal–fetal undernutrition (MFUN), maternal–fetal energy excess (MFEE), and maternal–fetal psychosocial stress (MFPS) may result in a mismatch between kidney capacity and excretory demand by altering epigenetic regulation of gene expression, resulting in low nephron number and changing postnatal energy homeostasis contributing to increased growth and excretory load. MFUN, MFEE, and MFPS may also increase risk for diabetes and hypertension in offspring, which may interact with stress placed on the kidney by nephron number: body mass mismatch, thereby further increasing risk for kidney disease.

These key drivers of developmental programming—MFUN, MFEE, and MFPS—and resulting perturbations in birth weight appear to occur at disproportionate rates among women living in poverty, in part as a result of higher rates of food insecurity, diabetes, obesity, and stress among low-SES women. Developmental programming was first recognized as a result of severe socioeconomic disparities driven by the Industrial Revolution in England and Wales and the resulting elevated rates of coronary death in later life.[138] An analysis of data on 37,620 singleton births from nationally representative

data sets across the US, the United Kingdom, Canada, and Australia showed a graded association between income quintile and low birth weights of less than 2500 grams, with stronger associations in the US where social support systems are relatively sparse.[139] In a study of 1498 women with gestational diabetes, maternal psychosocial vulnerability—measured by material goods, money, friend/family networks, health care, and leisure—was associated with delivery of infants who were large for gestational age (LGA).[140] In a longitudinal pregnancy cohort study of 2068 maternal–infant pairs from Alberta, Canada, serial mediation analysis suggested that lower neighborhood SES is associated with higher prepregnancy BMI, and in turn, increased risk of macrosomia and LGA.[141]

Clinical Considerations

Individuals of low SES may receive lower quality care than their higher-income counterparts, particularly with regard to access to transplantation. Data from numerous studies show that kidney failure patients with low income, less education, unemployment or underemployment are less likely to be placed on the transplantation waiting list, less likely to receive a kidney transplant, and more likely to receive an expanded criteria donor kidney compared to their higher SES peers.[142–147] In all but one[146] of these studies, the association remained despite controlling for potential confounders, including demographic and clinical factors that may influence clinical decisions for advancing the kidney transplantation process, insurance status, which may influence overall access to care, and transplantation center.

One possible explanation for these disparities is implicit or unconscious biases that may influence clinician decisions regarding course of care. In contrast to conscious biases, these implicit biases often influence behavior without knowledge or awareness of the existence of these biases. Studies using implicit association tests in clinicians including medical students, registered nurses, and surgeons suggest some clinicians experience unconscious preference for people of higher SES and White race; however, studies assessing potential effects of such associations on provision of care have shown variable findings.[148–150] These mixed findings may result from differences in the context under which decisions are made, as research suggests implicit biases are more likely to affect decision-making in situations of high stress and time pressure.[151] Those interested in assessing implicit biases regarding race, ethnicity, gender, and other factors may consult publicly available implicit association tests, such as the ones available through Harvard's Project Implicit: https://implicit.harvard.edu/implicit/iatdetails.html.

System-wide clinical interventions implemented within the Indian Health Service may provide a model for provision of high-quality CKD care in disadvantaged communities. These interventions, which were based on Wagner's Chronic Care Model[152] and included interdisciplinary approaches to care, routine eGFR reporting, yearly urine albumin monitoring, use of renin–angiotensin aldosterone system blockers, blood pressure control, and patient and provider education, have been associated with a 54% decrease in age-adjusted incidence of ESRD from diabetes in Native Americans, despite the high rates of poverty and low availability of resources in this population.[153] "Treating the adjacent neighborhood as a patient" through community partnerships that target negative social determinants of health may provide additional pathways for improving poverty-related health outcomes.[154]

Individual clinicians may improve their clinical care by considering their patients from a broad perspective that includes both clinical and contextual factors, such as poverty and the social determinants of health. Clinicians and their patients may benefit from remaining alert to the health risks of poverty. A study of community-dwelling adults in the Netherlands suggested screening for CKD in individuals with low SES may be more beneficial than screening among the elderly.[155] In addition, poverty and associated negative social determinants may act as barriers to engaging in health care and self-management. Therefore, patient counseling and education must be conducted in context of such potential barriers. For example, dietary counseling of patients must be conducted with recognition of the environmental barriers to accessing healthy foods and maintaining dietary recommendations for CKD.[54] The American College of Physicians recently acknowledged the role of social determinants in health and called for efforts to properly educate and equip clinicians with the requisite knowledge and skills to appropriately screen for, identify, and manage social determinants of health.[156] Such care, informed by broad contextual factors, may be facilitated by numerous ongoing efforts to better incorporate data on social determinants of health into the EHR.

CONCLUSION

Major disparities exist in both CKD and ESRD along socioeconomic lines. Poverty lies at the base of an interconnected web of negative social determinants of health that appear to interact with biological and clinical factors to increase risk for poor kidney health outcomes. While system level changes are needed to fully address the role of poverty in poor health, individual clinicians may improve the care they provide by considering patients from a broad perspective that incorporates contextual, as well as clinical, factors.

QUESTIONS AND ANSWERS

Question 1

Which of the following is not a kidney-related outcome associated with poverty?

A. Increased incidence and prevalence of CKD
B. Increased incidence and prevalence of ESRD
C. Racial/ethnic disparities in CKD and ESRD
D. Increased risk of polycystic kidney disease
E. Increased mortality in CKD

Answer: D

Increased risk of polycystic kidney disease is genetically determined. Poverty has strong associations with risk of CKD (Answer choice A), risk of ESRD (Answer choice B), racial and ethnic disparities in CKD and ESRD (Answer choice C), and increased mortality in CKD (Answer choice E).

Question 2

Which of the following is not one of the five domains of McLeroy's Social Ecological Model of Health Promotion?

A. Public policy
B. Community
C. Organizational
D. Interpersonal
E. Biological

Answer: E

Answer choices A through D are all domains within McLeroy's Social Ecological Model of Health Promotion. Biological factors are a single element within the "individual" domain of the model.

Question 3

A patient with CKD presents to the clinic with uncontrolled hypertension, despite prescriptions for lisinopril (20 mg daily) and furosemide (20 mg daily). What is the best first course of action to address the uncontrolled blood pressure in this patient?

A. Increase the dose of lisinopril
B. Increase the dose of furosemide
C. Add an additional hypertensive medication
D. Determine if the patient is following the prescription regimen. If not discuss contextual barriers that may be interfering with the patient's ability to take their antihypertensive medications
E. Refer the patient for dietary counseling regarding sodium intake

Answer: D

Before making changes to the patient's treatment plan (Answer choices A through C and E), it is important to ensure that barriers to adherence do not prevent the patient from adhering to the existing medication regimen.

Question 4

Which of the following is not a potential mediator on the pathway from poverty to poor kidney outcomes?

A. Larger social support networks
B. Negative social determinants of health
C. Increased risk for harmful developmental programming
D. Reduced access to and engagement in health care
E. Barriers to engaging in health-promoting behaviors

Answer: A

Poverty is associated with smaller and less robust social support networks, which in turn increases risk for poor health outcomes through reduced emotional, informational, and instrumental support. Evidence suggests that negative social determinants of health, increased risk for harmful developmental programming, reduced access to and engagement in health care, and barriers to engaging in health-promoting behaviors (Answer choices D through E) all mediate the poverty-poor kidney outcomes relationship.

Question 5

What mechanisms may explain associations between stress and poor kidney outcomes?

A. Altered inflammatory cytokine and endothelin-A levels, increased risk for negative health behaviors, and maternal–fetal undernutrition
B. Increased allostatic load, elevated sympathetic nervous system activity, and perturbations of the hypothalamic–pituitary–adrenal axis
C. Increased allostatic load, elevated sympathetic nervous system activity, and a mismatch between nephron number and body mass
D. Increased risk for negative health behaviors, elevated sympathetic nervous system activity, and reduced access to health care
E. Altered inflammatory cytokine and endothelin-A levels, reduced ability to renally clear and metabolize stress hormones in people with CKD and maternal–fetal overnutrition

Answer: B

Maternal fetal undernutrition (Answer choice A), mismatch between nephron number and body mass (Answer choice C), and maternal–fetal overnutrition (Answer choice E) all relate to developmental

programming of kidney disease. Reduced access to health care (Answer choice D) is associated with poor kidney health outcomes, but stress does not appear to lead to reduced health care access.

Question 6

How might a broad perspective of health—including understanding the roles of clinical and contextual factors in health—improve the provision of health care?

A. By enabling clinicians to work with patients to identify and resolve barriers that may prevent patients from achieving optimal health.
B. By encouraging clinicians to recognize and address potential implicit biases that may influence how they provide care, particularly during high stress or high-pressure time periods.
C. By promoting collaborative, interdisciplinary care across clinical and community settings.
D. By encouraging health care institutions to address neighborhood-wide social determinants of health in addition to individual clinical issues.
E. All of the above.

Answer: E

Among individual clinicians, an understanding of how poverty and social determinants may influence the patient's health as well as their individual implicit biases regarding a patient may help clinicians address all factors affecting the patient's health in an unbiased manner. At the institutional level, recognition of the role of contextual factors in health outcomes may enable population health strategies that target the whole patient through interdisciplinary community collaboration.

Abstract

Uremia is the syndrome attributable to kidney failure. The causes of many of the most prominent signs and symptoms of uremia are poorly understood. Current dialysis therapy mitigates many but not all of these disabilities. The persistent illness with standard care probably derives at least in part from the failure of dialysis to replace normal kidney functions. Dialysis is particularly deficient in removing certain classes of molecules that are well cleared by the normal kidneys. These include small proteins, protein-bound solutes, intracellular sequestered compounds, and those which undergo high rates of active secretion by the normal tubule. The sources of these retained solutes are varied but include diet, enhanced production from human metabolism, and retention of metabolites originating from gut microbes. Recent approaches have begun to identify toxic compounds by epidemiologic studies and animal and cellular experiments, but clinical trials to more specifically remove or reduce production of candidate toxins are still wanting.

INTRODUCTION

Uremia is the syndrome caused by kidney failure. The term has been usually applied to the terminal phase of progressive chronic kidney disease (CKD), the condition now termed end-stage renal disease (ESRD). Modern ESRD treatment can maintain the inorganic solutes/electrolytes within normal ranges and thus interdict previously lethal aspects of uremia such as hyperkalemia and acidosis. The classic symptoms of uremia not attributable to electrolyte disorders are listed in Table 14.1. Those marked by an asterisk are substantially mitigated by current therapy including dialysis itself. Only a few, marked by two asterisks, are essentially completely abrogated by present approaches. Many, those without asterisks, are either only modestly improved or unaided. However, the pathophysiologic bases of even those features that can be remedied are poorly understood. For example, anemia is successfully treated with erythropoietin analogs, but the causes of the shortened red cell life span in uremia remain unknown, and dialysis does not correct this abnormality. Furthermore, the apparent toxicity associated with normalization of hemoglobin by erythropoietin is still obscure. Hypertension is usually improved by careful removal of excess extracellular fluid through ultrafiltration, but many patients still remain hypertensive despite best efforts at fluid management. Full blown uremia such as seen before the advent of dialysis or transplantation is now a rarity, at least in affluent countries. Thus, presently uremia may be defined as the illness which remains when the extracellular volume and inorganic ion concentrations are kept normal and the known renal synthetic products (e.g. erythropoietin) are replaced in patients without kidney function. Contemporary ESRD treatment still leaves patients with substantial morbidity.

SIGNS AND SYMPTOMS OF UREMIA

That a fundamental metabolic disturbance such as uremia should have such a wide variety of consequences is not remarkable. The complications of untreated diabetes or hyperthyroidism are similarly extensive. But uremia is different in that we cannot trace all its complications to dysregulation of a single key compound. In addition, except for renal transplantation, current therapy for uremia cannot return affected patients as close to normal as those who require thyroid hormone or insulin replacement.

The level of renal function at which uremia can be said to appear is unclear. There is no easily definable point in the fall of glomerular filtration rate (GFR) when uremia supervenes. Furthermore, the diminution

of renal functions other than solute clearance also likely contributes to the symptoms and signs of uremia. In general, these other functions such as ammoniagenesis, erythropoietin, and 1,25-dihydroxy vitamin D synthesis, urinary concentrating capacity, and tubular secretion tend to decline in parallel with GFR, but not always. Nevertheless, defining the level of kidney function solely by GFR may be misleading. For example, certain potentially toxic solutes depend more on tubular secretion than glomerular filtration for their excretion, and renal synthetic processes are probably linked to GFR only by virtue of the loss of functioning renal tissue. However, until particular renal dysfunctions are attached to specific aspects of the uremic syndrome, GFR (or its estimate) will remain the principal index of kidney function.

Most of the clinical and biochemical characteristics of uremia have been defined in ESRD or at a level of GFR very near to ESRD. Thus, uremic characteristics may be hard to dissect from complications of the dialysis procedure. Other morbidities that are considered separate from the uremia also commonly interact with it. For example, the cardiovascular disease suffered especially by patients with diabetes and hypertension appears to be accelerated by CKD.[1] But the myocardial infarctions, strokes, and peripheral vascular disease suffered by these patients have not traditionally been considered features of the uremic syndrome. These conditions nevertheless add to patients' disabilities in ways that are often not easily distinguishable from uremia or the "residual syndrome" of ESRD. Similarly, the peripheral neuropathy and gastroparesis of diabetes are difficult to disentangle from uremic neuropathy and uremic anorexia, nausea, and vomiting.

Well-Being and Physical Function

Given the spectrum of signs and symptoms in Table 14.1, it is not surprising that health-related quality of life (HRQOL) tends to decline in patients with CKD. Patients with CKD consistently score poorly on HRQOL and other measures of well-being.[2] The point in the course of CKD at which quality of life begins to decline has not been dissected in great detail but some data exist. The authors of the KDOQI guidelines concluded that notable reductions in well-being appeared when GFR was less than 60 mL/min.[3] For example, participants in the Modification of Diet in Renal Disease Study with GFRs between 25 and 55 mL/min/1.73 m^2 were queried with several survey instruments and reported fatigue and reduced stamina that correlated with GFR.[4] In another study using the Medical Outcomes Study Short Form 36, persons with GFR less than 50 mL/min/1.73 m^2 but not yet treated with dialysis (or transplantation) scored significantly lower than the general population in 8 of the 10 scales comprising the instrument.[5] Interestingly, this study did not detect a correlation between HRQOL scores and GFR over the range examined, but did detect a correlation between hemoglobin and HRQOL.[5] As with other aspects of uremia, it is difficult to distinguish the effects of treatment on HRQOL from those of uremia *per se*. Dialysis undoubtedly imposes a burden on patients. Comparisons of HRQOL in patients treated with dialysis and patients with advanced CKD who are not on dialysis have yielded discordant results.[5–8] Other, often neglected features of treatment, such as pill burden, may also contribute to reduction in the perception of quality of life.[9] Patients with ESRD are on average

more depressed than healthy controls. But it is difficult to distinguish the extent to which depression is caused by uremic solutes, compared with the effects of comorbid disease and the knowledge of ill health and limited life expectancy. Patients identify insomnia, fatigue, cramping, and dysphoria as chief among their burdens[10] Not surprisingly, transplantation has rather consistently been found to improve perception of quality of life.[2]

Physical functioning in patients treated with dialysis is decidedly below normal. The exercise capacity of patients treated with dialysis has been found to be about 50% of normal, with a range of 40–80%.[11] Treatment of anemia improves this situation but does not normalize it.[11,12] The most detailed studies have identified multiple defects that are associated with fatiguability.[13] These include both muscle energetic failure and neural defects. The degree to which they are attributable to the uremic environment itself, deconditioning, and/or comorbid conditions such as diabetes mellitus is difficult to establish. Even highly functional patients on dialysis display notable physical limitations. Blake and O'Meara[14] reported that middle-aged dialysis patients with good nutrition and no significant comorbidities exhibit a wide range of quantifiable deficiencies. For example, balance, walking speed, and sensory function in these patients were clearly below those of matched controls.

Neurologic Function

A particularly interesting group of uremic signs and systems reflect altered nerve function. Classic descriptions emphasized that uremic patients could appear alert despite defects in memory, planning, and attention.[15,16] As kidney function worsened, patients progressed to coma or catatonia which could be relieved by dialysis. Modern patients maintained on dialysis exhibit more subtle cognitive defects.[17] A difficulty in identifying the effects of uremia in these patients is that the hemodialysis procedure and/or associated factors (e.g. hypotension) may transiently impair cognitive function.[18] Studies in patients with CKD suggest that cognitive impairment can be detected when GFR falls below 60 mL/min/1.73 m^2 and worsens as GFR declines.[19–21] As with other signs and symptoms of uremia, the degree to which cognition is influenced by uremia as opposed to other comorbidities, especially cerebrovascular disease, is difficult to ascertain. The population studies cited above have identified cognitive impairment in CKD independent of clinically recognized vascular disease and other comorbidities. Imaging studies suggest that subclinical cerebrovascular disease is common in CKD patients and that its role in poor cognition needs further definition.[17,22,23] The finding that kidney transplantation improves cognitive function suggests, however, that at least some of the impairment observed in ESRD patients is due to solute accumulation.[24]

A further reflection of altered central nervous system function in uremia is impaired sleep.[25,26] Sleep disorders are common in ESRD patients and are associated with patients' perceptions of quality of life, as well as depressive affect.[27] Sleep is fragmented by brief arousals and apneic episodes which are often associated with bursts of repetitive leg movement. When awake, patients may feel a need to continuously move their legs, referred to as the restless legs syndrome.[28]

Sensorimotor neuropathy was a recognized component of the uremic syndrome decades ago.[15] Studies of conduction velocity and other nerve functions have since repeatedly found that the majority of patients with uremia have peripheral neuropathy, albeit often subclinical.[16,29,30] Morphologic studies have shown that these functional changes are associated with axonal loss.[30] The extent to which peripheral nerve function is impaired earlier in the course of CKD is not clear. Autonomic neuropathy also develops in ESRD patients but has been less extensively studied than peripheral neuropathy. As with other uremic disturbances the cause of neuropathy is unknown. Parathyroid hormone, multiple retention solutes, and more recently potassium have been associated with peripheral neuropathy but without definitive proof of causality.[16,29]

Appetite, Taste, and Smell

Loss of appetite is a common uremic symptom and presumably contributes to malnutrition in patients with advanced CKD. A large number of causes have been proposed. Acidosis and inflammatory cytokines including tumor necrosis factor (TNF) and various interleukins have been identified as contributing factors.[31] Attention has recently been focused on the accumulation of small proteins that are produced by the gut and adipose tissue and act on the brain to regulate appetite in normal people.[32,33] Levels of leptin, an anorexigen produced by adipose tissue, are elevated in ESRD. Levels of ghrelin, an orexigen produced by the gut, are also elevated, but data showing increased food intake with administration of exogenous ghrelin in ESRD patients suggest the uremia causes ghrelin resistance.[34]

Studies in partially nephrectomized mice have begun to dissect the cerebral mechanisms by which these hormonal changes reduce appetite and contribute to loss of body mass in uremia.[33,35] An interesting feature of uremic anorexia which remains to be explained is a disproportionate reduction in the intake of protein. Along with overall loss of appetite, erosion of taste and smell has long been recognized in the ESRD

population.[36,37] As with most defects associated with uremia, transplantation reverses the blunted sense of smell.[36] Some studies have reported that odor threshold declines gradually with creatinine clearance, whereas others have found that even in dialysis patients odor detection remains normal unless malnutrition is present.[36,38,39] Taste acuity has been reported as lower in dialysis patients than in those with renal insufficiency.[40] The factors responsible for these defects are again unknown. However, a pilot study suggested that intranasal theophylline increased odor identification in patients with ESRD.[39]

Cellular Functions

The most general cellular abnormality reported has been the inhibition of sodium-potassium ATPase (Na-K ATPase). Decreased Na-K ATPase activity in red cells of uremic patients was reported in 1964.[41] In general, subsequent reports have confirmed the observation, noted the same effect in other cell types, emphasizing that the inhibition was attributable to some factor in uremic serum.[42] The evidence for a circulating inhibitor includes the findings that dialysis reduces the inhibitory activity and uremic plasma can acutely suppress pump activity.[42] However, the factor or factors responsible have remained elusive. A number of candidates have been considered. Much attention has focused on digitalis-like substances. Recently, several such compounds have been found in excess in humans with ESRD. These include marinobufagenin and telocinobufagin, which have structures related to digitalis. In one report, the plasma concentrations of each of these substances was four- to fivefold higher in patients treated with dialysis compared with normal controls.[43] This study employed detailed mass spectrometry and nuclear magnetic resonance identification of the compounds with their concentrations determined by high-performance liquid chromatography. Many other investigations in the field have relied on antibody-based assays whose specificity may be less reliable.

The Na-K ATPase-suppressing compounds, including digitalis-like factors, have generally been sought among endogenous products of metabolism. The two compounds noted above, however, may be made by various animals and some others, but apparently not these two, are synthesized by plants (as, of course, is digitalis). Increased concentrations in renal failure could thus reflect impaired clearance of ingested materials rather than overproduction of endogenous products. Investigations in the field have not settled and indeed largely failed to address this question. A major deficiency in the case for endogenous digitalis-like factors has been the failure to define a biosynthetic pathway in mammals for these compounds, although they can be synthesized by plants and toads.[44] One study of subtotally nephrectomized rats did report an increase in both plasma levels and urinary excretion of marinobufagenin.[45] Because both the excretion rate and the plasma level were about double the control values, the results suggest that overproduction was responsible for the increased plasma level and that the diminished renal function played very little role. Similar measurements of the excretion or production of other digitalis-like compounds in humans or even in animals are not available.

Several considerations militate against digitalis-like substances as mediators of uremic toxicity. Some of the classical features of digitalis toxicity such as AV nodal conduction delays, ventricular extrasystole, and visual disturbances are not prominent even in older descriptions of untreated uremia. Other toxicities of digitalis such as anorexia are, of course, common in uremia. Cardiac fibrosis, a common complication of uremia, has been induced in rats with infusion of exogenous marinobufagenin.[46] As with many other putative uremic toxins, the association in humans of the cardiotonic steroids with clinical complications, in this case cardiac hypertrophy and hypertension, has not been extensively explored. There has also been little study of the degree to which Na-K ATPase is inhibited at different levels of impaired renal function. Most studies have used sera from patients or animals with complete renal failure although some, such as the study of marinobufagenin in rats, have used models of renal insufficiency.[45] A report examining the depression in muscle membrane potential in humans with ESRD showed not only that the electrophysiological abnormality was improved by dialysis but also that it was detectable only at a GFR below about 10 mL/min/1.73 m^2.[47] The depression in muscle membrane voltage would be consistent with Na-K ATPase inhibition, and, if so, it seems a late event in the course of renal disease.

CAUSES OF PERSISTENT UREMIA WITH CURRENT ESRD THERAPY

The set of signs and symptoms still present in people receiving dialysis currently defined as adequate has been described by Thomas Depner, who wrote "Patients who would have died from uremia but survive because of dialysis suffer from a previously non-existent life-threatening disease that is labeled here for lack of a better term the 'residual syndrome.'"[48] As he described, this syndrome likely has complex origins. We assume that at least some of these residual morbidities are due to retained organic solutes that are poorly removed by dialysis.

Dialysis as practiced does not faithfully reproduce normal renal function or the endocrine functions of the kidney. Conventional hemodialysis treatment aims at removing about two-thirds of the accumulated total body urea content during each of three weekly sessions. Urea itself seems to have little toxicity.[49] Conventional hemodialysis also removes other unidentified toxic solutes, but removes them as well as urea only if they too are small, unbound, and traffic readily across capillaries and cell membranes. Removal of other compounds may be limited due to large molecular size, protein binding, or sequestration within body compartments. Consequently, conventional dialysis has widely different effects on uremic solute levels owing to their different chemical characteristics. Surveys of small organics accumulating in ESRD patients find more than 270 compounds. When proteins and peptides are considered, an even larger list is generated.[50,51] The application of new analytic methods is lengthening this list.[52,53] Thus, identification of the chemicals responsible for the residual syndrome is a formidable task. A rational approach is to first consider those general classes of compounds that are poorly removed by dialysis compared with urea.

PROPERTIES OF POORLY DIALYZED SOLUTES

Large Molecule Solutes

The early dialysis membranes provided diminishing clearance of solutes larger than urea, which has a molecular weight of 60 D, and afforded very little clearance for solutes larger than 1000 D.[54] Development of more permeable, "high flux" membranes allowed the removal of the larger molecule β-2 microglobulin (molecular weight 12 kD), which had been associated with acquired amyloidosis. However, uremic solutes that are relatively large compared with urea, including β-2 microglobulin, are poorly cleared by even high flux dialyzers compared with the normal kidney. For example, the clearance of β-2 microglobulin by the normally functioning kidney is close to the GFR or about 100 mL/min, whereas the clearance of β-2 microglobulin by a high flux dialyzer is about 35 mL/min. Summed over a week, the normal kidneys thus provide about 1000 L of β-2 microglobulin clearance, whereas high flux dialysis provides about 20 L. Even with high flux membranes, levels of β-2 microglobulin in dialysis patients are therefore more than 20-fold higher than normal and would indeed rise even higher if there were not some nonrenal clearance of this solute.[55,56] By comparison, the typical time-averaged circulating urea levels are usually about threefold normal because usual dialysis presumably provides about one-third the weekly total urea clearance of normal kidneys (Figure 14.1). Examples of potentially toxic large molecule compounds in addition to β-2 microglobulin include complement factor D, various advanced glycosylation end products, and fragments of parathyroid hormone. The application of proteomic techniques adds steadily to this list.[57] Techniques designed to further increase convective clearance, especially hemodiafiltration, and thereby remove larger molecules

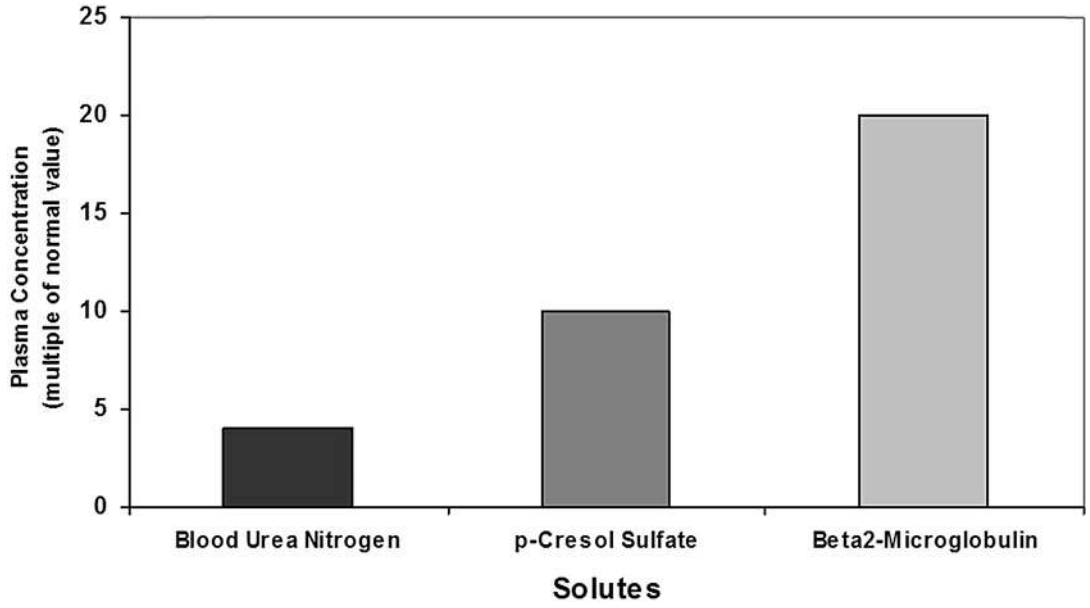

FIGURE 14.1 Time-average plasma solute levels in patients undergoing conventional thrice-weekly hemodialysis. Uremic solutes that are relatively large compared with urea are poorly cleared by even high flux dialyzers. The increase in the level of p-cresol sulfate would be of even greater magnitude if free rather than total plasma solute levels were compared.

have not shown consistent effects on outcomes such as cardiovascular events or mortality.[58–60] Furthermore, trials of this method have not as a group shown consistent lowering of β-2 microglobulin. Even in a trial that demonstrated lower levels with hemodiafiltration, the levels of β-2 microglobulin remained more than 10-fold normal.[58] This is not surprising because the clearances of such molecules by high flux membranes and novel dialytic approaches do not approach those of the normal kidneys.

Protein-Bound Solutes

The protein-bound uremic solutes have a low clearance because only the unbound fraction is available for diffusion across the dialysis membrane.[61–64] In the normally functioning kidney, the protein-bound solutes are removed through the active process of tubular secretion, which efficiently transports the free moiety across the tubule cells into the lumen. This process transpires with such efficiency that for many such solutes a large fraction of the incoming bound portion is removed in a single pass. Dialysis does not replicate secretion, however, and the weekly dialytic clearance of many of these compounds is less than one-tenth that provided by normal kidneys. As a result, their levels in people treated with maintenance dialysis are typically more than ten times their concentrations in normal serum.[64] The increase in plasma levels is of even greater magnitude if free rather than total solute concentrations are compared. Although experimental and clinical studies have suggested that the two most studied protein-bound solutes, indoxyl sulfate and p-cresol sulfate, have toxic effects both in experimental and clinical studies, some controversy still exists.[65–73] The time-averaged clearance of protein-bound solutes provided by peritoneal dialysis is even lower than that provided by hemodialysis. Yet plasma levels of p-cresol sulfate and indoxyl sulfate do not rise higher in peritoneal dialysis patients than in hemodialysis patients. The reasons for this are not completely understood, but appear to include reduced production of the solutes as residual renal function is lost in peritoneal dialysis patients.[62,63]

Sequestered Solutes

A third category of toxic solutes that are difficult to remove through conventional dialysis are those sequestered in compartments where their concentration does not equilibrate rapidly with that of the plasma. Dialysis rapidly reduces the plasma concentration of such solutes, but clears only a limited proportion of the total body solute content if they do not readily transfer out of intracellular water or other reservoirs. The best known example of a sequestered solute is phosphate, but some organic solutes including guanidinoacetic acid, guanidine, and methylguanidine appear to behave in this manner.[74] Similar to protein-bound solutes, sequestered molecules respond differently from urea to changes in the dialysis prescription.

Solute movement in and out of erythrocytes deserves additional consideration. Urea has selective membrane transporters that facilitate its diffusion in and out of red cells.[75] Therefore, with adequate dialysate flow and dialysis membrane size, urea is removed from both plasma and erythrocytes as blood transits the dialyzer. For this reason changes in hematocrit have little effect on urea clearance by hemodialysis.[76] Molecules without facilitated transport in and out of cells, like creatinine, cannot have a dialytic clearance exceeding plasma flow. Therefore, their dialytic clearances are lower than the dialytic urea clearance, and, unlike urea, their clearance may be dependent on hematocrit.

Methylamine and methylguanidine are molecules with higher intrared blood cell concentration compared with plasma.[77,78] They appear to be sequestered in other cellular compartments as they have volumes of distribution greater than the body water. For these reasons, their fractional removal by dialysis is less than that of urea and they display considerably more post dialysis rebound, as cellular compartments release them into the extracellular fluid after cessation of treatment.

Other Solutes with Very High Clearance by Native Kidneys

Urea and similar solutes are cleared at the highest rate by hemodialysis. All other solutes are cleared at lower rates. This is not true for the normal kidney. With normal renal function, urea clearance is only one-half of creatinine clearance. Other endogenous compounds, for example, hippurate, may be cleared at rates two or more fold the rate of GFR, or about five times the clearance of urea. Of course, these high clearances result from active tubular secretion, whereas dialytic clearance depends largely on diffusion. As a result of the much greater relative clearance by the native kidneys, patients treated with maintenance hemodialysis have hippurate levels twenty to forty times those in normal subjects.[79] Hippurate does not seem to be particularly toxic, but other undiscovered compounds that also have large secretory clearances by the normal kidney may be toxic and would also be expected to circulate in equally large multiples in dialysis patients. In 1939, the early renal physiologist James Shannon, who was also the first director of the National Institutes of Health, asked rhetorically whether loss of renal secretion might contribute to the symptoms of CKD. After raising this

possibility he wrote "The answer to this question must await the further identification of those substances which make up the unknown portion of the urinary constituents."[80] Studies of compounds secreted by people with normal kidney function have identified over 1000 protein-bound solutes that are secreted. The chemical identities of many of these are still unresolved, as they represent peaks in the chromatograms of high-resolution mass spectrometry. However, a subset that was chemically identified has extraordinarily high clearances of their free fraction, even exceeding renal plasma flow. For 11 of 13 such solutes, their levels in hemodialysis patients exceeded that in normal subjects by more than 20-fold.[81]

Sources of Retained Solutes

The sources of the compounds that accumulate to the largest molar concentrations in patients with CKD, urea and creatinine, are well known. They derive from protein metabolism and nonenzymatic breakdown of creatine, respectively. The retention of the inorganic components of the uremic extracellular fluid—potassium, phosphate, and hydrogen—is also well understood. The elevations in levels of small proteins such as β-2 microglobulin and complement Factor D seem largely to derive from their usual synthetic pathways in the face of impaired clearance. However, the origins of many retention products in patients with CKD are uncertain.

Uremia-induced increased production has been described for at least one solute long known to be elevated in the plasma of patients with CKD. Urinary guanidinosuccinic acid excretion rises in people with advanced CKD.[82] The biochemical causes for this increased production are not well worked out, but a complex interaction of urea, reduced protein intake, and homocysteine has been proposed.[83] Similarly, methylguanidine production seems to be increased in uremia. This finding is attributable to the reaction of creatinine with oxidants.[84]

The gut flora is an important source of many small solutes that accumulate in uremia.[85] One of the pioneers of dialysis therapy, Willem Kolff, suggested that this was likely to be so nearly 70 years ago. In a study comparing urine from control subjects and that from subjects with total colectomies, 91 solutes were four or more fold higher in the control urine, and 60 of these accumulated in ESRD patients. Many of these could be classed as secreted by the normal kidney and many were without previously known structure.[86] Evidence has begun to accumulate that some products of gut bacterial metabolism confer serious health risks. For example, trimethylamine oxide accumulates in uremia and is associated with cardiovascular disease in people with ESRD as well as those with normal renal function, suggesting that the accelerated vascular disease of uremia may be caused, at least in part, by this solute.[87–89]

Removal of Useful Vitamins and Minerals with Dialysis

Dialysis removes some important vitamins, minerals, and trace elements. Water-soluble vitamins are filtered through the dialysis membrane and require supplementation if intake is low. Vitamin C is one such compound. Hemodialysis removes 80–280 mg of vitamin C with each treatment.[90] Vitamin C deficiency is exacerbated by the restricted diets required for ESRD patients that prohibit potassium-rich foods which provide the major portion of dietary vitamin C. Another water-soluble vitamin, folic acid, was shown to be significantly cleared or lost during high-efficiency hemodialysis.[91] Furthermore, minerals like zinc are also removed by usual dialysis and may require supplementation. Loss of amino acids during dialysis has been documented and likely contributes to malnutrition in hemodialysis patients.[92] As there are presumably unknown toxic molecules that accumulate in dialysis patients, there may also be some unknown valuable molecules that are inappropriately removed by hemodialysis.

PROSPECTS FOR ADVANCES IN UREMIA THERAPY

Further dissection of the chemistry of uremia is possible with modern chemical techniques. However, additional complementary approaches are needed to determine which solutes are toxic and in what ways. Better endpoints than simply mortality or cardiovascular events are needed, and many of the disabilities presented in Table 14.1 should provide such targets. Epidemiologic associations of some solutes with standard endpoints have been determined, suggesting toxicities for indoxyl sulfate, p-cresol sulfate, and asymmetric dimethylarginine, for example.[69–71,93,94] Studies of specific solutes in intact animals have been few but seem a reasonable approach as do *in vitro* toxicity tests.[68,95] Selective reduction of a solute in ESRD patients, again with well-chosen endpoints, would be the most conclusive test of toxicity. Relatively straightforward adjustments to dialysis techniques enhance removal of protein-bound solutes, for example, but have not been tested for their effects on clinical endpoints.[96] Finally, understanding the origins of

established toxins might allow reduction in their production by dietary changes, sorbents, or manipulation of gut flora. Enhanced dialytic removal may not be the only route to better outcomes in uremia.

CONCLUSIONS

Hemodialysis has not only become widely available but has undoubtedly improved over the last 40 years. However, morbidities still persist, and attempts to understand their chemical etiologies have lagged behind other major advances in the field, such as more accurate ultrafiltration, bone and mineral therapy, and mitigation of anemia. Over the last decades, a few solutes have begun to receive serious attention as potential toxins, but progress has been slow. The reasons for this slow pace certainly include the chemical complexity of the uremic milieu and the multiplicity of clinical disturbances within the standardly dialyzed population. However, improving techniques for chemical analysis and the prospect of clinically meaningful quantifiable endpoints should propel more investigation. That one solute or even one class will account for all aspects of the residual syndrome seems unlikely. Undoubtedly, other components of chronic hemodialysis therapy beyond retained solutes, for example, episodic volume removal, also contribute to morbidities.

The effective therapy of most chronic conditions, however, requires targeting multiple mechanisms. Adequate treatment of diabetes encompasses not just glycemic control but also blood pressure and lipid therapies. Unraveling the complexity of the residual syndrome is daunting, but that does not mean that it is insoluble. Efforts to resolve the residual syndrome by employing yet more intensive dialysis based on urea removal may have some benefits. But such efforts will likely have only a modest impact on some important solutes, while significantly increasing the burden on patients and providers.

QUESTIONS AND ANSWERS

Question 1

Uremic patients may present with which of the following signs and symptoms?

A. Anorexia
B. Diminished smell
C. Hypothermia
D. Restless leg syndrome
E. All of the above

Answer: E

Anorexia, diminished sense of smell, hypothermia, and restless leg syndrome are all manifestations of uremic syndrome present in patients with ESRD. Other signs and symptoms of uremia include fatigue, inflammation, insulin resistance, nausea and vomiting, impaired cognition, and pruritus.[4,38]

Question 2

A 75-year-old man with diabetes mellitus for more than 20 years, proteinuria, hypertension, and CKD, presents to the emergency room complaining of chest pain and shortness of breath. He was noncompliant with his medical treatment and was last seen by a physician more than a year ago. The chest pain started suddenly, approximately four hours prior to admission. It was sharp, exacerbated by taking a deep breath and relieved by leaning forward. The patient stated that for the past month he had poor appetite, generalized pruritus, nausea, and vomited several times.

He had a blood pressure of 210/99 mm Hg, heart rate 88 beats/minute, and was afebrile. He had jugular venous distention, bilateral crackles in the lower two-thirds of lung fields, laterally displaced apical impulse, S3 gallop, a friction rub, and lower extremity edema up to the thighs. Approximately 30 minutes after being examined in the emergency department he had a generalized tonic-clonic seizure.

His laboratory findings were hemoglobin 7 mg/dL, sodium 140 mEq/L, potassium 6.5 mEq/L, chloride 101 mEq/L, bicarbonate 12 mEq/L, BUN 160 mg/dL, creatinine 12.5 mg/dL, phosphate 7.9 mg/dL, calcium 8.5 mg/dL, and albumin 3.8 mg/dL. Chest X-ray was consistent with an enlarged heart and increased interstitial markings.

The renal team was consulted and hemodialysis treatment was initiated emergently.

What manifestation of uremia will be completely resolved by the initiation of hemodialysis treatment?

A. Seizures
B. Anemia
C. Hypertension
D. Pruritus
E. Nausea and vomiting

Answer: A

Of the classic manifestations of uremia not attributable to electrolyte disorders, only uremic seizures present in ESRD patients prior to initiation of hemodialysis (Answer A) are completely abrogated by the current renal replacement therapies. Anemia (Answer B), though successfully treated with erythropoietin analogs, is not corrected by dialysis. Hypertension (Answer C) is usually improved by careful removal of the excess extracellular fluid through ultrafiltration, but many patients still remain hypertensive despite the best efforts at fluid management during dialysis. Pruritus (Answer D) is one of the most difficult uremic symptoms to treat and has a poorly understood pathophysiology. Nausea and vomiting (Answer E) in uremic patients are only partially corrected by the available dialysis therapies.

Question 3

A solute with which of the following properties is likely to be removed by hemodialysis to about the same extent as urea?

A. One that is 90% bound to albumin
B. One that has a molecular weight of 8000 D
C. One that is highly concentrated in cells
D. One that has a molecular weight of 100 D

Answer: D

Conventional hemodialysis treatment aims at removing about two-thirds of the accumulated total body urea content during each of three weekly sessions. Hemodialysis also removes other unidentified toxic solutes but removes them as well as urea only if they too are small (Answer D), unbound, and traffic readily across capillaries and cell membranes. Removal of other compounds may be limited due to protein binding (Answer A), large molecular size (Answer B), or sequestration within body compartments (Answer C).[74]

Question 4

Which of the following statements is true?

A. The protein-bound solutes have a high clearance due to the unbound fraction available for diffusion across the dialysis membrane
B. In the normal functioning kidney, the protein-bound solutes are removed through the active process of tubular secretion

C. The protein-bound solute levels in people treated with hemodialysis are generally lower than in normal individuals
D. Plasma levels of p-cresol sulfate and indoxyl sulfate are higher in peritoneal dialysis than in hemodialysis patients
E. Conventional hemodialysis treatment is able to remove a substantial fraction of protein-bound uremic toxins

Answer: B

Protein-bound solutes are removed through the active process of tubular secretion (Answer B). They have a low clearance in dialysis patients (Answer A), because only the unbound fraction is available for diffusion across the dialysis membrane. Therefore, their concentration is high in ESRD patients (Answer C). P-cresol sulfate and indoxyl sulfate, the most studied uremic toxins, are lower in peritoneal dialysis patients, due in part to better preserved residual renal function compared with hemodialysis patients (Answer D). Conventional hemodialysis treatment is able to remove only the unbound fraction of protein-bound uremic toxins (Answer E).[64,66]

Question 5

Which of the following statements is true?

A. Notable reductions in quality of life and well-being appear when GFR falls below 60 mL/min/1.73 m^2
B. The prevalence of depression is similar in patients receiving dialysis and those with a kidney transplant
C. Treatment of anemia in dialysis patients does not improve physical functioning
D. In patients with CKD, fatigue is present only when GFR falls below 15 mL/min/1.73 m^2
E. Middle-aged dialysis patients with good nutrition and no significant comorbidities exhibit the same physical functioning as those of matched controls

Answer: A

Reductions in quality of life and well-being appear when GFR falls below 60 mL/min/1.73 m^2 (Answer A). Transplant recipients have lower rate of depression compared with dialysis patients (Answer B). Physical functioning is improved by treatment of anemia in dialysis (Answer C). It is unclear at what level of GFR uremic symptoms begin to manifest but is likely much higher than 15 mL/min (Answer D). Relatively "healthy" dialysis patients with good nutrition and no significant comorbidities still have decline in physical functioning compared with normal individuals (Answer E).[4–6]

Question 6

All of the following statements regarding anorexia in ESRD are true, except?

A. Loss of appetite is a common uremic symptom and presumably contributes to malnutrition in patients with advanced renal failure
B. Acidosis and inflammatory cytokines including TNF-alpha and various interleukins have been identified as contributing factors
C. Levels of leptin, an anorexigen produced by adipose tissue, are elevated in ESRD
D. ESRD patients have a disproportionate reduction in the intake of protein
E. Anorexia is eliminated by proper dialysis

Answer: E

Anorexia is only alleviated, but not completely eliminated by proper dialysis treatment (Answer E). All the other statements are correct.[32]

Abstract

The presence of albumin in the urine has long been recognized as a hallmark of renal dysfunction. In systemic diseases, such as hypertension or diabetes mellitus, albuminuria is not only a marker of glomerular injury but may also contribute to renal function loss. The development of albuminuria and its adverse consequences is probably a multistep process where, initially, loss of endothelial barrier function may play a role. Endothelial activation within the glomeruli and subsequent shedding of the glycocalyx surface allows albumin to penetrate the subpodocyte space. Podocytes may then take up albumin through scavenger receptors and display actin skeleton rearrangements and injury. In addition, compensatory reabsorption in proximal tubules and the accompanying inflammatory responses may further contribute to the structural interstitial damage that has been associated with albuminuria and may ultimately lead to decreased nephron function.

Further evidence regarding the role of albuminuria in the setting of progressive renal functional loss comes from observational studies demonstrating that the presence of albuminuria is associated with a high risk of renal functional loss over time. This association is found in various diseases such as diabetes mellitus, hypertensive kidney disease, primary renal disease of diverse origins, and even in the general, otherwise healthy, population.

Certain drugs are available that decrease albuminuria, such as renin–angiotensin–aldosterone system inhibitors. More recently, other drugs such as sodium-glucose cotransporter 2 inhibitors, glucagon-like peptide 1 receptor agonists, and endothelin receptor antagonists have been shown to decrease albuminuria as well. It appears that the reduction in albuminuria, observed during the first months of therapy, correlates with the degree of long-term renal protection: the larger the reduction in albuminuria, the slower the rate of renal function decline. Collectively, these data suggest that albuminuria should not only be used to diagnose chronic kidney disease and estimate the risk for increased progressive renal functional loss, but albuminuria can also be used as a target for renoprotective therapy. As such, the level of albumin in urine should be regularly monitored and optimized as with high blood pressure or high cholesterol levels.

This chapter reviews the pathophysiology of albuminuria and clinical studies that support the use of albuminuria as an independent target for renoprotective therapy.

INTRODUCTION

The prevalence of kidney failure is increasing in the US and worldwide and is associated with poor outcomes and high costs.[1] During the last decade, much attention has been paid to early identification of individuals at risk for developing chronic kidney disease (CKD). The presence of albuminuria has emerged as an important risk marker of progressive renal functional loss in various populations. The importance of albuminuria as a diagnostic and prognostic risk marker has been recognized by policy and guideline makers, and albuminuria is currently included in a new CKD classification system in combination with estimated glomerular filtration rate (eGFR) to define the severity of CKD.[2]

The measurement of proteins or albumin in the urine dates to the 18th century, when Domenico Cotugno and Richard Bright noted that after heating and partial evaporation of urine of children with primary kidney diseases "a white mass loosely coagulated like egg albumin" remains.[3–5] The contribution of Hermann Senator, a German physician, further emphasized the importance of albuminuria. In a seminal article, he described that albumin could be present in otherwise healthy individuals, and he provided perspectives on the pathophysiology as well as suggestions for treatment.[6] Based on these early observations, nephrologists became increasingly interested in the measurement of all proteins in the urine

Chronic Renal Disease, Second Edition

(proteinuria) in patients with primary glomerular diseases. From 1960 to 1980, the standard techniques to measure proteinuria could detect only large quantities of proteins, typically in the range of urinary excretion of grams per day. These increased amounts of urinary proteins predicted faster progression of renal functional loss in patients with CKD.[7] In the 1980s, novel methods were introduced that enabled the measurement of small quantities of albumin in the urine, so-called albuminuria. The introduction of these techniques triggered the attention of diabetologists regarding measurement of urinary albumin in their patients. Clinical studies in the 1980s showed that small increases in urinary albumin excretion (termed microalbuminuria) predicted the development of overt nephropathy and the risk of mortality.[8–10] Over the ensuing years, the measurement of albuminuria was not limited to the CKD or diabetes populations but extended to the hypertensive and general population as well. Even in otherwise healthy persons, microalbuminuria was present in about 5%–10% of the population and predicted the rate of progression of kidney disease.[11]

Important clinical questions are whether interventions are available that decrease albuminuria, and whether the reduction in albuminuria induced by these interventions slow progression of CKD. There are indeed a number of drugs available that decrease albuminuria, such as drugs that intervene in the renin–angiotensin–aldosterone system (RAAS). Angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) are frequently used when treating high blood pressure in patients with CKD. Interestingly, although the blood pressure lowering effect of RAAS intervention reduces the risk of kidney failure, the albuminuria-lowering effects appears to contribute to this protective effect independent of the blood pressure-lowering effect. Thus, for an effective renoprotective use of RAAS inhibition and its dosing, one can not only use the blood pressure-lowering effect but one also needs other parameters to follow, such as albuminuria. This chapter will discuss the effects of various drugs, not limited to RAAS intervention, on albuminuria, and the use of changes in albuminuria as a target to optimize renoprotection. The use of albuminuria as a cardiovascular risk marker and target for treatment has been reviewed elsewhere and will not be discussed.[12,13]

CRITERIA TO ACCEPT ALBUMINURIA AS A TARGET FOR RENAL PROTECTION TREATMENT

Certain criteria should be met before one may consider albuminuria as a separate target for renal protective treatment in CKD patients:

- The mechanism by which albuminuria causes renal morbidity/mortality should be delineated.
- Different levels of albuminuria should indicate different levels of renal morbidity and mortality, independent of other risk markers and independent of the etiology of renal disease.
- A change in albuminuria (by whatever strategy) should predict a change in renal functional changes, morbidity and mortality, independent of other risk marker changes, independent of the underlying disease and independent of the medication that changes the albuminuria.

PATHOPHYSIOLOGY OF ALBUMINURIA

The glomerulus functions as a size-selective filter for protein filtration. Consequently, tubular fluid contains only proteins of low molecular weight (<60 kD) such as vitamin D-binding protein or free retinol-binding protein, while larger proteins are excluded.[14] Albumin, the most abundant plasma protein, is filtered in very low amounts (1–50 μg/mL). In addition, albumin can be reabsorbed by the tubular epithelium. Consequently, normal total urinary protein excretion in the normal adult should be less than 150 mg/day.[15] Higher rates of urinary protein excretion that persist beyond a single measurement should be evaluated. The increased protein leak can be caused by an increase in the circulating levels of several different proteins. For example, one may observe tubular proteinuria consisting of low molecular weight proteins (less than 25 kD). Such proteinuria usually reflects a systemic disease with overproduction of small peptide fragments that are filtered and may cause tubular damage (such as beta 2-microglobulin, immunoglobulin light chains, and polypeptides derived from the breakdown of albumin). In addition, interference with proximal tubular reabsorption, due to tubulointerstitial diseases or genetic mutations, or overproduction of immunoglobulins, such as occurs in myeloma, can lead to increased excretion of these smaller proteins.[16,17] This chapter will focus on proteinuria in which albumin is the major portion of the excreted urinary protein. Urine albumin excretion less than 30 mg/day is considered normal. Urinary albumin excretion more than 30 mg/day and less than 300 mg/day is called microalbuminuria. Urine albumin excretion greater than 300 mg/day is called macroalbuminuria.[18]

Electron microscopic studies in the 1960s by Farquhar demonstrated that in intact glomeruli only about 0.06% of plasma albumin is filtered, implying that the glomerular filter is capable of retaining macromolecules in the circulation, while allowing a large hydraulic conductivity.[19,20] While tubular reabsorption of albumin may determine whether or not albuminuria finally develops, dysfunction of the glomerular filtration barrier is

assumed to play the key role in initiating the development of albuminuria.

Glomerular Endothelium

The first part of the glomerular barrier that interacts with the flowing blood is the glomerular endothelium (Figure 15.1). The endothelium is highly fenestrated. Its pores are estimated to be around 60–80 nm in diameter.[21] These fenestrae do not contain a diaphragm and thus have to be considered real pores.[22] Although such fenestration greatly facilitates the formation of high volumes of ultrafiltrate, it also implies loss of macromolecules such as albumin, as suggested by some intravital microscopy studies.[23] However, as early as 1976 Ryan and Karnovsky demonstrated that under physiological conditions plasma albumin does not penetrate significantly beyond the endothelial layer of the glomerular capillary wall.[24]

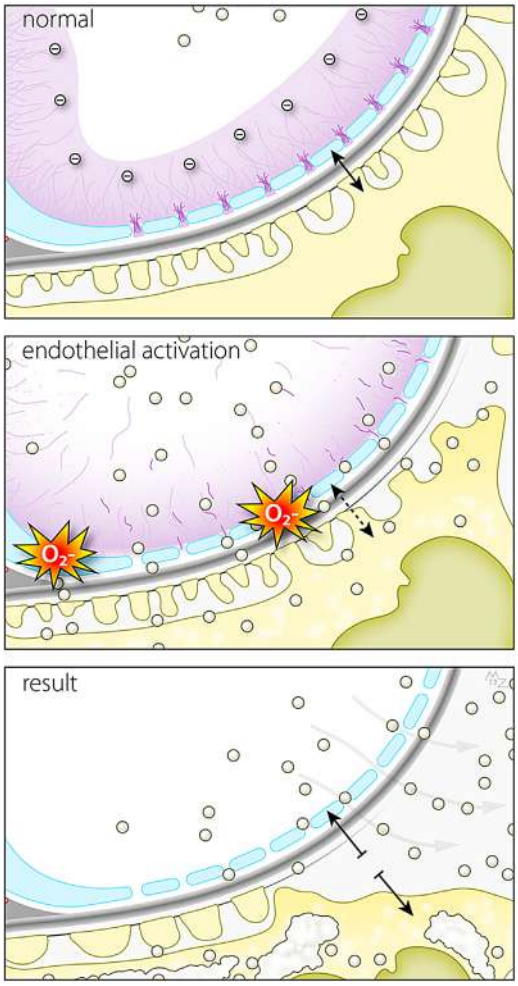

FIGURE 15.1 Proposed mechanism for the development of albuminuria in the setting of endothelial dysfunction and endothelial activation. The top panel shows the normal situation with a negatively charged glycocalyx. The middle panel shows on endothelial cell activation, through redox-sensitive signaling mechanisms, the endothelial glycocalyx is shed and albumin can pass the endothelial layer. Podocytes are subsequently exposed to modified albumin and the normal podocyte-endothelial signaling is disturbed. The lower panel shows podocytes take up albumin and undergo transformational changes that may result in podocyte effacement and podocyte drop-off.

In vivo, the endothelium is covered with a polysaccharide protein gel-like structure, the glycocalyx. This layer actively binds plasma proteins and growth factors and is referred to as the endothelial surface layer (ESL). The composition and biological activity of this surface layer differs in an organ-specific manner. The main constituents of the ESL are protein cores, typically syndecans, with large heparan sulfate side chains (about 60%) or chondroitin sulfate (about 15%).[25] The combination of negatively charged sulfates and the mesh-like structure of the less charged hyaluronan has been proposed to act as a charge-selective barrier against albumin filtration through the fenestrae.[26] Quantitative electron microscopy demonstrated that this glycocalyx acts as an almost perfect barrier against albumin filtration. This finding confirmed those of previous studies: no albumin can pass through the glomerular endothelium unless the glycocalyx is disrupted.[27] Studies in humans and animals have shown that kidney disease is associated with glycocalyx degradation.[28] Sustained endothelial activation, such as accompanies inflammation, results in increased activity of enzymes that degrade the glycocalyx. This direct link between endothelial function and glycocalyx properties may also explain, at least in part, the relationship between cardiovascular risk factors and albuminuria.

Mesangial Cells

Other determinants of the glomerular filtration barrier are the mesangial cells, which are contractile cells that constitute the central stalk of the glomerulus (Figure 15.2). On the capillary lumen side, mesangial cells are in direct contact with the glomerular endothelium without an intervening basement membrane, as one typically can observe with pericytes. Mesangial cells are considered to function as specialized pericytes and are consequently essential to stabilize glomerular endothelial function. The importance of the mesangium for function of the glomerular filtration barrier is shown by experiments where the mesangium is injured by toxins or antibodies.[29] The resulting mesangiolysis invariably results in endothelial injury and proteinuria. In the case of primary endothelial injury, widening of the subendothelial space and deposition of proteinaceous material precedes mesangiolytic changes. In the case of repetitive endothelial injury, this process may

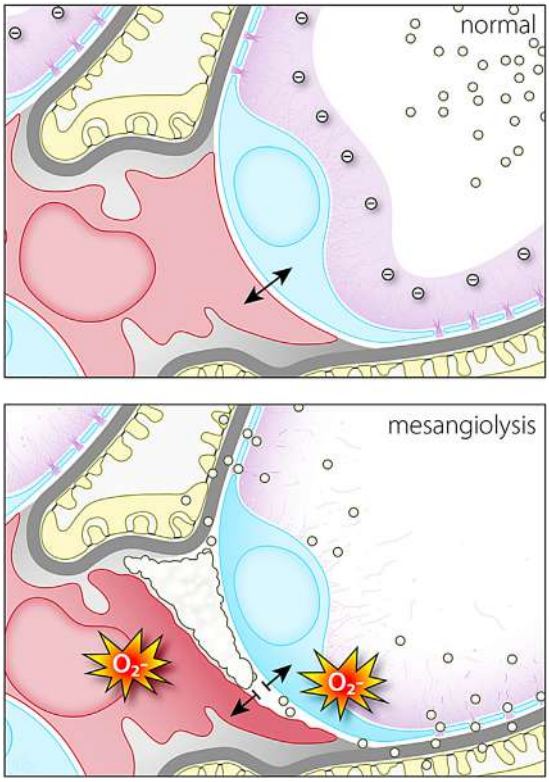

FIGURE 15.2 The proposed mechanism of how endothelial function in diabetes and hypertension may lead to mesangial lesions. The top panel shows the normal situation. Endothelial cells and mesangial cells are in close contact. Mesangial cells function as pericytes for the glomerular endothelium. On endothelial activation, this signaling is disturbed and subendothelial protein deposits may develop. This may result in mesangiolysis and subsequent development of nodular lesions (lower panel).

lead to the development of lamellated mesangial nodules. These phenomena typically can be observed in disease that primarily affects the endothelium, such as diabetes mellitus (Kimmelstiel–Wilson lesion) and thrombotic microangiopathy.

Glomerular Basement Membrane

The glomerular basement membrane (GBM) is the next critical component of the glomerular filtration barrier. It provides a scaffold that supports the physiological function of the glomerular endothelium and podocytes. Severe structural abnormalities of the GBM result in enhanced albumin leakage. Under normal conditions, the GBM probably allows for diffusive albumin transport and does not constitute a major charge barrier. The hydraulic conductance of the GBM accounts, however, for most of the fluid restriction of the intact glomerular barrier.[30] The GBM should therefore be considered an integral and essential component of the glomerular filtration barrier.

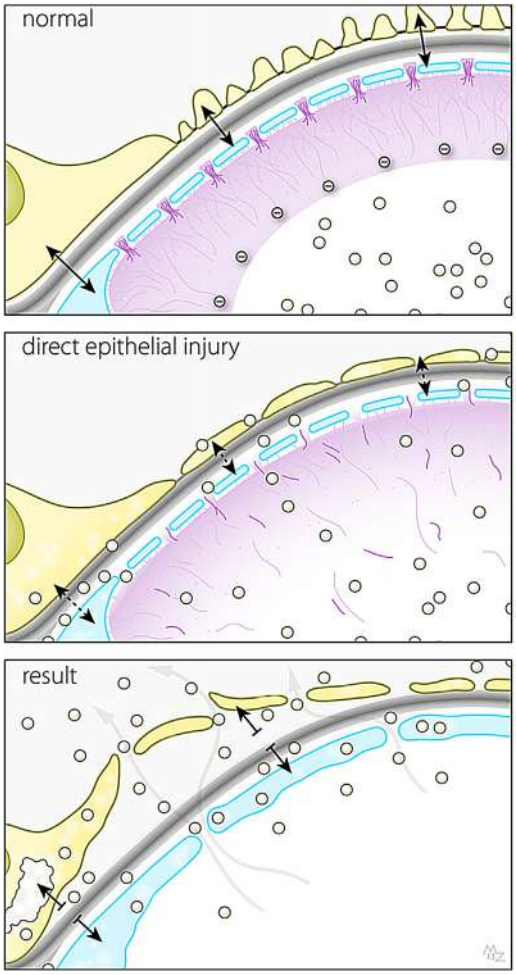

FIGURE 15.3 Proposed mechanisms by which primary epithelial injury leads to proteinuria. Genetic mutations of proteins that are required for podocyte function or direct antibody-mediated injury of podocytes may lead to podocyte effacement and dysfunction of the normal signaling between podocytes and endothelium. Consequently, the endothelium loses its highly specialized phenotype with fenestrations and the covering endothelial surface layer, the glycocalyx. This will result in albumin leakage through endothelium and disturbed slit diaphragm function. Together this results in loss of glomerular integrity (lower panel).

Podocytes

Finally, the glomerular filtration barrier consists of podocytes (Figure 15.3). There are at least two different mechanisms by which podocytes can become involved in, and contribute to, the development and extent of albuminuria. Haraldsson and Deen showed elegantly that the most selective part of a multilayered passive filter cannot be in the last layer (that is, the slit diaphragm), because retention and accumulation of albumin would occur within the filter immediately in front of the slit diaphragm and lead to clogging.[31] As we argued before, the endothelium appears to act as the primary filtration barrier. On endothelial activation,

albumin starts to leak through the GBM, and the podocytes are subsequently exposed to albumin. Interestingly, podocytes are equipped with a megalin-cubilin system,[32] as well as scavenger receptors such as the receptor for advanced glycation end products,[33] suggesting that podocytes may endocytose albumin. In the case of diabetes mellitus, podocytes may also be exposed to chemically modified and glycated albumin. Blocking uptake by these scavenger receptors reduces podocyte injury.

Experimental data suggest that endocytosed albumin induces a mesenchymal transformation in podocytes, with loss of slit diaphragm proteins and induction of desmin.[34,35] From this perspective, changes in podocyte structure can be regarded as a response to injury. Secondly, elegant murine studies have unambiguously demonstrated that normal podocyte function is required for the integrity of the glomerular filtration barrier. Podocyte-specific deletions of genes that control its phenotype lead to loss of the glomerular endothelial phenotype and the development of proteinuria. This has been best demonstrated for the paracrine regulation of components of the vascular endothelial growth factor (VEGF) axis by podocytes. Such gene deletion not only results in podocyte effacement but also in the disappearance of glomerular endothelial fenestration.[36,37] This is clinically exemplified by preeclampsia, a severe proteinuric kidney disease that occurs during pregnancy, where a circulating soluble form of VEGF receptor 1 (sFlt-1, also known as VEGFR-1), scavenges and neutralizes VEGF in the vasculature of the mother. sFlt-1 is secreted from the placenta and binds podocyte-derived VEGF at the glomerular filtration barrier, resulting in the development of albuminuria, severe endothelial damage, and hypertension.[38] Therefore, primary injury of podocytes, either by genetic mutations or immunological injury, results in severe derangement of the integrity of the glomerular filter and the development of macroalbuminuria.

Reabsorption of Albumin

Ultrafiltered albumin, whatever the total amount in the lumen of the initial proximal tubule under physiologic conditions may be, is reabsorbed because normal urine is virtually free of albumin. Albumin reabsorption takes place in the proximal tubule *via* receptor-mediated endocytosis. Two receptors, cubilin and megalin, have been identified as involved in albumin uptake. Under normal circumstances, the tubular concentration of albumin therefore is below the level that saturates this retrieval system. This means that even if some albumin passes through the glomerular filter, only very little albumin is excreted in the urine.

Genetics

With the increased clinical accessibility to whole exome sequencing, more genetic variants are being discovered that may render the glomerular filtration barrier susceptible to injury. One of the most striking examples is the presence of APOL1 gene variants in the African-American population. While evolutionary advantageous to resist trypanosomiasis, the presence of variants is also associated with podocytes more susceptible to injury, such as high blood pressure, perhaps explaining the strong association between blood pressure and proteinuria in this population.[39]

ALBUMINURIA LEVEL PREDICTS RENAL OUTCOMES

In general, the level of albuminuria predicts renal functional loss over time. The higher the concentration of albumin in the urine, the larger the chance of progressive renal functional loss. This is a consistent finding in various populations and diseases. The relationship between albuminuria and the incidence of end-stage renal disease (ESRD) is shown in Figure 15.4. The risk of ESRD starts to increase when the urinary albumin concentration is within the "normal" range. The incidence of ESRD progressively increases with higher urinary albumin concentration in the microalbuminuric or macroalbuminuric range. The association between albuminuria and the development of ESRD runs in parallel in different populations with different conditions (general

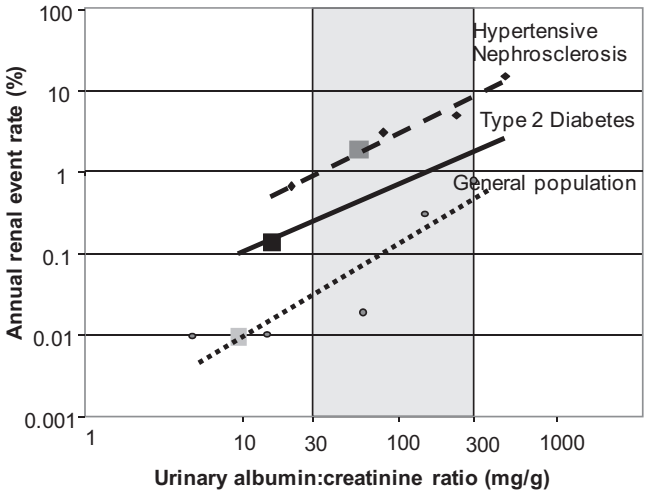

FIGURE 15.4 Level of urine albumin excretion predicts long-term renal function loss (end-stage renal disease (ESRD)). The relation (slope) between the albuminuria level and outcome (ESRD) is very similar for all different studied conditions. However, the level of risk varies per condition. *Adapted with permission from American Journal Nephrology.*[81]

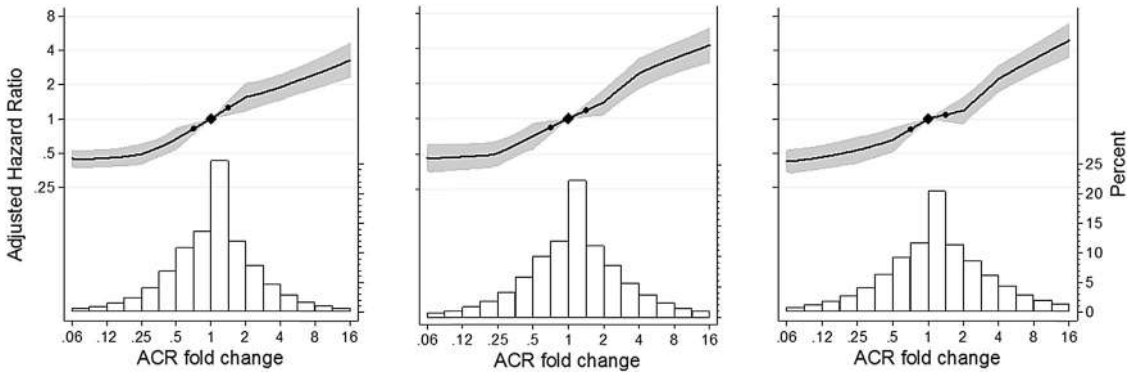

FIGURE 15.5 Adjusted hazard ratio for end-stage renal disease and population distribution of change in albuminuria evaluated over 1 year (a), 2 years (b), and 3 years (c). *Black circles* denote −30% and +43% (equivalent to 30% reduction on log scale) change in albuminuria. *Adapted with permission from Lancet Diabetes and Endocrinology.*

population, hypertension, diabetes) as depicted by the similar slopes of the regression lines in Figure 15.4.

The overall exposure to a certain albumin load over time is an important determinant of progressive renal functional loss, as well as the concentration itself.[40] In other words, a large amount of urinary albumin excretion during a relatively short time frame could well have completely different consequences compared with that associated with low amounts of albumin excretion over a long period of time. This has been illustrated in various studies of patients with glomerular diseases. These studies showed the time-averaged level of proteinuria is a stronger risk predictor of ESRD than the albumin concentration at a single time point. A large Chinese observational study showed patients with immunoglobulin A (IgA) nephropathy with time-averaged urinary protein excretion of more than 1 g/day had a 46-fold increased risk compared with patients with a time-averaged urinary protein excretion of 0.5 g/day.[41] In contrast, when the level of proteinuria at entry into the study was considered, more than 1.0 g/day proteinuria conferred a 4.5-fold increased ESRD risk. Similar findings were reported in patients with IgA nephropathies and diabetic kidney disease.[42,43] Thus, in certain conditions, massive amounts of albumin may pass the glomerulus. If this persists for a short period of time, it does not directly induce visible damage. However, if remission does not occur in a relatively short period of time (spontaneously or through therapy), the exposure to albumin may be sufficient to cause or accelerate renal damage, ultimately leading to the development of ESRD.

CHANGES IN ALBUMINURIA PREDICT CHANGES IN RENAL OUTCOME

Regression or progression of albuminuria frequently occurs, as shown in studies of patients with type 2 diabetes and in the general population.[44,45] Such changes in albuminuria are strongly and consistently associated with the risk of developing ESRD. For example, in a large health care utilization cohort, patients with a fourfold increase in albuminuria showed a threefold higher risk of developing ESRD.[46] These results were confirmed in a meta-analysis of 28 observational studies involving nearly 700,000 individuals.[47] The meta-analysis demonstrated that a 30% decrease in albuminuria over a period of 2 years was independently associated with a 22% reduction of risk of developing ESRD (Figure 15.5). These data imply that albuminuria should be regularly measured to monitor individual renal risk prediction.

SHORT-TERM TREATMENT-INDUCED CHANGE IN ALBUMINURIA INDICATES A TREATMENT-INDUCED CHANGE IN RENAL OUTCOME

According to the third criterion for validation of albuminuria as a target for treatment, the drug effect on albuminuria should correlate with the drug effect on ESRD. To determine whether albuminuria fulfills this criterion, one can analyze within a trial whether a drug-induced change in albuminuria correlates with change in the risk for a renal outcome. Initial relatively small studies demonstrated that the degree of albuminuria reduction in the first weeks of therapy with ACEIs inversely correlated with the degree of renal functional decline during subsequent years of follow-up. The larger the reduction in albuminuria during the first weeks, the slower the rate of subsequent renal functional decline.[48,49] These initial studies were later confirmed in larger clinical trials in different populations, which consistently reported that an early reduction in albuminuria during the first months of treatment with RAAS

inhibitors was independently associated with a lower risk of ESRD.

Is the association between drug-induced changes in albuminuria and renal outcomes only observed with RAAS intervention, since inhibition of angiotensin II protects the kidney and simultaneously reduces albuminuria, without a direct link between albuminuria reduction and renal protection? To answer this one can evaluate studies that used different strategies (drugs or dietary interventions) to lower albuminuria and also monitored renal function. A low protein diet, for example, results in decreased albuminuria, and the magnitude of the reduction in albuminuria correlates with the degree of renoprotection.[50] In addition, glucagon-like peptide 1 (GLP-1) receptor agonists and sodium-glucose transporter 2 inhibitors, both relatively novel oral glucose-lowering agents, have been shown to decrease albuminuria in patients with type 1 and type 2 diabetes.[51–54] Large cardiovascular outcome trials with these drugs have furthermore demonstrated that they slow the progression of renal functional decline. *Post hoc* analyses from these trials demonstrated that the degree of albuminuria reduction is associated with the degree of renal and cardiovascular risk reduction.[55–58] Finally, some statins appear to decrease albuminuria, which seems to be associated with less renal functional decline.[59]

Although these data point to a consistent association between albuminuria reduction and long-term renal protection, independent of the intervention that is used to lower albuminuria, most cited studies are either nonrandomized/open label or *post hoc* analyses of randomized/blinded studies, which are prone to bias. The bias arises from the possibility that patients who show a clear albuminuria response may be a specific population with a lower renal risk.

To address this type of bias, one should analyze multiple randomized controlled trials and correlate the effect of the intervention on albuminuria with its effect on hard renal endpoints across all trials. Such a "trial-level" approach has been recently conducted. A meta-analysis involving 41 studies, including nearly 30,000 individuals and 7 different types of interventions, demonstrated that each 30% reduction in albuminuria during the first 6 months of treatment with these interventions was associated with a 27% lower hazard for the clinical renal endpoint during a median follow-up of 3.4 years (Figure 15.6).[60] Results were consistent when either RAAS inhibitor or non-RAAS inhibitor studies were assessed. This study also reported that in patients with microalbuminuria or macroalbuminuria, an approximately 25% reduction in albuminuria is required to have high confidence that the drug will reduce the risk of a clinical renal endpoint. These data strengthen the notion that albuminuria is an independent target of renoprotective therapy. Most studies to date are not designed to establish that targeting of albuminuria results in additional renoprotection. To prove that targeting of albuminuria confers renal protection, one would need to randomize for the albuminuria response or design a trial to target albuminuria itself. The latter has been done in the ROAD study in nondiabetic patients. Indeed when one aims to achieve a maximal albuminuria response vs. a maximal blood pressure response, the targeting of albuminuria is associated with markedly better renal survival.[61]

The currently available interventions that lower albuminuria are registered for other indications. For

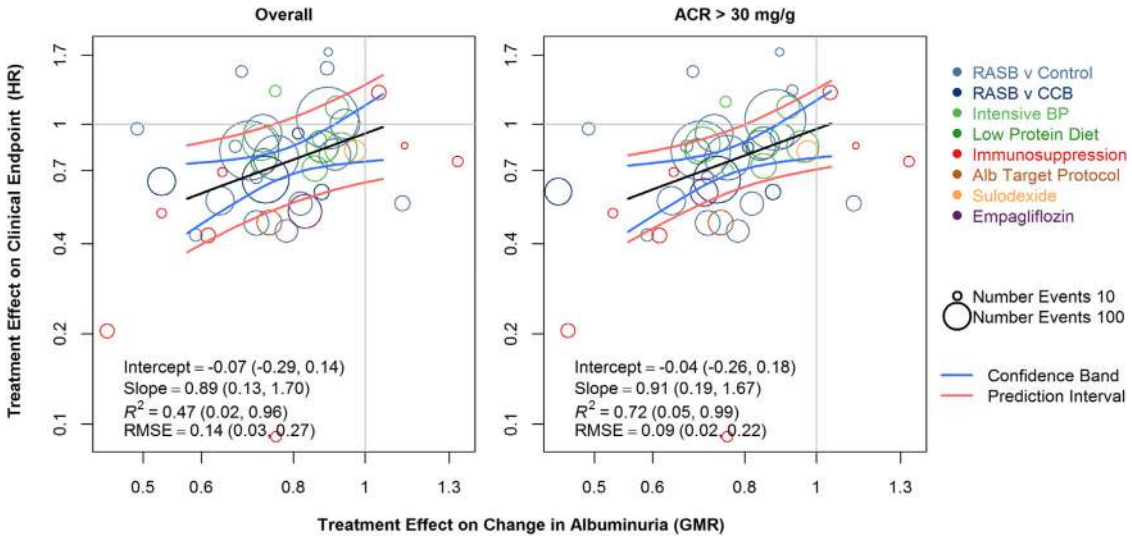

FIGURE 15.6 Meta-analysis of clinical trials showing the association between treatment effects on change in albuminuria and treatment effects on the clinical endpoint. *Adapted with permission from Lancet Diabetes and Endocrinology.*

example, ACEIs are indicated for hypertension and GLP1-RA and SGLT-2 inhibitors are indicated for treatment of hyperglycemia. The albuminuria-lowering properties of these drugs are unintended or off-target effects and are not the only off-target effects. RAAS inhibitors also increase S[K] and decrease hemoglobin levels. SGLT-2 inhibitors increase S[P] and FGF-23.[62] These effects may also determine long-term renal prognosis: higher S[K], S[P], and FGF-23 and low hemoglobin concentration are associated with increased renal risk. The balance of these positive (those leading to protection) and negative (those inducing harm) surrogate effects determine the ultimate efficacy of a drug on renal outcome.[63] This may also explain why some trials failed to demonstrate a reduction in renal risk with the new intervention despite a reduction in albuminuria. For example, clinical trials with dual RAAS intervention showed significant increases in the incidence of hyperkalemia and acute kidney injury during dual RAAS blockade, which may have increased renal risk and outweighed the positive effects of blood pressure and albuminuria lowering. Thus, a drug effect on a single target such as albuminuria should not be evaluated in isolation but considered in the context of all other off-target surrogate effects as well.[63]

OPTIMIZE CONDITIONS IN ALBUMINURIA RESPONSE

If one accepts that albuminuria is a separate target for treatment and one accepts that the risk relationship between albuminuria and renal outcomes is linear, with no lower threshold below which the risk does not decrease, one should pursue the lowest level of albuminuria for each individual. As mentioned, RAAS inhibition is currently the mainstay of therapy to decrease albuminuria. However, the albuminuria response to ACEI and ARB therapy is highly variable, ranging from no response (or even increased albuminuria) to as much as 90% reduction.[64] What options are available to further decrease albuminuria beyond RAAS inhibition? Several possibilities exist. First, the response to RAAS inhibition can be enhanced by optimizing extracellular volume control through either dietary sodium restriction or concomitant diuretic therapy.[65–67] Analysis of long-term follow-up studies suggests that dietary sodium restriction also enhances the long-term effect of RAAS on hard renal and cardiovascular outcomes, highlighting the potential health gain of widespread implementation of reducing dietary sodium consumption.[68,69]

Several drugs are in development that target albuminuria as a means to reduce renal risk beyond RAAS blockade. These drugs are mainly directed toward reducing the renal/vascular "leak" of albumin and or reducing the inflammatory sequelae of the albumin leak. Endothelin receptor antagonists (ERAs) have emerged as potent drugs which decrease albuminuria and reduce renal inflammation.[70–72] Despite potent albuminuria-lowering effects, a trial in patients with type 2 diabetes and nephropathy with the relatively nonselective ERA avosentan was prematurely terminated because of excess congestive heart failure and mortality. The high number of congestive heart failure events may be due to the high doses of avosentan used, which resulted in significant sodium and fluid retention. Newer ERAs, such as sitaxsentan and atrasentan, appear to be more specific for the endothelin A receptor, theoretically rendering them less prone to inducing fluid retention, edema, and heart failure, although caution in interpreting results remains required.[71,73] A study in 211 patients with type 2 diabetes and nephropathy showed that the ERA atrasentan at the low dose of 0.75 mg/day when added to RAAS blockade decreased albuminuria by 35%.[74] A long-term clinical trial (SONAR trial) with atrasentan at a dose of 0.75 mg/day in patients with type 2 diabetes and nephropathy was recently finished. This trial used a unique enrichment design to enhance the selection of patients most likely to benefit.[75] 2648 patients were randomly assigned to atrasentan 0.75 mg orally per day or placebo with median follow-up of 2.2 years. Atrasentan significantly reduced the risk of renal events with no differences seen in hospital admission for heart failure or death.

Novel antiinflammatory drugs decrease albuminuria in various relatively short-term studies.[77–79] The mechanism of the albuminuria-lowering effects of these agents are not completely understood, but they may exert their potential renal protective effects through albuminuria lowering, as well as through their specific antiinflammatory effects. Monocyte chemoattractant protein-1 (MCP-1), a potent cytokine, plays a key role in initiating and sustaining chronic inflammation in renal tissue. Inhibition of MCP-1 or its CCL2 receptor decreases albuminuria in patients with type 2 diabetes and macroalbuminuria.[77,78] Inhibition of the proinflammatory JAK-STAT pathway offers another therapeutic avenue to decrease albuminuria. In a small phase 2 study involving patients with type 2 diabetes and macroalbuminuria, baricitinib, indicated for the treatment of rheumatoid arthritis, decreased albuminuria by 41%.[79] This effect was accompanied by reduction in various proinflammatory biomarkers. Finally, vascular adhesion protein-1 (VAP-1) emerged as another proinflammatory mediator, implicated in various pathophysiological processes that involve oxidative stress and inflammation. VAP-1 inhibition with a potent orally active inhibitor has been shown to be effective in reducing albuminuria and may represent another therapeutic option to slow progression of renal disease.[80]

CONCLUSIONS

A growing body of evidence demonstrates that albuminuria can be considered a separate target for therapy. Emerging experimental data illustrate the importance of the glycocalyx in preventing albumin leakage by glomeruli. When increased amounts of albumin penetrate the subglomerular space, compensatory tubular reabsorption and the accompanying inflammatory responses may further contribute to the structural interstitial damage that has been associated with albuminuria. This may further aggravate progressive renal functional loss. Numerous large clinical studies showed that the level of albuminuria is associated with ultimate renal outcomes. Clinical trial analyses consistently show that drug-induced changes in albuminuria correlate with the long-term drug effects on renal outcomes. This association appears to be independent of the mechanism of action of the drug, and consistent in populations with different types of CKD. Collectively, these studies provide evidence that albuminuria can be viewed as a separate target for therapy.

QUESTIONS AND ANSWERS

Question 1

Type 2 diabetes mellitus is diagnosed in your patient. Her blood pressure is 143/81 mm Hg. Her last albuminuria measurement was done 1.5 year ago. What do you do?

A. Base your future steps on the urinary albumin level recorded 1.5 year ago
B. Ask the patient to collect a 24-hour urine for measurement of albumin excretion
C. No further action is required. Albuminuria should only be assessed 6 months after diagnosis of type 2 diabetes
D. Ask your patient to collect a first morning void and measure the albumin:creatinine ratio (ACR)

Answer: D

According to American Diabetes Association (ADA) guidelines, albuminuria should be measured in every patient starting at diagnosis and annually thereafter. 24-hour urinary albumin excretion is the "gold standard" measurement because albumin excretion follows a circadian rhythm. However, as 24-hour urine collections are impractical, an easier alternative is the measurement of the ACR in a first morning void urine. The best answer is D.[82]

Question 2

You decide to ask the patient to collect a first morning void. The lab results show an ACR of 85 mg/g. What do you do?

A. Start treatment with ramipril 10 mg/day
B. Ask the patient to collect another first morning void for confirmation
C. No further action is required as the ACR is below 300 mg/g
D. Start treatment with amlodipine 10 mg/day because the ACR is below 300 mg/g and the systolic blood pressure is above 140 mm Hg

Answer: B

Several guidelines recommend performing a repeat test to confirm the presence of microalbuminuria or macroalbuminuria.[83,84] Answer B is thus correct. However, it should be noted that not all guidelines are in agreement. For example, the ADA guideline does not mention the need for a confirmatory laboratory test. Guidelines do not provide clear recommendations in case the patient is already being treated with ACEI or ARB and a sustained high albuminuria level is present. However, one can consider increasing the dose of the ACEI or ARB, starting diuretic therapy, or recommending decreased dietary sodium intake.[82]

Question 3

A 63-year-old women presents for a routine visit. She has CKD and hypertension. On physical examination, her blood pressure is 139/88 mm Hg and body weight is 72 kg.

The following labs are obtained:

- Hba1c 6.1%
- Total cholesterol 165 mg/dL
- eGFR 46 mL/min/1.73 m^2
- Urinary albumin:creatinine ratio (UACR) 160 mg/g

Her medication consists of hydrochlorothiazide 25 mg/day.

Which of the following is correct?

A. No additional antihypertensive medication is required
B. An ACEI or ARB should be added to control blood pressure and albuminuria
C. A combination of ACEI and ARB should be started as the patient has abnormal albuminuria
D. ACEIs are always preferred over ARBs
E. Hydrochlorothiazide should be discontinued

Answer: B

According the Kidney Disease: Improving Global Outcome (KDIGO) guideline, all patients with nondiabetic kidney disease whose blood pressure is above 130/80 mm Hg should be treated with blood pressure lowering medication.[85] First-line therapies are ACEIs or ARBs. The right answer is thus B. Combination therapy with ACEI and ARBs is not recommended on the basis of the ONTARGET and ALTITUDE trials, which showed no benefit with combination therapy and more adverse events. The guideline does not differentiate between ACEI and ARBs, making Answer D incorrect. Combination of ACEI or ARB with diuretics enhances the effects of the combination vs. the single treatments on both blood pressure lowering and albuminuria lowering.[86]

Question 4

A 45-year-old man has type 2 diabetes mellitus and CKD. You have asked him to collect a first morning void urine for albuminuria measurement. In the past, his urinary albumin levels were always below 30 mg/g, but last month the ACR was 410 mg/g. You have asked the patient to return to your clinic to confirm

this finding. At physical examination, his blood pressure is 138/92 mm Hg and his body weight is 96 kg.

The following labs are obtained:

- Hba1c 7.9%
- Total cholesterol 200 mg/dL
- eGFR 38 mL/min/1.73 m^2
- UACR 680 mg/g

His medications consist of metformin 1500 mg/day, simvastatin 40 mg/day, amlodipine 5 mg/day, and venlafaxine 150 mg/day.

Which of the following is true?

A. No changes in medication are required
B. Any ACEI or ARB should be started
C. Increase the dosage of amlodipine to 10/day
D. Start treatment with atenolol 50 mg/day
E. A patient with type 2 diabetes mellitus and nephropathy should always be treated with an ACEI

Answer: B

According to the KDIGO guideline, all patients with type 2 diabetes mellitus and CKD whose blood pressure is above 130/80 mm Hg with macroalbuminuria should be treated with an ACEI or ARB. The guideline does not differentiate between ACEIs and ARBs, and their effectiveness is likely equivalent. Answer B is therefore the correct answer. Of note, the only two ARBs that have received an indication for the treatment of nephropathy in patients with type 2 diabetes and hypertension are losartan and irbesartan, on the basis of the RENAAL and IDNT trials. Thus, if one follows evidence-based medicine answers, one should start treatment with one of these drugs. Neither increasing the dosage of amlodipine nor starting treatment with atenolol is the best next step.[85,87,88]

Question 5

A 58-year-old man has type 2 diabetes mellitus and CKD. You have asked him to collect a 24-hour urine for measurement of albumin and sodium excretion. In the past, his urinary albumin levels were 900 mg/g (~900 mg/24 h), and you have started treatment with losartan 100 mg/day. Since then, his urinary albumin levels dropped to 600 mg/g. He does not receive other blood pressure-lowering medications. His blood pressure is 141/86 mm Hg.

The following laboratory values are obtained:

- eGFR 33 mL/min/1.73 m^2
- Urinary albumin excretion 630 mg/24 h
- Urinary 24-hour urinary sodium excretion 180 mmol/24 hr

You aim to improve albuminuria control. Which option is preferred?

A. Start treatment with amlodipine 5 mg/day
B. Add an ACEI to the therapeutic regimen
C. Instruct the patient to adhere to a moderately low salt diet of 5–6 g/day
D. Start treatment with atenolol
E. Start treatment with monoxidine

Answer: C

The patient's salt intake (as assessed by 24-hour urinary sodium excretion) is around 10 gram per day. World Health Organization guidelines recommend sodium intake of 5–6 gram of salt per day. Small studies and *post hoc* analyses of randomized controlled trials have shown that dietary sodium restriction and treatment with diuretics potentiate the antialbuminuric effect of ACEIs and ARBs. Thus, although hard evidence is lacking, from a clinical perspective sodium restriction or treatment with diuretics seems to be a rationale choice making Answer C correct.

Question 6

A 63-year-old woman has type 2 diabetes mellitus and CKD. You have asked her to collect a 24-hour urine for measurement of albumin and sodium excretion. In the past, her urinary albumin levels were 400 mg/g, and you started treatment with losartan 100 mg/day. Since then, her urinary albumin levels decreased to 200 mg/g. She also takes hydrochlorothiazide 25 mg/day and adheres to a low sodium diet. Her blood pressure is 135/83 mm Hg.

The following labs are obtained:

- HbA1c 7.3%
- eGFR 48 mL/min/1.73 m^2
- Urinary albumin excretion 630 mg/24 h
- Urinary 24-hour urinary sodium excretion 95 mmol/24 h

You aim to improve albuminuria control. Which option is preferred?

A. Start treatment with a calcium channel blocker
B. Add an ACEI to the therapeutic regimen
C. Start treatment with a sodium-glucose co-transporter inhibitor
D. Start treatment with a GLP-1 receptor agonist

Answer: C

Sodium-glucose co-transporter inhibitors and glucagon-like peptide receptor agonists have been shown to decrease albuminuria in patients with type 2 diabetes. In clinical trials of patients with type 2

diabetes and high cardiovascular risk, SGLT-2 inhibitors also slow progression of renal function decline. A dedicated renal outcome trial with an SGLT-2 inhibitor (canagliflozin) demonstrated a 30% lower risk for developing the primary composite outcome of time to dialysis or kidney transplantation, doubling of S[Cr], and renal or CV death with canaglifozin.[89] Based on this trial, it is expected that SGLT-2 inhibitors will be part of guideline recommended treatment in 2019 or 2020. Therefore, Answer C should be correct.

Protein Energy Metabolism in Chronic Kidney Disease

Manuel T. Velasquez, Sarah C. Andrews, Dominic S. Raj

Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States

Abstract

Chronic kidney disease (CKD) patients with protein energy wasting (PEW) have increased morbidity, mortality, and diminished quality of life. This dysfunctional metabolic state is characterized by anorexia, ineffective utilization of nutrients, and augmented muscle protein catabolism, which leads to loss of lean body mass. A multitude of factors contribute to PEW, including inflammation, oxidative stress, hormonal dysregulation, resistance to the actions of insulin and growth hormone (GH), and metabolic acidosis. These factors trigger muscle breakdown through activation of the ubiquitin-proteasome system, oxidation of branched-chain amino acids, and apoptosis. Several treatments for PEW have been proposed in the KDOQI guidelines, including nutritional goals to maintain protein stores. Potentially relevant treatments that have yielded controversial results so far include aerobic and resistance exercise, treatment with human GH, and bicarbonate supplementation. Other potential treatments requiring additional study for safety and efficacy in humans include ghrelin administration and testosterone treatment. Understanding the etiology of this maladaptive metabolic state is important for the development of new therapies for treatment of PEW. The current pathophysiology of PEW remains elusive, and treatment of PEW in the CKD population remains difficult.

SCOPE OF THE PROBLEM

Protein energy wasting (PEW) is a maladaptive metabolic state, well defined in end-stage renal disease (ESRD) patients. The International Society of Renal Nutrition and Metabolism (ISRNM) expert panel recommends use of the term "protein energy wasting" for loss of body protein mass and fuel reserves in patients with chronic kidney disease (CKD) and ESRD.[1] PEW should be distinguished from malnutrition. The latter is due to inadequate intake of nutrients with intact adaptive metabolic responses. PEW, or its extreme form, cachexia, is a dysfunctional state common in inflammatory conditions, which is resistant to nutritional supplementation.[1,2] PEW occurs in 20–70% of adults treated with dialysis. Its prevalence is affected by type of dialysis, the population studied, and the assessment tool used to estimate nutritional status.[3] Recently, a meta-analysis of Contemporary Observational Studies from the ISRNM reported the prevalence of PEW ranged from 11 to 54% in patients with CKD stages 3–5 and 28–54% in dialysis patients.[4] The prevalence of PEW and inflammatory markers increases with decline in glomerular filtration rate (GFR). Results from the National Health and Nutrition Examination Survey (NHANES) III confirm that renal function is independently associated with PEW.[5] Muscle wasting can also be caused by factors that may or may not be related to kidney disease. Quality of life is significantly affected by PEW, which is associated with increased frailty, decreased mobility, and psychological effects.[6] PEW is caused by a multitude of factors (Figure 16.1 and Table 16.1).

PATHOPHYSIOLOGY OF PEW

Anorexia and Nutrient Insufficiency

Insufficient nutrient intake is an integral component in the development and maintenance of PEW. The pathophysiology of PEW in CKD patients is multifactorial and includes anorexia, accumulation of uremic retention solutes or "toxins," increase in inflammatory cytokines, changes in taste, and disruption of appetite sensing molecules, such as ghrelin and leptin.[7,8] Most studies of

Contributors to PEW	Causes of Contribution to PEW	Organism	References
	E3 ubiquitin conjugating enzymes, atrogin-1 and MuRF1, and muscle breakdown. Diabetic ESRD patients have enhanced rate of muscle wasting compared with nondiabetic ESRD individuals.	Humans	Pupim et al. 2005[44]
	Mice have increased levels of inflammatory cytokines due to increased glucocorticoid levels and insulin and insulin-like growth factor resistance in muscle.	Mice	Hu 2009[43]
Growth hormone resistance	There are mixed results on levels of GH in CKD patients. Decreased activation of the JAK/STAT pathway leads to decreased IGF-1 expression. Inflammation antagonizes positive effects GH has on protein metabolism in ESRD patients.	Humans	Rabkin et al. 2005,[53] Garibotto et al. 2008[62]
Low testosterone	Men with low testosterone levels and CKD stages 3 through 5 had twofold higher mortality. In men with CKD stages 2 through 4, testosterone levels are an independent predictor of muscle strength and fat-free mass, potentially caused by increased expression of myostatin and altered IGF-1 signaling.	Humans	Cigarran et al. 2013,[65] Haring et al. 2011[67]
Metabolic acidosis	Rats with renal failure and metabolic acidosis had preferential degradation of muscle protein through the ubiquitin-proteasome pathway.	Rats	May et al. 1987[69]
	Metabolic acidosis leads to a decrease in serum levels of essential branched-chain amino acid levels in muscle. Metabolic acidosis also activates ATP-dependent pathway involving ubiquitin and proteasomes.	Humans	Carrero et al. 2013,[68] Mitch 1998[70]
Inflammation	Inflammation indicators were associated with GFR and cystatin C in CRIC Study participants.	Humans	Gupta et al. 2012[78]
	In ESRD patients, IL-6 expression in muscle intensifies muscle protein catabolism and amino acid release that results in acute phase protein synthesis. Inflammation also induces expression of protein catabolism genes in ESRD patients.	Humans	Raj et al. 2008,[84] Raj et al. 2003[85]
	NFκβ pathway activation decreases protein synthesis, inhibits differentiation of myocytes, and decreases MyoD expression.	Humans	Mak et al. 2012,[7] Guttridge 2000[87]
Muscle biology dysfunction	Patients and rats with CKD have increased expression of myostatin, FOXO, atrogin-1, MuRF1, ubiquitin, and the 26SW proteasome subunits as well as decreased expression of IGF-1.	Humans and Rats	Sun et al. 2006,[88] Verzola et al. 2011,[90] Xu et al. 2012[92]
	ESRD patients have increased levels of 14-kDa actin fragment, which is characteristic of muscle degradation.	Humans	Rajan and Mitch 2008[48]
Oxidative stress	Oxidative stress increases inflammation through the NFκβ pathway. Protein structure is modified to resist ubiquitination and breakdown, which leads to increased generation of reactive oxygen species.	Humans	Bonanni et al. 2011,[8] Grune et al. 2003,[101] Dounousi et al. 2006[102]
Comorbidities	Diabetic ESRD patients have higher rates of muscle catabolism and increased atherosclerotic CVD due to increased levels of proinflammatory cytokines. Diabetic ESRD patients also have increased CRP levels and chronic heart failure associated with pathways contributing to PEW.	Humans	Pupim et al. 2005,[44] Stenvinkel 1999,[104] Panichi et al. 2002[105]

PEW have focused on the dialysis population, where anorexia is present in 30–40% of patients, associated with increased mortality, poor quality of life, and an increased inflammatory state with high levels of proinflammatory cytokines.[9] In progressive CKD, increased uremic toxins are associated with nausea, vomiting, and anorexia.[8]

Nutrient insufficiency in CKD may be caused by factors that lead to decreased ingestion of nutrients due to anorexia, as well as inhibition of uptake of nutrients due to changes in gastric motility. HD patients were first noted to have problems with nutrition in a case report from 1960.[10] Uremic toxins influence nutritional absorption in rats after intraperitoneal injection of uremic plasma ultrafiltrate, and uremic toxins inhibit carbohydrate intake.[11,12] In CKD patients, a decrease in estimated glomerular filtration rate (eGFR) was associated with a spontaneous decrease in energy and protein intake.[13] Individuals with the lowest kidney function (GFR $<19.9\ \text{mL/min/1.73 m}^2$) had the smallest consumption of food, as well as the lowest values for body mass index (BMI), triceps skinfold thickness, and mid-arm muscle circumference. Children with CKD have stunted growth, which is present even when GFR levels are as high as $70\ \text{mL/min/1.73 m}^2$, which is associated with an increase in uremic toxins.[14] Growth rates in children were significantly diminished when normal nutritional intake decreased to less than 80% of recommended levels.[15] In addition, studies have shown impairment of gastric motility in patients with CKD. Hirako et al. demonstrated that patients with CKD prior to initiation of dialysis had gastric hypomotility, impaired gastric myoelectrical activity, and delayed gastric emptying.[16] Other factors that can influence nutrient intake in CKD patients include depression, socioeconomic status, and altered mental status.[6]

Energy Balance

Disruption of energy balance contributes to PEW, both through lack of nutritional intake and energy expenditure changes. Individuals with CKD potentially have changes in total energy expenditure through changes in resting energy expenditure (REE), physical activity, and thermoregulation. Contrary to expectation, after adjusting for lean body mass (LBM), ESRD patients treated with dialysis have normal REE.[17] CKD patients have a lower REE compared with individuals with normal kidney function.[18] In CKD, the lower REE can potentially be explained by decreased energy expenditure of the kidney due to loss of function, decreased glucose oxidation, and dysfunctional skeletal muscle energy utilization.[19] Lower REE in CKD is surprising, because chronic diseases such as diabetes, hyperparathyroidism, and increased inflammation lead to higher REE.[19,20] Indeed, a study in nondialysis CKD patients illustrated that increased REE was associated with inflammation.[20]

Not all studies of energy balance in ESRD patients have shown consistent results. Neyra et al. showed ESRD patients have increased REE.[21] Dialysis also affects energy balance. Patients treated with continuous ambulatory PD with higher REE had increased all-cause and cardiovascular mortality.[22] Uncoupling proteins could also play a role in increased REE, with their increased activity leading to increased energy expenditure. Uncoupling protein 1 (UCP-1) and uncoupling protein 3 (UCP-3) release energy in the form of heat *via* thermogenesis in humans and mice. Cheung et al. illustrated that mice with uremia had increased levels of UCP-1 mRNA and protein and UCP-3 protein in brown adipose tissue, which was associated with a 10% increased REE, compared with normal controls.[23]

Hormonal Dysfunction

A variety of hormones, including ghrelin, leptin, peptide YY (PYY), and cholecystokinin (CCK), modulate appetite, nutrient intake, nutritional status, and energy expenditure, which may be involved in PEW in patients with CKD. Neuropeptides function to maintain energy homeostasis by responding to changes in hormone levels that dictate satiety and hunger, such as leptin and ghrelin.[24] Leptin is a hormone secreted from adipocytes that modulates appetite and increases energy expenditure. CKD patients have increased circulating levels of leptin, possibly due to lack of breakdown of the hormone by the kidneys.[25] ESRD patients also have hyperleptinemia due to increased release of the hormone, as demonstrated when visceral adipocytes are exposed to plasma from ESRD patients.[26] Leptin has two concurrent effects within the arcuate nucleus in the hypothalamus that lead to satiety and an increase in energy expenditure. Leptin activates the melanocortin receptor-4 (MC4-R), causing increased energy expenditure and inhibition of food intake. Simultaneously, leptin inhibits the activity of the neuropeptide Y/agouti-related peptide (AgRP) neurons, which prevents the secretion of AgRP, a natural antagonist of MC4-R that stimulates food intake and increases both lean mass and fat mass.[27] Castaneda-Sceppa et al. showed that higher leptin levels were associated with lower muscle mass in patients with stage 3 and 4 CKD.[28] However, further evidence of increased leptin contributing to muscle wasting is lacking in humans. Hyperleptinemia is not associated with worse appetite in dialysis patients.[29]

Mak et al. demonstrated that blocking the activity of leptin using genetic and pharmacological interventions in rats attenuates PEW by decreasing energy expenditure and increasing muscle and fat mass.[30,31] AgRP

administration in CKD mice also normalized protein levels of the inflammatory biomarkers interleukin (IL)-6 and tumor necrosis factor-α (TNF-α), and expression levels of molecules involved in muscle mass turnover, such as myostatin and insulin-like growth factor-1 (IGF-1). Cheung et al. demonstrated that intraperitoneal administration of NBI-12i to uremic mice was associated with increased food intake, weight gain, lower basal metabolic rate, and gains in LBM and fat mass.[30] The oral MC4-R antagonist BL-6020/979 diminished cachexia-like symptoms in a murine C26 adenocarcinoma model, and increased energy intake and decreased energy expenditure in normal mice.[32] Future studies are necessary to evaluate whether MC4-R antagonists could be used as an effective and safe treatment for PEW in clinical settings.

Ghrelin is a peptide hormone released from the stomach that has a number of functions relevant to PEW, including appetite stimulation through orexigenic signaling to the hypothalamus and effects on gastric motility and food intake. Studies of ghrelin in dialysis patients have yielded conflicting results. A report in children with ESRD showed that plasma ghrelin levels were no different in children treated with PD, children receiving conservative treatment, and children of similar BMI with normal kidney function.[33] Pérez-Fontán et al. showed an increase in plasma ghrelin levels in HD and PD patients compared with controls.[34] Another study showed that HD and control patients had normal plasma ghrelin levels, but PD patients had decreased levels of ghrelin.[35]

The type of ghrelin measured in these studies may be a confounding factor, leading to the differences in these reports. There are two major types of ghrelin, with opposite functions. Acylated ghrelin stimulates food intake, whereas des-acyl ghrelin promotes negative energy balance. Des-acyl ghrelin plasma levels are elevated in CKD patients, with higher levels in those patients with worse renal function.[36] Muscaritoli et al. also showed des-acyl levels are higher in HD patients, suggesting that des-acyl ghrelin may contribute to the pathogenesis of anorexia.[37]

PYY is a gut hormone released during feeding, which suppresses gastric motility and appetite. Administration of PYY_{3-36} lowers total daily food intake in humans.[38] PYY and other gastric hormones are dysregulated and are present in higher levels in ESRD patients compared with patients with normal renal function, suggesting that these hormones may be involved in gastric dysregulation and its associated symptoms in CKD patients.[39] Further studies and better assay technologies are needed to determine if these gut hormones are potential targets to develop therapies to improve nutritional intake and appetite in this population.

CCK suppresses energy intake and satiety and slows gastric emptying when released from peripheral and central receptors from the intestine.[40] CCK has synergistic effects with leptin, suppressing food intake after a meal begins. ESRD patients have higher plasma levels of CCK compared with patients with normal renal function. Peripheral administration of CCK has been associated with a decrease in short-term food intake in humans.[41] However, CCK administration does not decrease body weight or influence changes in daily caloric intake due to compensation by eating more frequent meals. Blocking the action of CCK could be a potential way to influence decreased food intake, anorexia, nausea, and vomiting in CKD and ESRD patients.[40]

Insulin Resistance

Insulin resistance contributes to PEW by influencing pathways that control regulation of muscle regeneration and breakdown. In CKD, there are at least two major pathways that can cause insulin resistance in muscles that dysregulates protein breakdown: metabolic acidosis and an increase in glucocorticoids.[42] Inflammatory cytokines also contribute to insulin resistance by increasing glucocorticoid levels and promoting insulin and IGF-1 resistance in muscle.[43] The significant role insulin resistance plays in PEW is demonstrated by comparing individuals with diabetes and ESRD with their nondiabetic counterparts. Diabetic ESRD patients had enhanced muscle wasting compared with nondiabetic ESRD patients.[44]

Insulin and IGF-1 stimulate and act through specific pathways to prevent muscle degradation. The insulin receptor signaling (IRS)/phosphatidylinositol 3-kinase (PI3K)/Akt pathway regulates the metabolic activities of insulin and is involved in muscle maintenance.[45] The forkhead transcription factor (FOXO) family members are key regulators of the downstream catabolic effects of insulin resistance. FOXO activates muscle E3 ubiquitin conjugating enzymes atrogin-1 and muscle ring finger-1 (MuRF1), two key proteins functioning in muscle proteolysis by tagging proteins for degradation.[46] Activation of the IRS/PI3K/Akt pathway by insulin phosphorylates Akt, which suppresses the activity of FOXO and prevents activation of atrogin-1 and MuRF1. Rats with chronic renal failure have reduced phosphorylation of Akt, pointing to suppression of the IRS-1/PI3K/Akt signaling as a potential pathway leading to muscle breakdown.[47] Metabolic acidosis can also cause insulin resistance by inducing the ubiquitin signaling pathway.[48] Treating chronic renal failure rats with bicarbonate reversed muscle proteolysis and

recovered the function of the IRS/PI3K signaling pathway. The signal regulatory protein-α (SIRP-α) glycoprotein was identified as being involved in insulin signaling that contributes to PEW in mice with CKD.[45] Mice with overexpressed SIRP-α had insulin resistance and increased muscle breakdown.[45] Blocking SIRP-α expression led to phosphorylation of the insulin receptor and IRS-1, activating phosphorylated Akt, and preventing protein breakdown.[45]

Glucocorticoids and insulin have antagonistic roles in muscle degradation. Glucocorticoids can block PI3K from binding to the insulin receptor, either by binding to specific subunits of PI3K (such as p85) or stopping its activity by modifying the structure of its subunits.[43] Whichever modification occurs, the direct result is activation of atrogin-1 and MuRF1 by FOXO. Increase in circulating glucocorticoid levels also stimulates the glucocorticoid receptor, leading to binding of PI3K and suppression of Akt phosphorylation.[43] Glucocorticoids activate ubiquitin through the MEK/ERK signaling pathway and also cause expression of atrogin-1 and MuRF1, increasing muscle breakdown.[42]

Low vitamin D levels have been associated with insulin resistance. A NHANES III study demonstrated that individuals with the lowest eGFR (15−29 mL/min/1.73 m^3) had the lowest levels of 25-hydroxyvitamin D. CKD patients with eGFR between 30 and 59 mL/min/1.73 m^3 had vitamin D levels similar to those with normal kidney function.[49] Vitamin D levels and kidney function were inversely associated with insulin resistance measured by HOMA-IR. $1,25(OH)_2D_3$ functions in the pancreas by inducing insulin release from islet cells.[50] Increasing vitamin D levels by injection of vitamin D_3 was associated with a decrease in insulin resistance and induced insulin secretion in animals with low levels of $1,25(OH)_2D_3$ and in patients with ESRD.[51,52]

Growth Hormone Resistance

Growth hormone (GH) resistance is a major issue in patients with CKD that leads to stunted growth in children and PEW in adults. GH secretion from the pituitary gland is influenced by several factors, including ghrelin, PYY, and leptin.[53] The results of studies in CKD patients have not been consistent. Some studies report decreased, normal, or even increased production levels of the hormone. Studies in late prepubertal and early pubertal patients show low or normal levels of pulsatile secretion of GH, whereas prepubertal children and adults with ESRD have increased secretion of GH.[54] GH levels tend to be increased in patients with CKD, most likely due to decreased renal metabolic clearance rate (MCR) of GH. Haffner et al. showed the MCR of GH is decreased by 50% in patients with CKD or ESRD compared with healthy controls, and that the relationship between the MCR of GH and GFR is linear.[55]

The role of GH in PEW is thought to be due to defects in the GH and IGF-1 signaling pathways.[53] Studies in uremic rats reported low levels of the growth hormone receptor (GHR), documented by measuring hepatic GHR mRNA levels and growth plate GHR protein levels.[56,57] However, other studies in animals have found no difference in GHR levels between uremic rats and pair-fed controls.[58,59] In humans, GHR levels have been measured using GH-binding protein (GHBP) levels as a surrogate. This protein is enzymatically cleaved from the GHR receptor and released into the circulation. Most studies show low levels of GHBP in patients with CKD.[53] Powell et al., however, showed children with CKD had similar levels of GHBP at baseline, 3 months, and 12 months after treatment with GH.[60] Rabkin et al. also suggested that GHBP may not be the most accurate measure of GHR levels. In adult ESRD patients, GHBP levels were low, whereas levels of GHR from peripheral blood mononuclear cells were normal.[61] Further studies are necessary to determine what level of GHR is normal in specific tissues, and whether GHR levels influence GH resistance.

Muscle degradation in PEW may be the result of depressed IGF-1 expression due to decreased GH activation of the Janus kinase 2-signal transducer and activator of transcription pathway.[53] Garibotto et al. demonstrated GH response decreases with increasing age and inflammation, and that inflammation directly antagonizes the positive effect GH has on potassium and protein metabolism in the skeletal muscle of ESRD patients.[62]

Testosterone

Testosterone is an important hormone in muscle maintenance. Testosterone increases the efficiency of amino acid reuse in skeletal muscle, preserves nitrogen to facilitate skeletal muscle growth, causes myoblast differentiation, and increases fractional muscle protein synthesis.[63] Testosterone levels decrease with age and are further decreased in diseases such as hypertension, diabetes, CKD, and ESRD.[64] In addition, endogenous testosterone levels are associated with muscle strength and fat-free mass in men with CKD.[65] Low testosterone levels were associated with increased all-cause and cardiovascular disease (CVD)-related mortality in men treated with dialysis.[66] Haring et al. showed men with both total testosterone levels below the 10th percentile by age and kidney dysfunction (eGFR <60 mL/min/1.73 m^2) had more than a twofold higher all-cause mortality compared with men with kidney dysfunction

and total testosterone greater than the 10th percentile.[67] Both women and men with CKD have low testosterone levels.[63,68] A study in patients with stage 2−4 CKD demonstrated that endogenous testosterone is an independent predictor of muscle strength, measured by handgrip strength, as well as fat-free mass measured by bioelectrical impedance (BIA).[65] Men with CKD in the lower third of testosterone distribution had lower fat-free mass and handgrip strength of 31.9 ± 10.1 kg, compared with men in the upper third of testosterone distribution who had an average handgrip strength of 38.3 ± 8.8 kg.[65] Possible causes of low testosterone influencing PEW include increased expression of myostatin and altered IGF-1 signaling. Studies in humans and rats indicate that males are more affected by inflammation-induced anorexia compared with females, with appetite loss associated with gender.[42,68]

Metabolic Acidosis

Metabolic acidosis is an important contributor to PEW in CKD. Metabolic acidosis exacerbates muscle wasting through various mechanisms. In classic experimental studies, May et al. demonstrated that rats with renal failure and metabolic acidosis had preferential degradation of muscle protein.[69] This protein breakdown occurs even at moderate levels of acidosis (20 mmol/L bicarbonate).[70,71] Protein breakdown is mediated by activation of the adenosine triphosphate-dependent pathway involving ubiquitin and proteasomes.[72,73] Metabolic acidosis also causes a decrease in serum levels of essential branched-chain amino acid levels in muscle, contributing to muscle wasting.[68] Abnormal muscle signaling, inflammation, and dysregulation of IGF-1 signaling may also contribute to muscle wasting seen in patients with metabolic acidosis.[74] Metabolic acidosis induces insulin resistance.[75] Bailey et al. showed that acidosis in CKD leads to accelerated proteolysis through the IRS/PI3K/Akt pathway.[47] Correction of metabolic acidosis in rats decreased muscle catabolism through increasing IRS-associated PI3K activity, illustrating the importance of insulin and IGF-1 signaling in modulating muscle protein catabolism.[47]

Inflammation

There is considerable evidence that inflammation is intimately involved in the pathogenesis of PEW in CKD. CKD leads to a state of inflammation associated with increased morbidity and mortality.[76,77] Gupta et al. demonstrated that markers of inflammation were significantly associated with eGFR and cystatin C in Chronic Renal Insufficiency Cohort Study participants.[78] Increased cytokine levels in patients with CKD may be due to increased production or decreased renal clearance. Inflammation in patients with CKD could also be caused by volume overload,[79] chronic subclinical infections,[80] dysbiosis of the gut leading to endotoxin production,[81] oxidative stress,[82] and poor nutrition.

Inflammatory cytokines are involved in the pathways affecting PEW and contribute to anorexia and increased energy expenditure. Increased expression of proinflammatory cytokines contributes to GH, insulin, and IGF-1 resistance (Figure 16.2). In animal studies, infusion of inflammatory markers IL-6, IL-1β, TNF-α, and interferon (IFN)-γ leads to muscle catabolism, whereas blocking the action of these markers mitigates muscle breakdown.[83] When secreted from the muscle, IL-6 acts as a hormone, signaling and affecting the liver and adipose tissue. Raj et al. showed that IL-6 expression in skeletal muscle intensifies muscle protein catabolism and results in acute phase protein synthesis from the released amino acids rather than muscle protein synthesis in ESRD patients (Figure 16.2).[84] The expression of IL-6 also induces the expression of genes involved in protein catabolism.[85] Subclinical endotoxemia has been implicated as a key mediator of inflammation in CKD. Soluble CD14, a receptor through which endotoxin mediates its action, has been shown to be associated with PEW in ESRD patients, where it acts through the stimulation of inflammatory cytokines.[86]

Most of the inflammatory cytokines contributing to PEW induce muscle catabolism through the nuclear factor κβ (NFκβ) pathway, which regulates expression of downstream targets involved in the inflammatory response. The upregulation of TNF-α leads to activation of NFκβ, leading to inhibition of differentiation of myocytes and decreased protein synthesis induced by insulin signaling.[7] NFκβ signaling causes attenuation of MyoD expression, preventing muscle repair and differentiation.[87] Inflammation can also lead to increased production of glucocorticoids, which leads to increased muscle catabolism.[43] Activation of caspase 3 and the ubiquitin-proteasome pathway are the key mechanisms responsible for muscle wasting *via* inflammation.

Muscle Biology Dysfunction

Muscle catabolism in PEW occurs due to disruption in the balance of molecules involved in maintenance of muscle mass, especially myostatin and IGF-1.[88] These molecules have antagonistic roles in muscle. Myostatin expression increases muscle breakdown, whereas IGF-1 stimulates muscle protein synthesis and development.[89] Patients with stage 5 CKD before dialysis treatment have increased levels of myostatin mRNA, IL-6, and apoptosis in skeletal muscle, as well as decreased

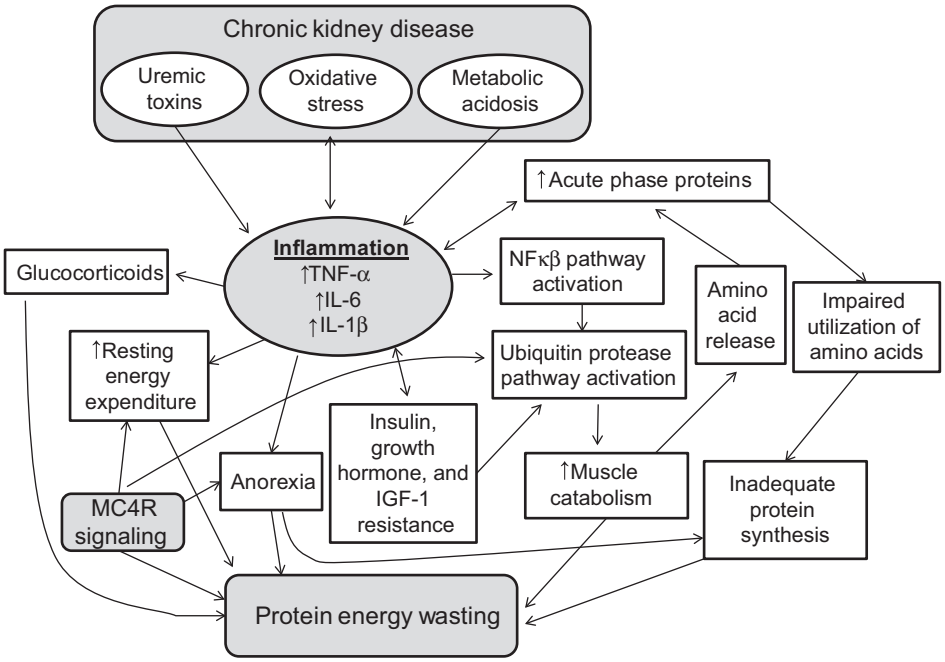

FIGURE 16.2 Interaction of different etiologies leading to protein energy wasting in chronic kidney disease (CKD). Uremic toxins, oxidative stress, and metabolic acidosis are present in CKD, leading to increased levels of proinflammatory cytokines (TNF-α, IL-6, IL-1β). Inflammation causes increased glucocorticoid production, increased resting energy expenditure, anorexia, insulin resistance, GH resistance, IGF-1 resistance, and activation of the NFκβ pathway. The ubiquitin-protease pathway is activated by NFκβ signaling, MC4-R signaling, and insulin and IGF-1 resistance, leading to increased muscle catabolism. Subsequently, muscle catabolism causes increased amino acid release, triggering release of acute phase proteins. These proteins cause impaired utilization of amino acids, leading to inadequate protein synthesis, and ultimately protein energy wasting. In addition, MC4-R signaling increases resting energy expenditure in end-stage renal disease patients and causes anorexia, both leading to protein energy wasting. Abbreviations: *IGF-1*, insulin-like growth factor-1; *IL*, interleukin; *NFκβ*, nuclear factor κβ; *MC4-R*, melanocortin; *TNF-α*, tumor necrosis factor-α.

levels of IGF-1.[90] Cheung et al. found AgRP antagonism of MC4-R in CKD mice reversed altered myostatin and IGF-1 gene expression, compared with untreated CKD mice.[30,31]

Modified muscle protein kinetics in PEW is responsible, at least in part, for increased muscle catabolism and decreased myogenesis.[91] The ubiquitin-proteasome system is the major pathway contributing to muscle breakdown, which is regulated by expression of FOXO transcription factors. Muscle-specific FOXO1 deletion in mice prevented muscle mass degradation compared with CKD control mice.[92] In addition, microRNA-486 inhibition of FOXO1 prevents loss of LBM.[92] Levels of ubiquitin, 26SW proteasome subunits, atrogin-1, and MuRF1 are increased in animal models of CKD,[48] and in patients with ESRD with muscle degradation.[93] In addition, caspase 3 degrades actomyosin to produce a 14-kDa actin fragment, a characteristic measure of muscle degradation. ESRD patients have increased levels of this 14-kDa actin fragment, along with increased rates of apoptosis in skeletal muscle. Studies by Workeneh and Mitch show the density of the 14-kDa actin fragment is significantly correlated with the rate of protein breakdown.[94]

Maintenance of cellular energy and metabolic balance during periods of decreased nutrient intake is fundamental to the structural and functional integrity of all cells. The main regulator of cellular energy homeostasis in virtually all eukaryotic cells is the AMP-activated protein kinase (AMPK).[95] AMPK is a serine/threonine protein kinase that acts as an energy sensor to regulate growth and metabolism at both the cellular and whole body levels.[96] An AMPK activator, A-769662, attenuated fibrosis and improved energy status in the kidneys in a murine model of CKD.[97] These findings suggest that a failure to sense AMP is a key mechanism underlying energy depletion and CKD progression.

Another protein kinase that mediates muscle protein loss in CKD is Rho-associated coiled-coil containing kinase 1 (ROCK 1). Peng et al. showed ROCK 1 enhances the activity of phosphatase and tensin homolog and reduces Akt activity.[98] A novel nuclear phosphatase, the small C-terminal domain phosphatase (SCP) 4, is another regulator of skeletal muscle protein synthesis and degradation implicated in muscle wasting. SCP4 expression was upregulated in the skeletal muscle of mice with CKD, as well as in the skeletal muscle of CKD patients.[99] Deletion of SCP4 significantly

suppressed FOXO1/3a-mediated expression of atrogin-1 and MuRF1 and prevented muscle wasting in mice with CKD. Thus, targeting SCP4 may prevent muscle wasting in CKD.

Dysfunction of satellite cells also contributes to the muscle degeneration seen in CKD. Satellite cells are located below the basal lamina of myofibers and are involved in repair and maintenance of muscle mass.[94] Satellite cells are induced after injury, and, once activated, they proliferate and differentiate to repair muscle. In CKD, breakdown of muscle occurs by decreasing the size of the muscle myofibers and inhibiting muscle regeneration by stopping satellite or stem cells from binding to myofibers.[68] Dysregulation of IGF-1 signaling in CKD prevents satellite cells from repairing muscle.[69]

Oxidative Stress

Oxidative stress can induce the NFκβ pathway, increasing levels of inflammation.[8] The opposite can also occur, where chronic inflammation causes oxidative stress. Both oxidative stress and inflammation can activate pathways contributing to muscle protein degradation and PEW. Oxidative stress modifies proteins, making them resistant to ubiquitination.[100] In addition, heavily oxidized proteins form covalent bonds with each other to severely inhibit proteolysis, in turn leading to buildup of protein aggregates in the cell.[101] A study in patients with CKD stages 1−4 showed oxidative stress increased with worsening kidney function, and oxidative stress significantly inversely correlated with GFR.[102] Studies in dialysis patients also show that overall secretion of malonaldehyde and carbonyl protein from the muscle acts as a marker of increased generation of reactive oxygen species.[103]

Comorbidities

CKD is associated with several comorbidities, such as diabetes mellitus, inflammation, chronic heart failure, hypertension, infection, and psychological changes, which may contribute to PEW. Diabetes affects muscle breakdown through insulin resistance. Diabetic ESRD patients have higher rates of muscle catabolism than their nondiabetic counterparts, illustrating that diabetes exacerbates PEW and the rate of protein breakdown.[44] CVD is a common comorbidity in CKD, with changes in the vasculature increasing the risk of myocardial infarction and stroke. In addition, malnutrition or PEW, along with increased levels of proinflammatory cytokines, is associated with atherosclerotic CVD.[104] One of the most used biomarkers in CVD is the C-reactive protein (CRP), which is a potent CVD risk factor. Panichi et al. illustrated that levels of CRP and IL-6 increase with decreasing GFR.[105] In addition, chronic heart failure is associated with low cardiac output, inducing glucocorticoids, increased angiotensin II, and sympathetic nerve activity,[68] pathways contributing to PEW. Finally, inflammation and proinflammatory cytokines can play roles in the pathogenesis of depression due to their effect on neurotransmitters and neurohormones in the brain.[106] These psychological changes can cause lack of appetite, fatigue, and physical inactivity, contributing to PEW.

DIAGNOSIS OF PEW IN CKD

The guidelines for diagnosis of PEW by the ISRNM establish standard nomenclature and definitions for PEW in CKD.[107] Diagnosis of PEW in CKD patients is determined by four key categories: (1) changes in biochemical indicators, (2) weight loss, decrease in total body fat, and low body weight, (3) decrease in muscle mass, and (4) low protein or energy intake (Figure 16.3). At least three out of these four categories, with at least one criterion from each of these categories, should be satisfied to establish the diagnosis of PEW in CKD patients. Fulfillment of these criteria should be observed at least three times at intervals of 2−4 weeks.

The ISRNM recommends that at least one of the diagnostic criteria includes a biochemical indicator, such as S[Alb]. Circulating levels of albumin and prealbumin are strong predictors of mortality in CKD and dialysis patients,[77,108] but can be affected by inflammation. In addition, hypoalbuminemia may reflect low levels of nutrition or inflammation. Kaysen et al., however, determined that after controlling for inflammation, hypoalbuminemia may not predict mortality in ESRD patients.[109] A biochemical indicator of PEW includes S[Alb] less than 3.8 g/dL. Low levels of serum prealbumin, or transthyretin, can also be a measure used for diagnosis in dialysis patients, but they vary in patients with CKD stages 2−5.[109] Serum cholesterol level less than 100 mg/dL is also a biochemical indicator of PEW.

A recent study of participants in the general and moderate CKD populations from the 1999−2004 NHANES showed the presence of all three nondietary categories was associated with significantly lower LBM and fat mass and very strongly associated with increased mortality.[110] The presence of dietary category in addition to two nondietary categories was also associated with significantly lower LBM and fat mass and mortality. However, when the dietary category alone was considered, the presence of any one of the categories was surprisingly associated with higher LBM and higher fat mass. Inclusion of dietary category undermines the face validity of the PEW criteria as a measure of protein or energy wasting. Thus, a modified

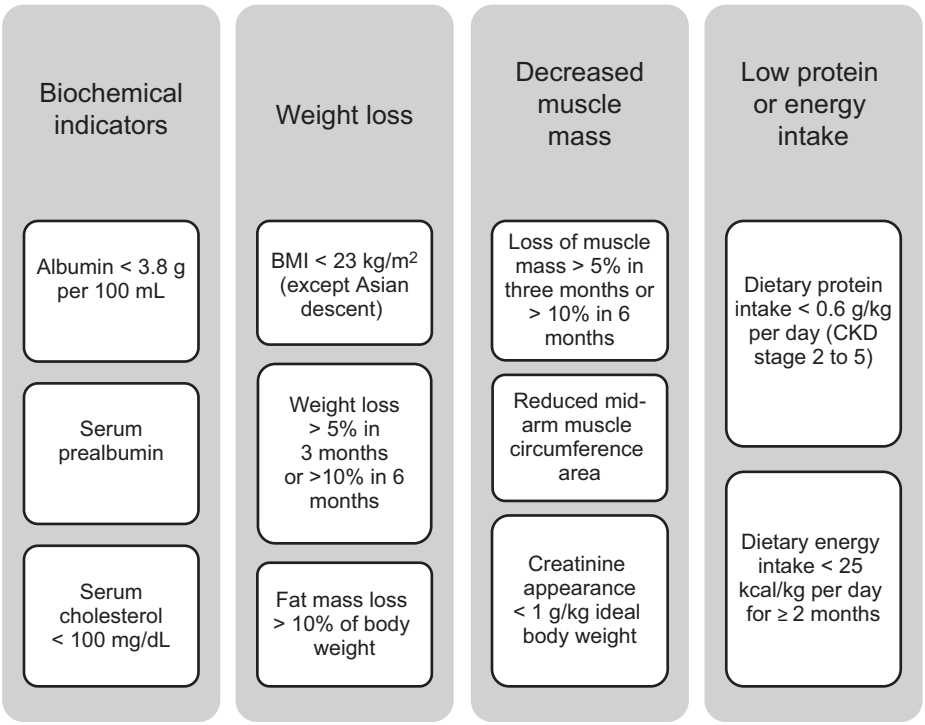

FIGURE 16.3 Diagnosis of protein energy wasting (PEW) in chronic kidney disease. At least three of these four categories must be met, with at least one criterion from each category satisfied for diagnosis of PEW. Fulfillment of these criteria should be confirmed at least three times at intervals of 2–4 weeks.

definition of PEW without dietary variables is likely a better indicator of protein or energy wasting. Similarly, in ESRD patients treated with hemodialysis, low protein or energy intake was not associated with PEW. Paradoxically, high dietary intake was associated with increased risk of the PEW.[111]

Decrease in body mass is also used to diagnosis PEW, with BMI being the most commonly used measure. Although BMI is heavily influenced by body fat and hydration status, BMI levels less than 23 kg/m^2 are an indicator of PEW in CKD and ESRD patients.[107] This threshold may not be suitable for individuals of Asian descent, where low BMI levels do not necessarily indicate chronic disease.[112] Unintended weight loss over a short amount of time is also used to diagnose PEW, independent of BMI. This includes more than a 5% loss of weight over 3 months and more than a 10% decrease over 6 months. Finally, loss of fat mass greater than 10% of an individual's body weight is an indicator of wasting. Decrease in body fat mass in dialysis patients is associated with increased mortality.[113]

Loss of muscle mass is the most consistent criterion for PEW in ESRD.[114] Although fat and muscle stores are both lost in PEW, the loss of LBM is thought to be more detrimental. This has been demonstrated by studies in dialysis patients, where the protective advantage of individuals with higher BMI is associated with the amount of lean muscle mass rather than fat mass.[115] Kalantar-Zadeh et al., however, have shown that fat mass is associated with an independent survival advantage in patients treated with dialysis.[116] Investigators have used several methods to estimate LBM, including dual X-ray absorptiometry (DEXA), near-infrared interactance (NIR), and BIA.[91,117] However, there is no good reproducible clinical measure that gives an accurate representation of muscle loss or protein catabolism.[118] Similarly to fat mass, a reduction in 5% of muscle mass over 3 months or 10% over 6 months is an indicator of PEW. Reduced mid-arm muscle circumference area measured by a trained anthropometrist can also be used in diagnosis. Creatinine appearance is an indirect clinical measurement that can be used to assess muscle mass, but it is influenced by meat intake and amount of muscle mass.[107] Creatinine appearance is a measure of the total creatinine generated after degradation and can be identified through 24-hour urine collection in patients with CKD. Levels of creatinine appearance less than 1 g/kg ideal body weight (IBW) can be used in the diagnosis of PEW.[119]

Low protein and energy intake is another key component of the rate of PEW, especially the amounts of dietary protein intake (DPI) and dietary energy intake (DEI). DEI can be measured using interviews or dietary diaries. DPI is measured as the normalized protein

equivalent of the total nitrogen appearance. DPI can be measured by urea kinetics to estimate the net protein degradation and protein intake. Levels of DPI unintentionally less than 0.6 g/kg/per day for patients with CKD stages 2–5 and DEI less than 25 kcal/kg per day for at least 2 months are both diagnostic criteria for PEW. The recommended DEI for CKD patients is 30–35 kcal/kg IBW per day to maintain protein stores.[120,121]

The ISRNM also identified several other measures of body composition, laboratory markers, nutritional scoring systems, and food intake and expenditure that are recognized as important indicators, but not diagnostic tools, for PEW. Measures of body composition that are used to measure body fat and muscle mass include CT or MRI of muscle mass, energy beaming technologies (DEXA, NIR, BIA), air or underwater displacement weighing, muscle measures (muscle fiber size, proportion of muscle fiber types, muscle alkaline soluble protein, and the 14-kDa fragment of actomyosin), total body nitrogen, and total body potassium.[107] The 14-kDa actomyosin fragment serves as a strong indicator of muscle breakdown. Its levels have been shown to be elevated in catabolic states, such as ESRD.[118] In patients with ESRD, the amount of the fragment increases before HD treatment and is further elevated after completion of dialysis.[122] Laboratory measures can also be used as indicators of PEW, including urea, triglycerides, and IGF-1. Transferrin and nutritional scoring systems, such as Subjective Global Assessment of Nutrition questionnaires,[123] can be used to estimate nutritional intake. Additional research is needed to see if these measures could potentially be used in the diagnosis of PEW in CKD patients in the future.

TREATMENT OF PEW IN CKD

Treatment of PEW begins with early identification of the etiologic factors causing nutrient insufficiency and muscle catabolism.[124] Once diagnostic criteria are met, specific therapies should be targeted to the address the presumed causes and the underlying pathophysiology. These therapies will hopefully prevent further muscle breakdown and circumvent worsening of function and perception of quality of life. Treatment of PEW includes changing diet, adding nutritional supplements, incorporating both aerobic and resistance exercise, and pharmacological therapy for metabolic acidosis, insulin, and GH resistance, as well as administration of anabolic steroids (Table 16.2). The treatment of PEW in CKD patients is a balancing act, requiring lifestyle changes and the correct pharmacological dosing to maintain muscle mass and prevent subsequent PEW.[125] Treatments for PEW target specific causes of muscle wasting, from the most experimental to the safest and most effective.

Ghrelin

Ghrelin is a sensor for appetite that may be a potential target for anorectic patients with PEW or cachexia. In 51 CKD and 15 HD patients, des-acyl ghrelin levels increased with decreasing eGFR.[126] Short-term clinical trials in anorexic ESRD patients demonstrated subcutaneous administration of ghrelin enhances appetite and energy intake without side effects.[127,128] Although ghrelin does have some benefits in the short term, it is unknown whether there will be long-term benefits, as appetite-regulating centers may become tolerant.[91] Further studies are needed before ghrelin can be used as a treatment for PEW in CKD patients.

Insulin Resistance and Sensitivity

Insulin resistance in muscle leads to PEW in ESRD patients.[129] Insulin-sensitizing medications, such as rosiglitazone, can improve mortality and suppress breakdown of muscle. Treatment with rosiglitazone, a peroxisome proliferator-activated receptor-γ agonist, suppressed breakdown of muscle in insulin resistant *db/db* mice.[130] In addition, mice treated with rosiglitazone had decreased expression of proteins in the ubiquitin-proteasome proteolytic pathway, including atrogin-1 and MuRF1. Diabetic HD patients treated with thiazolidinedione had improvement of both S [Alb] and 47% lower all-cause mortality at 1 year, compared with patients who did not receive thiazolidinedione.[131] These treatments demonstrate that increasing insulin sensitivity may decrease muscle breakdown by suppressing the ubiquitin-proteasome proteolytic pathway and decrease mortality. Additional studies are necessary to determine whether these treatments are safe and effective in patients with CKD.

Testosterone

Testosterone is an important anabolic hormone that maintains skeletal muscle mass. Male patients with ESRD have low testosterone levels, associated with inflammation and mortality.[132] Johansen et al. performed two clinical trials to investigate the effect of androgen therapy on body composition and muscle function in patients treated with dialysis. Patients treated with nandrolone decanoate, an anabolic steroid, had significant increases in LBM, along with decreased time to complete walking, stair climbing, and treadmill activities compared with a placebo group.[133] The other

TABLE 16.2 Types of Treatment for Protein Energy Wasting in Chronic Kidney Disease

Etiology	Treatment	Benefits	Organism	Reference
Nutrient insufficiency	Low protein diet and nutritional supplements	Suplena (low protein/high caloric) supplement slows progression of CKD and improves nutritional parameters	CKD patients	Montes-Delgado et al. 1998[170]
	Ketoanalogue supplements	Sustains kidney function and maintains S[Alb] and total protein levels	CKD patients	Prakash et al. 2004,[174] Kalantar-Zadeh et al. 2011[159]
Growth hormone resistance	Recombinant human growth hormone	Increases growth rate and catch-up growth to almost normal height (1.6±1.2 SD below normal)	Children with CKD	Fine et al. 1994,[137] Haffner et al. 2000[140]
	Super-agonist of human GHRH (AKL-0707)	Increases fat mass and decreases serum urea	CKD patients	Niemczyk et al. 2010[142]
Low testosterone	Nandrolone decanoate injections	Increases percentage of lean body mass	CKD patients	Eiam-Ong et al. 2007[135]
Metabolic acidosis	Oral bicarbonate	Increases lean body mass, improves dietary protein intake, and slows progression of CKD to ESRD	CKD patients	de Brito-Ashurst et al. 2009[154]
Muscle biology dysfunction	Resistance exercise	Increases muscle mass and mitochondrial DNA copy number, increases muscle strength and protein utilization, and lowers inflammation	CKD patients	Balakrishnan et al. 2010,[144] Castaneda et al. 2004[145]
Inflammation	Pentoxifylline infusion	Decreases whole body proteolysis	CKD patients	Biolo et al. 2002[146]

Abbreviations: *CKD*, chronic kidney disease; *GHRH*, growth hormone-releasing hormone; *S[Alb]*, serum albumin concentration.

clinical trial investigated the effects of resistance exercise along with nandrolone decanoate treatment on change in LBM measured by DEXA and quadriceps muscle cross-sectional area measured by MRI. Sixty-eight dialysis patients were randomized using a 2-by-2 factorial design, with 17 patients receiving nandrolone decanoate injections (women: 100 mg; men 200 mg), 16 patients receiving placebo injections, 19 patients participating in low extremity resistance exercise training (ankle weights), and 16 patients receiving nandrolone decanoate injections and participating in resistance exercise for 12 weeks.[134] LBM was significantly increased in the nandrolone decanoate group (3.1 ± 2.2 kg; $p < 0.0001$), but not in the exercise group. There was no significant additional increase in LBM for patients in the nandrolone decanoate with exercise group. However, there was an increase in quadriceps muscle cross-sectional area in the exercise group. These results indicate that androgen therapy is associated with an increase in LBM and may be a beneficial treatment to prevent muscle catabolism in patients with ESRD and PEW.

Preliminary evidence in patients with CKD shows testosterone treatment improves LBM. Sixteen patients were randomized to receive an intramuscular injection of 100 mg of nandrolone decanoate for 3 months, while 13 patients served as the control group, receiving conventional care.[135] The treatment group had increased LBM compared with the control group ($4.2\% \pm 1.5\%$, $CI = 2-8$; $p < 0.05$). Further studies are warranted in patients with CKD, but must take into account the potential side effects of testosterone treatment.

Recombinant Human Growth Hormone

Recombinant human growth hormone (rhGH) stimulates anabolic effects in patients with malnutrition and has been investigated as a treatment for PEW in children and adults treated with HD and PD.[136] Results are well established in children, where a randomized double-blind, placebo-controlled study showed that children with CKD treated with rhGH had significantly increased growth rate.[137] In the first year, children with CKD treated with rhGH grew 10.7 ± 3.1 cm compared with the placebo group who grew 6.5 ± 2.6 cm. Second-year growth was also significantly higher in children treated with rhGH, with a growth of 7.8 ± 2.1 cm vs. a growth of 5.5 ± 1.9 cm in children given placebo. These results provided the evidence necessary for allowing the use of rhGH as a treatment for growth failure in children with CKD.[138,139] Children with CKD treated with

rhGH have sustained catch-up growth compared with untreated CKD children. The mean final adult height of pediatric CKD patients treated with rhGH is only 1.6 ± 1.2 SD below normal, which is 1.4 SD above their standardized height at baseline ($p < 0.001$).[140] Untreated children with CKD had a final height of 2.1 ± 1.2 SD below normal, which is 0.6 SD below their standardized height at baseline.[140]

GH administration has been studied in ESRD patients.[136] A randomized controlled trial of 139 HD patients concluded that rhGH treatment was associated with a 2.5 kg increase in LBM compared with HD patients taking placebo, who had a decrease in LBM of 0.4 kg ($p < 0.001$).[141] The OPPORTUNITY™ trial, a randomized double-blinded clinical trial, attempted to investigate the use of rhGH in 2500 adult HD patients and its effects on mortality, morbidity, markers of body protein mass, inflammation, and exercise capacity.[136] However, the trial was stopped prematurely due to slow recruitment rates, and the resulting study ($n = 695$) was underpowered to accurately determine whether rhGH treatment improves clinical outcomes or mortality in HD patients.

There is limited support for the use of rhGH in adult patients with CKD. Niemczyk et al. completed a placebo-controlled, randomized clinical trial studying a super-agonist of human GH-releasing hormone (GHRH), AKL-0707, in 28 patients with CKD stages 4 and 5.[142] Treatment with AKL-0707 for 28 days was associated with increased fat-free mass, measured by DEXA, and decreased serum urea concentrations. Additional long-term studies using GH treatment in patients with CKD are warranted.

Exercise and Resistance Training

Few studies have been done to determine whether exercise improves health outcomes in CKD in relation to PEW. Forty patients with CKD stages 4 and 5 completed 6 months of walking exercise, which showed short-term improvement in body composition at 1 month. Fat mass was reduced by 0.71 ± 0.62 kg ($p = 0.001$), while lean mass increased 0.56 ± 0.98 kg ($p = 0.060$).[143] However, there was no improvement in anthropometric measures at 6 months. This study has several limitations. The study sample was quite small, and patients were not randomized to participate in the walking exercise, but assigned to the intervention.

Resistance training may be an effective treatment to improve muscle maintenance and repair in patients with CKD. A randomized controlled trial in patients with stages 3 and 4 CKD showed that 12-week high-intensity resistance exercise training was associated with increased mitochondrial DNA copy number, which was correlated with changes in types I and II muscle fiber cross-sectional area, both indicating increase in muscle mass.[144] Patients who performed resistance exercise also had increased muscle strength, as shown by improvement in protein utilization and muscle hypertrophy. However, these are surrogate measures of muscle strength, illustrating that more evidence is needed to determine if resistance exercise in patients with CKD actually improves muscle strength. A study by Castaneda et al. investigated the role of resistance training in CKD patients on a low protein diet (LPD) (about 0.6 g/kg/day). Patients in the training group had lower levels of the inflammatory biomarkers IL-6 and CRP, as well as increased types I and II muscle fiber cross-sectional area and muscle strength.[145] Additional studies are needed to determine how much and what type of exercise is needed for muscle preservation and prevention of PEW in patients with CKD, and whether exercise improves survival outcomes in such patients.

Inflammation

Inflammation contributes to PEW through a number of mechanisms including GH, insulin, and IGF-1 resistance, as well as activation of genes involved in protein catabolism. Targeting treatments for inflammation may alleviate or slow muscle wasting. Pentoxifylline, a xanthine-derived phosphodiesterase inhibitor, can suppress TNF gene expression and decrease circulating levels of TNF-α and TNF-α soluble receptor. Biolo et al. showed that pentoxifylline treatment was associated with decreased whole body proteolysis in patients with CKD (mean eGFR 17 mL/min/1.73 m^2) by suppressing the TNF-α system.[146] Studies are warranted to determine whether pentoxifylline and other antiinflammatory treatments may attenuate PEW in patients with CKD.

Metabolic Acidosis

There is both experimental and clinical evidence that correction of metabolic acidosis in CKD may improve PEW.[73] There are many studies of bicarbonate supplementation that have been completed in dialysis patients, with some showing increases in anthropometric measures of LBM,[147,148] while others do not.[149–151] Early studies indicated that sodium bicarbonate treatment in CKD patients before initiation of dialysis was associated with decreased protein degradation, amino acid oxidation, and plasma urea levels.[152,153] A short-term study in 20 patients with CKD (eGFR 15–45 mL/min/1.73 m^2) taking increasing doses of oral bicarbonate (0.3, 0.6, and 1.0 mEq/kg/day) studied the effect on functional status measured by sit-to-stand tests and handgrip strength.[74] The investigators showed that

sit-to-stand time for 10 repetitions decreased after 6 weeks of treatment, improving from 23.8 ± 1.4 seconds to 22.2±1.6 seconds ($p = 0.002$). However, handgrip strength was not statistically different after treatment, with average handgrip strength of 29.5 ± 9.6 kg before treatment and 28.4 ± 9.4 kg after treatment.

Only one long-term clinical trial has investigated the use of oral bicarbonate treatment on rate of creatinine clearance (CrCL) decline and progression to ESRD, as well as DPI, S[Alb], and mid-arm muscle circumference in CKD patients.[154] A total of 134 patients with CKD and low serum bicarbonate concentration (16−20 mmol/L) were randomized to oral sodium bicarbonate treatment vs. placebo and standard of care treatment. The investigators found that patients treated with bicarbonate supplementation had a lower decline in CrCL of 1.88 mL/min/1.73 m^2 compared with controls, who had a decline of 5.93 mL/min/1.73 m^2 ($p < 0.0001$). Only four patients treated with bicarbonate supplementation progressed to ESRD (6.5%) compared with 22 patients who did not receive bicarbonate treatment (33%; $p < 0.001$). Treatment was associated with slowing progression of CKD, with nine patients having fast progression vs. 45% of patients having fast progression receiving standard of care ($p < 0.0001$). In addition, patients with bicarbonate supplementation had improved DPI, decreased normalized protein nitrogen appearance, and increased LBM measured by arm circumference compared with patients receiving standard of care. In a single-center, open-label, randomized, prospective parallel-group study, 188 patients with CKD stages 3 and 4 and with venous bicarbonate levels <22 mEq/L were randomized to receive oral sodium bicarbonate supplementation to maintain venous bicarbonate levels at 24−26 mEq/L or to standard care alone. Individuals in the intervention arm had higher LBM and mid-arm circumference compared with the control group.[155]

Two additional studies, the Correction of Metabolic Acidosis with Use of Bicarbonate in Chronic Renal Insufficiency (UBI) Study ($n = 600$; 36 months) and the SoBic-Study ($n = 200$; 2 years), have been proposed to investigate bicarbonate treatment in patients with CKD stages 3 and 4.[156,157] Preliminary data from the UBI study showed that the largest HOMA-IR reduction was noted for serum bicarbonate concentrations between 24 and 28 mmol/L.[158]

Diet and Nutritional Supplements

A healthy diet and sufficient nutrient intake are essential for maintenance of muscle mass in patients with PEW. A plethora of studies evaluating the effectiveness of nutritional supplementation have been completed in patients treated with HD and PD.[159−166] Most studies,[161−164] but not all,[160,165,166] showed improved nutritional status as measured by S[Alb] levels.[159] For example, intradialytic parenteral nutrition (IDPN) has been shown to be an effective way to promote protein synthesis and decrease muscle protein breakdown in malnourished chronic HD patients.[164] However, patients who received oral supplementation had persistent anabolic benefits after dialysis treatment, whereas patients receiving IDPN did not have such benefits.[167] Cano et al. demonstrated that IDPN did not improve 2-year mortality compared with malnourished HD patients who received oral nutritional supplements.[168] Nutritional supplementation overall did improve prealbumin levels. Nutritional supplementation is associated with increased survival rates in those malnourished HD patients who had prealbumin levels that increased by more than 3 mg/dL after 3 months.[168] A recent study showed partial replacement of meat and fish with egg whites induced a significant decrease in S[P] without causing protein malnutrition. This intervention could represent a useful instrument to control S[P] in hemodialysis patients.[169]

The most significant reason for negative results in studies of oral supplementation may relate to intolerance and/or nonadherence, which is as high as 50% in some studies. Many patients experience nausea and other side effects.[159,160,165] However, this intolerance may be worse in sicker patients with more severe kidney disease, which may account for these negative results. Such findings support the notion that nutritional supplementation may not be effective in patients with more severe CKD. Teixido-Planas et al. showed that compliant patients taking the oral protein-energy supplement Protenplus had significantly improved LBM ($p < 0.002$), body weight ($p < 0.03$), tricep skinfold thickness ($p < 0.01$), and mid-arm circumference ($p < 0.025$).[166] However, in their intent to treat analysis, which included noncompliant patients, there was no significant improvement in these measures. Heaf et al. found no improvement in S[Alb] after 10 weeks of treatment with protein supplements, with a decrease in S[Alb] of 26 ± 108 μmol/L in noncompliant patients.[160] In addition, there was no significant improvement in compliant patients, with a decrease in S[Alb] of 16 ± 24 μmol/L.[160] Overall, most studies have shown improvement in nutritional markers when DPI and DEI levels are met in compliant patients, but further research is necessary to generate firm treatment recommendations.

Montes-Delgado et al. investigated the use of diet and/or nutritional supplements in patients with CKD before they progress to ESRD.[170] The study used Suplena, a low protein and hypercaloric supplement, in patients with CKD and compared them with patients

with CKD on a 0.6 g/kg/day LPD.[170] After months, patients in the supplement group had better retention of renal function measured by CrCL (smaller decrease in renal function compared with LPD control group), better nutritional parameters, and better compliance with the LPD and with therapy overall. However, this study is limited by the fact there were only 33 patients in the study and by a short treatment time (6 months). In addition, there is a possibility that changes in nutrition alter creatinine metabolism. This raises the question of the utility of CrCL as an endpoint measurement in CKD nutritional trials.

It has also been suggested that an LPD, by itself, may provide metabolic benefits in patients with CKD and slow progression of the disease.[171] However, the Modification of Diet in Renal Disease (MDRD) study showed that an LPD did not improve survival in CKD patients compared with patients ingesting a normal protein diet (1.3 g/kg/day).[172] Additional studies are necessary to determine whether there is long-term benefit to LPDs in preserving renal function, improving mortality, quality of life of patients, and other important nutritional outcomes.[124]

Ketoanalogues (KAs) of essential amino acids are another type of supplement that may provide nutritional benefit to CKD patients. Mitch et al. first showed that an LPD and KAs slowed progression of CKD.[173] 10 of the 17 patients treated with KAs had slower rise in S[Cr] than expected during 20 months of treatment. This study had several limitations, as it was not a randomized controlled trial and used historical controls. The use of KAs along with an LPD was investigated in CKD patients to determine if such an intervention slows the progression of CKD and maintains nutritional status.[174] Patients given the KA supplement and LPD for 9 months maintained S[Alb] and total protein levels and sustained kidney function based on GFR levels measured by the 99mTc-DTPA (99 m technetium diethylenetriaminepenta-acetic acid) plasma sample method.[174] The ketodiet patients had an average GFR of 28.1 ± 8.8 mL/min/1.73 m^2 at baseline, with an average GFR of 27.6 ± 10.1 mL/min/1.73 m^2 at the end of the study ($p = 0.72$). Patients taking placebo had an average GFR of 28.6 ± 17.6 mL/min/1.73 m^2 at baseline and an average GFR of 22.5 ± 15.9 mL/min/1.73 m^2 at study completion ($p = 0.015$). The MDRD study showed that it was the LPD of 0.5–1 g/kg/day rather than KAs that slowed progression of CKD.[175] Additional studies and randomized controlled trials are needed before KA supplementation becomes a valid treatment for patients along with nutritional supplementation specific for the CKD population.[159,176]

CKD patients are often advised to limit or avoid protein foods that are plant-based due to their potassium and phosphate content, implying that protein foods that are animal-based should be the primary protein food source.[177] However, those consuming a higher proportion of protein from plant foods had significantly higher bicarbonate concentrations.[124,178] Furthermore, animal protein intake may generate toxins such as trimethylamine N-oxide which is proatherogenic.[124,179] In a prospective, randomized, controlled trial, a KA–supplemented vegetarian very low–protein diet was shown to be nutritionally safe. The diet could defer dialysis initiation by ameliorating CKD–associated metabolic disturbances compared with a conventional low–protein diet.[180] This study suggests that the source of the protein (animal protein vs. plant based), not just the protein content of the diet, may be important.

RECOMMENDATIONS AND GUIDELINES

Several prospective, experimental, and clinical studies have investigated potential treatments for PEW in patients with CKD (Table 16.2). Overall, there are a very limited number of studies in CKD patients before ESRD, pointing to the need for more research in this population. Recommendations and guidelines for the treatment of PEW in patients with CKD have been published (Figure 16.4).

Nutritional supplementation has shown some promising results in HD and PD patients.[159] The use of supplements in patients with earlier stage CKD is not so definitive, with limited results available for evaluation of the effects of nutrition supplementation. Patients taking Suplena with an LPD had preserved renal function measured by CrCL. Additional studies are needed before nutritional supplementation can be prescribed as an intervention for PEW in CKD patients, especially investigating if there are long-term benefits maintaining muscle stores and determining whether supplements reduce morbidity and/or mortality.

A baseline nutritional evaluation by a renal dietitian is recommended for patients with PEW. Patients with PEW should undergo nutritional screening regularly at outpatient clinic visits, including 24-hour urine collections and measuring S[Alb], weight, and BMI.[124,181] Follow-up dietary consultations should be performed as required as dictated by change in clinical status.[124] The ISRNM also suggests the following mineral intake levels be met: potassium levels less than 1 mmol/kg if S[K] is elevated, 80–100 mmol/day of sodium, 800–1000 mg of phosphorus, and binders if S[P] levels are elevated (Figure 16.4).[181]

Stable uremic patients adapt well to an LPD and maintain energy stores.[121] KDOQI recommendations state a DPI of 0.6–0.8 g/kg IBW and energy intake of 30–35 kcal/kg IBW/day preserve protein stores in patients with CKD and reduce the generation of toxic

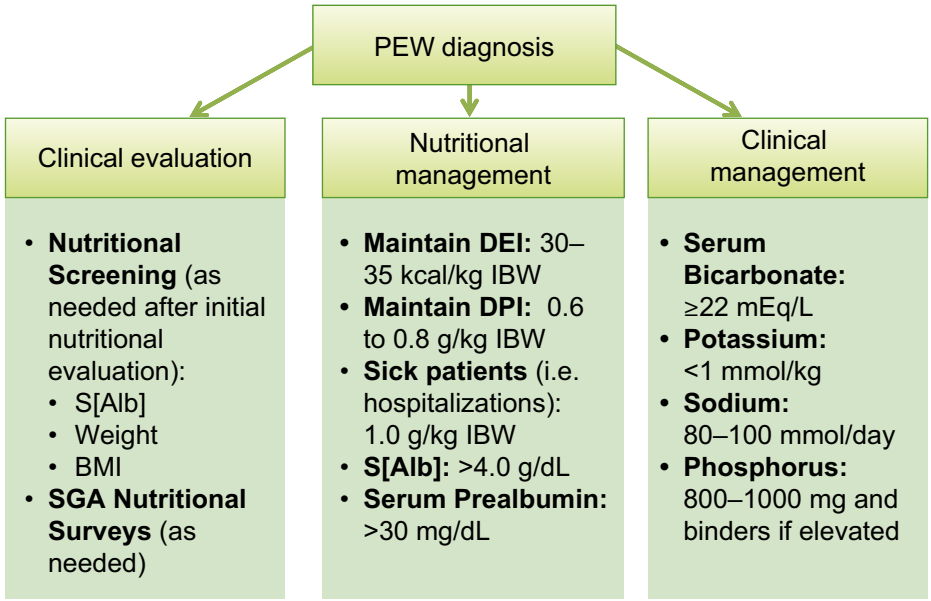

FIGURE 16.4 Recommendations and guidelines for treatment of patients with protein energy wasting (PEW) in chronic kidney disease (CKD). After diagnosis of PEW in CKD patients, they should have follow-up appointments in the clinic to undergo nutritional screening. This includes measurement of S[Alb], weight, BMI, DPI, and DEI. Patients should have nutritional surveys, such as Subjective Global Assessment, completed as needed. Patients should also have nutritional management, with intake levels described to maintain protein stores. Clinical management includes maintaining levels of important minerals as well as serum bicarbonate levels to maintain muscle mass. Abbreviations: *BMI*, body mass index; *DEI*, daily energy intake; *DPI*, daily protein intake; *IBW*, ideal body weight; *S[Alb]*, serum albumin concentration.

nitrogenous metabolites.[120,121,182] However, with catabolic conditions, such as metabolic acidosis and inflammation, nutritional supplementation with oral supplements does not maintain protein stores.[121] For patients with catabolic conditions, KDOQI recommends increasing the DPI to 0.75 g/kg IBW. This DPI may not only be beneficial and lead to an increase in nutritional intake but may also increase the rate of progression of CKD.[121] Those patients with illness or hospitalizations should have their DPI increased to 1.0 g/kg IBW/day.[181] Although these recommendations are extant, mixed results in the literature indicate that nutritional supplementation and LPD may not provide benefit or prevent PEW from occurring in CKD patients. Additional studies are needed to determine what dietary recommendation is best for preserving renal function and whether these diets are effective in delaying PEW and its comorbidities.

Resistance exercise has shown some promise as a potential way to increase muscle mass and decrease inflammation,[144,145] but specific guidelines and demonstration of long-term benefits from these interventions are lacking. There are no current recommendations that patients with CKD and muscle wasting should participate in resistance exercise to improve PEW.

Treatment with bicarbonate has been shown to be effective in decreasing progression to ESRD, slowing the rate of progression of CKD, and improving LBM in limited studies.[154] However, two additional large and long-term clinical trials have investigated the use of bicarbonate in patients with CKD, pointing to bicarbonate supplementation as a potentially effective treatment for PEW.[156,157] For now, KDOQI guidelines recommend that serum bicarbonate levels be maintained at 22 mEq/L or greater in CKD patients. Current research suggests that bicarbonate supplementation is a safe and effective way of improving serum bicarbonate levels,[71] but additional studies are needed before definitive recommendations can be made.

Additional research, especially long-term, randomized controlled clinical trials, is necessary before ghrelin, testosterone, and recombinant human GH can be used as treatments for PEW in CKD patients. Ghrelin has been investigated in very small and short-term studies in patients with ESRD, where it was associated with increased appetite and energy intake.[127,128] However, ghrelin administration to improve PEW has not been studied in CKD patients. rhGH treatment improves LBM in ESRD patients,[141] whereas administration of the super-agonist of GHRH AKL-0707 improves fat mass in CKD patients.[142] Preliminary evidence shows that testosterone treatment was associated with improvement in LBM in ESRD[133,134] and in CKD patients.[135] However, this increase in LBM must be balanced against possible adverse side effects of testosterone treatment, such as toxicity and potential for liver damage and prostate cancer.[132]

Additional pathways, such as neuroendocrine signaling cascades, are being pursued as targets for treatment of PEW. Preliminary evidence in animal studies shows that blocking the activity of leptin through pharmacological and genetic interventions increases muscle and fat mass, decreases inflammation, and increases energy intake.[30–32] This type of treatment is still far from being applied in clinical studies but represents a new field of research that should be investigated in the future as a potential treatment for patients with CKD.

CONCLUSIONS

PEW is a common problem in patients with CKD, and if undiagnosed or improperly treated, PEW leads to increased morbidity, mortality, and lower quality of life. The causes of PEW are multiple and include anorexia, increased energy expenditure, ineffective ingestion and utilization of nutrients, and increased muscle protein catabolism. In addition, understanding the factors or mediators contributing to enhanced muscle protein catabolism, namely, insulin resistance, inflammation, oxidative stress, hormone dysregulation, and metabolic acidosis, is of critical importance for management of PEW in the setting of CKD.

Both nonpharmacological and pharmacological approaches to prevent or reverse PEW have been recommended and used that specifically target the etiologic factors of PEW in CKD patients. These include dietary changes and nutritional supplementation to improve nutrient intake. Other studies have pointed to some clinical benefit of pharmacologic treatment with human GH, anabolic steroids, and insulin-sensitizing agents to treat hormonal deficiencies and insulin resistance. Bicarbonate administration and RRT to correct metabolic acidosis and reduce associated inflammation have also been considered potential treatments for PEW in CKD patients. Other potential therapeutic strategies to prevent or reduce protein catabolism by stimulating appetite, such as MC4-R antagonists and ghrelin administration, have also been suggested, but their safety and efficacy in CKD patients need further study. Other interventions, such as resistance exercise, antioxidants, and antiinflammatory or anticytokine agents, which indirectly or directly target the oxidative and inflammatory responses in PEW, have also been considered but their effects in CKD have not been adequately studied.

Additional studies focused on patients with CKD, before they progress to ESRD, are necessary to elucidate the mechanisms underlying PEW in this population and to identify therapeutic targets and develop potential therapies to prevent and potentially reverse muscle catabolism.

QUESTIONS AND ANSWERS

Question 1

A 35-year-old woman with type 1 diabetes mellitus since childhood (age 12) was admitted to the hospital because of recurrent nausea, vomiting, anorexia, and weight loss. Individuals like her with PEW in CKD have nutrient insufficiency due to which of the following reasons?

A. Anorexia, increased energy expenditure, changes in gastric motility, changes in taste
B. Anorexia, gastric hypermotility changes, increased energy expenditure, disruption of appetite sensing molecules, changes in taste, depression, and inflammation
C. Increased energy expenditure, disruption of appetite sensing molecules, depression
D. Anorexia, gastric hypomotility changes, disruption of appetite sensing molecules, changes in taste, depression, and inflammation
E. Anorexia, gastric hypomotility changes, increased energy expenditure, disruption of appetite sensing molecules, depression, and inflammation

Answer: D

CKD patients have (1) spontaneous decrease in energy and protein intake, (2) changes in gastric motility that prevent nutrient uptake, (3) disruption of appetite sensing molecules, such as ghrelin and leptin, (4) changes in taste, (5) changes in mental status, such as depression, and (6) increased inflammatory cytokines. Patients with CKD do not have increased energy expenditure, but patients with ESRD do show increased energy expenditure. However, adjustment for LBM in ESRD patients changes energy expenditure levels comparable to individuals with normal kidney function. This patient has gastric hypomotility issues which contribute to her nutrient insufficiency.

Question 2

Insulin resistance contributes to PEW by which of the following reasons?

A. Increasing glucocorticoid levels, increasing expression of FOXO, activation of atrogin-1 and MuRF1, increasing muscle proteolysis through the ubiquitin signaling pathway
B. Metabolic acidosis, increasing glucocorticoid levels, increased FOXO activity, activation of atrogin-1 and MuRF1, increasing muscle proteolysis through the ubiquitin signaling pathway
C. Increasing glucocorticoid levels, increased FOXO activity, activation of atrogin-1 and MuRF1, increasing muscle proteolysis through the ubiquitin signaling pathway
D. Increasing glucocorticoid levels, increasing expression of FOXO, activation of atrogin-1 and MuRF1, increasing muscle proteolysis through the ubiquitin signaling pathway, low vitamin D levels
E. Increased FOXO activity, activation of atrogin-1 and MuRF1, increasing muscle proteolysis through the ubiquitin signaling pathway

Answer: C

CKD patients have insulin resistance, which contributes to PEW in the following ways: (1) increased glucocorticoid levels, (2) increased FOXO activity, (3) activation of E3 ubiquitin conjugating enzymes atrogin-1 and MuRF1, (4) increasing muscle proteolysis through the ubiquitin signaling pathway. Metabolic acidosis and low vitamin D exacerbates insulin resistance but do not directly contribute to PEW through insulin resistance.

Question 3

A 62-year-old man with long-standing history of hypertension for 20 years and stage 4 CKD was admitted to the hospital due to fever, cough, and weight loss of one-month duration. A chest X-ray revealed a right-sided lobar pneumonia. Which of the following causes of PEW is most likely behind his symptoms?

A. Inflammation
B. Insulin resistance
C. Anorexia and nutrient insufficiency
D. Muscle biology dysfunction
E. Oxidative stress

Answer: A

This man is suffering from pneumonia, increasing his inflammation. Inflammation causes PEW by contributing to insulin resistance, GH resistance. It also activates the ubiquitin signaling pathway and induces expression of glucocorticoids.

Question 4

A 45-year-old female with recently diagnosed nephrotic syndrome was admitted to the hospital because of anorexia and increased leg swelling with 3+ leg edema. Urinalysis on admission showed 4+ proteinuria. Which of the following are necessary for a diagnosis of PEW?

A. Biochemical indicators such as albumin, serum prealbumin, or serum cholesterol
B. Weight loss
C. Loss of muscle mass
D. Unintentional low protein or energy intake
E. At least three of the four answers above

Answer: E

At least three of the four criteria above must be met: (1) biochemical indicators such as albumin, serum prealbumin, or serum cholesterol, (2) weight loss, (3) loss of muscle mass, (4) unintentional low protein or energy intake. In addition, measurement of these criteria should be seen at least three times at intervals of two to four weeks.

Question 5

Which of the following treatments has decreased inflammation as one if its benefits?

A. MC4-R antagonists
B. Resistance training
C. Insulin-sensitizing agents such as rosiglitazone or thiazolidinedione
D. A and B
E. All of the above

Answer: D

Both MC4-R antagonists and resistance training have demonstrated decreased inflammation as measured by inflammatory cytokines. Resistance training lowered levels of IL-6 and CRP, while MC4-R antagonism returned levels of IL-6 and TNF-α to normal.

Aging and the Kidney: Clinical and Pathophysiologic Issues

Lynn E. Schlanger, James L. Bailey, Jeff M. Sands

Renal Division, Emory University, Atlanta, GA, United States

Abstract

The aging kidney undergoes structural and functional phenotypic changes with time. There is a decline in glomerular filtration rate, renal plasma flow, and tubular function, characterized histologically by glomerulosclerosis, tubulointerstitial fibrosis, and atrophy. These changes appear to be influenced by the environment, genetic factors, and gender and result in a profibrotic, proinflammatory, apoptotic state. These adaptations may increase the elderly's susceptibility to acute and chronic kidney disease (CKD), allograft failure, and be responsible for the higher mortality rates frequently seen in the elderly. Modification of the cellular and molecular mechanisms underlying age-associated renal changes, with various medications, transcription factor inhibitors, or caloric restriction may modify or attenuate these changes and prevent progression to CKD.

INTRODUCTION

At the turn of the last century, a person's life expectancy was around 50 years of age, and it was rare for most individuals to live into their 70s. With advances in medical technology, the average life span has increased. It is now 76.1 years for men and 81.1 years for women in the US.[1] In parallel with this longevity, the population of the elderly (aged 65–80 years) and the very elderly (aged greater than 80 years) in the US has grown from 3.1 million at the turn of the 20th century to 40.3 million in 2010.[2] This number is expected to double by 2050.[2]

With this growth, there has been a rise in the prevalence of chronic kidney disease (CKD) in the elderly.[3–5] The National Health and Examination Nutrition Survey (NHANES) observed an increase in the prevalence of CKD from 10.3% in 1988 to 13.1% in 2004.[5] Over 48% of those with CKD stages 3–5 were 70 years of age or older. This rise in CKD was attributed to diabetes mellitus, obesity, and hypertension, which are factors commonly associated with aging. With aging, there is a decline in adaptive capacity to hemodynamic changes, an increase in apoptosis, and changes in gene expression that result in fibrosis and inflammation.[6–10]

The kidney undergoes structural changes beginning in the third to fourth decade of life that are associated with morphologic changes, such as an increase in glomerulosclerosis, tubulointerstitial fibrosis, vascular hyalinosis, and arterial intimal fibrosis.[9,11,12] Glomerular filtration rate (GFR), renal plasma flow (RPF), and renal tubular function decline, while renal vascular resistance (RVR) increases as patients[12] and experimental animals age.[13] These findings were underscored by the Baltimore Longitudinal Study of Aging, which observed middle- and upper-class male volunteers ranging from 22 to 97 years of age over a 23-year span.[14,15] During the study, five or more serial 24-hour urine collections for creatinine clearance determinations were obtained from each volunteer. After age 40, mean decline in the creatinine clearance was 0.75 mL/min/year in those with no underlying disease, renal disease, or hypertension.[15] There was a greater rate of decline with increasing age, -1.49 ± 0.29 mL/min/year in the 70 to 79.9 age group, compared with -0.35 mL/min/year in the 40–49.9 age group.[14] This decline correlated independently with an elevated mean arterial blood pressure greater than 107 mm Hg. Interestingly, this was not a universal finding. A third of the volunteers showed no decline of renal function with aging, and a very small percentage actually showed a statistically significant increase in renal function.[15]

Age-related kidney changes are associated with a mild loss of function in the presence of no underlying illness. What is considered normal kidney function in

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00017-6

the elderly and very elderly, and what are the consequences? The decline in GFR, RPF, and tubular function is usually well tolerated, with no adverse outcomes unless the kidney is exposed to exogenous or endogenous stresses. With aging, there is a decreased ability of the kidney to adapt to stress. This may account for the higher age-related incidence in acute kidney injury (AKI) leading to CKD,[16,17] an increase in electrolyte abnormalities,[18] and an increased risk of cardiovascular disease (CVD).[19,20] Understanding the changes in the cellular and molecular pathways in the aging kidney may provide insight into prevention and treatment and decrease the high prevalence of CKD with its associated morbidity and mortality.

PATHOPHYSIOLOGY

Structural and Morphologic Changes

The aged human kidney grossly appears granular and pitted because of underlying arterial disease and loss of lobulations. Although renal mass increases from 50 g at birth to greater than 400 g during the third and fourth decades of life, it generally declines to less than 300 g by the ninth decade of life.[9,21] Gourtsoyiannis and colleagues [22] studied renal parenchymal volume in 360 individuals, ranging from 20 to 80 years of age, with no underlying renal disease or radiologic abnormalities by computerized tomography (CT) scans. There was a 10% decline per decade in the renal parenchymal volume, irrespective of gender, beginning around the third to fourth decade. The most rapid decline occurred in the group 60–70 years of age. In another study, predonation CT scan images of 1520 living kidney donors showed an increase in cysts and smaller cortical volume:medullary volume ratio, that was associated with nephrosclerosis with aging and accounted for the decline in volume with aging.[23]

In humans, the histological and morphological changes seen in "aging-related nephropathy" were mainly gathered from postmortem exams[24,25] and living "healthy" kidney donors (LKD).[11,23,26,27] In rats, similar studies were done, but the changes varied among species and gender.[6,13,28–32] Certain strains developed severe changes accompanied by proteinuria, while others had only very mild changes. Therefore, conclusions and comparisons from animal studies to the human condition need to be made with caution.

The dominant "aging" morphologic findings include expansion of the mesangium in the cortical sclerotic glomeruli with sparing of the medulla, cell proliferation resulting in obliteration of the glomerular loop, capillary tuft collapse, podocyte enlargement and detachment, reduplication of glomerular basement membranes and Bowman's capsule with areas of focal thickening, synechiae of glomeruli within Bowman's capsule, tubulointerstitial fibrosis, and tubular atrophy (Figure 17.1 and Table 17.1).[9,11,12,24–27] Although these changes were noted in the mid-1900s, the expected number of sclerotic glomeruli with aging was not well established until 1975. At that time, Kaplan and colleagues[24] determined the incidence of glomerulosclerosis in 122 autopsied kidneys ranging from 1 to 89 years of age, from patients with no underlying renal disease. They

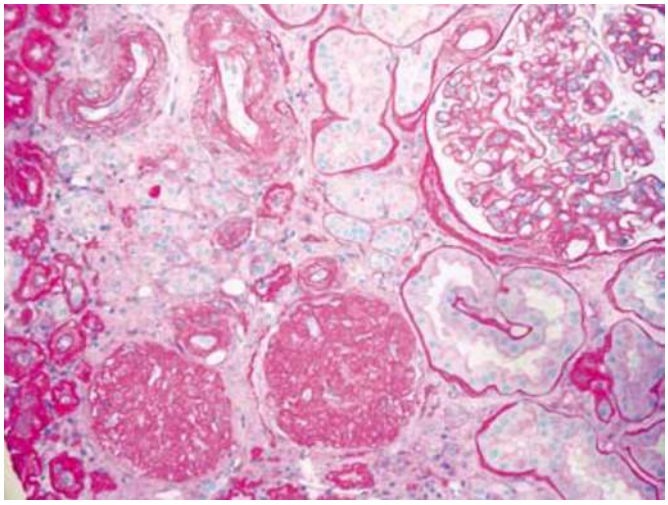

FIGURE 17.1 The aging kidney. Two glomeruli show solidified global glomerulosclerosis (GSG). The nonsclerotic glomerulus displays ischemic changes. There are also moderate tubular atrophy and interstitial fibrosis. The arterioles reveal significant hyalinosis (periodic acid–Schiff stain; ×200). Permission granted. Reference 9.

TABLE 17.1 Morphologic Changes in the Aging Kidney

	Changes
Glomeruli	Global sclerosis

Interstitium	Tubular atrophy
	Loss of peritubular capillaries
	Interstitial fibrosis
	Inflammatory cells
Vessels	Hyalinosis of arterioles
	Arterial intimal fibrosis
	Aglomerular afferent–efferent arterioles

observed less than 10% sclerotic glomeruli in those younger than 40 years of age, and greater than 10% sclerotic glomeruli in those older than 40 years of age. Forty years later, Kremers et al.[26] used quantile regression to estimate the 95th percentile of GSG as an upper reference limit for age in 2052 LKD kidney biopsies. In the 18- to 29-year-old group, there was 1 GSG compared with 5.5 GSG in those 70 years old, in biopsy samples with 17−32 glomeruli.[26] Those with hypertension had an increased risk of GSG compared with those without underlying comorbidities, suggesting that the upper limit of GSG in healthy LKD may help differentiate between aging and an underlying disease processes and prognosis.

In a cross-sectional study of LKD biopsies, there was a 48% lower number of nonsclerotic glomeruli (NSG) in the youngest group, compared with the oldest group of donors, from 990,661 to 520,410 NSG.[27] This was accompanied by a 15% increase in GSG on biopsy in the oldest group, as well as a 16% loss of cortical volume as determined from the predonation CT scan. This greater decline in NSG and a decrease in cortical volume was the result of both atrophy and reabsorption of the sclerotic glomeruli.[27]

As in other renal diseases, there are changes in the interstitium with aging that may correlate with prognosis and progression. Tubulointerstitial damage consists of tubular atrophy, intratubular casts, tubular dilation, thickening and splitting of the basement membranes, and widening of the interstitium from fibrosis.[9,30,31] Thomas and colleagues[30] evaluated the changes in the tubulointerstitial area by immunohistochemistry in Sprague-Dawley rats at 3 ($n = 9$) and 24 months of age ($n = 8$). The 24-month-old rats had an increase in interstitial fibrosis and tubular injury associated with areas of focal tubular cell proliferation, apoptosis, myofibroblast activation, and inflammation with macrophage/lymphocyte infiltration. This correlated with immunostaining for proliferating cell nuclear antigen, terminal deoxynucleotidyl transferase dUTP nick end labeling, α smooth muscle actin, and 1ED-1/OX-1, respectively. Type IV collagen was also increased. The loss of the cortical peritubular capillaries was associated with scarring and atrophy, with attenuation of endothelial nitric oxide synthetase (NOS) and a decline in the numbers of endothelial cells (RECA-1).

Abrass and colleagues[32] observed changes in the degree and composition of extracellular matrix (ECM) in aging Fischer 344 rats, with interstitial fibrosis being one of the earliest findings. The change in composition of the ECM consisted of a greater accumulation of fibronectin (FN) and thrombospondin, as well as accumulation of collagen III and extra domain A (ED-A)-FN, in areas adjacent to atrophic tubules. Other findings included thickening of both the glomerular basement membrane and Bowman's capsule with greater laminin isoforms than collagen IV and FN. In animal studies, these areas were associated with an increase in expression of transforming growth factor (TGF)-β RNA and protein, suggesting there is gene upregulation resulting in inflammation and fibrosis in aging.[6,7] The ECM accumulates as a consequence of an imbalance between production and degradation of the matrix.

Satoh and colleagues[33] observed loss of angiogenesis in the hypoxic areas in the cortex, characterized by decreased expression of vascular endothelial growth factor and decline in RECA-1 antibody staining in 24-month-old Wistar rats. This coincided with mitochondrial dysfunction, suggesting a decrease in O_2 sensing as a cause for the disturbance in angiogenesis.

Arteriosclerosis is found in the renal vessels with aging.[34,35] Takazakura et al.[34] noted an increase in two types of arteriole-glomerular units in 63 autopsied kidneys, ranging from 9 months to 92 years of age with aging. The cortex showed various stages of degeneration with aging and culminated in atrophic arteriole-glomerular units. In the medulla, continuity of afferent and efferent arterioles was maintained with an intervening degenerated glomerulus. This was termed the "continuous type," resulting in the diversion of blood to the medulla. In the smaller renal arteries, there was progressive reduplication of the elastic lamina and associated intimal thickening with medial hypertrophy, intimal proliferation, and hyalinization that was most pronounced in vessels less than 100 micrometers in diameter. In human studies, a greater correlation was observed between the degree of arterial intimal fibrodysplasia in the arcuate and interlobular arteries and glomerulosclerosis than from hyaline afferent arteriolosclerosis and glomerulosclerosis.[36,37]

Clinical and Functional Changes

With age, there is a decline in kidney function that is marked by a decrease in GFR and RPF,[12,38] inability to concentrate or dilute urine,[39] an alteration in sodium homeostasis,[40] decreased responsiveness to vasodilators,[41,42] decreased ability to excrete acid and potassium,[18,43] and decreased levels of serum renin and aldosterone.[44] (Table 17.2). Davies et al.[38] observed a decline in the GFR and effective renal plasma flow (eRPF) with advancing age in 72 males free of cardiac and renal disease, ranging from 24 to 89 years of age. There were declines in inulin clearance by 46% (from 122.6 to 65.3 mL/min/1.73 m^2), in eRPF by 53% (from 613 to 289 mL plasma/min/1.73 m^2), and tubular excretory capacity by 43.5%. The filtration fraction increased significantly with age.

TABLE 17.2 Functional Changes in the Aging Kidney

Decrease of renal blood flow by 10% per year after age 40
Glomerular filtration rate decreases after age 40
Increase in renal vascular resistance
Decreased diluting capacity
Decreased concentrating capacity
Slow response to salt deprivation or salt load
Decreased excretion of potassium and acid
Abnormal renal reserve

Hoang and colleagues[12] studied two groups to determine the mechanism for hypofiltration noted in aging. In group 1, with 152 healthy individuals ranging from 18 to 88 years of age, there was a negative correlation of advancing age and GFR and RPF, which was similar to previous findings. In group 2 with 33 LKD, with donor ages ranging from 23 to 69 years, morphometric analysis was performed to determine the glomerular hydraulic permeability and filtration surface area. Mathematical models were used to calculate the glomerular ultrafiltration coefficient (Kf) for 2-kidneys from the GFR determinants and a single nephron (SN) Kf from morphometric analysis. They observed a decline in the 2-kidney K_f from 53% to 21% ($p < 0.005$). SNKf declined by 30% ($p = 0.09$). Hoang and colleagues concluded that the decline in GFR with aging was from structural changes that lower the Kf, partly related to a decline in the number of functioning glomeruli.[12]

In a large study in 1388 LKD, the SNGFR was maintained until 70 years of age, with a decline in total GFR. The decline in total GFR in aging was from the decline in the number of functioning glomeruli.[45]

Glomerulopenia is likely one of the causes for the decline in GFR, but what influence does nephrosclerosis have? In a 10-year cross-sectional study, the prevalence of nephrosclerosis and its relationship to GFR in 1203 LKD was studied.[11] Nephrosclerosis was defined by the presence of two or more of the following: glomerulosclerosis, tubular atrophy, interstitial fibrosis >5%, and arteriosclerosis. Nephrosclerosis was noted to increase with age from less than 5% in people from 18 to 29 years old to 73% in people 70–77 years old. They found no correlation between the degree of nephrosclerosis and the decline in GFR with age, suggesting there were additional mechanisms responsible for the decline in kidney function rather than the degree of sclerosis.

Fuiano et al.[41] evaluated the maximal functional renal reserve in "healthy" kidney donors by infusing a combination of amino acids and renal dose dopamine in younger and older participants. The younger group had a greater increase in the GFR and RPF following the amino acid infusion than the older group (43% vs. 20%, $p < 0.05$ and 43% vs. 25%, $p < 0.005$, respectively). RVR was higher in the older group before and after infusion. There was also a blunted response to both the amino acid and dopamine infusion. This decline in RPF and increase in the RVR may be associated with functional or structural changes in the renal vasculature.

In both animal and human studies, there is an attenuated response to vasodilators including nitric oxide (NO), endothelial-derived hyperpolarizing factor, and prostacyclin, whereas there is an exaggerated response to angiotensin II in the aging kidney.[42,46–48] Hollenberg and colleagues[46] evaluated renal perfusion and vascular responsiveness in 207 subjects from 17 to 76 years of age undergoing renal arteriogram. The xenon washout technique was used to measure flow per unit tissue mass. Blood flow declined more than renal mass with aging, suggesting that the loss of renal perfusion was secondary to the loss of renal blood flow that began at age 40. The renal vascular response to acetylcholine, a vasodilator, and angiotensin II, a vasoconstrictor, was tested in a subgroup. The effect of acetylcholine on the renal vasculature was attenuated in the older age group, while the angiotensin II response was not different in either age group. In contrast, vasoconstriction increased with infusion of angiotensin II with aging in animal studies.

In the kidney, NO is a vasodilator and an inhibitor of mesangial growth and matrix production.[13,48] NO is synthesized from L-arginine by NOS. It is inhibited by a selective NOS inhibitor, asymmetric dimethylarginine, through competitive blockade.[13,42] Kielstein et al.[47] evaluated the effect of NO and the contribution of plasma ADMA on renal hemodynamics in young adults, healthy normotensive elderly, and mild hypertensive elderly participants. There was a decrease in GFR and RPF in the elderly groups compared with the younger subjects. Renovascular resistance and plasma levels of ADMA were increased significantly in the elderly groups compared with the younger subjects. In adjusted logistic regression analysis, only ADMA levels were an independent determinant of RVR ($r^2 = 0.67$) and RPF ($r^2 = 0.80$).

Loss of the vasodilator response may predispose the elderly to AKI[17] because of their inability to tolerate hypotension from sepsis, volume depletion, or certain medications. AKI in the elderly is associated with a poor prognosis. Although there may be recovery from the acute insult, renal function often worsens with time, culminating in a higher incidence of ESRD and increased mortality. A study of a cohort of hospitalized elderly Medicare patients examined the risk of ESRD in those who develop AKI.[16] After adjustment for age, gender, race, diabetes, and hypertension, the hazard ratio for developing ESRD was 41.2 for those with AKI and CKD, 25.2 for those with AKI only, and 8.4 for those

with underlying CKD without AKI. The likelihood of progressing to ESRD at 2 years was 7.0% for AKI only, 14.3% for AKI and CKD, and only 2.5% for CKD only. The risk was just 0.5% in those patients without AKI or CKD.

With aging, both animal and human subjects demonstrate a decreased ability to concentrate and dilute the urine. In large part, this accounts for the increased prevalence of hyponatremia (23.6%) and hypernatremia (1.3%) in the elderly population.[49] Hyponatremia is most likely to be iatrogenic, and commonly related to the many medications prescribed to the elderly, such as thiazide diuretics, selective serotonin reuptake inhibitors, and antiseizure medications.[50–53] Another common cause of hyponatremia is the syndrome of inappropriate antidiuretic hormone release. The hospital mortality associated with hyponatremia approaches 47% and is associated with both short- and long-term mortality.[52] Even mild hyponatremia has been associated with an increased risk for fractures, decreased reaction time and unstable gait, and an increase in short- and long-term mortality.[50,53]

Hypernatremia is common in the infirm, particularly in those with an inability to get to a water source.[54] The majority of elderly patients presenting to the hospital have a higher serum sodium concentration (S[Na]) than younger patients. This degree of hypernatremia does not correlate with an increase in mortality, but recurrence during the hospital stay is associated with an elevated mortality rate. The overall high mortality of 48.7% appears to be associated with the underlying disease process.[54]

Why are elderly persons more prone to water disorders? With aging, there is a decreased sensation of thirst, coupled with a decrease in intake of both water and solutes. There is also an inability to dilute and concentrate the urine, and total body water is decreased.[39,55,56] Although secretion of vasopressin is not decreased, older patients respond to dehydration with an increased release of vasopressin. The response may even be greater than seen in younger adults. Even so, elderly patients are unable to concentrate their urine to the level younger adults achieve. This suggests that renal responses may be involved in the development of both hyponatremia and hypernatremia in the elderly.

Animal studies show changes in the transporters in the distal nephron, which may play a role in the handling of water and solutes in the aging.[56–59] In rat studies, there is a decreased expression with aging of many of the transporters and channels responsible for maintaining the countercurrent system in the medulla, which is responsible in large part for dilution or concentration of the urine.[56,57] In older female WAG/Rij rats, there is downregulation of aquaporin (AQP) 2 and 3 in the inner medulla, by 80 and 50%, respectively, but only a modest decrease in AQP2 in the outer medulla compared with 3-month-old rats.[56] No changes in AQP1 or AQP4 expression were found.[56] Under normal conditions, older female WAG/Rij rats show a decline in the abundance of AQP2 vesicles and phosphorylated AQP2 located in subapical vesicles in the inner medullary collecting tubules.[57] With water deprivation, older rats showed an increase in abundance of AQP2 and P-AQP2 in the apical membrane location in the inner medulla. This was accompanied by an increase in urine osmolality, elevated vasopressin levels, and a decrease in urine volume, but the urine was never as concentrated as that attained in young adult rats.[57]

Urea transporters (UT) in the inner medulla also have a major role in concentrating the urine.[39,58] Downregulation of UT-A1, UT-A3, and UT-B1 expression in the tip of the inner medulla was observed in aging rats.[39,58] Other cotransporters and channels that have a role in diluting and concentrating ability are downregulated as well.[39,59] These include the sodium-potassium-chloride cotransporter (NKCC2), the epithelial sodium channel (ENaC) β- and γ-subunits, the sodium-chloride cotransporter ,and the sodium hydrogen exchanger.[39,59] The reason for the decrease in expression of these transporters is not known but may be secondary to an increased oxidative state found with aging. This is supported by a study examining the effect of N-acetylcysteine, a reactive oxygen species (ROS) scavenger and vasodilator in Wistar rats.[60] Compared with controls, the treated rats showed an increase in protein expression of AQP2, UT-A1, NKCC2, and klotho and a decrease in expression of p53 and inflammatory cells.

In older subjects, there is a decreased ability to excrete a potassium load.[43] This becomes apparent when medications that interfere with potassium excretion are prescribed. In both animal and human studies, there is a decrease in serum and urine renin and aldosterone levels that may contribute to a decline in potassium excretion.[44,61] There is also a decrease in excretion of an acid load and a decreased ability to conserve sodium or excrete a salt load with aging.[18]

PATHOGENESIS

The cellular and molecular mechanisms responsible for the phenotypic changes of aging are being identified. Cellular senescence, genetics, oxidative stress, and mitochondrial dysfunction are linked to cellular and molecular changes in aging (Figure 17.2).[62,63,66–73] Cellular senescence is characterized by cell cycle arrest in the G1 phase, either from loss of a critical telomere length known as “replicative senescence” or from stress related to aberrant signaling-induced senescence.[8,63] In humans, replicative senescence was observed *in vitro*

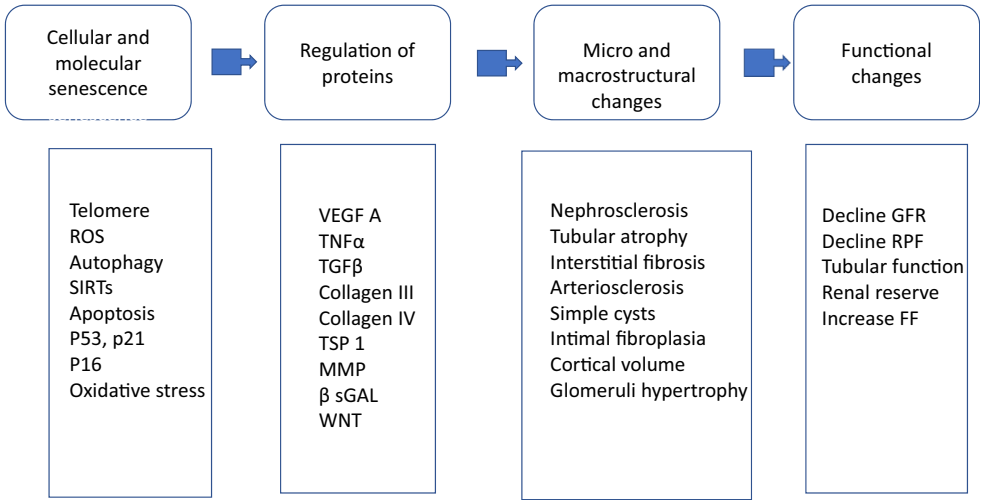

FIGURE 17.2 A schematic of senescence beginning at the cellular level with cellular arrest from loss of the telomere and increase in stress. There is a decline in cell replication and change in the expression of proteins disrupting the adaptability with an increase in fibrosis/atrophy and a decline in the regeneration of vessels and in the breakdown of extracellular matrix. This results in the loss of kidney function. References 20,25,32,40,41,43,62–65.

by Haylick, who noted cessation of replication after a critical number of cell divisions. With each cell division, there is a loss of the telomere DNA sequence, TTAGGG. TTAGGG is a nucleoprotein cap on the end of the double-stranded DNA that protects the DNA against chromosomal fusion.[8,63] When the telomere reaches a critical length, the cell cycle arrests, no further division through the $p53/p21^{WAF1/CIP1}$ pathway occurs, and apoptosis results. There is an increase in senescence markers, such as senescence-associated β-galactosidase (SA β-gal) and lipofuscin granules.[8,63] Interestingly, rodents contain telomerase that allows the telomere to repair and lengthen, but even so Melk et al.[63] showed cell cycle arrest in rats. Besides replicative senescence, cell cycle arrest can occur through stress with an increase in expression of $P16^{INK4a}$.[68] $P16^{INK4a}$ is a cyclin-dependent kinase (CDK) inhibitor of CDK 4 and 6. $P16^{INK4a}$ results in hypophosphorylation of a retinoblastoma protein as well, through the $p53/p21^{CIF1/WAF1}$ pathway.[67] The expression of $P16^{INK4a}$ has been found in the cortex and medulla in aging human kidneys and is seen in areas of inflammation, fibrosis, and apoptosis. These cells are metabolically active but are reprogrammed for expression of proinflammatory and profibrotic cytokines such as TGF-β, tumor necrosis factor-α, and vascular cell adhesion molecule (VCAM)-1.[6,67]

Wiggins and colleagues[71] performed an elegant study evaluating the linear alteration in glomerular gene expression in Fischer 344 rats from 2 to 24 months of age on an ad libitum vs. a caloric restricted (CR) diet. Using genetic techniques, they identified a pattern of gene expression in aging glomeruli that resembled atherosclerosis, involving proinflammatory and profibrotic processes. Nuclear factor-kappa B (NF-κB) was further identified as a transcription factor candidate for these alterations in gene expression, suggesting a common pathway for diseases and aging in organs.

Mitochondria have been proposed to play a key role in aging.[66,68,70] Mitochondrial (mt) DNA is altered more with aging and is partially responsible for the increase in ROS that results in disruption of the redox state and an increase in oxidative stress and damage commonly seen with aging.[69–71] Protein oxidation and lipid peroxidation cause cellular and protein damage that culminates in apoptosis and the decline in autophagy and replication.[70,74]

SIRT1[64,65,72,74–76] and klotho[73,77–83] are considered antiaging modulators. Sirtuins are members of the Sir2 (silent information regulator 2) family, and seven mammalian Sirtuins have been identified.[64,75] The most widely studied in the kidney is SIRT1. They are class III deacetylases. Of the seven Sirtuins, Sirt1 has been the most extensively studied, for its role in life span longevity in the setting of CR. SIRT1, a NAD^+-dependent protein deacetylase, functions as an intracellular energy sensor *via* NAD^+. It regulates and attenuates intracellular hypoxia-induced fibrosis, inflammation, and apoptosis. Sirt1 deacetylates many intranuclear transcription factors and proteins.[65,74,76] SIRT1 declines with aging, possibly from increased oxidative stress. Various roles of Sirt1 that occur through deacetylation have been identified. These include inhibiting the activity of NF-κB,[64] apoptosis by p53 deacetylation, increasing autophagy through forkhead box 03 (FOXO 3),[76] and suppressing TGF-β-related apoptosis

through Smad7 deacetylation.[65] More recently, it was shown that SIRT1 has a role in maintaining podocyte function. SIRT1 declines with age, resulting in damage and loss of podocytes.[72]

The *klotho* (kl) gene is known as the antiaging gene. Klotho-deficient mice display a premature aging phenotype, commonly found in humans, characterized by osteoporosis, arteriosclerosis, atrophic skin, emphysema, and shortened life span.[77] Klotho regulates calcium and phosphorus metabolism and is critical in the development of mineral bone disease.[78] The *klotho* gene encodes a single pass transmembrane protein that is expressed predominantly in the distal convoluted tubules, the parathyroid gland, and the choroid plexus.[79] There is a decline in the renal expression of both klotho mRNA and protein in CKD patients.[80] When its transmembrane protein binds with a coreceptor specific for fibroblast growth factor-23, phosphate reabsorption and production of $1,25(OH)_2D_3$ are suppressed. Besides the membrane-bound protein, there is a soluble klotho protein.[81] This soluble klotho protein is released from the extracellular membrane into the serum and urine, but declines with age, and has an inverse relationship with decline in estimated GFR (eGFR) in the elderly.[81]

Soluble klotho affects local transporters, including ROMK-1, transient receptor potential vallinoid (TRPV) 5 and 6, the calcium channel, and the NaPi-2a transporter.[82] In mutant kl^{-}/kl^{-} deficient mice, treatment with an intraperitoneal infusion of soluble klotho ameliorated the age-related phenotype. There was a decrease in renal fibrosis through the downregulation of TGF-β and $p21^{cip1}$ expression and a decrease in renal and aortic calcification compared with vehicle treated kl^{-}/kl^{-} mice.[83]

Autophagy plays a role in aging and the degradation pathway in the cell. Autophagy is responsible for the removal of damaged organelles and aberrant macromolecules, thereby preventing further injury and cellular dysfunction. Cellular homeostasis is maintained.[62]

DIAGNOSIS

There are no clinical laboratory tests to diagnose changes in the aging kidney in healthy elderly individuals with a GFR greater than 60 mL/min/1.73 m^2. The normal GFR for those who are elderly and very elderly has been an area of debate. Should those with eGFR slightly lower than 60 mL/min/1.73 m^2 with no other clinical findings to suggest CKD such as proteinuria, active urine sediment or radiologic findings be considered to have normal function consistent with aging, or do they have CKD? This can and will affect referrals, medical expenses, and concerns for patients.

The loss of muscle mass with aging makes S[Cr] a poor surrogate marker for changes in renal function.[84,85] On the other hand, cystatin C, a cysteine protease inhibitor, is not affected by changes in muscle mass or urinary secretion and is a more reliable marker for determining changes in renal function. Fliser and colleagues[78] compared serum cystatin C and S[Cr] as GFR markers to measured inulin clearance in 16 healthy normotensive young adults, 22 healthy normotensive older adults, and 19 hypertensive older adults. They observed cystatin C to be a superior marker for the decline in GFR compared with S[Cr] in the elderly. Unfortunately, cystatin C is not readily available for clinical use. Instead the Modification of Diet in Renal Disease (MDRD) GFR, which was formulated in 1999, is used to determine one's GFR clinically and has replaced the Cockcroft–Gault formula. The MDRD equation has been reformulated to improve its bias, accuracy, and precision in those with a GFR greater than 60 mL/min/1.73 m^2, because the S[Cr]-based GFR underestimates the measured (m) GFR in the general population. Many of the S[Cr]-based GFRs were validated in a younger population, but not in the elderly. In the healthy older population, the eGFR may fall within CKD stages 2 to 3a and be considered normal.

A newer formula, the CKD-EPI (CKD Epidemiology Collaboration), used a more diverse pool of patients and is more accurate and less biased than previous MDRD-derived formulas.[86] Unfortunately, these studies did not include a large older population. Using cross-sectional analyses, Inker and colleagues[87] developed CKD-EPI based on cystatin C alone or S[Cr]-cystatin C (cr-cyst) formulas and compared the two. A total of 5352 participants were included. There was good representation of the elderly (13% and 21% in each group, respectively). Improved accuracy and precision were found in the cr-cyst-based formulation, with 16.9% of the cr-cyst group reclassified into a higher CKD classification.

In a prospective cohort study, 394 participants greater than 74 years of age of European ancestry were recruited to validate four GFR formulas: $CKD\text{-}EPI_{cr}$, $MDRD_{cr}$, $CKD\text{-}EPI_{cyst}$, and $CKD\text{-}EPI_{cr\text{-}cyst}$, compared with mGFR. For GFR less than 60 mL/min/1.73 m^2, the $MDRD_{cr}$, $CKD\text{-}EPI_{cr}$, and $CKD\text{-}EPI_{cr\text{-}cyst}$ overestimated and $CKD\text{-}EPI_{cyst}$ underestimated the GFR.[88] All equations overestimated the GFR when it exceeded 60 mL/min/1.732 m^2, but the three CKD-EPI formulas were more accurate. Although using iothalamate to determine the GFR is ideal, it is not clinically feasible, so various eGFR formulas must be used. Overall, the creatinine-cystatin C formulated GFR was satisfactory in both older patients and in younger age groups. The overestimate of eGFR and use of S[Cr]-based formulas

in the elderly may underestimate the true number of elderly people diagnosed with CKD.

Albuminuria is a well-established clinical marker for underlying renal disease and endothelial dysfunction. In rodents, there is an increase in proteinuria that coincides with the decline in renal function and histological changes that typically occur with aging. This is not true for healthy elderly individuals. A Spanish population-based study evaluated the prevalence of albuminuria in men and women with aging.[89] There was a greater prevalence of albuminuria in the elderly than in the younger cohort, 10.9 vs. 3.4% ($p < 0.001$). Albuminuria was commonly associated with hypertension, and to a lesser degree with diabetes mellitus. Similarly, NHANES studies evaluated the prevalence of microalbuminuria in the US population, sampling 22,244 participants 6 years of age or older.[90] The presence of microalbuminuria increased after 40 years of age. There was a greater prevalence in those with underlying diabetes, hypertension, and female gender. The prevalence of microalbuminuria in those older than 60 years of age with no adverse conditions was only 4.9% in men and 5.4% in women.

TREATMENT

Understanding how the kidney ages may lead to interventions that prevent or retard the progression of CKD. Today, CR is the only established intervention shown to combat aging. CR has been shown to increase longevity in some animal species, decrease oxidative stress, improve metabolic parameters, and ameliorate phenotypic aging.[6,58,59,91–96] Two longitudinal studies in nonhuman primates involving rhesus monkeys, *Macaca mulatta*, showed mixed results.[91,92] The Wisconsin National Primate Research Center (WNPRC) study showed a benefit of CR, whereas the National Institute of Aging (NIA) study showed no increase in longevity.[92] The WNPRC found an increase in longevity with CR with a 37% incidence of death in the control group vs. 13% in the CR group.[92] NIA found no increase in life span with CR, but there was improvement in many of the health issues which accompany aging, including glucoregulatory function, oxidative stress, and a decreased incidence of malignancies.[91] The decrease in longevity was associated with hyperinsulinemia. Because of this discrepancy, a direct comparison of the longitudinal data from both studies was performed and included survival, body weight, food intake, fasting glucose level, and age-related morbidity.[93] Differences in diet, age of onset on CR diet, and origin of the rhesus monkey may have affected the differences; however, the authors concluded that both CR studies showed a benefit.[93]

In a randomized controlled study of healthy overweight sedentary individuals, Heilbrom and colleagues[94] evaluated biomarkers of longevity, metabolic adaptation, and oxidative stress when they were randomly placed on four different diets: (a) weight maintenance, (b) 25% CR diet, (c) 12.5% CR diet and 12.5% exercise energy expenditure, and (d) severe CR diet followed by a maintenance diet for 6 months. Over the short time period, those on the CR diet displayed a significant decline in body energy expenditure, insulin levels, core temperature, and a decrease in DNA damage. Sirtuins appear to play a role in the CR diet by decreasing oxidative stress, increasing autophagy, and decreasing apoptosis.[62,74] Wood and colleagues[95] observed increased longevity in metazoans placed on the sirtuin activator agent (STAC), resveratrol, which was similar to that seen with CR alone. In the presence of Sir-2.1 (mammalian homolog null mutants), the addition of STAC had no effect on longevity.

Besides increasing longevity, CR decreases oxidative stress and apoptosis while improving autophagy and cell survival in various animal studies.[74,96] Adult C57BL/6 mice on long-term CR showed attenuation of mitochondrial DNA oxidative damage, with improved histology and function, and an increase in autophagy in the proximal convoluting tubule (PCT) compared with *ad libitum* fed mice.[74] CR increased expression of the Sirt1/Foxo3/Bnip and p27Kip1 pathways and resulted in hypoxia-induced autophagy, cellular arrest, and decline in apoptosis in the PCT. Short-term CR can also attenuate oxidative stress. Jung and colleagues[96] evaluated a 10-day CR in Fischer 344 male rats aged 6 and 24 months. They observed suppression in oxidative stress and inhibition of the oxidative-induced proinflammatory transcription factor, NF-κB, and decline in expression of proinflammatory enzymes and adhesion molecules linked to aging (such as inducible NOS, cyclooxygenase-2, VCAM-1, and intracellular adhesion molecule-1).

CR may be difficult for elderly persons to sustain. Moreover, there is the danger that such a diet may result in malnutrition. An alternative might be prescribing an "antiaging medication." This may seem preposterous. However, certain medications prescribed for the elderly population for diabetes mellitus, hypertension, and atherosclerosis have been touted for their antiaging effects. These medications include N-acetylcysteine,[60] metformin,[97] thiazolidinedione,[98,99] resveratrol,[95] HMG-CoA reductase inhibitors,[100] and angiotensin receptor blockers.[30]

Recently, promising results using pioglitazone, a thiazolidinedione, which is a well-known peroxisome proliferation-activated receptor γ agonist, show that it may reverse or attenuate the aging process.[99] In a

murine model using atherosclerotic prone mice (apolipoprotein E-deficient ($ApoE^{-/-}$) mice), the effect of pioglitazone on aging phenotype and morphologic changes was studied. The long term and low dose of pioglitazone significantly reduced aortic atherosclerosis, age-related nephrosclerosis, hepatic steatosis, and improved skin turgor compared with control. The treated mice showed a decline in inflammation with a decline in myeloperoxidase, reduction of ROS, an increase in Sirt1 mRNA and klotho mRNA, and a decrease in p53.[99] Therefore, pioglitazone may be an agent against aging and age-related disorders. Further research is necessary to determine whether such treatments may have an effect on general aspects of aging, kidney function, and meaningful outcomes.

SUMMARY

The aging kidney undergoes structural and functional phenotypic changes with time. There is a decline in GFR, RPF, and tubular function, characterized histologically by glomerulosclerosis, tubulointerstitial fibrosis, and atrophy. These changes appear to be influenced by the environment, genetic factors, and gender and result in a profibrotic, proinflammatory, apoptotic state. These adaptations may increase the elderly's susceptibility to acute and CKD, allograft failure, and be responsible for the higher mortality rates frequently seen in the elderly. Modification of selected cellular and molecular mechanisms with various medications, transcription factor inhibitors, or CR may modify or attenuate these changes and prevent progression to CKD. As nephrologists, we need to be cognizant of changes in the aging kidney, shortcomings of the estimation of GFR in elderly, and the effect of medications frequently prescribed such as NSAIDS, diuretics, and RAAS-blocking agents in our patients.

QUESTIONS AND ANSWERS

Question 1

An 80-year-old woman was brought to her physician by her daughter for evaluation of confusion. The daughter, who was visiting from Las Vegas, noted that her mother thought that the year was 2000 and that the day was Sunday. The patient confirmed this. Her physician inquired if she was taking any new medications at the time the confusion started. The daughter related that her mother was placed on chlorthalidone and taken off amlodipine 2 weeks ago because of leg and ankle edema. Her blood pressure, which had been around 180/80 mm Hg, was now 150/79 mm Hg. Physical examination revealed resolution of the leg and ankle edema. S[Na] 125 mEq/L, S[Cl] 95 mEq/L, S[K] 3.0 mEq/L, and S[HCO_3] 27 mEq/L. Serum osmolality was 262 mOsm/L. Urinalysis was bland with specific gravity 1.015. What is the cause of her hyponatremia?

A. Poor intake
B. Excessive thirst
C. Chlorthalidone
D. Increased total body water
E. Lower basal vasopressin level

Answer: C

Thiazides are a common cause of hyponatremia in the elderly and account for over 30% of the cases. Multivariate analysis has shown that low total body water, female sex, and hypokalemia are associated with diuretic-induced hyponatremia. Although "beer potomania," which is associated with low solute intake and low urinary osmolality, is a possibility, it is unlikely given that her urine osmolality is not <100 mOsm/kg. The elderly have decreased thirst sensation as a consequence of a decrease in afferent sensory output from the oropharynx, stomach, and esophagus. Total body water decreases with age secondary to sarcopenia and results in a higher incidence of dysnatremias. Studies have shown elevated basal vasopressin levels and a greater response to tonicity in the elderly.

Question 2

An 86-year-old man is referred to a local nephrologist for evaluation of low GFR, 70 mL/min/1.73 m^2 found on laboratory examination done 3 weeks ago. He is independent and lives alone. He exercises three to four times a week, eats three meals daily, and is able to manage his expenses. Physical examination reveals a well-nourished man with a completely normal examination. Laboratory results including a urinalysis are normal. No microalbuminuria is detected (16 mg albumin:g creatinine). An ultrasound of the kidneys is normal. The right kidney measures 10 cm and the left kidney measures 10.5 cm in length.

The man is concerned about being diagnosed with CKD. What should you suggest to him?

A. The MDRD GFR and Cockcroft–Gault formulas underestimate the true GFR in those over 65 years of age
B. The MDRD GFR has not been validated in the elderly
C. Elderly patients diagnosed with CKD Stage IIIa (eGFR 45–60 mL/mm/1.73 m^2) are more likely to progress to ESRD than die from CVD
D. He has no evidence of CKD but a decline in renal function commonly occurs with aging
E. Refer the man to a dietitian to discuss restricting his dietary protein intake because this slows the rate of progression of kidney disease

Answer: D

After age 40, individuals can expect to lose renal function on the order of 10 mL/min/decade. However, this man has no microalbuminuria or any other urinary findings to suggest that he has any kidney disease. Recently, the MDRD-modified formula was validated, and it can be used to estimate GFR in the elderly. However, this estimate hinges on normal body habitus. If this man were cachectic, a 24-hour urine collection measuring creatinine clearance would be a far better estimate of his true GFR. The Cockcroft–Gault equation consistently underestimates the true GFR, whereas the MDRD GFR overestimates it. Moreover, this man is not likely to progress to ESRD but is more likely to develop CVD. At this point, he does not require dietary protein restriction as this maneuver has not been shown to slow the rate of progression of kidney disease at this level of GFR. Protein malnutrition, a consequence of low dietary protein intake, has been associated with an increased risk of mortality.

Question 3

A healthy 70-year-old woman, with no history of hypertension or diabetes mellitus, undergoes a right nephrectomy for renal cell carcinoma. Her postoperative recovery is uneventful, and her S[Cr] increases by 0.2 mg/dL and remains stable. Her physician inquires if she wants a copy of the pathology report which includes a biopsy report of the normal renal parenchyma. The patient is taken aback when she reads that scarring is seen and wants to know what this means. The light microscopy reports that 2 of 10 glomeruli are sclerosed. There is associated mild tubular atrophy, arteriolar hyalinosis, and fibrosis. The remainder of the glomeruli and interstitium appear normal. Except for the slight increase in S[Cr], the patient's laboratory examination is

normal. The patient makes an appointment to see you. How should you respond?

A. Aging is usually not associated with any morphologic changes within the kidney
B. The number of sclerotic glomeruli varies but usually approaches more than 50% by age 40
C. The amount of scarring seen on the biopsy suggests that the patient will experience a severe decline in renal function, and she should not have had the nephrectomy
D. These are normal findings seen in aging and should have no significant impact on her kidney function
E. She needs to follow-up with a nephrologist because she is at increased risk of developing CK

Answer: D

With aging there is an increase in sclerosis in the kidney, associated with a decline in GFR and RPF. This amount of scarring is commonly seen in her age group. Interestingly, a decline in GFR does not correlate with the degree of sclerosis, but the degree of sclerosis does correlate with the amount of glomerulopenia. The number of sclerosed glomeruli increases after 40 years of age but is usually not more than 5%. She is not at increased risk for development of CKD. To be effective, a CR diet is necessary.

Question 4

A 70-year-old man was reading the magazine *Aging — What Can You Do?* and came across an advertisement for resveratrol. After reading all the antiaging claims, he went online to read more about it. Which of the following information he found in the advertisement was true?

A. Resveratrol is an activator of Sirt1
B. The level of Sirt1 in the kidney is higher in older animals
C. Resveratrol has been shown to increase life span in humans
D. Sirt1 increases oxidative stress and cellular senescence
E. For resveratrol to be effective, a CR diet is necessary

Answer: A

Resveratrol increases the levels of Sirt1. In animal studies, the expression of Sirt1 decreases with aging. The addition of a CR diet and resveratrol showed no increased benefit with longevity in metazoans, and there has not been any documentation that resveratrol increases life span in humans. Increases in Sirt1 decrease oxidative stress, improve autophagy, and decrease apoptosis. Resveratrol does not have to be linked to a CR diet to be effective.

Question 5

A 75-year-old man with a history of peripheral vascular disease and tobacco use was started on the ACEI, lisinopril, 10 mg daily. A baseline S[Cr] was 1.0 mg/dL. Blood pressure was $\geq$140/90 mm Hg on three separate clinic visits. He returns in 1 week for laboratory evaluation and blood pressure check. He reports feeling a little lightheaded, but he had not taken his blood pressure because his machine had malfunctioned. His blood pressure in the office was 100/61 mm Hg. Laboratory work revealed that the S[Cr] had increased to 2.4 mg/dL. All of the following contribute to worsening renal function in the elderly except?

A. Renal blood flow decreases with aging
B. There is a decreased ability of the kidney to undergo autoregulation
C. There is an increased response to acetylcholine in the renal arteries that occurs with aging
D. NOS declines with aging
E. Maintenance of renal perfusion generally requires a higher mean arterial pressure

Answer: C

Responses to vasoactive substances change with aging. There is a decline in renal blood flow and an increase in renovascular resistance. Older people are less responsive to vasodilators such as acetylcholine and experience greater sensitivity to vasoconstrictors. This results in the decreased ability of the kidney to undergo autoregulation. Caution needs to be taken with excessive blood pressure control in the elderly.

Question 6

Look back at the information in Question 5. The patient stops lisinopril, expecting his renal function will improve. He returns to your clinic in another week to check his S[Cr]. It has now gone from 2.4 mg/dL to 6 mg/dL. As a nephrologist, you inquire if he was taking anything else with lisinopril. He states he was taking naproxen for shoulder pain. A microscopic urinalysis shows 3—4 coarse pigmented granular casts per high power field. The patient is instructed to discontinue naproxen and is admitted to the hospital. S[Cr] returns to baseline in 3 weeks, and he does not require renal replacement therapy. Should the patient have any concerns about his renal function in the future?

A. No, he has no underlying kidney disease so he should not be worried
B. No, he should not be concerned because he did not require renal replacement therapy

C. Because he experienced an episode of AKI, he is at higher risk for morbidity and mortality than if he had CKD alone

D. He is at a higher risk for morbidity and mortality if he just had CKD than if he had AKI alone

E. He needs to schedule an appointment for vein mapping because he will need dialysis soon because his renal function will rapidly deteriorate

Answer: C

Elderly individuals have an increased incidence of diabetes and hypertension. Although the incidence of diabetes declines after age 65, the incidence of hypertension continues to increase as people age. Both these conditions are associated with CKD and progression to ESRD. Besides developing CKD, the elderly are more likely to develop AKI. There is a higher mortality and higher likelihood for the development of ESRD in those who develop AKI while hospitalized than those with CKD without AKI. Ishani and colleagues[16] observed that the hazard ratio for ESRD was 24 vs. 8 for those who develop AKI vs. those with CKD alone.

Pathophysiology of Chronic Kidney Disease Progression: Organ and Cellular Considerations

Anupam Agarwal[a], *Karl A. Nath*[b]

[a]Division of Nephrology, University of Alabama at Birmingham, Birmingham Veterans Administration Medical Center, Birmingham, AL, United States; [b]Division of Nephrology and Hypertension, Mayo Clinic, Rochester, MN, United States

Abstract

Progression of chronic kidney disease (CKD) involves the recruitment and engagement of *cellular processes* originating in specific compartments of the kidney on the one hand and *biochemical pathways* of cell injury that contribute to these processes on the other hand. Many of these processes possess the capacity to ramify broadly beyond the compartment where they initially arose. It is this essential consideration that contributes so fundamentally to the increasing loss of functional nephrons and the progression of CKD. A number of different biochemical pathways contribute to CKD progression: angiotensin II induces TGF-β1 and the consequent elaboration of extracellular matrix; angiotensin II also induces oxidative stress which itself can upregulate TGF-β1 in vicinal cells and thus the propagation of a fibrosing response. This lack of containment of compartmental processes, and this versatility of injurious biochemical pathways, not only underlies the pathogenesis of CKD but also holds substantial therapeutic significance. Namely, the best hope for retarding or preventing the progression of CKD resides in a combined, multipronged therapeutic approach that interrupts these processes and pathways at separate and several steps.

INTRODUCTION

Along with a steady decline in glomerular filtration rate (GFR), the progression of chronic kidney disease (CKD) is attended by characteristic renal histologic changes.[1–3] These structural alterations usually involve all compartments of the kidney. Glomeruli exhibit varying degrees of extracapillary adhesion formation, sclerosis, and obliteration of the capillary tuft. Tubules become atrophic. The interstitium is expanded by a mononuclear cellular infiltrate and extracellular matrix, and the renal vasculature displays sclerosis and dropout of capillaries in the cortical interstitium. Nephrons are heterogeneously and asynchronously affected. Interspersed among variably atrophic tubules, sclerotic glomeruli, and amidst an expanded interstitium are hypertrophied and presumably hyperfunctioning nephrons. Progressive decline in renal function in CKD thus reflects the cumulative functional loss resulting from injury to and obsolescence of increasing numbers of nephrons, with hyperfunctioning by certain subsets of surviving nephrons offering a mitigating, but insufficient, response.

A concept common to all mechanisms proposed to date regarding the progression of CKD is that processes centered in a particular compartment of the kidney—glomerular, tubular, interstitial, vascular—can recruit injurious processes in others. It is this increasing elicitation and interaction of diverse pathobiologic processes, involving multiple renal compartments, that drive the progression of CKD.[1–5]

These compartmental processes and how they interact in the progression of CKD are reviewed in this chapter, in conjunction with the role of specific mediators and inhibitors of chronic renal injury. Mechanisms that are specific for diabetic nephropathy and polycystic kidney disease are discussed elsewhere.

COMPARTMENTAL PROCESSES

Glomerular Processes

Glomerular Extracapillary Processes

Glomerular diseases involve endocapillary, extracapillary, or both sets of processes. Processes confined to the endocapillary compartment are generally not considered critical in progressive CKD.[2] In contrast, alterations in the extracapillary compartment—in particular, alterations

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00018-8

involving podocytes—set the stage for progressive glomerulosclerosis, tubulointerstitial inflammation and fibrosis, and tubular atrophy.[2,6–8] Extracapillary processes may occur *de novo* or may reflect the extension of pathobiologic processes that initially resided in the endocapillary compartment.[9]

In health, podocytes and, in particular, their foot processes, determine glomerular permselectivity. Thus, injury to podocytes that disrupt their foot processes and their attachment to the glomerular basement membrane (GBM) leads to glomerular proteinuria and the consequent tubular trafficking of reabsorbed proteins.[2,6–8] Injured podocytes also exhibit a variety of ultrastructural changes including cellular extensions across Bowman's space. These extensions to parietal epithelial cells (PECs) lead to the formation of cellular bridges. Bridge formation is attended by increased extracellular matrix production and adhesions (synechia) with Bowman's capsule. Therefore, a sclerosing process can ensue that closes off the adherent capillary tuft.[2,6,8] Adhesions to Bowman's capsule can also occur at areas of the GBM denuded of podocytes. Adhesions impair the integrity of the parietal epithelium and the parietal basement membrane (PBM) such that glomerular filtrate insudates into the interstitium. This misdirected glomerular filtrate triggers an inflammatory interstitial response and the vicinal congregation of immune cells and fibroblasts. Glomerular filtrate may also aberrantly track inside the PBM around the glomerulus and extend around the glomerulotubular junction, thereby collecting in the space between the proximal tubular epithelium and the tubular basement membrane (TBM). Such fluid collection compromises tubular patency and transport activity, and thus promotes the development of tubular atrophy.[2,8]

Proliferation of PECs is often a consequence of podocyte injury.[2,10] Proliferating PECs may migrate across cellular bridges/adhesions and cover denuded areas of the GBM. Proliferating PECs, however, may also migrate circumferentially around Bowman's capsule to the glomerulotubular junction, narrowing this junction and impeding the flow of glomerular filtrate into tubules. Eventually, this migrating front of proliferating PECs severs off the tubule from the glomeruli, thereby producing atubular glomeruli and aglomerular tubules.

Podocyte Pathobiology and CKD

Major glomerular-based mechanisms in progressive CKD invariably involve pathobiologic processes/responses in podocytes, and the following are relevant considerations.[2,6–8,10–14] First, podocytes are terminally differentiated cells that cannot reproduce equivalently differentiated offspring. However, dedifferentiated podocytes can proliferate, migrate, assume a proinflammatory and profibrotic phenotype, and thereby promote the formation of bridges and adhesions. Notably, the concept of "mitotic catastrophe" in podocytes has been articulated wherein injured podocytes initiate DNA synthesis but ultimately fail to undergo mitosis. Podocytes exhibiting mitotic arrest are unstable and eventually undergo apoptosis or detachment from the GBM.[13] Second, the severity of the initial loss of podocytes determines the risk for and severity of glomerulosclerosis and progressive CKD.[15–17] This reflects not only the entrainment of injurious extracapillary processes in the early phase after podocytic injury and loss but also, in the later phases, the steady propagation of injury to previously uninjured surviving podocytes.[18,19] These responses include, in part, hypertrophy of surviving podocytes in an attempt to cover the bare areas of the GBM. However, such hypertrophic responses do not achieve the requisite coverage of the exposed GBM. Furthermore, hypertrophy of surviving podocytes may lead to less stable anchorage of the foot processes of these enlarged cells to GBM, such that, in time, these cells lose their footing to the GBM and are sloughed into the urinary space. In effect, a self-perpetuating cycle of injury to and loss of podocytes ensues. Third, podocyte injury and loss lead to the trafficking of plasma proteins across the filtration barrier. Endocytosis of these proteins by podocytes, however, can itself lead to podocyte injury, thereby providing another self-perpetuating pathway for progressive disease.[20] Fourth, podocytes are directly vulnerable to the damaging effects of many of the candidates involved in CKD, namely, the renin–angiotensin system, TLR4-dependent cytokines, monocyte chemoattractant protein (MCP)-1, TGF-β1, and endothelin-1. Other intracellular signaling systems that are instigated by these and other ligands, which can activate and injure podocytes, include Wnt, Notch, ERKs, Smads, and NK-kB.[21–24] Fifth, podocytes are a major source of vascular endothelial growth factor (VEGF), which preserves endothelial integrity. Podocyte injury and loss may lead to less availability of this trophic factor for endothelial cells, thereby jeopardizing the integrity of the endothelium and glomerular tuft.

Maladaptive Glomerular Responses in Surviving Nephrons

An accepted tenet in progressive CKD is that maladaptive processes in surviving nephrons damage these previously uninjured nephrons, thereby providing a self-perpetuating pathway of injury.[3,4,25,26] Nephrons that survive after a renal insult or subtotal reduction in renal mass exhibit hyperfunction and hypertrophy in glomerular and tubular compartments.[25,26] Glomerular filtration rates in surviving glomeruli are increased, in part, by the increased glomerular transcapillary hydraulic pressure gradient, the latter imposing hemodynamic stress on the capillary tuft.[25–27] Podocytes sense

and respond to mechanical stress, but if such responses are aberrant or insufficient, attendant podocyte injury can occur.[6,27] Additionally, as glomeruli enlarge in surviving nephrons, podocytes undergo hypertrophy, which, however, may be insufficient to cover the GBM. Areas of the GBM are thus exposed and vulnerable to adhesion formation.[2,6] Hemodynamic and structural alterations in surviving glomeruli may thus damage podocytes, and thereby recruit extracapillary processes contributing to CKD.

TUBULAR PROCESSES

Tubular Trafficking of Reabsorbed Proteins

Albumin and other proteins leaked into the urinary space are avidly taken up by the proximal tubule *via* megalin and cubilin receptors which are present on the apical surface of the epithelium. In health, small amounts of plasma proteins filtered at the glomerulus are reclaimed *via* these receptors and are metabolized by the endosomal-lysosomal system. However, in proteinuric states, this salvaging mechanism leads to enhanced trafficking of proteins and their metabolism by the proximal tubule. Such protein overload and protein metabolism generate assorted chemotactic species, proinflammatory and profibrogenic cytokines, other inflammatory mediators, and cytotoxic species—including IL-6, IL-8, MCP-1, endothelin-1, RANTES, TGF-β1, and complement C3—which induce interstitial inflammation, tubular apoptosis, and tubular atrophy.[3,4,28,29] Proximate events in triggering this proinflammatory response involve signaling pathways (protein kinase C, ERK, and JAK/STAT), oxidant generation, and the activation of the transcription factor NF-kB.

The following lines of experimental and clinical observations illustrate the applicability of this pathway to a specific chemokine, MCP-1 (CCL2), a potent, NF-kB-dependent chemotactic stimulus for monocytes and T cells. First, exposure of tubular epithelial cells to albumin *in vitro* or injection of albumin to rodents markedly induces MCP-1.[29] Second, in human CKD, expression of MCP-1 is increased in the renal tubular epithelium and correlates with interstitial leukocyte infiltration, whereas increased urinary excretion of MCP-1 in CKD correlates with interstitial leukocytic infiltration and renal dysfunction.[30–32] Third, strategies that interrupt receptor (CCR2)-mediated actions of MCP-1 (CCL2) reduce interstitial leukocytic infiltration and tubulointerstitial injury in murine models of protein overload nephropathy and renal fibrosis.[33–35]

Trafficking of protein as a pathway for progressive disease has been assessed in at least two studies of glomerular disease in which glomerular injury is imposed in mice with reduced expression of megalin, one of the apical receptors that enables tubular incorporation of filtered protein.[36,37] These studies came to divergent conclusions regarding the instigation of tubular injury when megalin is deficient in states of glomerular proteinuria.[36–38] Such lack of congruence between studies may possibly reflect the following considerations: the relative duration of these studies, the variability and extent to which megalin is deleted in these models, and that pathways other than megalin-dependent ones may also contribute to tubular uptake of protein in the diseased kidney.

Tubular Injury as the Basis for CKD

For many glomerulopathies, acute tubular injury is a prominent finding, and acute kidney injury (AKI) is now recognized as a risk factor for human CKD. A triphasic response has been described when the kidney is exposed to repetitive episodes of AKI, which sequentially includes sensitivity to AKI, resistance to acute injury, and, ultimately, chronic inflammation and CKD.[39] These studies undertaken 20 years ago were the first to specifically articulate the concept that AKI is a risk factor for CKD.[39] More recent studies have examined the long-term outcome from toxic insults specifically directed to the proximal tubule.[40] With low doses of such a toxic insult, AKI is restricted to the S1 and S2 segments and attended by a localized inflammatory response. Subsequently, these inflammatory responses entirely resolve and tubular integrity fully restored. However, when insults are administered at weekly intervals, chronic tubulointerstitial fibrosis ensues in conjunction with glomerulosclerosis.[40] These findings thus demonstrate that failure to recover from a localized insult to the proximal tubule, because of repetitive insults to the same site, can entrain cellular events that damage the glomerular compartment.[40,41] Mechanisms underlying this relay of injury include the following adverse effects emanating from injured proximal tubular epithelial cells: the attraction and activation of proinflammatory leukocytes, the secretion of cytokines such as TGF-β1 that can lead to cell cycle arrest and a profibrogenic response, and the dislodging of pericytes from peritubular capillaries, attendant capillary dropout, and ensuing interstitial fibrosis (*vide infra*).

Maladaptive Tubular Responses in Surviving Nephrons

Remnant nephrons in the diseased kidney or following reduction of renal mass exhibit not only glomerular enlargement and hyperfiltration but also tubular hypertrophy, hyperplasia, and hyperfunction.

These tubular processes are also implicated in CKD.[3,25,42,43] Increased single nephron glomerular filtration rates in surviving nephrons necessitate increased sodium reabsorption to achieve glomerulotubular balance. Sodium reabsorption by the kidney is the principal determinant of renal oxygen consumption. Indeed oxygen consumption/nephron in the remnant kidney model[44] and oxygen consumption/GFR in human CKD[45] are both increased. However, oxygen consumption factored for sodium transport in the remnant kidney, compared with the intact kidney, is higher, thereby indicating augmented metabolic costs entailed by the hyperfunctioning and hypertrophied nephrons.[44,45] Such metabolic alteration is implicated in CKD in at least two ways. First, such increased oxygen consumption may engender oxidative stress and attendant injury.[44] Second, increased oxygen consumption by surviving nephrons may contribute to cortical hypoxia, a recognized pathway for CKD.[46–48] Moreover, there may be a positive feedback between these pathways. Cortical hypoxia induced by increased oxygen consumption can itself promote mitochondrial oxidant generation, and oxidant stress can augment mitochondrial consumption.[47]

Another metabolic adaptation in surviving nephrons is enhanced ammoniagenesis, the latter needed to maintain net acid excretion in CKD.[49] Such increased ammonia production leads to increased cortical partial pressure of ammonia with accompanying activation of the alternative complement pathway.[49] Bicarbonate supplementation reduces renal ammonia production and tubulointerstitial injury. Other mechanisms underlying the beneficial effects of bicarbonate supplementation involve reduced generation of reactive oxygen species[50] and decreased production of endothelin-1.[51] A number of studies in humans demonstrate the beneficial effects of base supplementation in retarding the progression of CKD.[51]

Hematuria-Induced Tubular Injury

Hematuria occurs in a substantial portion of glomerular disease, and there is clinical evidence that hematuria is risk factor for progressive CKD.[52] Erythrocytes present in the urine are engulfed by tubular epithelial cells.[53] Such incorporation and destruction of erythrocytes in tubular epithelial cells, as previously suggested,[3] are harmful to the tubular epithelium because of increased intracellular content of hemoglobin, a heme-containing protein. Heme is prooxidant, proinflammatory, and profibrogenic, inducing, for example, NF-kB-dependent pathways such as MCP-1 production.[54,55] Heme also inhibits proliferation and can cause apoptosis.[56] Thus, hematuria may contribute to progressive CKD by activating heme-dependent pathways of CKD.

INTERSTITIAL PROCESSES

Interstitial Inflammation

One of the best histologic predictors of renal functional decline is the severity of interstitial cellular infiltration and fibrosis, a finding that emphasizes the importance of these processes in progressive CKD.[1] Interstitial inflammation involves infiltrating T lymphocytes and monocytes which are recruited by chemotactic cues originating from injured tubules, capillaries, and glomeruli and are activated to produce a host of inflammatory cytokines and other mediators.[4,5,57] Interstitial infiltration can congregate in areas surrounding injured glomeruli, especially in response to misdirected glomerular filtration. Such interstitial inflammation can synergize with extracapillary glomerular processes in the progression of CKD. Interstitial infiltration and accompanying fibrosis, if especially vigorous in the regions surrounding the S1 proximal tubular segment and the glomerulotubular junction, may encroach on the latter, eventually interrupting tubular patency and disconnecting the tubular and glomerular compartments.

Dendritic cells in the kidney are increasingly recognized for their capacity to drive interstitial inflammation and their contribution to progressive CKD following glomerular inflammation.[58] For example, dendritic cells can activate T cells by presenting antigens leaked from injured glomeruli.[59,60] Dendritic cells can also generate antigens from processing of filtered protein which leads to the activation of T lymphocytes.[61] However, there are subsets of dendritic cells that inhibit inflammatory responses as there are for T lymphocytes (Tregs) and macrophages (M2 macrophages).

If interstitial inflammation continues unchecked, increased extracellular matrix production and interstitial fibrosis inevitably ensue. The predominant cellular source of such matrix synthesis is the interstitial fibroblast and, in particular, the activated myofibroblast.

Interstitial Fibrosis

Interstitial myofibroblasts vigorously synthesize interstitial collagens I, III, and IV and other extracellular matrix proteins (such as fibronectin), express alpha-smooth muscle actin (αSMA), and are motile.[4,5,57,62,63] αSMA is a critical component of stress fibers in myofibroblasts. *Via* these stress fibers, myofibroblasts are linked with the interstitial extracellular matrix. Myofibroblasts possess properties of both fibroblasts and myocytes, the former underlying their capacity to elaborate extracellular matrix proteins, the latter enabling their contractility and motility. To the extent that αSMA largely reflects myofibroblastic activity, the significance of myofibroblasts in CKD is highlighted

by the fact that expression of αSMA correlates with renal fibrosis and functional decline.[62] There is considerable debate regarding the origin of the myofibroblast, the latter variably ascribed to epithelial-mesenchymal transition (EMT), endothelial-mesenchymal transition, renal interstitial resident stromal cells (such as pericytes, perivascular fibroblasts), and bone marrow-derived cells (fibrocytes and macrophages).[4,5,57,62–70] From such analyses, it appears that the role of EMT is controversial; the involvement of the renal interstitial resident stromal cells such as pericytesis is increasingly accepted; and the contribution of the bone marrow-derived cells and endothelial-mesenchymal transition is currently unclear.

EMT describes the transformation of epithelial cells into mesenchymal cells and is a recognized phenomenon during normal development and carcinogenesis.[5,57,63,66] Applied to CKD, EMT reflects the transitioning of polarized renal tubular epithelial cells into nonpolar mesenchymal cells and eventually into myofibroblasts. EMT requires not only cell transition but also cell migration across the TBM into the interstitium. The evidence for such transition is especially strong in studies *in vitro* which expose renal tubular epithelial cells to TGFβ1-containing media, recapitulating the fibrogenic milieu presumably present in the diseased kidney. Under such conditions, cellular transitioning is readily observed, as cells lose epithelial-specific markers (for example, β-catenin and E-cadherin) and acquire mesenchymal features and markers (for example, fibroblast-specific protein-1 and αSMA).[5,57,63,66] The evidence against EMT as a principal pathway for interstitial fibrosis *in vivo* has been reviewed and is summarized along at least three main lines.[66] First, while there is one study based on the mapping of cell fate for the existence of this phenomenon *in vivo*, an increasing number of recent, rigorous studies have failed to demonstrate that interstitial myofibroblasts arise from EMT. Second, there is little or no evidence *in vivo* that tubular epithelial cells putatively undergoing EMT do produce collagen I (a critical component of interstitial matrix).[66] Third, convincing histologic confirmation is not yet available that sequentially demonstrates, *in vivo*, the structural conversion of the epithelial cell into a myofibroblast or has captured these transitioning cells in the act of migration across the TBM and into the interstitium.[66] Thus, there is an emerging view that while many of the salient features of EMT are clearly demonstrable *in vitro*, there is circumspection regarding whether this phenomenon, as originally articulated, occurs *in vivo* in CKD and serves as a significant source for interstitial activated myofibroblasts. "Partial EMT" is a term used by some experts to reflect the fact that the early steps in the transition, but not the complete transition, may be relevant to the progression of CKD.[68–70]

In contrast, the pericyte is increasingly recognized as the precursor of the myofibroblast in CKD.[64–66] In health, pericytes are implanted in the capillary basement membrane surrounding peritubular capillaries, precapillary arterioles, and postcapillary venules. Through cytoplasmic extensions, pericytes connect with endothelial cells of the peritubular capillary they surround as well endothelial cells in vicinal capillaries. Pericytes maintain the structural and functional integrity of capillaries with which they are in contact.[64,65] Studies based on cell fate and lineage-mapping in models of CKD demonstrate that an early event is the dislodgement of pericytes from the peritubular capillary basement membrane, their migration into the interstitium, and their transformation into myofibroblasts. Furthermore, the loss of the pericyte around the capillary perturbs the integrity and viability of endothelial cells and the capillary, thereby leading to endothelial cell loss, capillary dropout, and capillary rarefaction. This sets the stage for cortical ischemia and hypoxia and attendant tubular atrophy.[64,65]

In health, there is a clear symbiosis between the capillary endothelium and the pericyte, and injury to one of these cells may beget injury to the other.[67–70] The molecular basis for cellular events that perturb and dislodge the pericyte in CKD may involve, in part, perturbed growth factor-dependent signaling between the endothelial cell and the pericyte.[71] Endothelial cells express the VEGF receptor and produce platelet-derived growth factor (PDGF), whereas pericytes express PDGF receptors and produce VEGF. Aberrant or inordinate production and signaling of these or other growth factors may injure either the endothelial cell or the pericyte, with attendant damage to the other. Interestingly, a pairing of molecules that maintains the mutual health of the capillary endothelium and the pericyte involves ephrinB2 and its receptor EphB4, both of which are expressed on these cells. Disrupting the dialogue between these molecules may also contribute to capillary rarefaction and interstitial fibrosis.[72]

Myofibroblast production of collagen I and III and fibronectin, and other key matrix components that constitute interstitial fibrosis, is transcriptionally regulated and is driven by TGF-β1, PDGF, connective tissue growth factor (CTGF), fibroblast growth factor, and angiotensin II.[5,57,62,67–70] Intracellular signaling processes instigated by these fibrogenic stimuli are collated, at least in part, by integrins, which are transmembrane proteins that interface between these intracellular processes and the extracellular buildup of matrix proteins.[5] Seminal studies by Humphreys and colleagues have shown that, in models of tubulointerstitial disease, kidney perivascular cells that express the zinc finger transcription factor glioma-associated oncogene homolog 1 (Gli1) account for the majority of activated renal

myofibroblasts and much of the attendant interstitial fibrosis that ensues.[69] The mechanisms whereby such Gli1 expression account for this effect on activated myofibroblasts and the specific origin and significance of Gli1-negative myofibroblasts are both uncertain at the present time.[69]

Capillary Rarefaction

The destabilization and dropout of peritubular capillaries because of pericyte disengagement lead to tubular ischemia and cortical hypoxia, the latter exacerbated as remaining capillaries are increasingly separated from tubules by progressive interstitial fibrosis.[64,65,71] Cortical hypoxia exerts diverse inflammatory and fibrogenic effects.[46–48] Hypoxia promotes the differentiation of dendritic cells and their attendant ability to stimulate T-cell proliferation.[73] Hypoxia fosters hypoxia-induced factor (HIF)1α-dependent, TGF-β1-dependent, and other pathways for fibrosis.[5,46,47,57] Capillary rarefaction also adversely affects the glomerular compartment because attenuation in the peritubular capillary network increases post glomerular resistance, thereby predisposing to increased glomerular hydrostatic pressure and hemodynamic glomerular injury.[1]

Crosstalk in the Tubulointerstitium and the Progression of Chronic Kidney Disease

Disease-provoking interactions occur between relevant cells in the tubulointerstitium and include crosstalk among the following[67–70]: different tubular epithelial cells, tubular epithelial cells and interstitial pericytes, tubular epithelial and inflammatory cells, inflammatory cells and myofibroblasts, and endothelial and other tubulointerstitial cells. It is such aberrant interactions between and among these cell populations, culminating in the activation of myofibroblasts and elaboration of interstitial matrix, that largely drive the progression of CKD.[67–70]

A salient series of interactions begins with injury to tubular epithelial cells (for example, by proteinuria or cytokines leaked into the urinary space from diseased glomeruli).[67–70] Such tubular epithelial cell injury promotes dedifferentiation of tubular epithelial cells through TGF-β1 and other mediators. Injured tubular epithelial cells cause pericytes to transform into activated myofibroblasts *via* such mediators as TGF-β1, PDGF, hedgehog, and Wnt, among others, thereby engendering the production of large amounts of extracellular matrix. The destabilization of the pericyte *pari passu* impairs the integrity of the capillary endothelium. This along with excessive matrix production promotes capillary rarefaction and cortical hypoxia. The latter instigates proinflammatory and fibrogenic effects, thereby perpetrating continued harm to the interstitial milieu. Moreover, the injured tubular epithelium and injured capillary endothelium activate innate immunity, thereby recruiting inflammatory cells and immune processes as additional effectors of tubulointerstitial injury.

Recent insights have identified two key drivers of disease-provoking cellular crosstalk in the tubulointerstitium. The first is the senescence-associated secretory phenotype (SASP) of the dedifferentiated tubular epithelial cell. The second is the secretome of the injured capillary endothelium.[74,75] When tubular epithelial cells are injured and dedifferentiate, they acquire a senescence phenotype characterized by cell cycle arrest, resistance to apoptosis, and the production of SASP factors. SASP factors represent a plethora of cytokines, growth factors, and proapoptotic, profibrotic, and vasoactive molecules, among others, that engender aberrant communication among tubulointerstitial cells. Similarly, injury to the capillary endothelium instigates an abnormal and copious endothelial secretome, the constituents of which not only display pleotrophic cellular effects resembling those of SASP factors but may also activate the myofibroblast.[75]

INTEGRATION OF GLOMERULAR, TUBULAR, INTERSTIAL, AND VASCULAR PROCESSES IN PROGRESSIVE CKD

Table 18.1 summarizes the salient processes in each compartment and their interaction in progressive CKD.

SPECIFIC MEDIATORS AND INHIBITORS OF CHRONIC KIDNEY DISEASE

Transforming Growth Factor-β

TGF-β has a central role in initiating and modulating tissue repair. Its aberrant expression is directly involved in the pathogenesis of progressive CKD, regardless of the underlying etiology.[76] TGF-β is a member of a large family of proteins that include the inhibin/activin family, the bone morphogenetic protein (BMP) family, and the TGF-β family.[77] TGF-β signals through binding to a serine-threonine kinase receptor, the type II TGF-β receptor (TβRII), which then results in the activation of the type I receptor (TβRI). The intracellular signaling of TGF-β is mediated by a group of proteins called Smads.[78] The receptor-regulated Smads (Smad 1, 2, 3, 5, and 8) are then phosphorylated by interaction with the receptors.[78,79] This allows the receptor-regulated Smads to form oligomeric complexes with the common

TABLE 18.1 Summary of Major Compartmental Processes Contributing to Progressive Chronic Kidney Disease

GLOMERULAR PROCESSES
• Injury to and/or loss of podocytes and adhesion formation
• Proliferative PECs migrate around the glomerulus and eventually disrupt the glomerulotubular junction, leading to atubular glomeruli and aglomerular tubules
• Misdirected glomerular filtration tracks into the interstitium and incites inflammation
• Misdirected glomerular filtration tracks around the glomerulus, insudating between the TECs and TBM and leading to tubular atrophy
• Tubular trafficking of filtered protein
• Delivery of antigens from injured glomeruli to the tubulointerstitium
• Seepage of cytokines from inflammed glomeruli into the tubulointerstitium
• Alterations in glomerular hemodynamics as a pathway for injury in surviving nephrons
TUBULAR EPITHELIAL CELL PROCESSES
• Tubular trafficking and metabolism of filtered proteinuria with attendant interstitial inflammation and fibrosis
• Tubular injury leading to interstitial inflammation and fibrosis
• Tubular injury induced by hematuria
• Metabolic tubular adaptations in surviving nephrons
• Dedifferentiation and senescence of TECs and the production of senescence-associated secretory phenotype (SASP) factors
• Partial epithelial-mesenchymal transition (EMT)
INTERSTITIAL PROCESSES
• T lymphocyte-monocyte/macrophage–dendritic cell interaction and proliferation
• Congregation of interstitial inflammation in periglomerular areas and the synergizing of such inflammation with extracapillary glomerular processes
• Interstitial inflammation congregating around the glomerulotubular junction may disrupt this junction and may predispose to the formation of aglomerular tubules
• Recruitment of pericytes, the major myofibroblast precursor, from peritubular capillaries
• Proliferation and increased synthetic activity of interstitial myofibroblasts
• Recruitment of fibrocytes
• Increased extracellular matrix production and fibrosis
VASCULAR PROCESSES
• Loss of pericapillary pericytes destabilizes interstitial capillaries leading to dropout
• Interstitial capillary rarefraction
• Tubular ischemia and cortical hypoxia leading to tubular atrophy
• Cortical hypoxia as a stimulus for further interstitial inflammation and fibrosis
• Loss of peritubular capillaries increases postglomerular vascular resistance, thereby increasing glomerular hydrostatic pressure and predisposing to glomerular hemodynamic injury
• Endothelial-mesenchymal transition
• Adverse effects of the secretome of the injured endothelial cell

For details please see text. *EMT*, epithelial mesenchymal transition; *PECs*, parietal epithelial cells; *TBM*, tubular basement membrane; *TECs*, tubular epithelial cells.

Smad protein (Smad 4), subsequently to translocate to the nucleus and activate transcription of target genes.[78,79] Another class of Smad proteins, Smad 6 and 7, is responsible for inhibiting the activity of the receptor-regulated Smads.[78,79] TGF-β is also involved in activation of target genes through Smad-independent pathways (e.g. mitogen-activated protein kinase, Rho family, and phosphoinositol-3 kinase).[80]

Three of five distinct members of the TGF-β family (TGF-β 1, 2, 3) are expressed in mammals and have been extensively studied.[81] TGF-β and BMP-7 share similar signaling pathways through the Smad proteins but are counterregulatory to each other to maintain a balance. In CKD, TGF-β is increased *via* Smad2/3, whereas BMP-7 is downregulated through Smad1/5/8. Increased levels of TGF-β blocks BMP-7 signaling and increased BMP-7, reverses TGF-β signaling. BMP-7 is expressed in multiple cell types and serves to promote repair mechanisms in the kidney. Studies using an orally administered BMP7 agonist (THR-123) showed promising results in animal models of kidney disease including diabetic nephropathy, where it attenuated renal fibrosis.[82]

TGF-β1 is implicated in a number of pathological conditions such as IgA nephropathy, cyclosporin-induced nephrotoxicity, focal segmental glomerulosclerosis, crescentic glomerulonephritis, lupus nephritis, diabetic nephropathy, obstructive nephropathy, light chain deposition disease, and chronic transplant rejection.[76,83–85] In experimental and human disease, TGF-β1 has been implicated in the pathogenesis of renal fibrosis, not only by inducing apoptosis and promoting ECM accumulation but also by decreasing the synthesis of proteases and increasing the levels of protease inhibitors such as tissue inhibitor of metalloproteinases and integrins.[86,87] TGF-β1 overexpressing mice exhibit nephrotic syndrome and progressive glomerulosclerosis and uremia and die by 15 weeks of age.[88] TGF-β1 expression

is associated with apoptotic tubular cells that are thought to underlie the mechanism of tubular atrophy seen in CKD.[89] TGF-β has also been implicated in the pathogenesis of proteinuria by inducing podocyte apoptosis and depletion.[90] Similarly, TGF-β induces apoptosis in endothelial cells that may explain the loss of peritubular capillaries associated with tubulointerstitial fibrosis and tubular atrophy.[91] TGF-β also regulates the expression of several microRNAs (miRNAs) that are pathogenic in the progression of renal fibrosis in CKD.

In diabetes, advanced glycation end products induce TGF-β overexpression in proximal tubular cells, leading to tubulointerstitial fibrosis.[92] High glucose is a potent stimulus for increased TGF-β expression in various renal cell types.[93,94] Additionally, both experimental animals and humans with diabetes display marked increase in the renal levels of TGF-β.[95,96] Overexpression of TGF-β in the glomerulus causes proteinuria and fibrosis,[97] and the early manifestations of diabetic renal disease in mice are attenuated by administration of anti-TGF-β antibody.[98] Transient hyperglycemia in healthy individuals is associated with increased urinary levels of TGF-β1 along with F2-isoprostanes, a marker for oxidative stress.[99]

Although chronic elevation of TGF-β1 plays an important pathogenic role in the progression of renal diseases, TGF-β1 also stabilizes and attenuates tissue injury and displays a "good" side. One mechanism by which the beneficial effects of TGF-β may be mediated and its harmful effects counteracted is through induction of cytoprotective proteins such as heme oxygenase-1 (HO-1) (discussed below).[100–103] Studies have demonstrated the importance of the TGF-β receptor in renal epithelial cells in progressive CKD. Deletion of the TGF-β type 2 receptor in proximal tubular epithelial cells in mice results in tubular damage and tubulointerstitial fibrosis.[104] In this study, the kidneys showed dysregulated Wnt/catenin signaling. Restoring β-catenin activity was able to reverse the phenotype observed.

The central role of TGF-β in renal fibrosis and CKD is widely accepted. The TGF-β/Smad signaling pathway is now a viable candidate for antifibrotic therapeutic strategies. Encouraging results in preclinical models have led to clinical trials with a monoclonal TGF-β antibody (fresolimumab) in patients with steroid-resistant focal and segmental glomerulosclerosis, as well as in diabetic kidney disease, although the results have not been promising.[105,106] Another therapeutic target for the TGF-β pathway involves thrombospondin-1 (TSP-1), a multifunctional protein that regulates the activation of latent TGF-β. Peptide antagonists of TSP1 block only TGF-β activity stimulated by mediators such as high glucose or angiotensin II, and may represent a better approach to block TGF-β signaling.

The Renin–Angiotensin–Aldosterone System

The renin–angiotensin–aldosterone system (RAAS) is a highly regulated hormonal system that plays an important role in the control of blood pressure, cardiovascular and renal function, particularly for fluid and electrolyte balance.[14] The juxtaglomerular cells in the macula densa of the nephron secrete renin into the circulation on sensing decreased renal perfusion. Renin converts angiotensinogen (from the liver) into angiotensin I, the latter subsequently converted into angiotensin II by angiotensin-converting enzyme (released from the lungs). Angiotensin II acts on target tissues *via* type 1 (AT_1) and type 2 (AT_2) receptors (both G protein-coupled receptors). Two other receptor subtypes for angiotensin II and its metabolites have also been described (AT_3 and AT_4). The AT_1 receptor is abundant in the kidney, heart, vasculature, adrenal cortex, lung, and the brain and mediates the vasoconstrictor effects of angiotensin II. The AT_1 receptor also mediates aldosterone release and vascular smooth muscle cell proliferation. The AT_2 receptor is involved in apoptosis, regulation of extracellular matrix production and cell differentiation.

The mechanisms by which activation of the RAAS perpetuates progression of CKD include systemic and local hemodynamic effects, and key nonhemodynamic effects which promote oxidative stress, inflammation, and fibrosis.[14] These actions are mediated through direct and indirect effects on the intrarenal vasculature, particularly the afferent and efferent arterioles and intraglomerular capillary network, mesangial cells, podocytes, and the tubulointerstitial compartment.[68] While the hemodynamic effects of the RAAS are well known and extensively studied, the prooxidant, proinflammatory, and profibrotic effects have important implications in progression of CKD.[69] Angiotensin II promotes superoxide generation through activation of NADH and NADPH oxidase enzyme systems in vascular smooth muscle cells. Angiotensin II activates the proinflammatory transcription factor, NF-kB, and also regulates a number of cytokines, growth factors, chemokines, and adhesion molecules. Angiotensin II also interacts with growth factors (e.g. TGF-β and CTGF) and extracellular matrix proteins (e.g. collagen, fibronectin) to promote renal fibrosis. Angiotensin II also mediates renal hemodynamic effects by interacting with the nitric oxide pathway and activation of the heme oxygenase-1 enzyme system. Angiotensin II also stimulates aldosterone release from the adrenal glands.

Experimental animal models suggest an important role for aldosterone, a steroid hormone with mineralocorticoid activity, in the progression of CKD.[70] Aldosterone mediates its effects through genomic and nongenomic pathways, predominantly *via* the mineralocorticoid

receptor (MR), although other aldosterone receptors such as GPR30 have also been identified. In addition to the well-recognized actions of aldosterone in the kidney in regulating fluid and electrolyte balance, direct effects on the vasculature and the kidney and other organ systems through increased oxidative stress, inflammation, and fibrosis also contribute to the potential harmful effects of aldosterone in progressive CKD.[68]

Oxidative Stress

Oxidative stress is defined as tissue damage resulting from an imbalance between an excessive generation of prooxidants and insufficient antioxidant mechanisms. The predominant source of oxidants comes from the univalent reduction of molecular oxygen by membrane-bound NAPDH oxidases, as well as in the mitochondrial electron transport chain, resulting in the liberation of superoxide anion, which is rapidly converted by superoxide dismutases into hydrogen peroxide, the latter detoxified by glutathione peroxidase (a high affinity, low capacity enzyme) and catalase (a low affinity, high capacity enzyme). Superoxide can interact with nitric oxide to produce peroxynitrite. Hydrogen peroxide can undergo the Fenton reaction, to generate the hydroxyl radical. Myeloperoxidase can catalyze the interaction between hydrogen peroxide with chloride to form hypochlorous acid. The kidney generates hydrogen peroxide during the course of normal metabolism, the latter driven by the relatively high rates of oxygen consumption largely needed for sodium transport. Oxidants can be produced all along the nephron, from resident and infiltrating interstitial cells and from the intrarenal vasculature. Because red blood cells contain high levels of glutathione and antioxidant enzymes, the presence of anemia of CKD also fosters a prooxidant state.

The markers used to measure oxidative stress are usually measures of modification of lipids, proteins, DNA, or carbohydrates, representing "footprints" of oxidative stress. Direct measurement of oxidants is challenging, due to the highly reactive nature of these molecules, most with very short half-lives of a few seconds. Commonly used markers that are increased in CKD include thiobarbituric acid reactive substances (TBARS), malondialdehyde, oxidized lipids, F2 isoprostanes, protein carbonyls, nitrotyrosine, asymmetric dimethylarginine and even nucleic acids, and 8-hydroxy-2-deoxyguanosine. On the other hand, several in built antioxidant mechanisms are decreased in CKD. For example, levels of antioxidant enzymes such as superoxide dismutase, glutathione peroxidase, and catalase are decreased. Antioxidant vitamins E and C as well as metal-binding proteins such as transferrin and selenoproteins are reduced.

The evidence for oxidative stress in CKD is supported by the findings of (a) increased generation of oxidants in animal models and humans with primary and secondary glomerular diseases, (b) antioxidant strategies are beneficial in animal models, and (c) oxidants can induce changes in normal kidneys that resemble CKD.[72] Several factors implicated in progressive renal disease mediate their effects *via* oxidant generation or are activated *via* oxidant species. These include albumin from proteinuria, angiotensin II, oxidized lipids, uric acid, nitric oxide, growth factors, shear stress, aldosterone, and others. As a consequence of loss of glomerular permselectivity, proteins gain access to the urinary space. Proteins such as albumin are endocytosed by receptor-mediated mechanisms involving megalin and cubilin and can result in the activation of a number of signaling cascades, transcription factors such as NF-kB, and its target genes including MCP-1, endothelin-1, cytokines, and chemokines, which are released at the basolateral surface of the proximal tubule and can have effects in the tubulointerstitial compartment. Proteins can also activate complement and induce apoptosis. Several of these effects are preceded by increased generation of reactive oxygen species, are mimicked by oxidants, and are blocked by antioxidants.

Proteinuric renal diseases are often associated with lipid abnormalities. Renal tubular cells are exposed to an array of macromolecules including lipoproteins. Filtered lipoproteins can undergo oxidation in the glomerular microcirculatory bed, in the prooxidant urinary space by metals such as iron from transferrin or by heme released from red blood cells, or by tubular cells following intracellular uptake. Analogous to the pathogenic role of lipids in atherosclerosis, modified lipids can also instigate tubulointerstitial injury by increasing reactive oxygen species, activating NF-kB and proinflammatory genes, expansion of extracellular matrix, inducing tubular cell apoptosis, and promoting vascular injury.

Oxidants have diverse cellular actions, and disruption of the balance between prooxidants and antioxidants leads to increased oxidative stress, thus representing an appealing target for therapies to prevent progression of renal disease.[72] While results from animal models are encouraging, human studies have not proven their effectiveness. A phase 3 clinical trial, BEACON, testing the efficacy of an antioxidant and antiinflammatory agent, bardoxolone methyl, in CKD from diabetic kidney disease was prematurely terminated due to adverse cardiovascular side effects.[74] This agent is a potent activator of the redox-sensitive transcription factor, Nrf2 (NF-E2 related factor-2). In initial phase 2 studies, bardoxolone methyl showed promising results in slowing progression of diabetic kidney disease.[75] *Post hoc* analyses of the BEACON study have reported

that bardoxolone resulted in significant weight loss[107] and preserved kidney function, delaying the development of ESRD in type 2 diabetics with Stage 4 CKD.[108]

Endothelin

Endothelins are a family of peptides with highly potent vasoconstrictor actions, including ET-1, ET-2, and ET-3 isoforms. ET-1 is the major isoform expressed in endothelial cells and in the kidney, wherein the protein localizes to the glomerulus (endothelial, podocytes, and mesangial cells), renal tubular epithelial cells, the collecting duct, and interstitial cells (resident and infiltrating).[104] The protein is produced as a 212 amino acid prepro-ET-1, which is cleaved to big ET-1 with 38 amino acids, and then by the action of ET-converting enzyme, active ET-1 is generated. Several stimuli that are involved in the pathogenesis of CKD result in the generation of ET-1, including angiotensin II, vasopressin, reactive oxygen species, growth factors (TGF-β and PDGF), and acidosis. On the other hand, stimuli such as nitric oxide, prostacyclin, and natriuretic peptides inhibit ET-1 expression. ET-1 mediates its effects *via* binding to two receptors, ET_A and ET_B. Activation of the ET_A receptor, present abundantly in vascular smooth muscle cells, causes vasoconstriction, whereas activation of ET_B receptors, found predominantly in the vascular endothelium, mediates vasodilatory responses *via* nitric oxide and prostacyclin. ET_B receptors are also abundant in the collecting system.

Endothelin plays an important role not only in maintaining normal physiologic functions but also is a major factor in several pathophysiologic processes in the kidney and other organ systems.[109] In the kidney, ET-1 regulates renal blood flow and glomerular filtration, natriuresis, volume, and acid-base balance.[106] In pathophysiologic states, ET-1 contributes to the development of hypertension, endothelial dysfunction, increased vascular tone, and arterial stiffness and can increase proteinuria through effects on glomerular hemodynamics. ET-1 serves as a chemoattractant for monocytes, binds to interstitial fibroblasts, and promotes their proliferation and extracellular matrix production by these cells, contributing thereby to tubulointerstitial inflammation and fibrosis. Although characterized as the most potent vasoconstrictor, ET-1 has a number of effects that are independent of changes in blood pressure.[104] Systemic overexpression of ET-1 in mice results in inflammation and fibrosis of the kidney, heart, and lungs.[107] Endothelial-specific ET-1 overexpression leads to vascular inflammation in the absence of hypertension.[108] The pathophysiologic roles of ET-1 in the progression of CKD have led to ongoing clinical studies to evaluate the efficacy of ET-1 receptor antagonists to ameliorate changes in blood pressure, proteinuria, inflammation, and fibrosis in diabetic and nondiabetic kidney diseases.[104]

Micro RNAs

miRNAs are noncoding small RNAs, 22 nucleotides in length, which bind to the 3′-UTR of target genes and, thereby, repress translation and/or induce degradation of target mRNAs of a variety of genes. miRNAs regulate numerous molecular and cellular processes. Aberrant expression of miRNAs is associated with initiation and progression of pathologic processes, including progression of CKD, most notably with renal fibrosis.[110] Primary miRNA transcripts are initially generated that are processed to precursor miRNAs in the nucleus by an enzyme, Drosha, and a double strand RNA-binding protein, DGCR8. The ~70-nucleotide hairpin precursor miRNAs are exported out of the nucleus by exportin 5, and then cleaved by Dicer to RNA duplexes. The miRNA duplexes are unwound and the mature single strand, miRNA, containing the complementary mRNA target sequences, is loaded into the RNA-induced silencing complex (RISC)—the latter containing Argonaute 2, Dicer, and transactivating response RNA-binding proteins. The miRNAs in this complex are then guided to the 3-UTR of target genes.[39] In addition to inhibiting posttranscriptional mechanisms involving initiation and elongation, miRNAs can also target promoter regions and repress gene expression.

Several miRNAs are expressed in the kidney, and their levels are increased or decreased in diseased states.[110,111] For example, miRNA-192, an miRNA highly expressed in the kidney, is increased in glomeruli in animal models of diabetic kidney disease. High glucose and TGF-β increase the expression of miRNA-200 and miRNA-192 family in mesangial cells and promote expression of extracellular matrix genes such as collagen. In contrast, in cancer cell lines, TGF-β downregulates miRNA-200 and miRNA-192 expression, suggesting that the effects mediated by miRNAs are cell-type specific. Another miRNA, miRNA-377, has also been shown to be pathogenic in mouse models of diabetic kidney disease, wherein it downregulates p21-activated kinase and manganese superoxide dismutase and increases fibronectin levels. In animal models of renal inflammation and fibrosis, miRNA-21, one of the first mammalian miRNAs to be identified, is markedly upregulated and blocking miRNA-21 or miRNA-21 knockout mice display reduced renal fibrosis.[49,54] These effects are mediated through attenuation of TGF-β, extracellular matrix production, inflammation, and epithelial metabolic pathways, particularly the PPAR-α-regulated lipid metabolic signaling pathway. Studies using cell-specific deletion of Dicer in podocytes have

revealed important roles of miRNAs in glomerular biology causing significant phenotypical changes characterized by proteinuria, foot process effacement, GBM abnormalities, and rapid progression of kidney disease.[112,113]

Specific targeting of miRNAs using antagomirs is being explored in preclinical models of CKD as potential therapeutic strategies. It is important to note that a single miRNA can regulate different genes, and several miRNAs may be involved in the regulation of the same gene. Hence, it is important to consider the specificity of the gene−miRNA interaction in determining the functional effects. There is also considerable redundancy within miRNA families, and understanding miRNA−miRNA interactions would be critical before embarking on specific therapeutic targeting strategies.[39]

Wnt Signaling

The Wnt pathway is a highly complex and conserved cell-to-cell communication pathway that regulates many critical aspects of cellular functions, including cell fate decisions, branching morphogenesis, cell proliferation, polarization, and migration.[114] The term Wnt was derived from a combination of Int (the Integration 1 gene) and Wg (the Wingless gene) and stands for Wingless-related integration site. Three Wnt pathways have been described, including the canonical Wnt pathway (or Wnt/β-catenin pathway), the noncanonical planar cell polarity pathway, and the noncanonical Wnt/calcium pathway. The Wnt/β-catenin pathway causes an accumulation of β-catenin in the cytoplasm, and its eventual translocation into the nucleus, where it activates transcription factors (T-cell factor and/or lymphoid enhancer factor) and regulates expression of several downstream target genes involved in matrix production and fibrosis (e.g. plasminogen activator inhibitor-1 (PAI-1), fibronectin, fibroblast-specific protein 1, and matrix metalloproteinase-7). The noncanonical planar cell polarity pathway regulates cytoskeleton functions and dictates cellular shape. The noncanonical Wnt/calcium pathway regulates intracellular calcium levels. Wnt signaling also interacts with other pathways, such as the GSK3 signal pathway.

The critical role of the Wnt signaling pathway in the developing kidney is well established. The importance of reactivation and dysregulated Wnt signaling in kidney diseases including diabetic nephropathy, chronic allograft nephropathy and polycystic kidney disease, particularly in the pathogenesis of renal fibrosis, is recognized.[114] Monocytes from patients with Stage 4 and 5 CKD display high levels of activation of the Wnt/β-catenin signaling pathway, compared with healthy controls.[115] Studies have also identified the anti-aging protein, Klotho, as an endogenous antagonist of the Wnt/β-catenin pathway.[116] Klotho blocks Wnt-triggered activation and nuclear translocation of β-catenin and its target genes.[116] Orally active Wnt modulators are in development and could provide important tools for further investigating the role of Wnt/beta-catenin signaling in renal fibrosis.[109]

Heme Oxygenase

Heme oxygenases catalyze the rate-limiting step in the degradation of heme into equimolar amounts of iron, carbon monoxide (CO), and biliverdin.[117−119] Biliverdin is subsequently converted into bilirubin *via* biliverdin reductase, while iron is sequestered by ferritin. Two isoforms of heme oxygenase (HO-1, HO-2) have been identified.[117−119] HO-1 is induced by heme products, as well as a wide variety of nonheme stimuli, several of which are pathogenic in the progression of CKD, including angiotensin II, hypoxia, and growth factors (e.g. PDGF and TGF-β1).[117−119] In contrast, HO-2 is a constitutive enzyme and functions as a physiologic regulator of cellular function. The cytoprotective effects of HO-1 induction are due to the degradation of the heme moiety (a prooxidant molecule) and the generation of beneficial products such as biliverdin/bilirubin and CO. Bilirubin has antioxidant properties *via* scavenging peroxy radicals and inhibiting lipid peroxidation.[120] Ferritin, an intracellular iron repository, is coinduced with HO-1, allowing safe sequestration of unbound iron liberated from heme degradation.[121] CO has vasodilatory effects mediated *via* cGMP and potassium channels,[122] as well as antiapoptotic and immunomodulatory functions.[123] The protective effects of HO-1 overexpression have also been attributed to the upregulation of the cell-cycle regulatory protein, p21.[124]

The antifibrogenic properties of HO-1 and its products, particularly CO, in different pathological conditions and tissues have been extensively studied. Fujita et al. demonstrated that inhaled CO increased survival of HO-$1^{-/-}$ mice with lethal ischemic lung injury by inhibiting a key profibrotic agent, plasminogen activator inhibitor-1.[125] In a rat hypoxia model, chemical inhibition of HO-1 increased type I and III collagen and TGF-β expression, an effect attributed to a decrease in CO levels.[126] Exogenous CO administration has also been shown to decrease proliferation of human fibroblasts.[127]

Numerous studies have demonstrated the protective effects of HO-1 in both *in vitro* and *in vivo* models of injury and disease.[117−119] Repeated exposure of HO-$1^{-/-}$ mice to heme proteins leads to intense interstitial cellular inflammation, with significant increase in MCP-1 expression and activation of nuclear factor-κB.[55] In addition to protecting against acute cytotoxicity, HO-1 downregulates the inflammatory response in both

renal and nonrenal tissues.[128] The phenotype of the HO-$1^{-/-}$ mouse (at ages beyond 20–24 weeks) is characterized by chronic renal and hepatic inflammation, tissue iron deposition, anemia, splenomegaly, and increased susceptibility to cardiovascular diseases, which highlights the functional and biological significance of HO-1.[129]

These *in vitro* and animal model findings are also corroborated in human case reports. Two patients with HO-1 deficiency have been described who presented with several phenotypic similarities with the HO-$1^{-/-}$ mouse and had extensive atherosclerosis and marked renal tubulointerstitial injury associated with tubular dilation and atrophy, inflammatory cell infiltration and interstitial fibrosis.[130,131] The level of HO-1 expression can be variable within the human population, because the promoter of human HO-1 gene is highly polymorphic and contains a (GT) repeat region. Evidence suggests that patients with lower (GT)n repeats have higher HO-1 expression, thereby associated with better patient outcomes in a number of clinical conditions such as renal graft survival,[132] vascular stenosis,[133] arteriovenous fistula patency in hemodialysis patients,[134] polycystic kidney disease, and IgA nephropathy.[135] Furthermore, there are now ongoing clinical trials examining the beneficial effects of HO-1 by-products including CO in kidney transplantation (clinicaltrials.gov, NCT 00531856) and bilirubin in endotoxemia (clinicaltrials.gov, NCT 00916448).

Acid-Base Status

Acid-base disturbances, specifically metabolic acidosis, are a frequent complication during the later stages of CKD, emphasizing the key role of the kidney in the maintenance of normal acid-base homeostasis. A major source of acid load to the kidney is from the diet. Metabolic acidosis is linked to progression of CKD and also contributes to muscle wasting seen in patients with end-stage renal disease.[136] The mechanisms underlying the progression of CKD by acidosis have been studied in animal models.[49] A reduction in renal mass results in increased renal ammoniagenesis from the remnant nephrons. Ammonia instigates local tubular toxicity and inflammatory pathways *via* the alternative complement pathway by the reaction of ammonia with the C3 thiolester, leading to complement-mediated tissue injury.[49] These changes are reversed by sodium bicarbonate supplementation in the remnant kidney model. Acid loading also increases expression of angiotensin II, aldosterone, and endothelin-1, which promote hydrogen ion excretion and are also pathogenic in the progression of CKD and renal fibrosis.[137]

Metabolic acidosis fosters a catabolic state in skeletal muscle by inhibiting albumin production through activation of the ubiquitin-proteasome pathway. Chronic metabolic acidosis increases urinary calcium excretion due to effects on osteoclastic bone resorption, leading to bone and muscle loss and growth retardation in children. Metabolic acidosis also results in abnormalities in growth hormone and thyroid secretion, insulin sensitivity, and β2-microglobulin deposition. A proposed mechanism by which metabolic acidosis in CKD is pathogenic in the progression of the disease is summarized in Figure 18.1. A single-center randomized clinical trial has shown that exogenous bicarbonate supplementation slows progression of CKD in patients.[138] More recently, a sodium-free, nonabsorbable hydrochloric acid binder, TRC101, was shown to increase sodium bicarbonate levels in patients with CKD,[110] although its effects on slowing progression of CKD have not as yet been studied. Further large multicenter clinical studies will be needed to provide clear evidence for the use of alkali supplementation in slowing progression of CKD.

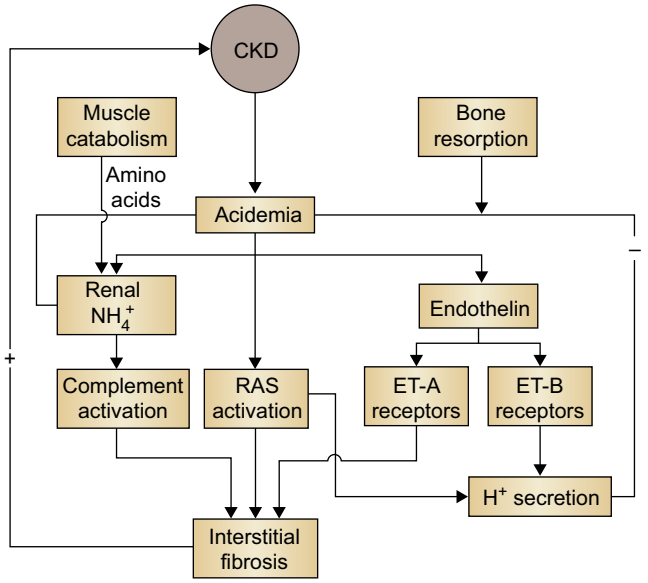

FIGURE 18.1 **Proposed mechanisms by which metabolic acidosis worsens progression of chronic kidney disease**. To maintain isohydria, nephrons show an increase in ammoniagenesis, which activates the alternative complement pathway and synthesis of inflammatory mediators. Another nephrotoxic agent is endothelin-1 (ET-1), which induces vasoconstriction, inflammation, and fibrosis, as well as renal acidification. This activity is associated with angiotensin II and free-radical reactions. Increased ET-1 synthesis is caused by acid retention concomitant with decreased glomerular filtration rate, which also causes increased serum aldosterone concentration. Further consequences of acidosis include disturbances of muscle and bone metabolism, leading to renal osteodystrophy. *CKD*, chronic kidney disease; *RAS*, renin–angiotensin system. *Reproduced with permission from Loniewski, Wesson.* Kidney Int *2014.*[137]

CONCLUSIONS

This perspective regards the progression of CKD as involving the recruitment and engagement of *cellular processes* originating in specific compartments of the kidney on the one hand and *biochemical pathways* of cell injury that contribute to these processes on the other hand. Many of these processes possess the capacity to ramify broadly beyond the compartment where they initially arose, and it is this essential consideration that contributes so fundamentally to the increasing loss of functional nephrons and the progression of CKD. For example, processes begun in the extracapillary glomerular compartment elicit processes in renal tubules and the interstitium that drive pericyte recruitment and interstitial fibrosis, the latter, eventually, feeding back to adversely affect glomerular behavior. This capacity to propagate injury is also true for the described biochemical pathways. Angiotensin II induces TGF-β1 and the consequent elaboration of extracellular matrix. Angiotensin II also induces oxidative stress, which itself can upregulate TGF-β1 in vicinal cells and thus the propagation of a fibrosing response. This lack of containment of compartmental processes, and this versatility of injurious biochemical pathways, not only underlies the pathogenesis of CKD but also holds substantial therapeutic significance. The best hope for retarding or preventing the progression of CKD resides in a combined, multipronged therapeutic approach, which will interrupt these processes and pathways at separate and several steps.

Abstract

Diabetic nephropathy affects approximately 25–35% of patients with type 1 or type 2 diabetes mellitus. The disease progresses through various clinical stages, from hyperfiltration to microalbuminuria to macroalbuminuria to nephrotic proteinuria to progressive chronic kidney disease, which eventually leads to end-stage renal disease. These stages are generally associated with structural pathological changes affecting all compartments of the kidney: the glomerulus, the tubules, the vasculature, and the interstitium. With increased glycemia, various metabolites and by-products, including advanced glycation end-products and reactive oxygen species, are stimulated. These metabolic insults converge with the main driver of the hemodynamic insult, angiotensin II, to induce diabetic renal pathology at its different levels. Advances in genetics and molecular biology will continue to reveal more about the pathogenesis of diabetic nephropathy, but the multifactorial nature of the disease has defied attempts at a general theory that unifies all the known cellular and biochemical pathways.

INTRODUCTION

As most of the world faces an epidemic of obesity and diabetes (also termed diabesity), the prevalence of diabetic kidney disease (DKD) has been on the rise. DKD is the major cause of end-stage renal disease (ESRD) in the industrialized world and many developing countries and is a significant cause of serious morbidity and increasing mortality. While still considered a microvascular complication of diabetes, nephropathy involves more than just kidney capillaries, extending its damage across the various kidney cells and associated extracellular structures. This chapter will provide a comprehensive review of our current understanding of the pathophysiology of DKD.

PATHOLOGY

DKD is associated with a series of histopathological changes involving all compartments of the kidney, reflecting changes in organ function, and associated with clinical manifestations of the disease (Figure 19.1).

Glomerular basement membrane (GBM) thickening is one of the earliest quantifiable changes in DKD. The thickening results from the build-up of extracellular matrix (ECM) components such as type IV collagen, laminins, and nidogen/entactin in the lamina rara interna of the GBM. Further deposition of matrix components in the other layers of the GBM occurs with progression of the disease, resulting in a near doubling of its normal size.[1] Concurrently, there is a change in the nature of the GBM, with a switch from the classical (ubiquitous) α1(IV) and α2(IV) collagen chains to the restricted α3(IV) and α4(IV) collagen chains.[2] This transition likely affects the compositional quality of the GBM and could explain, at least in part, the correlation of GBM thickness with its functional properties such as macromolecular "leakiness" or the magnitude of proteinuria.[3]

The GBM forms part of the glomerular filtration barrier and is maintained by the glomerular endothelial cells and podocytes, both of which are compromised in the diabetic glomerulus. The podocytes undergo cytoskeletal rearrangement, dedifferentiation, and autophagy manifested by effacement of their foot processes, and decrease in slit diaphragm length with downregulation of its core components, such as nephrin.[4] Importantly, reduction in podocyte density secondary to detachment and dropout of the cells or apoptosis might be a useful predictor of DKD and its progression.[5,6] On the other side of the GBM, the glomerular endothelium is a highly specialized, fenestrated layer

Gaut, MD, PhD Department of Pathology, Washington University School of Medicine, St. Louis.*

that sustains significant damage to its negatively charged glycocalyx.[7]

Another hallmark lesion of DKD is expansion of the mesangium. This is mostly due to increased deposition of extracellular mesangial matrix components, and only minimally to mesangial cell hypertrophy or proliferation. There is indeed only a very modest and self-limited increase in cell number per glomerulus, both early on and as DKD progresses.[8,9] In general, mesangial expansion is diffusely uniform within the glomerulus. As collagen deposition progresses with advanced DKD, diffuse diabetic glomerulosclerosis ensues, and eventually leads to scarring of the glomeruli. However, nodular glomerulosclerosis or the so-called Kimmelstiel–Wilson lesions may also be present. These develop due to continued local expansion of the mesangial matrix, or more likely as a result of mesangiolysis, with separation of the glomerular capillary from the

TABLE 19.1 Glomerular Classification of Diabetic Kidney Disease (DKD)

Class	Description	Inclusion Criteria
I	Mild or nonspecific LM changes and EM-proven glomerular basement membrane (GBM) thickening	Biopsy does not meet any of the criteria mentioned below for class II, III, or IV GBM >395 nm in female and >430 nm in male individuals 9 years of age and older (a)
IIa	Mild mesangial expansion	Biopsy does not meet criteria for class III or IV Mild mesangial expansion in >25% of the observed mesangium
IIb	Severe mesangial expansion	Biopsy does not meet criteria for class III or IV Severe mesangial expansion in >25% of the observed mesangium
III	Nodular sclerosis (Kimmelstiel–Wilson lesion)	Biopsy does not meet criteria for class IV At least one convincing Kimmelstiel–Wilson lesion
IV	Advanced diabetic glomerulosclerosis	Global glomerular sclerosis in >50% of glomeruli Lesions from classes I through III

LM, light microscopy. (a) The basis of direct measurement of GBM width by EM, these individual cutoff levels may be considered indicative when other GBM measurements are used.
From Tervaert et al.[14]

mesangium, and the formation of capillary aneurysms. The new capillary space is subsequently filled with mesangial matrix.[10] Kimmelstiel–Wilson lesions are usually focal, segmental, and only occasionally diffuse. Overall, they can be present in up to 50% of diabetics.

The effect on the renal vasculature is notable for the accumulation of periodic acid–Schiff (PAS)-positive material around both the afferent and efferent arterioles, referred to as arteriolar hyalinosis. Deposition of similar material in the subendothelial space of the glomerular capillaries is referred to as a hyaline cap. These, together with capsular drops (hyaline material underneath the parietal epithelial cells of Bowman's capsule), constitute the exudative lesions of DKD.

Tubular basement membrane thickening develops in parallel with that of the GBM. The width of either of the membranes correlates strongly with the degree of hyperglycemia in type 1 diabetes.[6] A mild degree of interstitial inflammation with some macrophage recruitment can also be seen. Progressive interstitial fibrosis and tubular atrophy reflect advanced DKD and the progression toward ESRD. The degree of tubulointerstitial fibrosis correlates strongly with the progressive decline in glomerular filtration rate (GFR).[11–13]

A classification of the pathology of DKD was introduced by the Renal Pathology Society.[14] This may help with staging the nephropathy, based on the degree of glomerular pathology, with a separate scoring system for tubular and vascular lesions (Table 19.1). However, the classic description of DKD is mostly based on the glomerular pathology of kidneys in type 1 diabetes. While patients with type 2 diabetes and DKD (T2DKD) have been found to have the same pathognomonic glomerular changes,[15] the overall pathological picture within the glomerulus and in the different renal compartments in these patients is more heterogeneous. In T2DKD patients with microalbuminuria, less than a third have the typical glomerular lesions expected in a similar stage of T1DKD.[16,17] This may suggest a different pathogenesis for the kidney disease in patients with T1D compared with T2D. More likely though, it is due to variability in the duration of DKD and the presence of comorbidities such as hypertension, obesity, and aging that have independent effects on the kidney.

CLINICAL COURSE

DKD was classically described by Mogensen and others to progress through distinct clinical stages (Figure 19.2), defined on the basis of the values of the GFR, urinary albumin excretion (UAE), and systemic arterial blood pressure.[18] In T1DKD, these clinical stages correlate, in general, with the severity of renal pathology as described above. However, as with the kidney pathology, DKD in type 2 diabetes is a more heterogeneous disease, with variable degrees of glomerulosclerosis, tubulointerstitial fibrosis, and vasculopathy.[19]

Normoalbuminuria

The initial stage of DKD is a clinically silent period during which the patient remains normoalbuminuric with a normal or high GFR. A relatively large increase in GFR (greater than 150 mL/min/1.73 m^2) occurs in about one-third of T1DM and seems to be positively

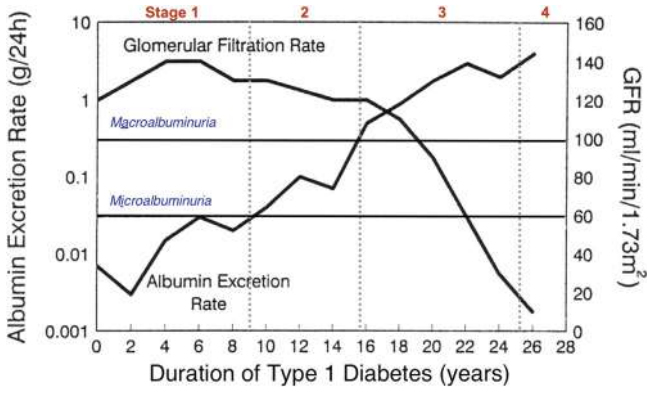

FIGURE 19.2 Progression of albumin:excretion ratio and glomerular filtration rate with time in patients with type 1 diabetes. *Adapted from Molitch ME.* Am J Med ***1997***;*102*:392–8.

associated with glycemic control.[20,21] This hyperfiltration is less common or much more attenuated in T2DM patients.[22]

While still somewhat controversial,[21] hyperfiltration has been shown to predict or be causally linked to the progression of DKD. In a meta-analysis of cohort studies in T1DM, the pooled odds for development of at least microalbuminuria was 2.71 (95% CI 1.20–6.11) in patients with hyperfiltration compared with those with normofiltration.[23] Similar findings were noted by the GFR Study investigators.[24] In their longitudinal study of T2DM patients, the hazard ratio for progression to a minimum of microalbuminuria was 2.16 [95% CI 1.13–4.14]. It was noted that 23.4% (11 of 47) of patients with persistent hyperfiltration progressed to micro- or macroalbuminuria compared with 10.6% (53 of 502) of patients who had hyperfiltration ameliorated at 6 months or who did not develop hyperfiltration since study inclusion.

Microalbuminuria

Microalbuminuria, defined as a UAE of 30–300 mg/day or 20–200 μg/min, can develop beyond the first five years of disease in 20–40% of type 1 diabetic patients. Microalbuminuria can be present at the time of diagnosis in 20–40% of type 2 diabetic patients. Hyperglycemia, hypertension, and elevated body mass index are all independent risk factors for the development of microalbuminuria in type 1 and type 2 diabetic patients.[25] Structurally, the glomerular and tubular basement membranes continue to thicken, and there is some degree of podocyte loss. Mesangial matrix expansion and diffuse glomerulosclerosis may become manifest.

Earlier longitudinal studies suggested that approximately 80% of type 1 diabetic patients progress from microalbuminuria to proteinuria over a period of 6–14 years.[26] More recently, this has been evaluated to be closer to 40%.[27] These findings could be the result of improved control of glycemia and hypertension over the years, and the widespread use of renin–angiotensin system blockers in microalbuminuric patients. They also suggest that microalbuminuria is not a predictor of macroalbuminuria in all diabetic patients.[28] On the other hand, UAE has been repeatedly and strongly validated as a risk factor for cardiovascular disease, peripheral vascular disease, strokes, and mortality from coronary heart disease.[29–32]

This stage is also characterized by the onset of hypertension within 1 or 2 years of microalbuminuria in T1DM. GFR remains normal or is slightly elevated in type 1 diabetic patients with microalbuminuria for at least 5 years if clinical overt nephropathy does not develop.[33] In microalbuminuric type 2 patients, GFR begins to normalize and then decline at rates approximating 3–4 mL/min/yr.[34]

Overt Nephropathy

As the glomeruli start demonstrating diffuse and/or nodular glomerulosclerosis, and as more podocyte loss occurs, overt proteinuria (total urinary protein excretion exceeding 500 mg/day) or macroalbuminuria (UAE exceeding 300 mg/day) becomes established (Figure 19.2). In type 1 patients, this occurs after an average of 15 years of diabetes. Proteinuria by itself is an independent risk factor for further worsening of renal damage.[35] Concurrently, progressive mesangial expansion leads to a reduction in the glomerular surface area available for filtration and has been shown to inversely correlate with declining GFR[36]. Hypertension is almost always present at this stage. The poorer the blood pressure control is, the more rapidly the GFR declines.

Untreated patients may progress to nephrotic-range proteinuria. The GFR drops at a mean rate of 1 mL/min/month (Stage IV) until ESRD ensues, which will require renal replacement therapy (Stage V). Note, however, that this time course is extremely variable among individual patients. The average time from the initial diagnosis of type 1 diabetes to the progression to ESRD is around 20–25 years, with a more rapid course developing in patients with uncontrolled hypertension and/or heavy proteinuria.

Nonetheless, growing evidence suggests that not all patients with diabetes progress through the timeline of stages in a linear manner. Many have been shown to regress from micro- to normoalbuminuria. In a study that followed 386 type 1 diabetic patients for a total of 6 years, Perkins et al. showed that close to 60% of the patients had a significant drop in their UAE.[28] A similar trend was confirmed in type 2 diabetic patients.[37] While the more frequent use of renin–angiotensin–aldosterone system (RAAS) inhibitors may contribute to this trend, some studies have failed to confirm this correlation.[38] Furthermore, it appears that the worsening of GFR may occur during the microalbuminuric stage or even before the development of albuminuria.[39] Data come from cross-sectional studies such as the Developing Education on MicroAlbuminuria for Awareness of renal and cardiovascular risk iN Diabetes study. In this global perspective on DKD, of the 11,315 subjects who were reported to have decreased kidney function, 30.7% had microalbuminuria and a sizable 20.5% were normoalbuminuric.[40] Similar findings have been reported in other prospective studies in type 1 and type 2 diabetes.[41,42] There are several proposed explanations for the disassociation of the grade of albuminuria from the declining GFR. In some patients, RAAS inhibitors may be curbing albuminuria but not halting the loss of GFR. It is possible that there are two parallel but largely independent mechanistic pathways that are responsible for albuminuria progression and GFR loss.

Alternatively, kidney function may preferentially decline secondary to aging or other nondiabetic renal insults not identified in these studies.

METABOLIC DYSREGULATION OF DIABETIC NEPHROPATHY

Hyperglycemia acts as the main driver for the development and progression of DKD. Glycemic control slows the progression of nephropathy and, at times, may reverse the original pathology.[43–47] Under normal conditions, intracellular glucose is metabolized by oxidative phosphorylation. When glucose accumulates to excess, there is increased flux through glycolysis, and possibly through the TCA cycle, with less efficient oxidative phosphorylation.

Indeed, diabetic kidneys upregulate key steps in the control of cellular glycolytic rate. The enhanced expression of glucose transporters GLUT1 and 4 in the glomeruli and the glycolytic enzymes hexokinase and phosphofructokinase are likely sufficient to promote flux into aerobic glycolysis, in a manner reminiscent of the Warburg effect.[48–50] Multiomics approaches to diabetes and diabetic kidney have confirmed the changes in glucose metabolism that are characteristic of the diseased state.[51,52] This altered metabolism has been associated with mitochondrial dysfunction, including increased mitochondrial fission and fragmentation and reduced levels of peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α) levels in the tubules, abnormalities in electron transport chain complex assembly/activity, and increased expression of uncoupling protein UCP1.[52–54] The mechanisms underlying mitochondrial dysfunction are not fully understood, and it is unclear whether the altered glucose metabolism is the cause or result of diseased mitochondria in diabetic kidneys, or if a bidirectional causality exists.

The alteration in glucose metabolism is associated with increased flux into alternative pathways: the pentose phosphate pathway, sorbitol/polyol pathway, advanced glycation end-products (AGEs) pathway, protein kinase C (PKC) pathway, and hexosamine pathway. In the kidney, these metabolic pathways had long been thought to contribute to glucotoxicity through various mechanisms. Polyol pathway activation was hypothesized to render the kidney susceptible to oxidative stress by consuming NADPH, which is an essential cofactor for production of reduced glutathione.[55] The hexosamine pathway can lead to posttranslational modifications that affect the function of transcription factors and signaling molecules.[56] Activation of the hexosamine pathway in diabetes stimulates the activity of the transcription factor Sp1, that then leads to induction of key prosclerotic factors including transforming growth factor-beta 1 (TGF-β1) and plasminogen activator inhibitor-1.[57]

Alternatively, research from the Joslin Medalist Study suggests that increased glycolytic flux and sorbitol/polyol pathway protected patients with greater than 50 years of T1DM from diabetic nephropathy by reducing the accumulation of glucose toxic metabolites and improving mitochondrial function.[58,59] Further studies will be needed to understand the differences in the regulatory function of glucose metabolism in glomerular and tubular cells and throughout the progression of diabetes.

Evidence is emerging that lipid metabolism may play a role in the progression of DKD. Kimmelstiel and Wilson noted significant intratubular lipid accumulation in their seminal work on diabetic pathology.[60] Defective lipid metabolism likely contributes to lipid accumulation and may be associated with impaired mitochondrial function, and the development of tubulointerstitial fibrosis.[61] Lipotoxicity can also manifest in the podocyte with intracellular accumulation of lipid droplets, abnormal glucose metabolism, inflammation, oxidative stress, endoplasmic reticulum stress, and actin cytoskeleton rearrangements.[62]

Advanced Glycation Reactions

AGEs are proteins, lipids, or nucleic acids that are irreversibly cross-linked with reducing sugars. While AGEs are produced in small amounts with aging, their production is markedly increased in the setting of hyperglycemia both in cellular and extracellular compartments, especially in richly vascularized organs such as the kidney.[63]

The evidence for the role of AGEs in DKD comes from multiple levels. First, various AGEs accumulate in both glomerular and tubular cells in experimental and human DKD.[64,65] Moreover, as renal function declines, higher concentrations of these products are retained in the plasma.[66] Second, the infusion of AGEs into normal rodents leads to increased glomerular volume, accumulation of PAS-positive deposits, basement membrane widening, mesangial matrix expansion, and glomerulosclerosis.[67] Third, the inhibition of AGEs in experimental animal models of diabetes ameliorates albuminuria and glomerulosclerosis.[68]

The modus operandi of AGEs in DKD involves, on the one hand, an alteration in the function of the glycated proteins. For example, ECM proteins may become less susceptible to enzymatic hydrolysis by matrix metalloproteinases (MMPs), facilitating their accumulation in the extracellular space.[69] Furthermore, glycation of sulfated proteoglycans modifies the charge-selective properties of the basement membrane and contributes to the development of microalbuminuria.[70] On the other hand, AGEs act as signaling molecules either by directly acting intracellularly or by interacting with their receptor RAGE that is expressed on the surfaces of podocytes

and tubular epithelia. AGEs induce intracellular oxidant stress and activate NF-κB by redox-sensitive signaling pathways.[71] AGEs also activate PKC and regulate the expression of diverse growth factors and cytokines such as angiotensin II (Ang II) and TGF-β1.[72]

Protein Kinase C Signaling

The activation of the PKC signaling pathway is a direct product of glucotoxicity in DKD. In fact, the channeling of glycolytic metabolites to react with glycerol phosphate leads to the *de novo* formation of diacylglycerol (DAG), the major endogenous activator of PKC.[73] Further activation of PKC occurs secondary to activation of the polyol metabolites, AGE accumulation, RAGE activation, reactive oxygen species (ROS) production, and Ang II stimulation.[74] On the other hand, altered lipid metabolism and particularly the imbalance between lipid delivery and intracellular oxidation of fatty acids could lead to accumulation of DAG.[75]

It appears that the PKC isoforms may cooperate in the pathogenesis of DKD. While PKC-beta can lead to renal hypertrophy and glomerulosclerosis, PKC-alpha appears to contribute primarily to diabetic albuminuria by acting through vascular endothelial growth factor (VEGF) and by affecting nephrin expression.[76] Animal experiments with double knockouts of PKC-alpha and PKC-beta, or the administration of an inhibitor of both PKC isoforms, confirmed this hypothesis.[76] However, a randomized, double-blind, placebo-controlled pilot study found that type 2 diabetic patients receiving renin–angiotensin system inhibitors failed to respond to the addition of a PKC-beta inhibitor, ruboxistaurin, and did not have a significant reduction in their albumin:creatinine ratios.[77]

Oxidative Stress

Oxidative stress has long been considered a central pathogenic mechanism in diabetes that synthesizes and amplifies the metabolic dysregulations of hyperglycemia.[56] Diabetes is accompanied by the increased generation of superoxide, hydroxyl radicals, hydrogen peroxide, and peroxynitrite, all commonly referred to as ROS. The ROS along with associated oxidized proteins, lipids, nucleic acids, and carbohydrates contributes to glomerular hypertrophy, causes injury to the podocyte, and promotes fibrogenesis in the glomeruli and tubules.[78,79]

The notable sources of ROS production in the diabetic kidney are the mitochondria, the cytosolic NADPH oxidase (NOX), nitric oxide (NO) synthases, xanthine oxidase, and lipoxygenase.[75,80] The prevailing hypothesis in diabetic microvascular complications was that glucose metabolism increased mitochondrial electron transport chain activity, a high proton gradient, and a high electrochemical potential difference that enhance the generation of mitochondrial superoxide.[56] However, more recent evidence from metabolomic studies suggest decreased efficiency of the electron transport chain. Moreover, measuring mitochondrial superoxide is difficult and has yielded inconsistent conclusions, with some groups finding a decrease in mitochondrial ROS.[54,75,80,81] Some level of mitochondrial superoxide may in fact be beneficial and may retard organ dysfunction.[80,81]

While more sensitive spatiotemporal ROS measurements are being pursued to elucidate the role of mitochondrial ROS in DKD, NOX4 has been consistently shown to be upregulated in animal models of DKD.[68] Various mediators of the diabetic milieu are now known to alter the activity or expression of the Nox proteins, including hyperglycemia, Ang II, TGF-β, AGEs, VEGF, endothelin, and aldosterone.[78] NOX4-mediated stimulation of PKC-alpha may contribute to many of the NOX4-dependent effects in DKD.[82] In addition, NOX4 has been shown to drive the accumulation of fumarate by inhibiting fumarate hydratase.[83] Fumarate, a TCA cycle metabolite with oncogenic properties, has been linked to stimulation of hypoxia-inducible factor 1-alpha, TGF-β, and other matrix genes promoting fibrosis.[83]

GLOMERULAR HEMODYNAMICS

One of the earliest pathophysiologic features of DKD is hyperfiltration. It is particularly pronounced in newly diagnosed T1D patients and during periods of poor glycemic control. There are four factors that determine the GFR: (a) the glomerular plasma flow, (b) the systemic oncotic pressure, (c) glomerular transcapillary hydraulic pressure difference, and (d) the glomerular ultrafiltration (permeability) coefficient, K_f. Several mechanisms have been proposed to explain glomerular hyperfiltration. First, as diabetic glomeruli become hypertrophied, filtration surface area increases, leading to increased ultrafiltration coefficient.[84] Second, and more importantly, abnormal vascular control in diabetic nephropathy leads to differential reduction in afferent glomerular arteriolar resistance and a net increase in efferent arteriolar resistance. This results in increased renal blood flow and glomerular capillary hypertension, all resulting in an elevated single nephron GFR.[85] This intraglomerular hemodynamic stress occurs in response to an imbalance of a variety of vasoactive substances and growth factors including the RAAS, atrial natriuretic peptide, insulin-like growth factor-1, endothelin, prostanoids, eicosanoids, and the NO system secondary to endothelial dysfunction.[86,87] The rise in glomerular capillary

pressure accelerates renovascular complications of DKD. Induced by the diabetic milieu, this hemodynamic stress promotes the production of various mediators of DKD.[88] Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers lower glomerular pressure and limit hyperfiltration by blocking the effect of Ang II on the efferent arteriole.[89–92]

Some studies have suggested that glomerular hyperfiltration is a result of increased proximal tubular reabsorption of glucose and sodium (Na).[93] Hyperglycemia, tubular growth, and increased SGLT2 expression in the proximal tubule increase Na/glucose reabsorption *via* SGLT2 and SGLT1, as well as increase Na reabsorption *via* NHE3.[94] This causes decreased sodium delivery to the macula densa, suppresses tubuloglomerular feedback, and results in facilitated dilation of the afferent arteriole. Indeed, glomerular hyperfiltration is blunted in diabetic mice deficient in the adenosine receptor A1, which lack the tubuloglomerular feedback mechanism.[95] However, there have been conflicting results using this mouse model.[96] In addition, the decreased distal delivery lowers the tubular back pressure in Bowman's space, which increases the effective glomerular filtration pressure and may explain a significant portion of diabetic hyperfiltration.[97,98]

More importantly, the tubule-centric hypothesis of diabetic hyperfiltration has been proposed as one mechanism for the renoprotective effects of the Na-glucose cotransporter SGLT2 inhibitors. Indeed gene-targeted SGLT2 knockout and pharmacologic inhibition of SGLT2 prevent glomerular hyperfiltration in animal models of diabetes.[99] Treatment of T1D and T2D patients with the sodium glucose cotransporter 2 inhibitor empagliflozin has been shown to attenuate renal hyperfiltration, as reflected by eGFR.[100,101] This effect appears to be independent of lowering blood glucose.[102,103]

Overall, clinical trials are building evidence that SGLT2 inhibitors can lower the risk of kidney failure in patients with diabetes. The CREDENCE (Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation) trial emphasized the preliminary findings from previous cardiovascular outcome trials.[104–107] This randomized, double-blind, placebo-controlled, multicenter clinical trial was designed to assess the effects of the SGLT2 inhibitor canagliflozin on renal outcomes in patients with T2DM and albuminuric CKD.[104] The result was a 30% relative risk reduction of the composite primary outcome of ESRD, doubling of the serum creatinine level, or death from renal or cardiovascular causes.[104] Moreover, Canagliflozin decreased the average urinary albumin:creatinine ratio by 31% (95% CI, 26–35), and reduced the rate of eGFR loss by 1.52 mL/min/1.73 m^2/yr (95% CI, 1.11–1.93).[104] This effect appears to be additive to ACEIs and ARBs. Further studies are being conducted to determine whether the renoprotection is consistent across the class of SGLT2 inhibitors, and to better understand the side effect profile of these medications.

CELLULAR AND MOLECULAR MECHANISMS OF GLOMERULOPATHY

Glomerular hyperfiltration and hypertension exert a biomechanical stress on the endothelial cells, the mesangial cells, and the podocytes. Laminar shear stress that occurs in the setting of glomerular hyperfiltration likely further promotes endothelial nitric oxide synthase dysfunction initiated by hyperglycemia and metabolic dysregulation.[108] In parallel, the mesangial cells respond to increased mechanical stretch by upregulating GLUT1, thus indirectly promoting the metabolic derangements of DKD.[109] Stretched mesangial cells have also been shown to promote fibrosis either by directly expressing ECM proteins or by activating TGF-β1.[110]

The podocytes rely on complex interactions between their intricate actin-based cytoskeleton, cell–cell, and cell–matrix contact proteins to maintain the glomerular filtration barrier in the face of mechanical challenges resulting from pulsatile blood flow and filtration of this blood flow.[111,112] In the setting of diabetes, glomerular hypertrophy, thickening and stiffening of the GBM, and glomerular hyperfiltration and hypertension result in shear and tensile stress on the podocyte that challenge the cell's attachment to the GBM.[111] Meanwhile, the hyperglycemic milieu further compromises the cytoskeletal architecture of the podocytes. Podocytes downregulate the expression of nephrin under the effect of glucotoxicity, Ang II, TGF-β, VEGF, and other signaling pathways.[4] Nephrin is not only a key slit diaphragm protein but is also important in podocyte cytoskeletal function and insulin signaling, as well as in maintaining overall podocyte health.[4] Moreover, hyperglycemia, AGEs, ROS, and others result in dysregulation of the Rho family GTPases.[4] This family of enzymes is a key regulator of actin cytoskeleton remodeling. Lastly, studies have shown that podocyte integrin expression is decreased in diabetes, compromising cell–matrix interactions.[4] All these stressors together result in effacement of the foot processes, detachment, and loss of a number of podocytes in the urinary space. Another fate of the podocytes in diabetes is apoptosis under the effect of hyperglycemia, ROS, and on activation of the TGF-β pathway.[113] For the remaining podocytes to cover the newly denuded GBM, they have to adapt by hypertrophy with activation of mammalian target of rapamycin.[114] However, once podocyte loss reaches 20%, the remaining cells die and glomerulosclerosis develops.[115]

Overall, the metabolic and hemodynamic dysregulation in the diabetic kidney interact to activate second

messenger signaling pathways, transcription factors, and cytokines, including the RAAS, TGF-β, VEGF, and others, all of which can lead to the development of albuminuria and glomerulosclerosis characteristic of diabetic nephropathy.

The RAAS is one of the most important pathways in DKD pathophysiology. Intriguingly, intrinsic renal cells such as mesangial cells and podocytes and even tubular cells synthesize Ang II and express receptors for this humoral mediator, which may contribute to the regional activation of RAAS.[109,116] In the setting of diabetes, various factors stimulate the RAAS. Hyperglycemia by itself has been shown to directly upregulate the expression of renin and angiotensinogen in mesangial cells.[81] Further stimulation occurs secondary to the ROS and AGEs.[117,118] As Ang II builds up in the kidney, it exerts its effects not only by sustaining the hemodynamic changes of DKD but also by independently activating a multitude of cytokines such as TGF-β, connecting tissue growth factor, interleukin-6, monocyte chemoattractant protein-1 (MCP-1), and VEGF-A. Accordingly, high levels of Ang II can contribute to the early hyperplasia and hypertrophy of the renal cells observed in diabetes and modulate glomerular ECM deposition in the later stages of diabetes.[119]

VEGF has been proposed to be one of the cornerstones of the all-important crosstalk between glomerular endothelium and podocytes. In healthy glomeruli, VEGF-A is mainly produced by podocytes and binds to vascular endothelial growth factor receptor 2 (VEGFR2) located on the endothelium, maintaining the cell's structure and function.[120] Targeted genetic deletion of all VEGF-A isoforms from podocytes causes glomerular disease in healthy animals.[121] In diabetes, there were conflicting findings initially. Some studies reported increased VEGF-A activity in diabetic glomeruli, with improvement of DKD on inhibition of VEGF-A or VEGFR2.[122–125] Other research showed that total glomerular VEGF-A levels decrease as diabetic nephropathy progresses, and that targeted genetic deletion of all VEGF-A isoforms from podocytes accelerated nephropathy in diabetic animals.[123] In fact, VEGF balance is tightly controlled in the glomeruli, and too much or too little is likely to be pathogenic.[126] Moreover, other crosstalk signals such as NO and angiopoietins can also feed into this paracrine signaling and tip the balance toward pathogenesis. More recent evidence has also shown that the isoforms of VEGF-A may have different roles in health and disease. VEGF-A_{165a} is a potent vasoactive agent, increasing vasodilation, vascular permeability, and angiogenesis.[127] Meanwhile, VEGF-A_{165b} is a protective factor in diabetic nephropathy.[128] The $VEGF_{165b}$ isoform was higher in the kidneys of patients that were protected from advanced nephropathy.[128] In diabetic mice, podocyte-specific $VEGF_{165b}$ overexpression or $VEGF_{165b}$ administration reduced albuminuria, likely by maintaining the glycocalyx and preventing endothelial and podocyte cell death.[128]

Other components of podocyte and endothelial cell crosstalk may serve as potential treatment targets in DKD. New insights have revealed that endothelin-1 (ET-1), an endothelial-derived vasoconstrictor, can signal to the podocyte and then back to the endothelial cell.[129] Atrasentan, an ET-1 receptor antagonist, has been shown to ameliorate early microalbuminuric DKD.[130]

TGF-β has been shown to play an essential role in the pathogenesis of DKD and appears to be a common pathway that leads to the early hypertrophic and later prosclerotic changes in all stages of DKD.[131,132] TGF-β is activated by a multitude of mediators that are generated secondary to the metabolic and hemodynamic forces in DKD. These include high glucose concentration[133]; AGE-modified proteins[134]; ROS[56]; cyclical stretch/relaxation of mesangial cells in culture[135]; PKC activation[136]; and Ang II.[137] All these factors depend on TGF-β to stimulate the synthesis of ECM proteins and prevent their degradation, leading to their deposition and accumulation. Experimental evidence has shown that this cytokine increases the expression of type I collagen, type IV collagen, fibronectin, and laminin. Furthermore, TGF-β inhibits MMPs and can also stimulate the inhibitors of proteases.[138] Blocking the renal TGF-β system in diabetic animals has ameliorated DKD, providing proof of the cytokine's central role. Whether TGF-β is inhibited upstream of its receptor or downstream in the intracellular signaling cascade, numerous studies have demonstrated marked improvement in glomerulosclerosis, ECM deposition, GBM thickening, and other histological and molecular parameters of diabetic renal disease.[86,125,139,140]

TUBULOPATHY IN DIABETES

While glomerulopathy is of great importance in the pathophysiology of DKD, it may not be the sole determinant of renal prognosis. There is growing clinical and pathological data suggesting that tubular damage plays a critical role in the pathogenesis of DKD.[141] For instance, elevated baseline plasma biomarkers of tubular injury such as KIM-1 have been significantly associated with the risk of early decline of kidney function, independent of albuminuria.[142] Moreover, in DKD, significant numbers of glomeruli are attached to dilated and atrophic tubules and may even be atubular.[143,144] Such tubular dysfunction and tubulointerstitial fibrosis are known to correlate significantly with GFR and the progression of kidney disease.

Various mechanisms come into play in diabetic tubulopathy.[145] First, diabetes promotes a hypoxic environment for the proximal tubule. Indeed, the increase in SGLT2 and NHE3 reabsorptive capacity in diabetes results in a commensurate demand for ATP to maintain the Na^+/K^+ ATPase activity.[145] Moreover, proximal tubular epithelial cells are unique in their ability to undertake gluconeogenesis, an energy-requiring process that is increased in the setting of diabetes.[145] However, because of the metabolic dysfunction of hyperglycemia and the mitochondrial injury, the proximal tubular cells consume more O_2 for each molecule of ATP generated. This increased demand and inefficient utilization of O_2 is met with reduced blood supply due to concomitant endothelial injury, intrinsic capillary loss within the tubulointerstitium, and as a consequence of glomerular capillary occlusion.[145]

As a result of hypoxia, proximal tubular epithelial cells not only undergo apoptosis but also promote tubulointerstitial fibrosis *via* TGF-β and other mechanisms.[145] The expansion of the ECM results in further hypoxia and microvascular rarefaction, starting the spiral of fibrosis and CKD.

In addition to hypoxia, several other pathomechanisms target the proximal tubule in DKD. These include the RAAS and the toxic effects of albuminuria and albumin-bound fatty acids among others.[145,146]

The role of the tubules in DKD is likely to be further studied in light of the recently demonstrated protective effects of the SGLT2 inhibitors. Moreover, recent animal studies have shown that selective proximal tubular injury can lead to podocytopathy and extensive glomerular injury reminiscent of diabetes.[147] Indeed, there is evidence of retrograde crosstalk between the proximal tubules and the podocytes. Tubular epithelial cells can protect against albuminuria in diabetes by maintaining nicotinamide mononucleotide concentrations around glomeruli and influencing podocyte function.[148]

INFLAMMATION

Hypoxia and inflammation frequently coexist in injured tissues and have been shown to modulate each other. Furthermore, in diabetes, metabolic and hemodynamic abnormalities, including hyperglycemia, AGEs, ROS, Ang II, and TGF-β, precipitate a proinflammatory state.[149]

Multiple components of the immune system are involved in the pathophysiology of DKD.[150] First, from an innate immunity standpoint, the kidney is home to mononuclear phagocytic cells that are activated in diabetes and are joined by renal cells in the release of proinflammatory cytokines and paracrine signals.[151] Consequently, additional monocytes and macrophages are recruited into the kidney, and there is further amplification of cytokine and chemokine release from the kidney.[152,153] Another type of innate immune cell that infiltrates the tubulointerstitium in DKD is the mast cell. Its degranulation releases inflammatory mediators such as TGF-β and proteolytic enzymes, the most notable of which is chymase.[150] Mast cell chymase is 40 times more potent than ACE at converting Ang I into Ang II.[154,155]

Essential to proper function of the innate immune system are pattern recognition receptors (PRRs), including Toll-like receptors and nucleotide-binding oligomerization domain-like receptors. PRRs are upregulated in mononuclear phagocytic cells, as well as in endothelial cells and podocytes.[150] They recognize pathogen-associated molecular patterns and endogenous stress signals or damage-associated molecular patterns that indicate cellular stress and injury, including uric acid, extracellular ATP, and glucose and ROS. On sensitization of PRRs, there is activation of the inflammasome and, among other effects, release of inflammatory cytokines.

Numerous cytokines have been implicated in the pathogenesis of DKD. For instance, IL-1, IL-6, and IL-18 correlate with morphological changes of DKD, such as GBM thickening, and are associated with increasing albuminuria and more rapid loss of GFR.[150] Early in diabetes, both glomerular and tubular cells increase expression of TNF-α.[156] This cytokine has been demonstrated to be cytotoxic to glomerular mesangial and epithelial cells, to increase vascular endothelial permeability, induce oxidative stress, and affect glomerular hemodynamics and GFR.[157,158] Its receptors, TNFR1 and TNFR2, are candidate biomarkers of DKD. Serum level of TNFR1 was a predictor of ESRD, even after adjustment for clinical covariates in a cohort of T1D.[159]

Chemokines mediate the migration of monocytes and macrophages into kidney tissue and are also upregulated in DKD. Of particular interest is the CC-chemokine ligand 2 (CCL2; also known as MCP-1). Its expression is upregulated in response to metabolic and hemodynamic features of the diabetic milieu, including Ang II.[160] Because its receptor CCR2 is also expressed on podocytes, the effects extend beyond the recruitment of macrophages to the tubulointerstitium.[161] Several studies have implicated CCR2 in effacement of the foot processes, podocytopenia, and damage to the slit diaphragm leading to albuminuria.[162] CCR2 inhibitors are being evaluated for the management of DKD.[163]

Another therapeutic target in DKD is the Janus kinase-Signal Transducer and Activator of Transcription (JAK-STAT) pathway. This pathway transduces inflammatory signals from cytokines and chemokines as well as AGEs, growth factors, and hormones.[164] The JAK-STAT pathway has been shown to be upregulated

in DKD, including in intrinsic renal cells. Baricitinib, an oral, reversible, selective inhibitor of JAK1 and JAK2, is showing promise as an intervention to slow the progression of DKD.[164] Overall, the activation of the innate immune system in DKD is a concerted effort between resident immune cells, infiltrating cells, and resident renal cells. The involvement of renal cells arises from the production of cytokines and chemokines and the expression of adhesion molecules that facilitate adhesion of the inflammatory cells.[149,150] Eventually, the adaptive immune system is also involved in diabetes, as T cells infiltrate kidneys in DKD, albeit not as prominently as macrophages.[150] T helper phenotype in DKD appears to be shifted toward Th1/Th17 cells rather than Tregs.[150,165] This promotes further macrophage-induced injury rather than repair of the kidney. There is limited evidence for involvement of B cells in DKD.

GENETIC AND EPIGENETIC PROGRAMMING OF DKD

Nephropathy is not an inevitable complication of diabetes. Only 25–35% of type 1 or type 2 diabetes ultimately develop kidney disease. Differences in the control of glycemia and blood pressure by themselves do not explain this unequal distribution. The propensity for DKD appears to be driven, at least in part, by familial and genetic factors.

The initial evidence for genetic predisposition comes from familial clustering studies. Having a sibling or parent with DKD increases the risk of diabetic family members to develop elevated UAE or ESRD. The finding was consistent across families with various ethnic backgrounds and was, to a large extent, independent of blood glucose concentration.[166–168] It was also validated in larger multicenter trials such as the ESRD network and the Diabetes Control and Complications Trial.[169,170]

Because family members often share environmental factors and habits, nurture may be difficult to tease apart from nature in the study of DKD. A better analysis comes from the calculation of the heritability factor h^2, which estimates the proportion of total variation of a trait caused by genetic effects. In the case of albuminuria, h^2 was between 0.27 and 0.39 in families with type 2 diabetes.[171–175] On the other hand, GFR was found to be as strong a heritable trait, with an h^2 ranging from 0.29 to 0.75.[173,174] Because a heritability factor of 1 indicates Mendelian transmission of a trait, these h^2 values suggest a strong genetic component in the susceptibility to DKD.

Since the advent and evolution of genomics, multiple studies have attempted to localize the genetic drivers of DKD. Based on the known or theorized roles in the mechanisms of disease, numerous genes were tested for polymorphisms in patients with kidney disease compared to controls. One notable example is that of the ACE insertion/deletion (I/D) polymorphism. Patients homozygous for the D allele have stronger ACE activity and appear to be at a higher risk for DKD progression. Multiple studies have attempted to prove this effect with variable results. These were recently pooled into a meta-analysis that somewhat confirmed the association of the D allele with DKD, with the evidence being stronger in the Asian subgroup.[176]

Another level of evidence comes from linkage analysis, which hunts for human disease genes relative to known genetic markers. The technique is based on the principle that markers in proximity to DKD susceptibility genes are unlikely to be segregated and are therefore "linked," thereby narrowing the genomic region that needs to be searched.[177] Genome-wide association studies (GWASs) cast a wider and, arguably, unbiased net across the genome and allow the analysis of population-based samples. They offer a better screen for genetic associations.[178] Whole exome sequencing methods are emerging for DKD. They help investigate low-frequency and rare variants not detected on GWAS platforms. Data on candidate genes is starting to appear, such as RREB1 gene, an upstream regulator of RAAS, and COL4A3 which encodes the α3 collagen chain subunit of type IV collagen, which is the major structural component in the mature GBM.[179,180] Although multiple areas of interest have been noted, no significant genes have been pinpointed as specific mediators of DKD. Diabetic nephropathy continues to be a complex disease, so its inheritance is most likely polygenic. Moreover, environmental factors influence its incidence and progression.

Environmental factors from intrauterine environment to diet and hyperglycemic control can modify genome expression through epigenetic mechanisms. These include changes in DNA methylation, histone modification by methylation and acetylation, among others.[181] Epigenetic modifications can shape the transcription of specific genes, and therefore affect disease pathogenesis. Accumulation of TCA intermediates and other metabolic dysregulations in diabetes may result in epigenetic modifications of renal and immune cells, potentially explaining some of the gene expression in DKD.[182] Such epigenetic modifications may persist, perpetuating some of the glomerulopathy, tubulopathy, and inflammation in DKD, even after normoglycemia is reestablished.[182]

Researchers have also been conducting epigenome-wide association studies to identify epigenetic marks associated with disease across the whole genome. For example, looking at differentially methylated genes in

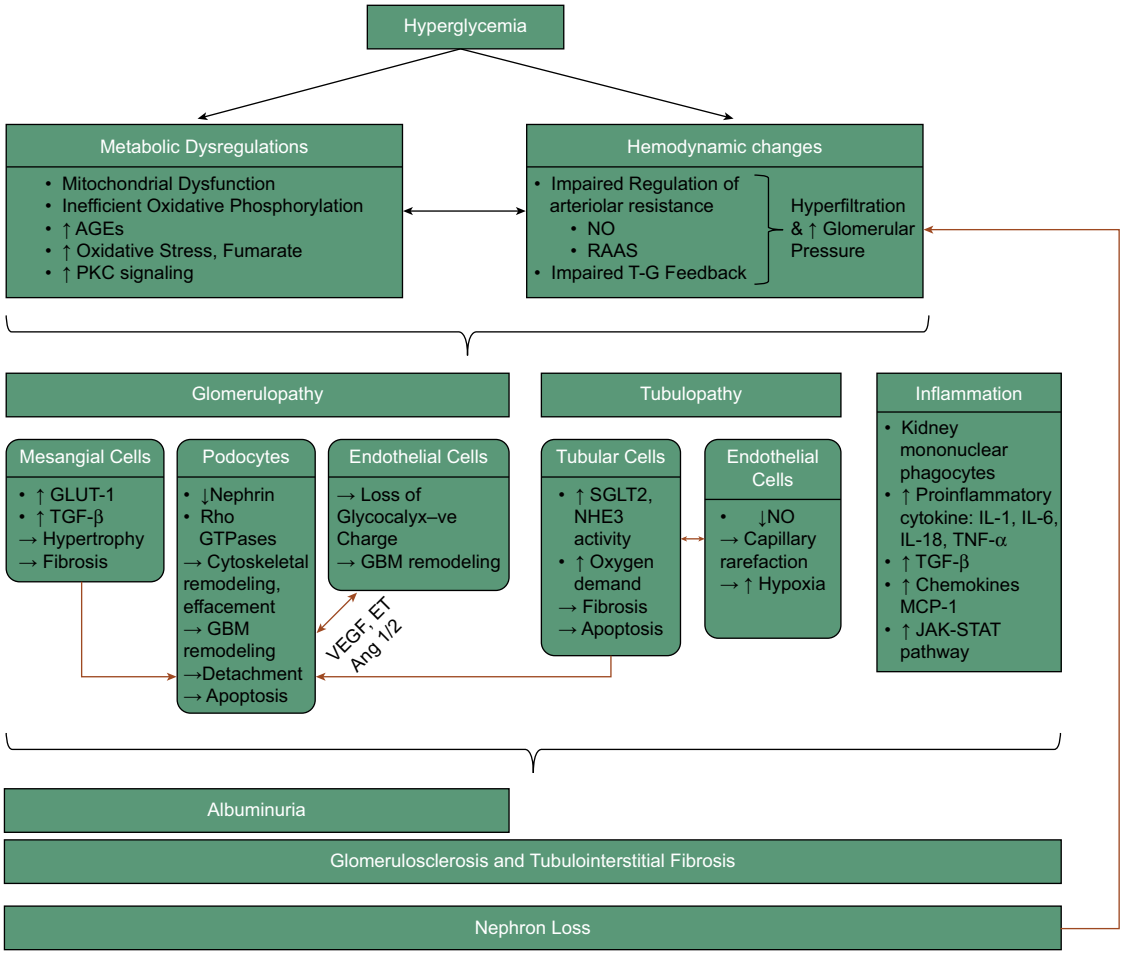

FIGURE 19.3 Conceptual model of the pathogenesis of diabetic kidney disease.

DKD cases vs. controls without renal complications is a new approach toward understanding predisposition to DKD.[181]

Because the epigenome is responsive to internal and external stimuli, harnessing this plasticity has fast become a new line of investigation to assessing dysregulated gene function. However, the broader utility for individual patients beyond conventional risk factors, such as glycemia, nutrition, and exercise, remains to be established.[182]

CONCLUSION

The pathogenesis of DKD is complex (Figure 19.3). Engendered by glucotoxicity and glomerular hypertension, deleterious combinations of toxic metabolites, growth factors, and cytokines are foisted on the various compartments of the kidney, and the damage manifests clinically as albuminuria and progressive loss of renal function. Although we discussed DKD pathogenic mechanisms separately, in reality, they intersect/overlap and occur simultaneously and perhaps even act synergistically. The reductionist approach is powerful but needs to be balanced by a desire to synthesize the "big picture," as unifying the theories of DKD remain a laudable goal. There is some suggestion that many of the inciting factors may converge on a final, common pathway. The armamentarium for the treatment and prevention of DKD in clinical practice had long remained limited to the blockade of the renin-angiotensin-aldosterone system (RAAS) and the control of hypertension and hyperglycemia. The SGLT2 inhibitors offer hope for additional nephroprotective effects. Overall we are optimistic that newer and more effective therapies will be on the horizon, and that progress will be made possible by further elucidating the pathophysiology of DKD.

QUESTIONS AND ANSWERS

Question 1

A 48-year-old man with a past medical history of 6 years of diabetes mellitus and poor medical follow-up presents with generalized edema and is found to have nephrotic-range proteinuria. He undergoes kidney biopsy that shows PAS-positive nodules in some of the glomeruli. These lesions are best known as?

A. Arteriolar hyalinosis
B. Hyaline caps
C. Exudative lesions
D. Kimmelstiel–Wilson bodies
E. Collapsed glomeruli

Answer: D

Kimmelstiel–Wilson bodies are nodular deposits of extracellular material that develop due to continued mesangial matrix expansion or to mesangiolysis and the formation of capillary aneurysms. They are present in up to 25% of diabetic patients at postmortem examination.

Question 2

Which of the following diabetic nephropathy mediators exerts its effects by direct modification of molecules as well as by activation of signaling pathways?

A. TGF-β
B. PKC
C. The polyols
D. Angiotensin II
E. AGE and ROS

Answer: E

AGEs are generated both intracellularly and extracellularly in the setting of hyperglycemia. They are at higher levels in vascular organs like the kidney. They induce their effects *via* direct modification of molecules and alteration of their function or by transformation into signaling molecules that act *via* the receptor RAGE. ROS generation is tightly linked to AGE formation and signaling. ROS oxidize a host of proteins, lipids, and carbohydrates in the cells affecting the cell's normal function, eventually leading to cell death. ROS can also affect DNA contributing to the differential gene expression in DKD.

Question 3

The rise in intraglomerular pressure can best be explained by which of the following effects?

A. The sole translation of systemic hypertension into the kidney
B. Abnormal autoregulation of the glomerular arterioles
C. Increased oncotic pressure
D. Increased glomerular filtration coefficient
E. Shift in pressure distribution with progressive loss of nephrons

Answer: B

Intraglomerular hypertension is best explained by alteration in autoregulation of the glomerular arterioles. While systemic blood pressure will likely be increased in later stages of diabetes, early glomerular hypertension has been described as an isolated phenomenon. Oncotic pressure and filtration coefficient have not been found to contribute to the hemodynamic changes in the kidney.

Question 4

Which of the following mediators and signaling pathways likely represents the best link between the hemodynamic and metabolic mechanisms of diabetic nephropathy?

A. The RAAS pathway
B. TGF-β
C. ROS
D. AGE
E. PKC

Answer: A

The RAAS pathway is activated by various metabolic drivers in diabetic nephropathy, including glucose, AGE, and others, and in turn activates TGF-β signaling among other pathways. It is likely one of the main drivers of glomerular hypertension *via* its selective vasoconstrictive effect on the efferent arteriole.

Question 5

A 46-year-old woman with a past medical history of diabetes mellitus is initiated on empagliflozin, an SGLT2i. Her GFR measured by inulin clearance was 185 mL/min/1.73 m^2 prior to the initiation of therapy and decreased to 150 mL/min/1.73 m^2 after two weeks on empagliflozin. Her volume status, glycemic control, and overall clinical condition remained relatively stable during this period. The decrease in GFR can best be explained by?

A. An acute kidney injury secondary to empagliflozin-related tubulointerstitial nephritis
B. Impairment of tubuloglomerular feedback as a result of glycation of the macula densa from increased distal delivery of glucose

C. Day-to-day variation in GFR measurement
D. Increased sodium chloride delivery to the macula densa results in afferent vasoconstriction *via* the tubuloglomerular feedback
E. Decreased pressure in the tubules and Bowman's space with SGLT2i therapy

Answer: D

In diabetes, there is an increase in sodium and glucose absorption in the proximal tubule, thus impairing the tubuloglomerular feedback and contributing to hyperfiltration by persistent afferent arteriolar dilation. SGLT2i has the opposite effect. Sodium and glucose that are not absorbed proximally *via* SGLT2 and the NHE3 transporters are delivered distally. There is increased delivery of NaCl to the macula densa, triggering tubuloglomerular feedback and inducing afferent arteriolar vasoconstriction. Simultaneously, the osmotic effect of glucose and sodium also increases the pressure in the tubules and Bowman's space, thus reducing the transglomerular filtration pressure and the GFR.

Question 6

Genetic predisposition to the development of diabetic nephropathy is likely due to which of the following?

A. Acquired mutations as a result of ROS modifications of DNA
B. Mendelian single gene inheritance
C. Epigenetic pathways
D. Mitochondrial inheritance of overactive glucose metabolism pathways
E. Multifactorial genetic inheritance

Answer: E

Only a proportion of diabetic patients ever develop diabetic nephropathy. The predisposition to diabetic nephropathy is likely due to a multifactorial inheritance, with involvement of multiple genes being associated with the disease. Environmental factors may contribute to epigenetic modifications of DNA. That said, the analysis of genetic predisposition to diabetes is largely affected by the difficulty in separating predisposition to renal involvement from tendency to poorly controlled diabetes.

CHAPTER

20

Prenatal Antecedents of Chronic Kidney Disease

Valerie A. Luyckx[a,b]

Abstract

Hypertension and chronic kidney disease are common in disadvantaged communities, where maternal health is also suboptimal and risk factors for poor pregnancy outcomes are common. Multiple exposures during pregnancy and early childhood impact fetal and infant growth and nephrogenesis, which in turn affect the risk of hypertension and kidney disease throughout the life course. Being small for gestational age is the strongest risk predictor for renal programming, but being born preterm, of low birth weight, large for gestational age, or being exposed to gestational diabetes and preeclampsia are also risk markers. This programmed risk could be mitigated by optimization of maternal health before pregnancy, education about healthy lifestyles, and screening of individuals who may have experienced developmental programming, to permit early diagnosis and intervention. Given that millions of babies are born too small, too early, or in complicated pregnancies, increased awareness of programmed risk of hypertension and kidney disease should provide a window of opportunity to reduce the global burden of these conditions across the life course through prevention, early diagnosis and treatment, and education.

SCOPE OF THE PROBLEM

Chronic kidney disease (CKD) has been called a "silent epidemic," affecting around 10% of adults and an estimated 750 million people worldwide.[1] Individual susceptibility to kidney disease varies but tends to be higher among disadvantaged populations and those of certain ethnicities, including Aboriginal Australians, Native Americans, and people of African descent.[2] CKD also tends to manifest earlier, i.e. prematurely, in these populations compared with Caucasians and other nondisadvantaged populations. In addition to some monogenic disorders, multiple risk factors underlie the susceptibility to CKD including hypertension, diabetes, genetic factors such as ApoL1, lifestyle, socioeconomics, environmental factors in certain world regions, acute kidney injury (AKI), and infections such as hepatitis and HIV. Not every individual who has such risk factors, however, develops CKD. Increasingly, developmental factors occurring during fetal life are recognized as modulators of individuals' risk of CKD throughout their life course.[3] Multiple adverse circumstances experienced *in utero*, some of which are manifest by extremes of birth weight or preterm delivery, affect development of the fetal kidney, which then impacts lifetime risk of CKD.

The Developmental Programming Paradigm

The phenomenon of intrauterine exposures translating into lifelong risk for chronic disease, termed developmental programming, was first proposed by Barker and colleagues[4] who observed an increase in premature cardiac deaths among adults who had been born with low birth weight (LBW), decades earlier. Since then, evidence has shown that programming occurs in multiple organ systems, including the kidney, and has been recognized by the World Health Organization as an important pathway in the pathogenesis of noncommunicable diseases.[5] LBW (birth weight under 2.5 kg), being small for gestational age (SGA, birth weight <10th percentile for gestational age), or being born preterm (birth before 37 weeks of gestation) are the most obvious surrogate markers for adverse fetal developmental circumstances.[6] High birth weight (HBW, >4 kg) may also reflect suboptimal intrauterine exposures.[3,7]

Infants born with LBW, SGA, and preterm are at increased risk for premature CKD.[3] Globally 10–15%

Chronic Renal Disease, Second Edition

of babies are born with LBW, SGA, or preterm (Table 20.1). Other developmental risk factors which have been associated with increased risk of hypertension and CKD in the offspring include maternal hyperglycemia, preeclampsia, and maternal obesity, which occur in around 15%, 4%, and up to 30% of pregnant women, respectively (Table 20.1). Many babies born each year are therefore at potential risk of CKD, which may be consistent with the estimated prevalence of CKD of around 10%.[1] Poor maternal nutrition is associated with LBW, SGA, and preterm birth in offspring; however, birth weight and prematurity are also affected by many other circumstances, including maternal age, access to antenatal care, maternal chronic disease, maternal infections, and social stress, among others.[3] HBW often results from maternal diabetes or obesity.[3] More subtle exposures that may affect fetal kidney development may not be easily detectable by history or clinically at birth but are important to consider regarding an individual's lifelong risk of CKD.[3,8]

This chapter discusses the impact of developmental programming on the kidney in terms of structure and function and the associations with long-term levels of blood pressure and kidney function. Risk factors for developmental programming are discussed in terms of global prevalence and the potential to modify these as targets for CKD prevention. Developmental programming of related conditions, such as cardiovascular disease, diabetes, and obesity, that may impact kidney function are expertly reviewed elsewhere.[3]

TABLE 20.1 Global Prevalence of Birth Weights, Preterm Birth, and Risk Factors

	Global	Ref.
Low birth weight (birth weight <2.5 kg, % live births)	15	106
Preterm birth (births, <37 weeks of gestation, %, range)	11.1 (9.1–13.4)	a
Term small for gestational age (% SGA, birth weight <10th percentile)	13.8	107
Preterm small for gestational age (% SGA, birth weight <10th percentile for gestational age)	26.6	107
High birth weight (birth weight >4 kg, %)	Up to 20	7
Preeclampsia (% deliveries)	4.6	108
Hyperglycemia in pregnancy (%)	17	109
Teenage pregnancy (adolescent births 15–19 years per 1000 deliveries)	44.1 (2015)	b
Obesity in pregnancy (BMI >30 kg/m^2 %)	Up to 32	47
Maternal iron deficiency anemia (<110 g/L, %, range)	19.2 (17.1–21.5)	110
Maternal vitamin A deficiency (serum retinol <0.70 μmol/L, %, range) 2005	7.8 (6.0–24.6)	110
Antenatal clinic attendance (% ≥four visits)	62	c

PATHOPHYSIOLOGY

Developmental Programming in the Kidney

The Nephron Number Hypothesis

It is generally accepted that under normal circumstances nephrogenesis in humans continues *in utero* until 36 weeks of gestation, and that no new nephrons develop in term infants after birth.[9] In preterm infants, however, some nephrogenesis may continue for up to 40 days postnatally, but the nephrons formed may not be normal.[9] How nephrogenesis is modulated by preterm birth is not yet understood. Growth restriction *in utero*, the change in neonatal redox state which occurs at birth, suboptimal nutrition, and the many pharmacologic interventions required in postnatal care may all play pathogenic roles.[10] As early as 1968, Zeman[11] noted a reduction in nephron number in kidneys of LBW offspring of pregnant rats fed on a protein-deficient diet. Subsequently, building on the Barker hypothesis, Brenner and colleagues proposed that LBW may be associated with a reduced number of nephrons, and that this in turn may predispose to subsequent hypertension and kidney disease.[12] It was postulated that kidneys with fewer nephrons would be less efficient in excreting salt, and less able to withstand kidney injury, thereby contributing to a higher risk of hypertension and CKD.[12] This hypothesis could plausibly explain, at least in part, the higher rates of hypertension and CKD seen in disadvantaged populations where LBW is more prevalent.[8,13]

Experimental Corroboration of the Nephron Number Hypothesis

Many animal studies have since shown a link between various developmental exposures, including maternal dietary restrictions, reduction in uterine perfusion during gestation, maternal hyperglycemia and corticosteroid or other drug administration in pregnancy, and reduced nephron number in offspring (Table 20.2).[14,15] In many of these models, reduced

TABLE 20.2 Experimental Conditions Associated With Programming of Low Nephron Number and Kidney Function and Blood Pressure

Experimental Model	Renal Phenotype	Nephron Endowment
Uteroplacental insufficiency	↑ Apoptosis	↓
Vitamin A-deficient diet from 3 weeks before mating throughout pregnancy	Not evaluated	↓
Low sodium diet (0.07%) during pregnancy and lactation	Hypertension at 5 months	↓
High sodium diet (3%) during pregnancy and lactation	Glomerular hypertrophy, hypertension at 5 month	↓
Partial ligation of uterine ligation	↓ GFR, glomerular hypertrophy	↓
Ethanol (1 g/kg/day) at gestational day 13.5 and 14.5	↓ GFR at 6 months	↓
Lipopolysaccharide (0.79 mg/kg/day) i.p. at gestational day 8, 10, and 12	↓ GFR	↓
Dexamethasone (0.1 mg/kg/day) throughout pregnancy	↓ GFR, glomerular hypertrophy	↓
Dexamethasone (0.2 mg/kg/day) at gestational days 15 and 16 or 17 and 18	↔ GFR, unchanged glomerular morphology	↓
Low protein diet (8% protein) during lactation	Hypertension at 5 months	↓
Cyclosporine (3.3 mg/kg/day) from gestational day 10 to postnatal day 7	↔ GFR, glomerular hypertrophy	↓
50% caloric restriction during pregnancy and lactation	↔ GFR, glomerular hypertrophy, hypertension, tubulointerstitial injury	↓
Streptozotocin-induced diabetes during pregnancy	↔ GFR, hypertension, tuburointerstitial injury	↓
Multideficient diet during pregnancy	↑ GFR, glomerular hypertrophy	↓
Dexamethasone (0.1 mg/kg/day) from gestational day 16–22	Hypertension	↓
Low protein diet (85% protein) during pregnancy	↔ GFR, hypertension	↓
Iron restriction diet (3 mg/kg diet) from 1 week before mating and through pregnancy	Glomerular hypertrophy, hypertension	↓

Studies tabulated according to age at evaluation. GFR = glomerular filtration rate, ↑ = increased, ↓ = decreased, ↔ = unaltered.

nephron number in turn is associated with higher blood pressure and kidney dysfunction in later life (Table 20.2).[15,16] These associations tend to be stronger in males.[17] Although the pathophysiology of this sexual dimorphism is not yet fully understood, it may relate to differences in placental size and function, and differential growth rates of male and female fetuses, which may affect susceptibility to programming exposures.[18,19] There is, however, also varying susceptibility to gestational perturbations depending on the animal species and experimental model, as well as varying effects of the degree to which nephron number is reduced, suggesting a complex interplay of factors likely determines final nephron number.[3,14,15]

A pathophysiologic link between reduced nephron number and CKD is plausible. In the setting of a reduced nephron number, filtration surface area has been observed to be relatively preserved as a result of compensatory glomerular hypertrophy.[20] Whole-kidney glomerular filtration rate (GFR) therefore may not change in the setting of a mild or moderately reduced nephron number; however, single nephron GFR (SNGFR) should be increased. Indeed, in the Munich Wistar Fromter rat, which develops spontaneous glomerular injury, nephron numbers are reduced and SNGFR is increased compared with control rats.[21] Sustained hyperfiltration would be expected to increase susceptibility to further renal injury, as illustrated in Figure 20.1.

Consistent also with the nephron number hypothesis, experimental salt-sensitivity (increase in systemic blood pressure in response to a sodium load) has been

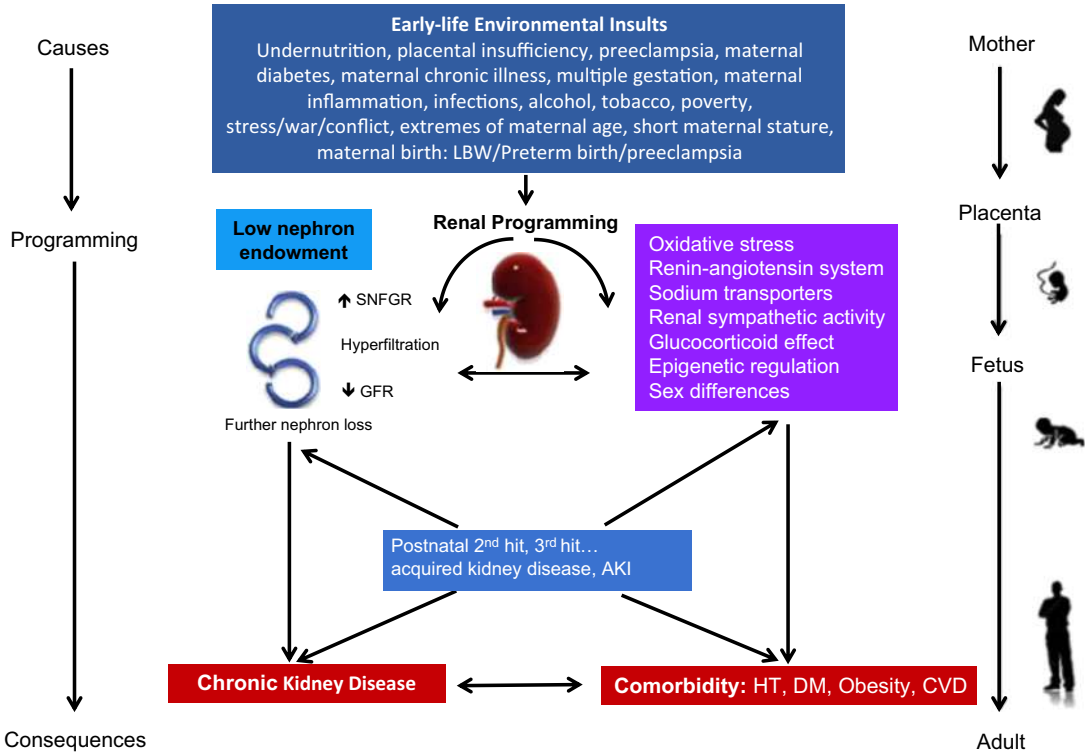

FIGURE 20.1 Representation of interactions between risk factors and pathophysiology of developmental programming in the kidney and modulation of renal disease risk by events accumulating over the life course. *Adapted under the terms and conditions of the Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/) from reference 15.*

reported in association with LBW and low nephron number or exposure to diabetes *in utero*.[22,23] This, however, is not universal, and in some models is only inducible with aging. Interestingly, in glial cell line-derived neurotrophic factor (GDNF) heterozygous mice, which have either 65% or 25% fewer nephrons than wild-type mice, depending on whether they have one or two kidneys, the degree of salt sensitivity was found to be proportional to the nephron endowment.[24] Consistent with this, having 30% more nephrons protected transforming growth factor-β2 heterozygous mice from developing high blood pressure with chronic salt loading.[25] Nephron number and filtration surface area therefore appear to be factors predisposing to programmed hypertension.

That not all experimental programming interventions lead to lower nephron number, hypertension or kidney disease, however, may explain some of the variability in hypertension and CKD risk observed in humans.[3] It is likely that programming of nephron number may be the first "hit," which increases susceptibility of the kidney to subsequent "hits" such as a primary kidney disease, programmed hypertension, or diabetes, which then leads to premature CKD (Figure 20.1).[3,26] It is not yet known whether a reduced nephron number *per se* affects the risk of AKI, or a kidney's capacity to recover from AKI, beyond a recognized significantly increased risk of AKI among preterm neonates.[3] LBW rats were, however, more susceptible to ischemia reperfusion injury than normal birth weight (NBW) rats, suggesting increased susceptibility to AKI.[27]

Experimental Evidence of Additional Programmed Changes in the Kidney

In some experimental models, modulation of the amino acid composition of maternal low protein diets abrogated the development of hypertension in rat offspring, despite persistence of low nephron numbers; in other models, augmentation or nephron number through postnatal hypernutrition did not prevent hypertension.[28,29] A recent report found that the salt-sensitive hypertension observed in GDNF heterozygous mice was associated with an increase in total body chloride, but not in total body sodium.[30] This finding remains unexplained but suggests that sodium retention may not be the only mechanism contributing to programmed hypertension. Taken together, these observations suggest that a reduction in nephron number does not explain all programmed hypertension; therefore, other potential programming effects in the kidney have been investigated.[16]

Altered Renal Sodium Transport In various LBW models and offspring of diabetic rats, expression of the tubule sodium transporters Na-K-2Cl (NKCC2) and Na-Cl and sodium-hydrogen exchanger type III was significantly increased, and activity of both NKCC2 and ENaC was significantly increased.[16] A programmed increase in sodium transport in all segments of the renal tubule therefore seems likely, although it is not known whether this is related to glomerulotubular balance required in the setting of fewer nephrons or is intrinsic to the transporters.

Renin–Angiotensin–Aldosterone System Dysregulation of elements of the renal renin–angiotensin–aldosterone system (RAAS) has been described in various programming models. Inhibition of this system during kidney development is often associated with system upregulation in adulthood and changes in blood pressure.[31] Such changes are model- and timing-dependent and are differentially regulated by sex hormones.[31] For example, aldosterone levels were higher among adolescent male offspring of mothers who had preeclampsia who had been preterm and very LBW, although the effect was attenuated when adjusted for body mass index (BMI).[32] Plasma angiotensin II/Ang-(1-7) and urinary angiotensin II/Ang-(1-7) levels were increased in adolescents who had been born preterm; however, these differences were variably modulated by gender, obesity, or prenatal corticosteroid exposure.[33,34] Among matched 18- to 29-year-old subjects who had been born preterm or at term, renin and alamandine levels were significantly higher among those born preterm, which correlated with higher blood pressure, smaller kidneys, and higher urine albumin excretion.[35] When stratified by gender, renin levels were higher in males in both birth groups, but alamandine levels were significantly higher among preterm males.[35] The interactions of multiple developmental exposures and offspring gender on programmed changes in the RAAS is highly complex and requires further investigation, especially to understand the utility of medications that modulate this system.

Sympathetic Nervous System and Renal Vascular Reactivity The sympathetic nervous system contributes to blood pressure regulation through modulation of RAAS activity, sodium transport, and vascular tone.[36] Renal denervation modulates blood pressure and sodium transporter expression in LBW rats and is associated with differential age and gender effects.[37,38]

Factors Impacting Renal Programming

Maternal Nutrition

Maternal nutrition, preconception and throughout pregnancy, has an important impact on pregnancy outcomes and fetal growth.[3,5] Mothers who themselves may have been born small, as reflected by short maternal stature or maternal underweight, are anemic, smoke, drink alcohol, or consume caffeine during pregnancy have a higher risk of having a LBW, SGA, or preterm infant.[3,16] Maternal diets deficient in calories, protein, Vitamin A, sodium, zinc, or iron have been associated with reduced nephron numbers in offspring of experimental animals (Table 20.2).[8] Maternal vitamin A deficiency was associated with smaller newborn kidney size in Indian neonates.[39] Optimization of maternal nutrition is therefore important for fetal kidney development.

In humans, exposure to famine at the time of conception or at various stages of gestation has also been associated with higher risk of hypertension, proteinuria, and renal dysfunction in offspring in later life.[8] In these studies, blood pressures were higher and rose earlier in Nigerian compared with Caucasian and Chinese populations.[8,40,41,42] Fasting during Ramadan has not been found to affect offspring birth weight, which may suggest that intermittent fasting may not affect fetal growth.[43]

Maternal Diabetes and Obesity

HBW is associated with an increased risk of later life hypertension, obesity, diabetes, and kidney disease.[3] HBW is often a complication of maternal obesity or diabetes in pregnancy, which are becoming increasingly common worldwide (Table 20.1).[5] Infants of diabetic mothers have an increased risk of congenital abnormalities, including of the kidney.[44] In experimental animals, offspring of diabetic mothers have reduced nephron numbers in proportion to the degree of maternal hyperglycemia; however, control of maternal glucose with insulin in the latter half of pregnancy failed to restore nephron number in mice, suggesting a very early effect of hyperglycemia.[45,46] These observations emphasize the importance of good and early control of maternal blood sugar, ideally before conception, and the need to screen for gestational diabetes.

Maternal obesity is associated with a higher risk of pregnancy complications including gestational diabetes, hypertensive disorders of pregnancy, preterm birth, HBW and LBW, and perinatal mortality.[3,47] Nephron numbers were found unchanged or increased in rat and mice offspring of high-fat fed mothers, although in some blood pressures were high and renal injury and proteinuria were evident.[48,49] Studies of children of obese mothers have shown an increased risk of ischemic heart disease, type 2 diabetes, and obesity, suggesting a potential indirect, if not direct, impact on CKD risk in these individuals.[47]

Uteroplacental Insufficiency

Reduction in uteroplacental blood flow restricts nutrient transfer to the fetus and induces LBW, low

nephron number, and hypertension in rat offspring, which is more evident in males.[50] In high-income countries, placental insufficiency is a common cause of fetal growth restriction, given increasing pregnancies at advanced maternal age, maternal chronic illness, and use of assisted reproduction technologies. Therefore, even in settings where nutrition may be adequate, fetal nutrition may not be optimal.[3] Recent evidence points to differences in male and female placentas which may enhance male susceptibility to developmental programming and may explain some of the observed sexual dimorphism in developmentally programmed risk for CKD.[19] Preeclampsia and gestational hypertension are common and are common causes of placental insufficiency (Table 20.1). Higher blood pressures have been observed in children born in preeclamptic pregnancies, but systematic study of renal function in such patients has not been performed.[51]

Fetal Exposure to Glucocorticoids

Under conditions of maternal stress or exogenous therapy, fetal exposure to glucocorticoids can increase.[52] The effect of maternal dietary protein restriction on offspring nephron number and blood pressures in rats has also been found to be mediated at least in part by increased fetal steroid exposure.[52] Fetal glucocorticoid exposure is associated with reduced nephron numbers and higher blood pressures in experimental animals (Table 20.2).[14,15] Short-term perinatal exposure to corticosteroids is common in human infants at low gestational age, but so far there has been no consistent evidence of increased blood pressure or kidney dysfunction long term.[53] Follow-up of children of mothers treated with steroids throughout pregnancy has not been systematically performed.

Fetal Exposure to Medication

Exposure to exogenous medications or substances during fetal life may affect nephrogenesis (Table 20.2).[3] Medications including aminoglycosides, ampicillin, ceftriaxone, and cyclosporine, which may be commonly used during pregnancy or early postnatally, especially in preterm infants, impact nephrogenesis in animals.[3,16] Caution with use of these medications in humans is therefore advised. Longer follow-up studies of individuals exposed to these medications are required.

Congenital Obstruction of the Kidney

Congenital obstruction is a major cause of childhood end-stage renal disease (ESRD).[54] Congenital abnormalities of the urinary tract are frequently associated with obstruction and impaired nephrogenesis, which may be further impacted by associated fetal growth restriction.[54] Animal studies have also shown that long-term changes also occur in the contralateral unobstructed kidney, suggesting that relief of obstruction should occur as early as possible to rescue both kidneys. Long-term follow-up of such patients is required.[54]

Common Genetic Variants

Many genes implicated in congenital abnormalities of the kidney and urinary tract are associated with branching morphogenesis. Compared with wild-type alleles, common polymorphisms[16,55] in *PAX2* and *RET* and *BMPR1A* which regulate ureteric bud signaling and branching, *OSR1*, which interferes with mRNA splicing, and the angiotensin-converting enzyme (ACE) gene were all associated with approximately 10% reductions in newborn kidney volume and nephron number. In contrast, a common variant of the *ALHD1A2* gene, which modulates RET expression in the ureteric epithelium, was associated with 22% larger newborn kidneys. Such polymorphisms may therefore contribute to population variance in nephron number, although interactions with birth weight remain to be studied.

Epigenetics

Dietary composition, the degree of nutrient restriction, specific amino acid content, and source of carbohydrate may all affect nephrogenesis through epigenetic DNA methylation, increased fetal exposure to glucocorticoids, angiogenesis, and global downregulation of gene expression.[8,15] In addition, diabetes and obesity-associated programming effects are mediated *via* inflammation, oxidative stress, and epigenetic processes.[15,47] Epigenetic processes therefore may be modifiable, but further work is required to understand their role in determining organ structure and the premature aging and organ dysfunction observed in programmed animals.[15]

Nephron Number in Human Kidneys

Thus far, it has only been possible to estimate nephron number in human kidneys *post mortem*, using the physical disector/fractionator technique.[56] New techniques are being developed to estimate nephron number *in vivo* based on kidney biopsies combined with CT scan measurements of kidney volume or measurements which appear relatively consistent with post-mortem estimates.[57] Promising MRI techniques are also being investigated, which may permit direct correlation of nephron number with kidney function.[58]

Overall, the average number of nephrons per kidney is around 1,000,000, but this ranges from 210,000 to 2.7 million per kidney.[59] This high interindividual variability likely contributes to the interindividual susceptibility to CKD. Much of this variability already exists at birth, pointing to a programming effect.[60,61] Nephron number in humans increases with gestational age and is therefore reduced in infants born preterm compared

with term infants.[9,62] Whether the reduced nephron number observed in preterm infants reflects cessation of nephrogenesis at the time of birth, the impact of factors which may have predisposed to preterm birth, the frequent accompanying growth restriction, deranged nephrogenesis which can continue for a few weeks after birth, or a combination of these is unknown.[10] Growth restriction *in utero* is also associated with reduced nephron number, which has been found to be lower in infants with LBW or born SGA, compared with those born with appropriate birth weights for gestational age (AGA).[9,63,64]

In a population of 58 Caucasian and African Americans, aged 1.5–50 years and having birth weights ranging from 2.18 kg to over 4 kg, Hughson and colleagues[65] reported a correlation between birth weight and glomerular numbers, predicting an increase of 257,426 glomeruli per kg increase in birth weight ($r = 0.423$, $p = 0.0012$, Figure 20.2). When the analysis was confined to 11 individuals who had died under 18 years of age, to control for the known decline in nephron number with age, the regression coefficient predicted a steeper increase of 518,038 glomeruli per kg increase in birth weight ($r = 0.773$, $p = 0.0053$).[65] In this study, females had a nonsignificant 9% fewer glomeruli than men, but the association with birth weight was stronger in men. There was no difference in glomerular number between Caucasian and African-American subjects.[65] Only African-American subjects had birth weights <2.5 kg ($n = 4$). Four of six subjects with birth weights >3.8 kg were African American, which may explain the wide range of nephron numbers seen in these subjects.[65] In further studies, the highest and lowest observed nephron numbers have been seen among African Americans, with the range approaching 13-fold, compared with 2- to 7-fold in other populations.[59]

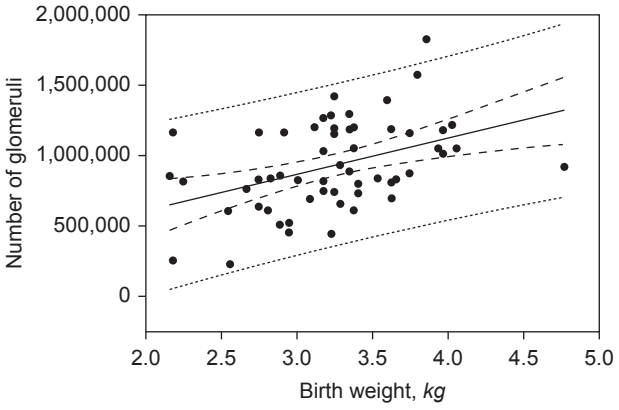

FIGURE 20.2 The relationship between birth weight and total glomerular number. Symbols are (•) Nglom vs. birth weight; (——) Nglom vs. birth weight regression; (– –) 95% regression CI; and (……) regression prediction interval. The regression coefficient predicts a gain of 257,426 glomeruli per kg increase in birth weight, $r = 0.423$, $p = 0.0012$, $N = 56$, all ages included (Nglom—glomerular number). *Figure reproduced with permission from reference 65.*

Clinical Correlates for Nephron Number and Renal Programming

As nephron number cannot currently be measured *in vivo*, potential clinical markers highlighting risk of reduced nephron numbers include female gender, shorter adult height, maternal vitamin A deficiency, and Australian Aboriginal or Japanese ethnicity, in addition to LBW, SGA, preterm birth, and possibly HBW.[13,39,66] Glomerular hypertrophy increases inversely with nephron number. Therefore, glomerulomegaly on biopsy may be a crude indicator of reduced nephron numbers.[59] Kidney weight/size correlates positively with glomerular number, although more strongly in infants than in adults.[67]

DIAGNOSIS

Developmental Associations with Blood Pressure

Systematic reviews have found associations between LBW,[68] preterm birth,[69] HBW (in children but not adults),[70] being born to mothers with diabetes (in males but not females)[71] or preeclampsia,[51] and subsequent risk of higher blood pressures and hypertension.[3] All of these observations strongly suggest a developmental programming impact on lifelong risk of hypertension.[3]

Among children who had been born with LBW or preterm, blood pressures may be higher but are generally still within the normal range. As these populations age, blood pressures reach hypertensive ranges.[68] Male gender, BMI, and rate of "catch-up" growth in early childhood appear to modify the relationship between blood pressure and birth circumstances in childhood and adolescence.[72] These associations between developmental exposures and blood pressure have been most frequently studied in Caucasian populations, although evidence from other ethnic groups is largely similar.[72] The association is, however, less consistent among children of African origin, suggesting that birth weight may be one of several factors contributing to the overall higher risk of hypertension in this population.[72,73] Recent data from a multiethnic cohort of adolescents participating in the NHANES study (aged 12–15 years) found an increased odds of hypertension (blood pressure ≥95th percentile for age, height, and sex) among those who had been LBW (OR 2.90, 95% CI 1.48–5.71) or very low birth weight (VLBW, <1500 g at birth: OR 5.23, 95% CI 1.11–24.74).[74] Large twin studies, which permit controlling for genetic contributors to

blood pressure, have corroborated the association between lower birth weights and higher blood pressures, suggesting an important role for the intrauterine environment in programming risk of hypertension.[75]

Nephron Number and Blood Pressure

Nephron numbers have been found to be lower in adults with essential hypertension compared with normotensive subjects.[13,66,76] Although the birth weights were unknown in these studies, the association supports a role for lower nephron number in development of hypertension. In a cohort of subjects where blood pressures and birth weights were available in the same individuals, a significant correlation was found between birth weight and nephron number, blood pressure and nephron number, and blood pressure and birth weight among Caucasian subjects.[77] These relationships did not reach significance among African-American subjects; however, hypertension was twice as prevalent among African Americans with nephron numbers below the mean, suggesting that developmental programming likely contributes to the risk of hypertension in this population.[77] The observation that salt sensitivity is more prevalent among subjects with lower birth weights (<3050 g vs. higher) is consistent with a likely role for nephron number in blood pressure regulation.[78]

Developmental Associations with Kidney Function

Nephron Number and CKD

One study has examined nephron numbers in subjects with known CKD. Among Japanese men with CKD, glomerular numbers were significantly lower than among matched men without CKD (mean nephron numbers 298,348 ± 116,526 in CKD vs. 666,140 ± 159,775 without CKD, $p < 0.001$).[66] Lower nephron numbers were associated with greater glomerular hypertrophy. The authors suggested these findings are unlikely to reflect loss of nephrons secondary to CKD, as the number of sclerosed glomeruli was similar in both groups.

Birth Weight, Preterm Birth, and Kidney Function

Individuals born with a severe reduction in nephron number, such as those with renal hypoplasia or unilateral renal agenesis, develop early and progressive proteinuria and renal dysfunction.[79] A frequent argument against the nephron number hypothesis, however, is that loss of a single kidney through kidney donation, although associated with higher risks of hypertension and proteinuria, has infrequently been associated with long-term kidney failure.[80] This risk has, however, recently been found to be higher than previously thought, especially in African Americans compared with Caucasians, and in overweight individuals, which may suggest a programming effect.[81] How many nephrons are enough to protect an individual from future CKD is not known and may depend on the degree of nephron deficit and the severity of the subsequent "hits," including the development of hypertension and obesity after being born small. Intriguingly, the timing of nephron loss may also be important. In experimental animals, uninephrectomy before nephrogenesis was completed, compared with uninephrectomy in adulthood, and was associated with later-life higher blood pressure and accelerated loss of kidney function.[82,83]

Glomerular Filtration Rate

As discussed above, because of compensatory glomerular hypertrophy, filtration surface area in kidneys with fewer nephrons is similar to that in kidneys with normal nephron numbers.[20] GFR at baseline would therefore be expected to be preserved. If kidneys with fewer nephrons are constantly hyperfiltering, however, they would have less functional reserve capacity in the face of superimposed injury or injury accruing over time, and GFRs would decline. Indeed, LBW and preterm birth are now recognized risk factors for reduced GFR.[3] Meta-analysis of five studies including data from over 27,000 subjects reported an overall odds ratio of 1.79 (95% CI, 1.31−2.45) for eGFR <60 mL/min/1.73 m^2 and/or eGFR 10th percentile for sex with LBW (Table 20.3).[84] The odds of a reduced GFR were nonsignificantly higher in males. A distinction between LBW resulting from growth restriction or preterm birth was not made in this analysis, and studies on very preterm (<32 weeks gestation) and VLBW (<1500 g birth weight) subjects were excluded. Preterm birth has, however, also been associated with lower renal function compared with subjects born at term.[10,85,86] Measured GFRs were lower in children aged 7 years who had been born preterm and experienced intrauterine growth restriction or growth restriction immediately postbirth, compared with those who maintained appropriate weights for their gestation age, suggesting an additional effect of growth restriction on longer-term kidney function.[87] Consistent with this, a trend toward reduced renal functional reserve capacity was observed in young adults born preterm with SGA, compared with preterm AGA and term with NBW.[88] Indeed, in the NHANES cohort described above, the odds of a reduced GFR was higher among those born with VLBW (OR 2.49, 95% CI 1.20−5.18) than with LBW (OR 1.49, 95% CI 1.06−2.10), suggesting a compounding effect of growth restriction (Table 20.3).[74] This study estimated a population attributable fraction among adolescents with systolic blood pressures ≥95th percentile and/or eGFR <90 mL/min/1.73 m^2 of 1 in 13 for LBW or 1 in

TABLE 20.3 Associations Between Birth Weight and Preterm Birth and Later Risk of CKD[§]

Age	Subject Number	Study Design	Renal Outcome	Programming Risk Marker	Risk Ration	Ref.

5 for VLBW.[74] Twin studies have also demonstrated a consistent association between lower birth weight and lower creatinine clearances, highlighting the impact of feto-placental factors in renal programming.[89] Renal functional reserve capacity was also reduced in young adults who were born in diabetic pregnancies compared with those with diabetic fathers, again pointing to an environmental impact during gestation rather than genetic factors.[90]

Reduced renal function may, however, not only reflect reduced glomerular filtration but may also reflect abnormal renal tubular function. Whether tubular function may be independently programmed or result from congenital obstruction or perinatal AKI in individuals born with LBW or preterm remains to be elucidated.[54,85]

Proteinuria

If kidneys with low nephron numbers do indeed hyperfilter at baseline, over time this may manifest as proteinuria. Across eight studies and 6758 individuals, a meta-analysis reported an odds ratio of 1.81 (95% CI, 1.19−2.77) for albuminuria with LBW (Table 20.3).[84] The prevalence of albuminuria was also increased among 4-year-old children with normal height who had been born preterm.[91] Albuminuria was not significantly increased among preterm children who remained short, suggesting exacerbation of risk of albuminuria with catch-up growth in height. Among 19-year olds who had been preterm with VLBW, albuminuria was highest among those who had been SGA compared with AGA, again suggesting an additional programming effect of growth restriction.[86] LBW and VLBW, however, were not associated with increased albuminuria in the NHANES cohort despite reduced GFRs, which may be a true observation or may reflect potential inaccuracy introduced by a single-spot measurement for albuminuria.[74]

Among Pima Indians, a U-shaped relationship was observed between birth weight and proteinuria, with the risk being elevated at birth weights below 2.5 kg or over 4.5 kg. Proteinuria was most strongly associated with having been exposed to diabetes during gestation.[92]

Developmental Associations with CKD

Chronic Kidney Disease

Meta-analysis of 18 studies including over 2 million subjects reported an odds ratio for a composite endpoint of CKD (albuminuria, decreased GFR, or ESRD) of 1.73 (95% CI, 1.44−2.08) with LBW (Table 20.3).[84] A recent Finnish study examined this association across the life course (Table 20.3).[18] Among men, the hazard ratio for CKD was found to decrease by 0.73 (95% CI, 0.64−0.83) for every increase in standard deviation of birth weight and by 0.81 (95% CI, 0.7−0.93) for birth length. This increased risk in men was seen at all ages but was higher among those under 60 years of age and for hypertensive CKD (HR 0.57, 95% CI 0.40−0.80).[18] Among women, the risk of CKD was significantly higher if they had been born before 34 weeks of gestation (HR3 3.2, 95% CI 1.4−7.4).[18]

Among children born preterm, case series have shown evidence of secondary focal and segmental glomerulosclerosis (FSGS) and glomerulomegaly in kidney biopsies performed for proteinuria.[93] This observation suggests a programmed predisposition to hyperfiltration and glomerulosclerosis. LBW and preterm birth are associated with CKD in children, with a population attributable fraction around 20% (Table 20.3).[44,94] Exposure to maternal diabetes, overweight, and obesity is also associated with a higher risk of childhood CKD, including dysplasia/aplasia and congenital obstruction (Table 20.3).[44]

Preterm birth is a major risk factor for neonatal AKI.[3,10] The long-term impact of this on pediatric and adult CKD is not yet known.

It is unlikely that developmental alterations in kidney development alone are enough to cause CKD, but a smaller kidney, which may be hyperfiltering at baseline, may be more susceptible to superimposed kidney stresses or injury, and lose function more quickly (Figure 20.1). Indeed, several studies have reported associations of greater severity or more rapid progression of a variety of primary kidney disorders in individuals who had LBW.[3]

Conceivably, hyperfiltration injury would also be exacerbated in the face of increased BMI. Consistent with this, among children born preterm who had experienced neonatal AKI or who had proteinuric kidney disease, obesity and excessive weight gain were associated with more rapid loss of kidney function.[8,95] A recent study of young Australian Aboriginal adults also illustrates the likelihood of the "multihit" hypothesis in programmed CKD. Albuminuria levels were highest among individuals who simultaneously had been of LBW, had poststreptococcal glomerulonephritis, and had higher BMIs.[96]

End-Stage Renal Disease

In a meta-analysis of four studies reporting associations of birth weight with ESRD, the odds of ESRD with LBW were found to be 1.58 (95% CI, 1.33−1.88) (Table 20.3).[84] A subsequent Norwegian registry study, restricted to subjects under 42 years, reported a hazard ratio for ESRD of 1.63 (95% CI 1.29−2.06) for LBW (defined as birth weight <10th percentile) (2.87 kg for males, 2.8 kg for females) and of 2.25 (95% CI 1.59−3.19) for LBW defined as < 2.5 kg (Table 20.3).[97] Overall, the risk of ESRD was increased in all those

born SGA (HR 1.67, 95% CI 1.30−2.07), but not in those born preterm (HR 1.36, 95% CI 0.91−1.99). When both preterm birth and SGA coexisted, however, the risk was markedly increased (HR 4.03, 95% CI 2.08−7.80).[97] When the analysis was restricted to subjects between 18 and 42 years, in an attempt to control for potential confounding from congenital causes of early ESRD, SGA remained the only significant association with ESRD in both term (HR 1.53, 95% CI 1.15−2.03) and preterm (HR 4.2, 95% CI 1.79−9.03) individuals.[97] These findings suggest that growth restriction (SGA) may be the most important risk marker for renal programming.

The incidence rate ratio of developing ESRD after exposure to diabetes during gestation was found to be 4.12 (95% CI 1.54−11.02) compared with nonexposure in a cohort of Pima Indians younger than 45 years.[98] Birth weights were not reported in this study, but this effect appeared to be largely driven by earlier onset of diabetes in these subjects compared with those whose mothers had not been diabetic during pregnancy, demonstrating that renal disease risk can be indirectly impacted through developmental programming of related disorders, in this case diabetes. In a multiracial US dialysis cohort, HBW was associated with a significantly increased risk of ESRD among those with diabetes (OR 2.4, 95% CI 1.3−4.2).[99] HBW may have resulted from exposure to maternal diabetes.

TREATMENT

Optimization of Maternal Health and Nutrition

Given the associations between fetal growth restriction, preterm birth, maternal diabetes and obesity, and preeclampsia with developmental programming of hypertension and kidney disease, optimization of maternal health and maternal and fetal nutrition during pregnancy may have a long-term impact on offspring blood pressure and kidney function.[8] Potential experimental strategies to rescue nephron number are reviewed in reference 16.

In humans, routine micronutrient supplementation, as a means to improve fetal growth and early childhood outcomes, has been introduced in many countries. Overall, from a comprehensive global review, iron and folate supplementation reduced the incidence of LBW by 19%, multiple micronutrient supplements reduced LBW by 11−13%, and balanced energy supplementation reduced SGA births by 34%.[100] Vitamin A supplementation did not change birth weights.[100] In terms of impact on blood pressure and kidney function, as recently reviewed by Lee and colleagues[101] from 10 studies, blood pressure and microalbuminuria at age 10 years were not affected by maternal vitamin A supplementation. Maternal supplementation with folate was associated with a reduction in microalbuminuria in 6- to 8-year-old Nepalese children, higher maternal blood folate levels were associated with larger kidney size in Dutch children, and GFR in 4- to year-old children in Bangladesh was higher among those whose mothers had received higher dose iron supplementation.[101] Given the relatively young ages and the diverse settings of these studies, firm conclusions regarding supplementation strategies cannot yet be drawn.

Optimization of maternal health prior to and during pregnancy through optimizing nutrition, socioeconomic support, education, ensuring access to health care, planned pregnancy, and attendance at antenatal clinic are all associated with improved pregnancy outcomes.[3] Treatment or prophylaxis for infections such as syphilis, malaria, and lower genital infections in pregnant women are associated with reductions in SGA and preterm births.[102] Management of maternal diabetes and obesity before and during pregnancy can improve outcomes.[3,5] Prophylaxis with aspirin and calcium can prevent preeclampsia.[3]

Intergenerational Effects of Programming

The risk of gestational diabetes and/or preeclampsia is increased in women who themselves had been preterm, and, in turn, preeclampsia is a major risk factor for preterm delivery and fetal growth restriction.[3,103] The risk of gestational diabetes is increased in women who themselves had a low or a high birth weight.[104] Having herself been born from a preeclamptic pregnancy increases a woman's risk for preeclampsia.[105] All these factors contribute to pregnancy outcomes and affect the infant's subsequent risks for the same outcomes.[3] Careful identification of these risks in such women may permit attenuation of the risk and reduction of risk in subsequent generations.[3,16]

Optimization of Infant and Child Health to Preserve Kidney Function

Documentation of birth weight and gestational age is important to identify children who may have experienced developmental programming. Careful avoidance of nephrotoxins and optimization of growth and nutrition in preterm infants may reduce AKI and permit nephrogenesis to proceed.[3] Close attention should be paid to timely management of congenital obstruction.[54] In children born small, avoidance of rapid catch-up growth and overweight/obesity through nutrition and physical exercise can reduce the long-term risks of development of hypertension and CKD.[3] In children with FSGS and proteinuria, response to inhibitors of the renin−angiotensin system has been favorable.[93]

CONCLUSIONS

Hypertension and CKD are common in disadvantaged communities, which are often the same communities where maternal health is suboptimal and risk factors for poor pregnancy outcomes are highly prevalent.[2,3,16] Diverse environmental exposures during gestation impact fetal growth and nephrogenesis, which in turn affect the risk of hypertension and kidney disease throughout the life course.[3] Being SGA is the strongest risk predictor for renal programming. Worldwide millions of babies are born each year who may have experienced developmental programming. Infants and mothers of infants who are growth restricted, preterm, of HBW, or who experienced preeclampsia or gestational diabetes require lifelong follow-up. Their programmed risk promises to be mitigated by adherence to healthy lifestyles, and early diagnosis and treatment of high blood pressure, diabetes, overweight, or kidney dysfunction. Prevention of developmental programming is the most proximal form of primary prevention. A holistic, multisectoral approach to optimize health of women and girls from birth throughout childbearing and beyond is therefore required to improve their socioeconomic and physical circumstances and improve pregnancy outcomes globally.

QUESTIONS AND ANSWERS

Question 1

Which of the following are known factors which impact nephron number?

A. Growth restriction
B. Preterm birth
C. LBW
D. HBW
E. Male gender

Answer: A, B, and E

Nephron number is proportional to gestational age, and babies born preterm have fewer nephrons than babies born at term. Growth restriction in preterm infants was associated with lower nephron numbers and therefore impacts nephrogenesis. Females tend to have fewer nephrons than males. Answers C and D are incorrect, because birth weight *per se* does not impact nephrogenesis, but is rather a marker for developmental programming.

Question 2

As nephron number cannot be measured *in vivo*, which of the following are clinical surrogates that may serve to identify an individual who may have a lower nephron number?

A. Shorter adult height
B. HBW
C. Small glomeruli on kidney biopsy
D. Being a twin
E. Being born to a teenage mother

Answer: A, D, and E

It has been estimated that nephron numbers increase by around 28,000 nephrons per cm adult height. Being born in a twin pregnancy or to a teenage mother increases the likelihood of preeclampsia, preterm birth, and lower birth weight, and therefore lower nephron numbers. HBW is associated with higher nephron numbers. Kidneys with fewer nephrons have glomerular hypertrophy which most likely occurs as a compensatory response to preserve GFR.

Question 3

Programmed hypertension is associated with which of the following?

A. Salt sensitivity
B. Maternal preeclampsia
C. Maternal diabetes during pregnancy
D. HBW
E. Preterm birth

Answer: All of the above

Salt sensitivity has been found to increase with decreasing birth weight below 3050 g. From multiple meta-analyses, it has emerged that blood pressures are higher in children and adolescents born in preeclamptic pregnancies; male children of mothers who had diabetes during pregnancy; children who had a HBW; and individuals born preterm. Exposure to maternal diabetes was not associated with higher blood pressure in females and HBW was not associated with higher blood pressure in adulthood.

Question 4

Factors which may be implicated in developmental programming of hypertension include which of the following?

A. Altered activity of the RAAS
B. Reduced sympathetic tone
C. Catch-up growth
D. Low current BMI
E. Reduced renal tubular sodium transporter activity

Answer: A and C

Modulation of the activity of the RAAS has been shown in many programming models, although magnitude and specificity of changes vary with time and model studied. In adult animals, however, the RAAS tends to be upregulated. Catch-up growth and an increased BMI have been associated with higher blood pressures in children born small or preterm. Sympathetic tone and activity of renal sodium transporters have been shown to be increased by developmental programming and therefore may contribute to hypertension.

Question 5

A 29-year-old woman who was born preterm is planning a pregnancy and comes to you for a consultation to discuss potential risks for her and her child should she get pregnant. Which of the following factors are important to ascertain?

A. Her gestational age
B. Whether she had AKI postnatally
C. Her current BMI
D. Precipitant of her own preterm birth
E. Smoking history

Answer: All of the above

Women who were born preterm have a higher risk of having a preterm delivery as well as preeclampsia and gestational diabetes, and this is proportional to the degree of prematurity. AKI is common in preterm

infants. If the patient had experienced AKI, it is possible she may have some subtle residual renal dysfunction, which may affect her pregnancy outcomes. Individuals who were born preterm and become overweight or obese have a higher risk of hypertension and renal dysfunction. Overweight and obesity are risk factors for poorer pregnancy outcomes, including LBW, HBW, preterm birth, preeclampsia, and gestational diabetes. Smoking increases the risk of preterm birth, which declines on cessation of smoking.

Question 6

The mother of a 9-month-old boy who had been born at 36 weeks with a birth weight on the eighth percentile of normal (SGA) brings him in for a routine vaccination. What will you recommend to his mother to preserve the child's kidney health?

A. Start an ACE inhibitor now
B. Ensure that he catches up in weight to his peers
C. Encourage a balanced healthy diet
D. Suggest yearly checkups for microalbuminuria and blood pressure
E. Educate her about a healthy lifestyle for the whole family

Answer: C, D, and E

The child has a high risk of developing kidney dysfunction having been both preterm and SGA. Maintaining a healthy weight and BMI through healthy diet and lifestyle are likely the best strategies to mitigate against programmed hypertension and kidney disease, by reducing the avoidable second "hits" such as obesity, which may be a consequence of rapid catch-up growth. The child does require life-long follow up, but the frequency and intensity of such care has not been established. It is reasonable to monitor blood pressures, and once the child is old enough, to consider screening for microalbuminuria at least at well-baby and well-child/vaccination visits. If proteinuria becomes evident, it may be beneficial to consider initiation of an ACEI. It is important to emphasize the preventive nature of such activities, and that they do not mean the child is sick or will become sick.

CHAPTER

21

Pathophysiology of Hypertension in Chronic Kidney Disease

Raymond R. Townsend

Department of Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States

Abstract

Elevated blood pressure is a ubiquitous finding in patients with chronic kidney diseases. The kidney, recognized as both a villain and a victim when it comes to high blood pressure, has a significant regulatory role in many aspects of blood pressure. When kidney function is impaired, the ability of the kidney to maintain balance in the internal milieu of electrolytes, hormones, adrenergic activity, and endothelial function, particularly in the presence of comorbidities such as diabetes and prevalent cardiovascular disease, contributes greatly to hypertension. In this chapter the reader will be presented with the epidemiology of hypertension in chronic kidney disease, a summary of what we know about the dysregulation of traditional factors in blood pressure maintenance, and information on the emerging roles of inflammation, immune system influence, the gut microbiome, and arterial stiffness, which should aid in the evaluation and management of elevated blood pressure.

SCOPE OF THE PROBLEM AND PUBLIC HEALTH IMPLICATIONS

The prevalence of chronic kidney disease (CKD) continues to increase among certain groups, such as African Americans and Hispanics, while it appears to have stabilized among Caucasians, with an estimated prevalence of 13–14% adults in the US.[1,2] Hypertension using older definitions (usually >140/>90 mm Hg) is a common occurrence in CKD, with more than 80% of patients with CKD having coexistent hypertension. More severe stages of CKD are associated with more severe hypertension,[3] that is usually more difficult to control and requires a greater number of medications to reach target blood pressure (BP) goals.[4] This prevalence may be even higher as the newer ACC/AHA guidelines lowered the definition to 130/80 mm Hg.[5] Patients with more severe hypertension are also more likely to develop CKD.[6] Based on data from the USRDS, it is estimated that hypertension occurs in 23.3% of individuals without CKD and 35.8% of stage 1, 48.1% of stage 2, 59.9% of stage 3, and 84.1% of stages 4–5 CKD patients. Most patients with CKD require multiple antihypertensive agents to control BP.[7] Nonadherence to antihypertensive medications does not appear to be more common in CKD patients compared with the general population.[7]

Rates of awareness and control of hypertension have improved in the general population and appear to be improving in patients with CKD. Recent studies have shown that both awareness and control of hypertension in the general population have improved from 69% to 80% and 27% to 50%, respectively, compared with earlier decades.[8] Reports from CKD patients enrolled in prospective observational studies have shown similar improvements in the rates of awareness and BP control in the CKD population.[4,7] CKD patients have also been shown to be more likely to receive adequate treatment for hypertension when compared with prior decades.[9,10]

Ambulatory blood pressure monitoring (ABPM) provides superior BP measurements compared with office BP measurements in CKD patients. ABPM measurements are often abnormal in CKD, with CKD patients frequently showing an altered circadian rhythm with an increased rate of nondipping and reverse dipping.[11] The prevalence of nondipping and reverse dipping increases progressively as stage of CKD progresses. Masked hypertension is common in CKD, occurring in 28% of participants enrolled in the Chronic Renal Insufficiency Cohort (CRIC) Study.[12] In the African American Study of Kidney (AASK) Disease Cohort Study, of the 61% of participants with controlled clinic BP, 70% had masked hypertension.[13] Target organ damage (proteinuria and left ventricular hypertrophy) was more

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00021-8

common in those with elevated night time BP, masked hypertension, or sustained hypertension.[12,13] Masked hypertension, particularly nocturnal BP control, may account for the disappointing results from the AASK study, where progression of kidney disease occurred despite excellent in-office BP control.[14]

The likelihood of hypertension in CKD patients is also influenced by the type of underlying renal disease. Tubulointerstitial diseases typically have a lower prevalence of elevated BP compared with glomerular diseases.[15] Hypertension was reported in one study to be present in 93% of patients with renal artery stenosis, 87% of patients with diabetic nephropathy (87%), and 74% of patients with polycystic kidney disease.[16]

African Americans have a higher incidence of hypertension and CKD than Caucasians and are at greater risk of developing progressive CKD and end-stage renal disease (ESRD) than any other racial group in the US.[17] African Americans develop cardiovascular disease approximately 5 years earlier and have higher mortality rates compared with Caucasians of similar ages.[18,19] This is largely due to the increased prevalence and severity of both hypertension and CKD. African Americans with risk variants of the APOL1 gene that encodes apolipoprotein L1 have been linked to higher risk of hypertension-attributable kidney disease.[20,21]

Treatment of hypertension in the patient with CKD can often be challenging, as CKD patients often have severe hypertension requiring the use of multiple medications to achieve target BP goals. Target BP goals have traditionally been set lower in patients with CKD than in the general population. The goal BP for patients with CKD is currently recommended to be <130/80 mm Hg.[5]

Hypertension is also very common among patients treated with either peritoneal dialysis or hemodialysis, as well as in patients who have had a renal transplant. Because of fluid accumulation between hemodialysis sessions, the definition of hypertension and goal BP in this population is difficult to define, as there are large differences between pre-, post-, and interdialytic BPs.[22] It has been suggested that a predialysis BP of 150/85 mm Hg be the target BP in hemodialysis patients, as data have shown that with a predialysis BP greater than 150/85 mm Hg, there is an 80% sensitivity in predicting elevated interdialytic ambulatory BP.[23] Based on this definition, one study showed that 86% of hemodialysis patients had hypertension, of whom only 30% had adequate control.[24] The prevalence of hypertension in peritoneal dialysis patients is similar, and greater than 70% of renal transplant recipients have hypertension.[25,26] There is controversy surrounding the benefit of BP control in dialysis patients. Similar to the general population, dialysis patients with higher BPs have increased cardiovascular mortality, but there is also an increased mortality of dialysis patients with lower BPs, presumed to be due to poor underlying cardiac function. In the Frequent Hemodialysis Network Daily Trial, patients receiving more frequent dialysis had improved BP control and improved outcomes with respect to LV mass and CV death.[27] In renal transplant recipients, posttransplant hypertension is an independent risk factor for graft failure and death. The risk is improved by adequate BP control.[28,29]

PATHOPHYSIOLOGY OF HYPERTENSION IN CHRONIC KIDNEY DISEASE

The pathogenesis of hypertension in CKD is complex. There is a remarkable breadth of factors implicated in BP dysregulation in CKD. A compilation of factors discussed in this chapter that contribute to hypertension in CKD is shown in Figure 21.1.

Hypertension in CKD patients results from four basic interrelated mechanisms by which BP is regulated: (1) sodium and fluid retention, (2) hormonal factors such as the renin–angiotensin–aldosterone axis, (3) the activity of the sympathetic nervous system, and (4) endothelial autoregulation. These four basic servos for BP control are shown in Figure 21.2. The factors affecting these servos are often modifiable, and treatment of hypertension in CKD takes this into account when lifestyle measures and medications are selected. Each of these mechanisms are discussed separately below.

SODIUM AND FLUID RETENTION

The maintenance of sodium and fluid homeostasis by the kidneys has long been implicated as the key regulator of BP. A defect in kidney function is a common element in the development of hypertension.[30] Intact kidneys are very sensitive to BP changes, which, in the range of 1–3 mm Hg in mean arterial pressure, result in prompt changes in sodium and fluid excretion or retention. In normal kidneys, this regulatory mechanism accurately adjusts sodium and fluid balance across a wide range of BP. The rapid response of the kidneys in handling sodium and fluid are the results of changes in tubular sodium and fluid reabsorption, rather than total renal blood flow or glomerular filtration rate (GFR). In CKD, however, the tubular reabsorption of sodium and fluid is often not suppressed adequately, resulting in inappropriate sodium and fluid retention and the development of elevated BP.

The kidneys are very effective in handling of sodium and fluid balance by excretion during the periods of surplus and retention during the periods of deficit. In normal kidneys, variations in dietary sodium intake usually result in less than 10% fluctuation in

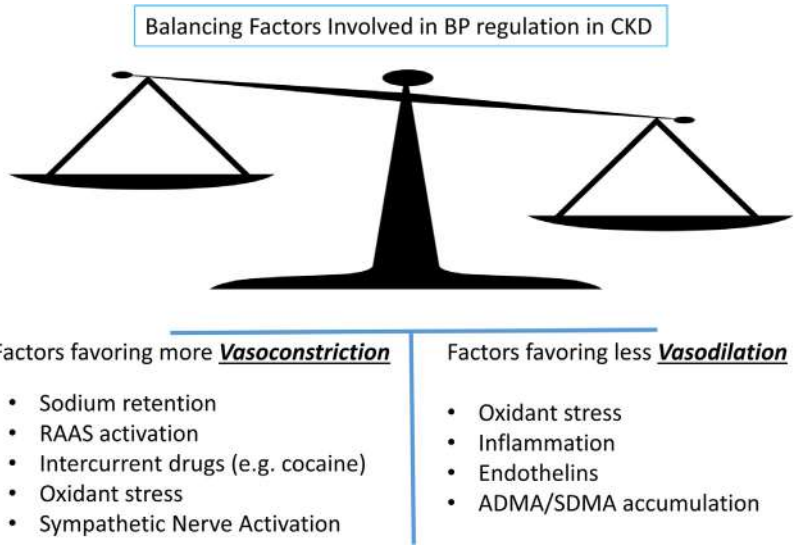

FIGURE 21.1 The balance of factors covered in the text and their effects to promote vasoconstriction, impair vasodilation, or act through both mechanisms. *ADMA*, asymmetric dimethylarginine; *BP*, blood pressure; *CKD*, chronic kidney disease; *RAAS*, renin–angiotensin–aldosterone system; *SDMA*, symmetric dimethylarginine.

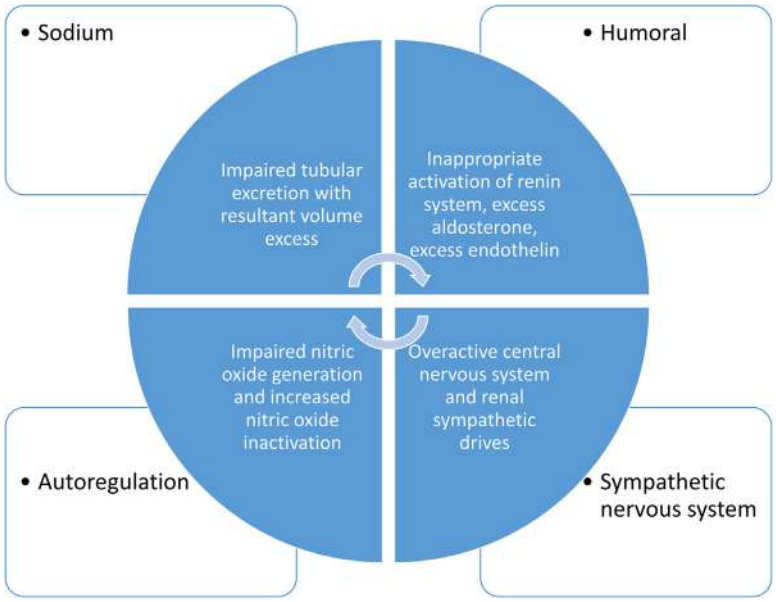

FIGURE 21.2 The major domains of blood pressure regulation in the outer squares with specific contributors to the pathogenesis of hypertension in chronic kidney disease in the areas within the circles.

extracellular fluid and intravascular volume, and only subtle changes in BP. In CKD, however, BP becomes more responsive to variations in dietary sodium intake and often increases significantly with increasing dietary sodium intake. This "salt-sensitive" component of BP increases progressively as the GFR declines.

Sodium retention and volume expansion are common concomitants in the hypertension of CKD. The ability to eliminate sodium and fluid decreases progressively as kidney function declines. Heart failure in CKD further challenges the maintenance of volume status. Sodium intake increases BP to a great extent as kidney function declines, and to an even greater extent than simple volume expansion alone would predict at the lowest levels of kidney function.[31] This finding suggests that the effect of sodium intake on BP is enhanced by the CKD milieu.

Independent of the effect of increasing BP through effects on volume, high sodium intake also results in

increased arterial stiffness, reductions in vascular nitric oxide (NO), and promotion of inflammatory processes.[32] Moreover, sodium intake is well known to abet the prohypertensive effects of angiotensin II[33] and norepinephrine.[34]

RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM ACTIVATION

The renin–angiotensin–aldosterone system (RAAS) is recognized as an important humoral regulator of BP. Renin activity and angiotensin II production are regulated closely in response to changes in dietary sodium intake. Increased sodium intake leads to suppressed renin activity and reduced angiotensin II production, resulting in a prompt and effective elimination of sodium by the kidneys to maintain normal BP. Inappropriate activation of RAAS has been implicated in the hypertension associated with CKD.[35] The presence of volume expansion in CKD further potentiates the vasoactive effects of RAAS activation. Some of the increase in RAAS activation appears to be the result of increased sympathetic input into the juxtaglomerular apparatus through the β_1-adrenoreceptor.[33]

Increased RAAS activation in CKD is supported by several lines of evidence. First, CKD patients often do not have normal suppression of plasma renin activity given their usual state of sodium retention and volume expansion. Secondly, CKD patients often have a good antihypertensive response to both angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. In addition, bilateral nephrectomy results in BP normalization in many of these patients. Thirdly, a direct relationship between plasma renin activity and BP is often seen in CKD. Aside from the hemodynamic consequences of renin activation, the excess angiotensin II produced likely contributes to progressive renal function loss and other target organ damage, through its stimulation of aldosterone release, potentiation of the effects of various growth factors, and in particular its stimulating effects on the fibrogenesis-promoting cytokine transforming growth factor-β.[36,37]

A component related to renin system activation is aldosterone. A large increase in aldosterone occurs in the five-sixth (5/6) nephrectomy rat model.[38] Aldosterone contributes to BP in CKD through its effects to stimulate sodium reabsorption, which occur both through epithelial sodium transport channels and through upregulation of sodium absorption in the sodium-chloride channels of the distal tubule.[39] Other actions of aldosterone that contribute to increased BP in CKD include inhibition of NO action, hyperfiltration and proteinuria, inflammation and hypertrophy at the glomerular level, and podocyte injury related to reactive oxygen species generated by aldosterone.[40]

SYMPATHETIC NERVOUS SYSTEM ACTIVATION

The neural control of the kidneys is mainly sympathetic,[41] and the sympathetic nervous system appears to be overactive in CKD.[42] As with the RAAS, the kidneys are both the source and target of neurogenic activity.[43] Activation of the renal efferent sympathetic nerves, which carry central sympathetic input into kidneys, results in increased renin secretion and tubular sodium reabsorption. There is an extensive network of sensory nerve fibers in the kidneys, and much laboratory data indicate that renal sympathetic activation plays a role in hypertension in CKD through direct vascular constriction and interactions with the RAAS and salt handling. The recent results of impressive BP reduction in drug-resistant hypertension with renal nerve ablation support the importance of sympathetic system in hypertension.[44–47] In addition, pilot studies showing similarly impressive BP lowering with renal sympathetic denervation in patients with CKD[48] and ESRD[49] further support the important role of sympathetic overactivity in hypertension associated with CKD.

Sympathetic activation in CKD is manifested in several ways. Direct measures of muscle sympathetic activity through microneurography in dialysis patients shows increased neuronal firing consistent with activation.[50] Bilateral nephrectomy dramatically reduces both BP in drug-resistant hypertensives on dialysis and muscle sympathetic nerve activity.[50] A relatively new aspect in catecholamine metabolism has emerged from the work of Desir and colleagues who have isolated an enzyme, renalase, from the kidney which degrades catecholamines. Reduced kidney function is associated with less renalase activity, reducing catecholamine clearance and potentially allowing more effect because of greater catecholamine exposure.[51]

Another sympathetic mechanism involved in BP control is an increase in renin secretion, induced by renal sympathetic activity mediated by β_1-adrenoreceptors, which can be offset by beta-blocking drugs. Several studies attest to the efficacy of beta-blocker therapy in hypertensive patients with CKD.[52,53]

Although increases in tubular sodium reabsorption and renal vascular resistance are mediated by α_1-adrenoreceptors and can be offset in the short term by alpha-blocking drugs, the exacerbation of heart failure with longer-term use of these agents suggests that the interaction of α adrenoreceptors in the kidney is complex.[54] As a result, enthusiasm for use of α_1-blocking drugs has relegated their use largely to men with prostate hypertrophy. Centrally acting antihypertensive agents such as clonidine reduce renal sympathetic activity and renin activity.

ENDOTHELIAL FUNCTION

A great deal of effort has gone into understanding the role of disordered endothelial function in the pathogenesis of atherosclerosis and hypertension in the setting of impaired kidney function. The endothelium is a large organ, having both an antithrombotic function and a significant role in regulating vascular smooth muscle tone through a series of locally acting mediators. One of the most potent vasoactive mediators generated by the endothelium is NO. Asymmetric dimethylarginine, an inhibitor of NO production and availability, is elevated in CKD and ESRD and is an independent predictor of death in ESRD patients.[55] NO activity is impaired by oxidative stress, which is commonly found in CKD.[56] Oxidative stress denatures NO into peroxynitrite ($ONOO^-$) and dissociates tetrahydrobiopterin (BH4), a necessary cofactor for NO action, from NO. The intracellular substrate for NO generation is the amino acid L-arginine. In CKD, urea competes with L-arginine for uptake into endothelial cells creating a relative L-arginine deficiency.[56] In addition, asymmetric dimethylarginine (ADMA) and symmetric dimethylarginine (SDMA) concentrations are elevated in CKD, partly due to diminished degradation pathways (such as DDAH which metabolizes ADMA) and partly through decreased excretion through the urine. ADMA competes with NOS inhibiting the generation of NO, and SDMA inhibits endothelial NO production by limiting the availability of its main substrate L-arginine, as well as stimulating proinflammatory mediators such as IL-6 and TNF-alpha, which participate in increasing BP through inflammatory pathways that damage vessels.[57]

Vascular endothelial dysfunction is common in CKD.[56] One of the most important vascular endothelial functions is the ability to produce local vasodilator NO. Several pathways have been proposed to explain the endothelial dysfunction linked with the impaired NO production, including oxidative stress, L-arginine deficiency, and formation of ADMA and N-monomethylarginine.

Oxidative stress is a particularly potent means to impair endothelial function and potentiate hypertension. Cellular oxidation generates several species that are important signaling molecules. One potent stimulus to reactive oxygen species generation is angiotensin II. This is particularly evident when angiotensin II is infused in an animal model that is deficient in antioxidants. There is an increase in BP and urinary protein excretion, and kidney function declines substantially, more so than in other models, such as the DOCA-salt form of hypertension.[58] Other sources of oxidant stress include xanthine oxidase and NADPH oxidase. Testimony to the importance of xanthine oxidase is the reduction in the rate of kidney function loss when allopurinol is given to patients with CKD,[59] and the reduction in BP that occurs when adolescents with hyperuricemia are treated with allopurinol.[60]

Several other systems are also active to a pathologic degree in some patients with CKD. Among those amenable to potential drug treatment are endothelin[61] and aldosterone.[62] Endothelin levels are elevated in many CKD patients with uncontrolled BP, which may respond to an endothelin antagonist,[61,63] though this class of drugs is technically only FDA-approved for pulmonary hypertension.

DRUGS AND OTHER EXPOSURES

The anemia accompanying CKD is often treated by erythropoiesis-stimulating agents, which are known to increase BP. In addition, lead, nonsteroidal antiinflammatory drugs (NSAIDs), calcineurin inhibitors, and the use of illicit compounds such as cocaine are also potential contributors to increases in BP in CKD and ESRD patients.[64]

There is some progress on the role of genetic factors in BP regulation. There are several infrequent genotypes in which the link between the kidneys and hypertension has been described, mostly in the realm of sodium absorption, shedding light on important intrarenal BP regulation pathways.[65] Aside from diagnostic value, little new antihypertensive drug development has resulted from the pursuit of genetic studies.

NOVEL/NONTRADITIONAL MECHANISMS

Inflammation and the Immune System

Inflammation and immunity are gaining greater recognition as factors in the increased BP noted in several situations, including CKD. The role of T-regulatory cells in hypertension, and in CKD-associated hypertension, remains an active area of investigation. The various cells involved in the immune system generate reactive oxygen species, such as superoxides and hydrogen peroxides, which although intended to kill pathogens may lead to endothelial dysfunction through oxidant stress. Persistent inflammation results in a decrease in available NO, which results in impaired vascular relaxation. Both effector T cells, which participate in innate immunity, and regulatory T lymphocytes, which participate in adaptive immunity, contribute to vasoconstriction in hypertension through their participation in inflammation.[66] This is mediated in part through cytokine generation, adding another dimension to the impairment of endothelial function.[67]

Gut Microbiota

A growing body of evidence links metabolites and small peptides derived from gut microorganisms (bacterial, fungal, and viral) to changes in BP and uremic symptoms in CKD. Although the effects of the gut microbiome on BP, and uremic symptoms, appear to be mediated through pathways linked to metabolism, and pathways that intersect with immunity/inflammation, little is understood about specific mechanisms involved in BP effects from the microbiome.[68]

Arterial Stiffness

Several large cohorts have shown that, in addition to BP itself, arterial stiffness and increased pulse wave reflection are prominent in CKD and ESRD and are independent risks for death, CKD progression, and cardiovascular endpoints in CKD.[69–73] In the longitudinal follow-up of arterial stiffness measurements in the CRIC Study, increasing aortic stiffness, as estimated by carotid-to-femoral pulse wave velocity, was independently associated with death and the development of ESRD.[74] Several longitudinal studies have observed that increased arterial stiffness precedes a diagnosis of essential hypertension.[75,76] Given the frequent comorbidities present with a diagnosis of CKD, it is likely that underlying arterial stiffness plays an independent role in the increased BP noted with CKD.

CONCLUSIONS

Hypertension is highly prevalent in CKD and increases progressively as kidney function declines. The pathogenesis of hypertension in CKD is complex and multifactorial. Sodium/fluid retention and salt sensitivity, sympathetic dysfunction, and abnormalities in endothelial function are prominent features which contribute to hypertension, and which in turn potentiate the hypertensive effects of other factors.

There remain unanswered questions in the pathogenesis of hypertension in CKD. Large genetic studies may add more light on precise patient-related factors related to the development of hypertension, especially in CKD.[77] Immunity/inflammation, the microbiome, and arterial stiffness are newer areas of investigation to develop further our understanding of the pathogenesis of hypertension in the complex milieu of CKD.

QUESTIONS AND ANSWERS

Question 1

Hypertension in patients with underlying CKD is more likely to be associated with all of the following except?

A. More severe hypertension than matched controls without CKD
B. Difficulty in control
C. Requirement for more BP medications to achieve control of hypertension
D. Poorer compliance with BP medications than matched controls without CKD
E. Increased risk of cardiovascular disease

Answer: D

Hypertension in CKD is more severe, more difficult to control, requires more medications, and is associated with increased CVD than patients with hypertension without preexisting CKD. Although most CKD patients require multiple antihypertensive agents to control BP, nonadherence does not appear to be more common in CKD patients compared with the general population.

Question 2

A 55-year-old man with stage 3 CKD, hypertension, and gout presents for a routine office visit. He says when he checks his BP at home, it is usually around 150/90−95 mm Hg. He has no other complaints. He takes lisinopril 20 mg daily, amlodipine 5 mg daily, and hydrochlorothiazide 25 mg daily. On examination, his BP is 132/84 mm Hg and 136/82 mm Hg in the office. The rest of his physical examination is benign. His laboratory examination is stable, S[Cr] is 1.6 mg/dL. The next step in his management would be?

A. Increase lisinopril to 40 mg daily
B. No change to his management
C. Schedule a 24-hour ambulatory BP monitor
D. Increase amlodipine to 10 mg daily
E. Add a fourth BP agent to his current regimen

Answer: C

Masked hypertension is defined as patients who have normal office BP readings but elevated BP readings on ABPM or home BP. Masked hypertension is more common in CKD and has been shown to be present in studies using ABPM in this population. It is important to identify masked hypertension so the physician can appropriately treat BP to the desired goal. In the AASK Disease Cohort Study, of the 61% of participants with controlled clinic BP, 70% had masked hypertension. This is thought to be the reason why these patients had progressive CKD despite good office BP control.

Question 3

All of the following dugs contribute to increased hypertension in CKD except?

A. Erythropoietin and other erythropoietic agents
B. NSAIDs
C. Use of illicit substances such as cocaine
D. Acetaminophen-containing agents
E. Calcineurin inhibitors

Answer: D

Many drugs contribute to worsening hypertension in CKD patients, including erythropoietin-stimulating agents, NSAIDS, calcineurin inhibitors, and cold preparations containing pseudoephedrine type substances. Some migraine preparations and use of illicit drugs such as cocaine also may contribute to or exacerbate hypertension. Acetaminophen does not worsen hypertension.

Question 4

A 54-year-old woman has an ambulatory BP monitor performed for suspected white coat hypertension. Which of the following is not typically associated with CKD?

A. Masked hypertension
B. White coat hypertension
C. Night time dipping of 10%
D. Reverse dipping pattern
E. Altered circadian rhythm

Answer: C

Patients with CKD may have an abnormal circadian rhythm associated with nondipping, reverse dipping, and frequency masked hypertension. White coat hypertension is also frequently seen and may lead to overdiagnosis of hypertension in CKD.

Question 5

Which of the following is not typically associated with the pathophysiology of hypertension in CKD?

A. Hyperactivation of the RAAS
B. Low renin
C. Hyperactivation of the sympathetic nervous system
D. Salt sensitivity
E. Disordered endothelial cell dysfunction

Answer: B

Hypertension in CKD is associated with hyperactivation of the RAAS and sympathetic nervous systems and disordered endothelial dysfunction. CKD patients often do not have normal suppression of plasma renin activity given their usual state of sodium retention and volume expansion; therefore, renin activity is inappropriately

high. CKD patients are also salt sensitive, with increasing salt sensitivity as GFR declines.

Question 6

A 44-year-old man with stage 4 CKD and S[Cr] 2.8 mg/dL due to focal segmental glomerulosclerosis presents to the renal clinic for ongoing routine care. He does not check his BP at home regularly. He has no specific complaints. His antihypertensive regimen currently is losartan 100 mg daily, clonidine 0.2 mg t.i.d., amlodipine 10 mg daily, and metoprolol XR 50 mg daily. His BP is 165/98 mm Hg. His heart rate is 65 beats/minute. Trace pedal edema is present. 100 mg of proteinuria per 24 hours is present. The rest of the physical examination is benign.

What adjustment would be appropriate to improve BP control?

A. Add lisinopril 20 mg daily
B. Change to catapres patch #3
C. Increase metoprolol to 100 mg daily
D. Add torsemide 20 mg daily
E. Add minoxidil 5 mg daily

Answer: D

All of the above medication changes could be implemented, but the most critical would be to add a diuretic. Resistant hypertension is defined as BP greater than 140/90 mm Hg in a patient on maximal doses of at least three antihypertensive agents, one of which must be a diuretic. Addition of furosemide to this patient's regimen should result in lowering of BP and improved control. Use of minoxidil causes fluid retention, and this should not be used without concomitant use of furosemide.

CHAPTER

Chronic Kidney Disease and the Vascular Endothelium

Michael S. Goligorsky

Departments of Medicine, Pharmacology and Physiology, Renal Research Institute, New York Medical College, Valhalla, NY, United States

Abstract

Although historically the contribution of the endothelium to chronic kidney disease (CKD) had been neglected, recent investigations provide conclusive evidence of its role in maintaining tissue homeostasis, supporting tissue regeneration, and, when dysfunctional, instigating development and progression of tissue fibrosis. These findings are of critical importance for understanding the development of nephrosclerosis and the progression of CKD. Three endothelial pathways involved in the progression of CKD include stress-induced premature senescence of endothelial cells, the endothelial–mesenchymal transition, and the loss of the endothelial surface layer. These abnormalities are involved in the pathogenesis of proteinuria, a pro-inflammatory microenvironment, microvascular rarefaction, a profibrotic state, and failure of regeneration. Therapeutic strategies to overcome endothelial cell dysfunction and its renal consequences are discussed.

Weighing 1 kg and covering a surface area of 7000 m^2, the human vascular endothelium constitutes a large monolayer organ penetrating almost all compartments of the body. The main functions of this organ include regulation of vasomotion through production of endothelium-derived vasoactive substances, fine tuning of vascular permeability; and exchange of solutes, gaseous molecules, and macromolecules between the blood and the interstitium, regulation of coagulation and fibrinolysis, control of the trafficking of circulating immune-competent cells, and a recently discovered angiocrine-mediated regulation of tissue regeneration. Some or all of these functions may become compromised in CKD, leading to far-reaching consequences, such as predisposition to cardiovascular morbidity and progression of CKD. This chapter will (a) illustrate the role of the vascular endothelium in the induction and maintenance of CKD, (b) discuss established and potential mechanisms whereby the endothelium can affect CKD progression, (c) outline pathways that explain the role of endothelial stem and progenitor cells in regenerative processes, and (d) propose strategies to alleviate endothelial dysfunction and, by doing so, slow the progression of CKD.

DEVELOPMENT AND LIFE-SPAN OF THE VASCULAR ENDOTHELIUM

During early embryonic development, mesodermal cells migrate toward the extraembryonic yolk sac and create "blood islands." The outer luminal layer of blood islands contains endothelial precursors, and the inner mass consists of hematopoietic precursors. The aorto-gonado-mesonephric region (AGM), which harbors endothelial progenitor cells (EPC), becomes the first hematopoietic organ due to the ability of EPC to give rise to hematopoietic stem cells (HSC) and mesenchymal stem cells (MSC).[1,2] This ability is conserved in mammals throughout adulthood, long after the disappearance of the AGM. The process of embryonic endothelial–hematopoietic transition in zebrafish occurs through a unique Runx1-dependent mechanism of endothelial cell bending and escaping the aortic ventral wall in the direction of the subaortic space.[3] This process bears some similarities to the transition of adult endothelial cells (EC) into pericytes, as described in adipose tissue.[4,5] EC insert or "dive" into the basement membrane, in the process transitioning to the pericyte, which later acquires the properties of MSC and preadipocytes. It is not known whether similar processes take place in the renal microcirculation.

EPC and endothelial stem cells are represented in all vascular beds and play a role in vasculogenesis and

https://doi.org/10.1016/B978-0-12-815876-0.00022-X

angiogenesis.[6] Solitary cells or small clusters of EPC are present in all three layers: adventitial, medial, and intimal. These c-Kit+/VEGFR2+/CD45 cells are clonogenic and can differentiate toward EC, smooth muscle cells (SMC), and fibroblasts.[7] A small number of c-Kit-expressing EC (lin−CD31+ CD105+ Sca1+ CD117/c-Kit+) reside in the adult blood vessel endothelium. This subpopulation can undergo clonal expansion *in vivo* and *in vitro*, whereas other EC have a very limited proliferative capacity.[8,9] These c-Kit+ adult vascular endothelial stem cells (VESCs) comprise only 0.4% of all adult vessel wall lin-CD31+ CD105+ ECs. Transplantation of isolated VESCs confirmed that a single c-kit+ VESC can generate *in vivo* functional blood vessels that connect to the host circulation. By performing repeated rounds of cell isolation and *in vivo* serial transplantation, it has been demonstrated that VESCs also display long-term self-renewal capacity.

Yoder and coworkers[10] determined that the expression of neuropilin-1 (NP-1) in human pluripotent stem cells confers on them commitment toward endothelial lineage, which results in formation of NP-1+CD31+ cells highly resembling those obtained from the cord blood. Future studies are required to compare lin− CD31+CD105+ Sca1+CD117/c-Kit+ with NP-1+CD31+ cells to elucidate whether these are overlapping populations or distinct ones.

Endothelium-dependent vasorelaxation and angiogenic competence are reduced in aging compared to young animals.[11] A similar defect occurs in prematurely senescent Klotho mice.[12] Caloric restriction rescues angiogenic competence.[13]

One of the downstream targets of caloric restriction, sirtuin-1, is robustly expressed in EPC and EC. Sirtuin-1 expression declines with age and following application of cardiovascular stressors.[14] The mechanism of sirtuin-1 deficiency leading to premature senescence of EPC and EC is demonstrated by the stress-induced loss of integrity of lysosomal membranes and leakage of cathepsins, which are capable of directly degrading this deacetylase, as shown in *in vitro* studies.[14] EPC isolated from the bone marrow of mice genetically engineered to lack endothelial sirtuin-1 exhibit higher rates of premature senescence and apoptosis even at young ages.[14]

Endothelial cell turnover is very slow under physiological conditions. In different vascular beds it has been estimated to vary from 2 months to 3 years.[15] The disposal of damaged EC occurs as a result of the patrolling function of a noninvading subset of $Ly6C^{low}$ monocytes. Intravital microscopy studies demonstrated that these monocytes crawl on the luminal surface of glomerular and peritubular capillaries and scavenge microparticles.[16] In response to nucleic acid "danger" signaling, $Ly6C^{low}$ monocytes exhibit prolonged dwell times in glomerular and peritubular capillaries, more complex patrolling routes, attachment to damaged EC, and recruitment of neutrophils, which induce focal necrosis and disposal of cellular debris. Cells that escape this *in situ* disposal mechanism detach from their basement membranes and appear in the circulation.

STRUCTURAL COMPONENTS OF RENAL MICROVASCULATURE

EC are heterogeneous. They have specialized functions in every organ. In addition to nutrient delivery, gas exchange, and removal of waste products, they produce diverse paracrine-trophic, angiocrine factors necessary for differentiation and regeneration of tissues as dissimilar as pancreatic acini, neurons, hematopoietic precursors, hepatocytes, or alveolar epithelia.[17] Angiocrine factors relevant to the kidney are yet to be characterized.

Glomerular and peritubular capillary endothelium is fenestrated. Fenestrae, most probably, lack diaphragms. Instead, EC are coated with an endothelial surface layer (ESL), consisting of an electron-dense, fluffy glycocalyx composed of covalently membrane-bound proteoglycans and the inner, luminal cell coat layer composed of charge-interacting proteoglycans, glycosaminoglycans, glycoproteins, and plasma proteins.[18] Of note, these layers, in addition to the basement membrane and slit diaphragms in podocytes, are in part responsible for glomerular permselectivity, as demonstrated by enzymatic degradation or high-salt elution of glycosaminoglycans resulting in proteinuria, with other structures of the glomerular filtration barrier remaining intact. These structures remain similarly intact in transgenic mice overexpressing angiopoietin-2 in podocytes, characterized by apoptosis of glomerular EC and development of proteinuria.[19] Salmon et al.[20] demonstrated that old Munich-Wistar-Fromter rats exhibit a widespread loss of ESL, not only in fenestrated glomerular EC but in continuous mesenteric microvessels as well, and develop increased microvascular permeability and proteinuria.

Glomerular EC and podocytes together with the basement membrane form a functional filtration and permselectivity unit. The endothelium maintains podocytes through secretion of platelet-derived growth factor (PDGF), while podocytes maintain the endothelium through release of VEGF to the glomerular basement membrane. Furthermore, increased production of endothelin-1 by stressed EC triggers shedding of the key component of slit diaphragms, nephrin, from podocytes.[21] Therefore, any damage to each of the members

of this functional unit results in a defective performance of the other.

PRIMARY ENDOTHELIAL DYSFUNCTION LEADING TO KIDNEY DISEASE

The cooperative behavior of EC and pericytes or podocytes plays a key role in the development of kidney disease induced by activation of and damage to the vascular endothelium. This is best illustrated by cases of development of kidney disease in preeclampsia, HUS, TTP, and complications of anti-VEGF treatments.

In preeclampsia, which complicates 3–5% of pregnancies, the immune- and/or cytotrophoblast-mediated activation of EC results in the imbalance of prostacyclin/thromboxane production, elevated production of asymmetric dimethylarginine (ADMA), reduced generation of annexin-V,[22] increased shedding of the VEGF receptor-1 (soluble VEGFR1, sFlt-1), and endoglin.[23] All these factors conspire to compromise the viability of EC, induce thrombophilia, impair vasomotion, and eventually affect the renal microcirculation exemplified by the appearance of proteinuria and hypertension. A similar mechanism may contribute to endothelial dysfunction in CKD. Di Marco et al.[24] demonstrated that in patients with CKD plasma levels of sFlt-1 were elevated compared to healthy controls. Levels of sFlt-1 were found exclusively to be associated with renal function and degree of endothelial dysfunction, and they may predict cardiovascular risk.

In TTP, exocytosis of Weibel–Palade bodies and release of multimeric von Willebrand factor (vWF) are impaired, due to the defect in the metalloprotease ADAMTS13 (either due to genetic abnormalities as in Upshaw–Schulman syndrome, or due to autoimmune production of anti-ADAMTS13 antibodies), which normally cleaves ultralarge multimers of vWF. Defective cleavage results in formation of vWF multimeric "strings" on the surface of EC and in the circulation, leading to platelet aggregation and disseminated thrombophilia,[25] followed by the development of proteinuria and renal insufficiency. Damage to the endothelium in HUS is mediated by members of the Shiga toxin family, which bind to their specific receptor globotriaosylceramide on the surface of EC. After receptor-mediated endocytosis, they inactivate 28S ribosomal RNA and inhibit protein synthesis.[26–28] Despite these differences, there is growing realization that both syndromes have common roots, as Shiga toxin was found to induce release of vWF from EC and impair its cleavage *in vitro* and *in vivo*, producing a TTP-like syndrome in mice lacking ADAMTS13.[29] In both cases endothelial dysfunction plays a paramount role. Both disorders only rarely result in CKD. Perhaps this can be explained by the fact that the acutely developing endothelial dysfunction is reversible on removal of the causative agent, while persistent activation of the endothelium may lead to the development of chronic disease.

Therapeutic use of anti-VEGF antibodies in cancer patients revealed development of proteinuria as their on-target side effect.[30] Analogous functional and morphologic perturbations are observed in genetically engineered mice lacking VEGF production by podocytes. These findings reinforce the role of VEGF in the maintenance of glomerular endothelial architecture and the existing cross talk between the endothelium and the neighboring podocytes.

ANGIOGENIC INCOMPETENCE IN CKD

Studies by Bohle et al. demonstrated microvascular rarefaction at the sites of tubulointerstitial fibrosis.[31,32] These observations were confirmed and mechanistically expanded in a series of studies by Johnson's group,[33] giving rise to the idea that microvascular rarefaction and tubulointerstitial fibrosis are causally linked. Such a link has been also established in glomerulosclerosis. In a rat renal ablation model, injury and activation of EC was associated with a biphasic response, characterized by an early hypertrophic phase, followed in 3 weeks by increased expression of fibronectin, laminin B1, angiotensinogen, and TGF-β1 RNA transcripts, all becoming widespread among endothelial and mesangial cells in sclerotic areas 2.5 months after ablation.[34] This scenario is typical of the angiogenic wound-healing response to injury, which is triggered by proinflammatory mediators, causing local release of VEGF by platelets and ischemic parenchyma, followed by increased microvascular permeability with the leakage of matrix proteins (some of which have antiangiogenic properties) and culminating in vascular drop-out and tissue scarring. This process is partially recapitulated in rat models of focal segmental glomerulosclerosis and other human glomerulopathies. Kriz et al.[35] described the development of synechia between glomerular capillaries and Bowman's capsule. Because synechia contain perfused glomerular capillaries, this leads to filtration of plasma proteins into the paraglomerular and peritubular spaces, proliferation of interstitial fibroblasts, and eventual remodeling toward glomerulosclerosis, tubulointerstitial fibrosis, and formation of atubular glomeruli. The biphasic response of the renal microvascular endothelium to injury, namely, the initial proliferative, angiogenic phase and the later antiangiogenic microenvironment predisposing to obliteration of vascular beds explains the divergent results of several

therapeutic strategies. For instance, in the early proliferative stages of diabetic nephropathy, anti-VEGF treatments may be beneficial, whereas stimulation of angiogenesis may become preferable during fibrotic remodeling in CKD. In most cases the second phase predominates, as is the case with anti-GBM nephritis, where within 3–8 weeks after induction of injury, peritubular capillaries are found to be rarefied, EC undergo apoptotic cell death, and fibrosis ensues.[36] The loss of the glomerular capillary endothelium occurs within a similar time course. These findings are consistent with the conclusion that glomerular capillary regression due to the injury and angiogenic incompetence lead to glomerular sclerosis.[37] Similar observations were made in other models of renal disease, as well as in the aging kidney, where the loss of endothelial nitric oxide synthase and peritubular capillaries is associated with the development of tubulointerstitial fibrosis.[38] Severe acute renal ischemia leads to the gradual loss of peritubular capillaries in the inner stripe of the outer medulla even before the development of manifest tubulointerstitial disease.[39] In humans with different types of chronic tubulointerstitial disease, rarefaction of peritubular capillaries occurs in association with a variable pattern of VEGF expression. Increased VEGF expression in morphologically intact areas and decline in sclerotic glomeruli have been described.[40] Persistent, cyclosporine A-resistant rejection of transplanted kidneys differs from the treatment-responsive cases in that the former exhibits the loss of peritubular capillaries and proliferation of myofibroblasts, leading to progressive interstitial fibrosis.[41]

The main process responsible for ablation of the microvasculature involves the following steps. Damaged EC precipitate cessation of normal blood flow and perturb the flow-dependent shear stress–induced activation of eNOS, leading to further cell damage and apoptosis. These damaged and apoptotic EC induce local platelet adhesion and attract macrophages, which in turn recruit other leukocytes, eventually disposing of cell debris.[15] That leaves behind a decellularized basement membrane, referred to as a string vessel or empty basement membrane tube. The remaining scaffold of the basement membrane is rich in endothelial and pericyte growth factors, such as VEGF, basic fibroblast growth factor, and PDGF. These growth factors guide repopulation of string vessels with EC, leading to the deposition of a new layer of basement membrane material, potentially restoring blood flow to the area. Restoration of the endothelial lining of string vessels occurs by proliferation of EC and is assisted by EPC.[42] Sequential rounds of recellularization of string vessels result in the appearance of thickened basement membranes, a frequent morphologic companion of renal disease.

Why does the rarified microvasculature in CKD not undergo self-repair *via* angiogenic or vasculogenic processes? Sprouting angiogenesis is initiated by the gradient in VEGF-A and Notch receptor, which guides the pathfinder "tip" EC to navigate within the interstitium and direct the "stalk" EC to the growing vessel branch.[2] Endothelial SIRT1 exerts an inhibitory effect on signaling by the Notch intracellular domain, which is usually expressed in stalk cells of sprouting angiogenic vessels, thus resulting in enhanced angiogenesis. Reduced NAD abundance in aging cells leads to reduced SIRT1 activity. This can be reversed by supplementation with an NAD precursor, nicotineamide mononucleotide.[43] Other guidance cues, such as class 3 semaphorins, netrins, and SLIT proteins assist in orchestrating this process. Forming sprouts undergo lumenization and mature by recruiting mural cells, pericytes and SMC, to stabilize and maintain their structure. Bone marrow-derived EPC were proposed to contribute to angiogenesis, but their direct contribution through engraftment of growing vessels has recently been questioned. This multistep angiogenic process can be disrupted at multiple, but as of yet not precisely identified, stages. Endothelial dysfunction is the main contributor to the insufficiency of angiogenesis to meet metabolic requirements. EC exposed to diverse cardiovascular risk factors exhibit impaired ability to form angiogenic sprouts even in the presence of VEGF-A.[44,45] Angiopoietin-1 deficiency further contributes to microvascular rarefaction.[46] This imbalance between the demand and supply leads to the observed microvascular rarefaction, patchy tissue hypoxia, and fibrosis (Figure 22.1).

ENDOTHELIAL CELL DYSFUNCTION IN CKD—TRANSCRIPTOMIC AND METABOLIC ANALYSES

Multiple lines of evidence indicate that endothelial cell dysfunction (ECD) develops in CKD. Flow-dependent relaxation of conduit vessels, a function of endothelium-derived relaxing factors, mainly NO production, is suppressed in patients and animals with CKD. Different modifications of testing endothelium-dependent vasorelaxation have become the standard for diagnosing ECD, together with other surrogate biomarkers such as markers of oxidative stress (8-iso-PGF2α and oxidized LDL), markers of inflammation (high-sensitivity CRP, lipoprotein-associated PLA2, soluble ICAM-1, IL-6, von Willebrand factor), the inhibitor of eNOS ADMA, circulating procoagulants, and others.[47] Diverse traditional and nontraditional risk factors for cardiovascular disease (CVD), such as ADMA, advanced glycation end products, and prooxidants, all accumulating in CKD, conspire to induce ECD by eNOS uncoupling (Figure 22.2). Cardiovascular microarray gene screens of EC with inhibited or uncoupled eNOS revealed that this condition is associated with upregulation of the receptor for oxidized LDL (LOX-1),[48] induction of 3-hydroxy-3-methylglutaryl coenzyme A reductase leading to endothelial lipidosis,[49] upregulation and redistribution of a gap-junctional protein connexin-43, resulting in perturbed transmission of endothelium-derived hyperpolarizing factor to vascular SMC,[50] increased synthesis of collagen XVIII[51], and accumulation of its antiangiogenic fragment, endostatin, which actuates endothelial−mesenchymal transition (Endo-MT).[52] Transcriptomic analyses of iliac arteries from renal transplant recipients and renal arteries from healthy living kidney donors revealed 15 differentially expressed gene transcripts with upregulation of mRNAs associated with apoptosis, NF-kB signaling, smooth muscle contractility, HIF-3α, and vimentin, among others.[53]

ECD is associated with profound metabolic abnormalities. Such abnormalities can not only initiate but also tend to aggravate preexisting ECD. Screening renal microvascular isolates obtained from mice with inhibited eNOS revealed (using 2-D electrophoresis, in-gel digestion and mass-spectrometry analyses) at

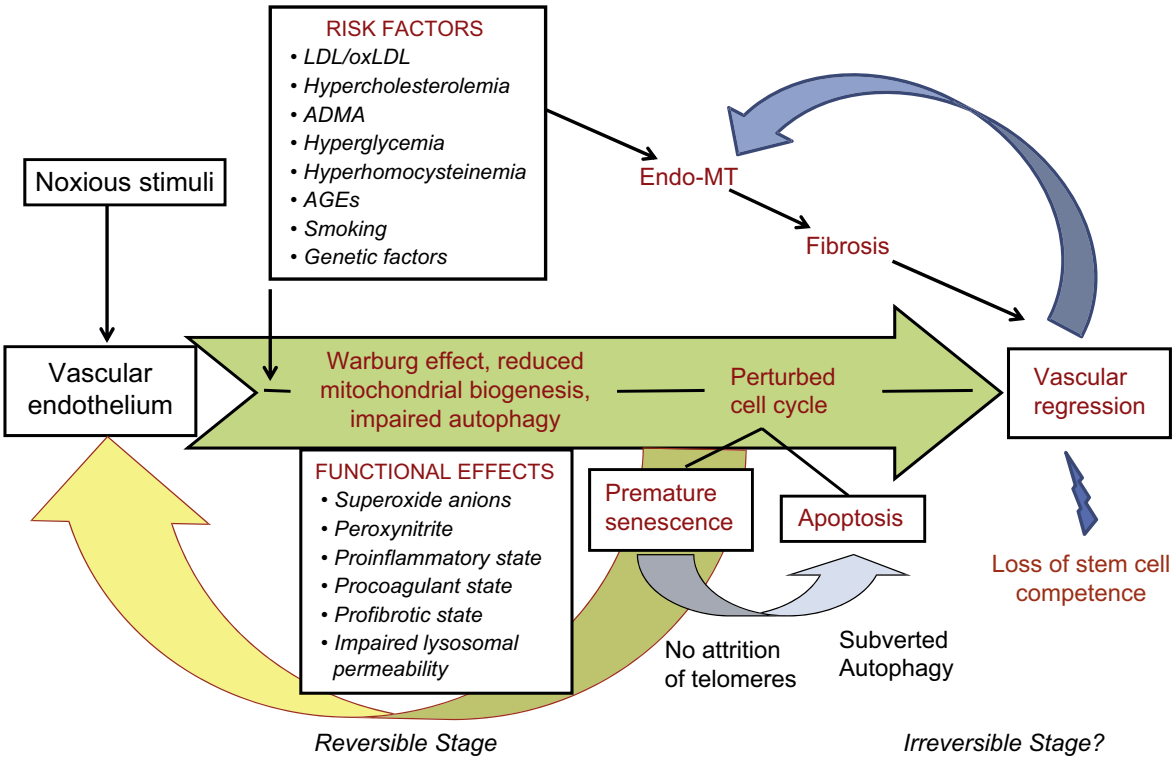

FIGURE 22.2 Mechanisms of endothelial dysfunction, premature senescence and microvascular rarefaction. A long list of traditional and nontraditional risk factors illustrates the vulnerability of endothelial cells, which respond to these stressors by evoking a cascade of reactions summarized under the rubric "Functional Effects." These result in impaired intermediary metabolism with a switch toward a Warburg-like normoxic glycolysis, reduced mitochondrial biogenesis, and subverted autophagy, a result of lysosomal dysfunction. Cell cycle arrest and development of premature senescence of endothelial cells follows. Notably, this type of senescence is not associated with attrition of telomeres and, if the effects of noxious stimuli and risk factors are eradicated, the cells have the potential to reverse to a normal state. The point-of-no-return is not well-defined, but perhaps is determined by the persistence of noxious stimuli, loss of stem cell competence, endothelial−mesenchymal transition, and progressive microvascular drop-out. The details of this sequence of events are provided in the text. *Endo-MT*, endothelial−mesenchymal transition.

least 13 nonredundant differentially expressed proteins with high level of confidence. Five of those are specific for mitochondria, and two downregulated proteins, aconitase-2 and enoyl-coA-hydratase-1, are components of the Krebs cycle.[54] This deficiency of key enzymes is associated with reduced mitochondrial mass, mitochondrial oxidative stress, and a switch to normoxic glycolysis (Warburg type of metabolic hypoxia seen in chronic uncoupling of eNOS) to support energy metabolism. Moreover, by supplying cultured cells with the metabolic intermediate downstream of the deficient aconitase-2—α-ketoglutarate (which enters the Krebs cycle bypassing the enzymatic bottleneck)—it becomes possible to restore energy metabolism and prevent cell death or premature senescence. These findings raise the question whether it could be possible to restore EC metabolism in ECD by supplementing animals with glutamine. This question has been addressed in follow-up metabolomic studies of isolated renal microvasculature and plasma of mice chronically receiving an eNOS uncoupler with and without glutamine supplementation. This treatment ameliorated vasculopathy (as judged by restored endothelium-dependent vasorelaxation) and decreased proteinuria.[55] In addition, metabolomic studies conducted using liquid chromatography−mass spectrometry analyses disclosed multiple metabolite abnormalities developing in ECD and restored by glutamine supplementation. Among those were elevated lysophospholipids and hippuric acid, and reduced levels of glutamine/glutamate, which were normalized after glutamine supplementation.[55] Hence, metabolic abnormalities affect EC functions. Correcting these abnormalities leads to amelioration of ECD and vasculopathy, both of which contribute to the progression of CKD.

Another metabolic aberration typical of CKD consists of the activation of glycocalyx-degrading enzymes such as heparanases, hyaluronidases, and ADAM17, which leads to structural and functional damage to the endothelial glycocalyx, the structure that is normally responsible for the mechanotransduction of flow parameters to eNOS, regulation of permeability, deterrence of leukocytes, protection from oxidative stress, and harboring growth/survival factors.[56–58]

PREMATURE ENDOTHELIAL CELL SENESCENCE IN CKD

A role of telomere attrition and cell senescence in aging and diseased kidneys has been initially promoted by Halloran's group.[59] It has become clear from studies by Chen et al.[60] that stress-induced premature senescence (SIPS) of EC occurs even in the presence of relatively unaffected telomeres. A diverse group of stress signals, such as prooxidants, ADMA, and nonenzymatically glycation-modified proteins induce cell cycle arrest, SIPS, and eventual apoptosis in low-passage cultured cells and in young mice. A flow-chart depicting the role of SIPS in microvascular drop-out is shown in Figure 22.2. It emphasizes the fact that SIPS can be reversed after the withdrawal of the offending stressor. If the stressor persists, SIPS becomes irreversible, and EC may undergo apoptosis, which culminates in microvascular rarefaction.

Senescent EC not only disrupt the function of the endothelial lining of the vessels but also affect the neighboring cells by their secretome, collectively designated as senescence-associated secretory products (SASP). SASP contain TGF-alpha, galectin-3, IGFBP-3, -4, and -6, and MIC-1.[61] Dysfunctional senescent EC also release collagen XVIII and its C-terminal antiangiogenic fragment, endostatin.[52] High-resolution mass spectrometric analysis of the secretome of EPC disclosed 133 proteins, some known as membrane-bound, others as secreted.[62] Specifically, soluble forms of VEGF receptors, adhesion molecules, semaphorin 3F and TGF-β, CD109, members of the roundabout (robo) family, and endothelial markers were detected. Mass spectrometry screen of the secretome of colony-forming units, precursors of mature EC, identified 272 nonredundant proteins, of which 124 were also found in cultured EPC.[63] Secretory products included MMP-9, IL-8, MIF, various cathepsins and protease inhibitors, S100 proteins A11, A8 and A4, PAI-2 and apolipoprotein E, as well as a proangiogenic and prosurvival factor, thymidine phosporylase. These investigations explain the observed incipient shift from "cell-based therapy" to "cell-free therapy". Several successful and on-going clinical trials, conducted mostly in patients with CVD, are underway.

Regeneration of the microvasculature is further impaired by the production of antiangiogenic substances, such as endostatin, and developing incompetence of EPC. EST has been described as an interactive partner of another profibrogenic factor, transglutaminase 2 (TG2), an enzyme cross-linking extracellular matrix proteins, rendering them resistant to proteolytic degradation, which is elevated in kidney disease and aging.[64] Individually EST and TG2 suppress angiogenesis. Transgenic mice overexpressing EST show renal interstitial fibrosis at a young age. Injection of TG2 in the intact kidney produces increased cross-linking within 24 hours, and increased matrix accumulation was detected after two weeks. Subcapsular injection of TG2 or EST in kidneys of young mice not only induced fibrosis but also increased the proportion of prematurely senescent cells. In addition, obliteration of the microvasculature occurs *via* Endo-MT.

ENDOTHELIAL-MESENCHYMAL TRANSITION

Endo-MT is a physiological developmental stage occurring during embryonic formation of heart valves and septa. In adulthood, Endo-MT is implicated in pulmonary hypertension, vein graft failure, atherosclerosis, and metastatic spread of malignant cells. Endo-MT is a major contributor to vascular drop-out and development of tubulointerstitial fibrosis, as detected in three different models of renal disease—unilateral ureteral obstruction, streptozotocin-induced diabetic nephropathy, and a mouse model of Alport syndrome.[65,66] About 30–50% of interstitial fibroblasts were found to originate from the endothelium. TGF-β is a major mediator of Endo-MT, and BMP-7 is a factor counteracting Endo-MT, as demonstrated using an endothelial cell fate-tracing technique. Actions of TGF-β are mediated *via* activin receptor-like kinases 1 and 5 (Alk1 and Alk5). Activation of Alk1, selectively expressed on EC, results in cell migration, proliferation, and angiogenesis, while stimulation of Alk5 induces (*via* Smads 2/3 phosphorylation) the transcription of SM22α, fibronectin, and PAI-1, which mediate differentiation along the smooth muscle/mesenchymal phenotype, leading to formation of myofibroblasts. The balance between activation of these two Alk pathways is regulated by endoglin, another specific endothelial TGF coreceptor. Prolonged activation with TGF-β results in the escape of Alk1 signaling and predominant signaling *via* Alk 5, thus promoting Endo-MT.[67] A recent study of Endo-MT showed that energy-supplying mitochondrial β-oxidation of long-chain fatty acids (FAO) in EC is inhibited by TGF-β signaling.[68] Reduced activity of FAO results in a fall of acetyl-CoA levels and impaired acetylation of SMAD7, leading to the liberation of SMAD2.

Endo-MT is also a contributing factor in the acute-to-chronic kidney disease continuum and the development of chronic graft dysfunction.[69,70] The role of endothelial dysfunction in kidney transplantation is further emphasized by a recent study on enhancing protection of EC using a Corline Heparin Conjugate (CHC™), which improved early outcomes in preclinical investigations.[71]

Gene microarray analysis of cultured EC treated with an inhibitor of nitric oxide synthase revealed upregulation of collagen XVIII and its antiangiogenic fragment endostatin, a finding confirmed *in vivo* in mice chronically treated with an NOS inhibitor.[52] Enhanced generation of endostatin in these animals leads to the development of Endo-MT and eventual rarefaction of renal microvasculature, thus further compounding vascular and parenchymal pathology. EC exposed to diverse stressors respond with lysosomal dysfunction, leakage of cathepsins, and degradation of SIRT1. SIRT1 depletion, in turn, leads to downregulation of MMP-14 and accumulation of ECM.

While the secretory products of intact EC contribute to the maintenance of the surrounding parenchyma, the dysfunctional endothelium secretes a host of profibrogenic factors that activate resident fibroblasts, as well as further worsening endothelial dysfunction, Endo-MT, and microvascular rarefaction.[72]

LYMPHATIC ENDOTHELIUM

Lymphatic EC originate as sprouts from the embryonic veins and, perhaps, the adjacent mesenchyme, then sprout, branch and proliferate to form the lymphatic network, which drains into lymph nodes and eventually into the venous circulation at subclavian veins. The first podoplanin-positive lymphatic EC appear in the hilus of a developing kidney. From there they form tubular structures that branch and invade renal parenchyma. Terminal lympatics, blind-ended capillaries, collect and evacuate protein-enriched fluid, lymphocytes and antigen-presenting dendritic cells from the interstitium, thus participating in tissue homeostasis and immune surveillance.[2] VEGF-C, and to a lesser extent VEGF-D, fibroblast growth factor, hepatocyte growth factor, PDGF, and insulin-like growth factors are necessary for sprouting and maintenance of the lymphatic architecture. Lymphatic capillaries lack pericyte coverage and have a discontinuous basement membrane and discontinuous button-like cell–cell junctions, allowing the entry of fluid, lymphocytes, and dendritic cells.[73] In chronic inflammation, infiltrating macrophages produce VEGF-C that induces lymphangiogenesis, which in turn provides an outlet for the resolution of inflammatory infiltrates and the reduction of edema. In the rat remnant kidney model, fibrotic interstitial areas are characterized by a massive proliferation of lymphatic vessels. If specific markers of lymphatic endothelium such as podoplanin are not used for characterization, these cells could be readily mistaken for vascular endothelium.[74] In the setting of renal transplantation, CCL21 produced by host lymphatic vessels serves as a guidance cue for CCR-7–expressing dendritic cells.[75] These cells elicit antigen recognition and immune response. Therefore, strategies designed to curtail lymphangiogenesis may be beneficial for graft survival.

The emerging understanding of the role of lymphatics in cardiovascular homeostasis is attributed to the fact that these vessels are present in the adventitia of arteries where they accompany vasa vasorum. During progression of atherosclerosis, plaque areas develop dysfunctional lymphatic vessels, which by interfering with the normal processes of eliminating inflammatory cells and lipids contribute to their expansion.[76]

The lymphatic endothelium has been linked to the maintenance of blood pressure, with the failure of lymphangiogenesis resulting in development of hypertension in animals with high-salt consumption.[77] Salt load results in the elevation of osmotic pressure of the skin interstitium, attracting macrophages that produce VEGF-C and stimulate lymphangiogenesis. This in turn restores tissue homeostasis and helps maintain the blood pressure. Disruption of this adaptive lymphangiogenic mechanism leads to the development of salt-sensitive hypertension, even though the expression of eNOS is elevated. These seminal studies establish the macrophage–lymphatics axis as an extrarenal regulator of extracellular volume and blood pressure homeostasis.

The relationship between the lymphatic microvasculature and CKD remains to be fully explored, and it awaits investigation into the role of this system in maintaining interstitial pressure and renal function in health and disease.

MICROVASCULAR AND TISSUE REGENERATION: ROLE OF STEM AND PROGENITOR CELLS

The identification of EPC[78] and their potential to regenerate blood vessels resulted in a body of experimental evidence confirming their role in diverse diseases. Specifically, adoptive transfer of EPC has been shown to improve the course of several cardiovascular and renal diseases. Recent studies, however, have questioned the direct involvement of stem cells in general and EPC in particular in regenerative processes. Using genetic fate tracing technology, it has been documented that bone marrow-derived or circulating cells do not contribute to regeneration of a distal phalanx in an adult mouse. The germ layer and lineage-restricted stem/progenitor cells are responsible for the regeneration.[79] It has been concluded that endothelial stem/progenitor cells involved in adult angiogenesis must be local, nonhematopoietic, and noncirculating, tissue resident cells. Furthermore, it has been demonstrated[7] that c-Kit+ adult VESCs reside in the vascular wall. The importance of the vascular endothelium for tissue regenerative processes has been amply illustrated in a study by Rafii's group,[80] which provides evidence for angiocrine signals generated during vascular regeneration through production of EGF-like laminin fragments. The latter foster growth of the pulmonary epithelia. Whether analogous processes takes place in the kidney remains unknown, although the recently discovered product of EC and platelets, SCUBE1 protein containing several EGF-like repeats, has been shown to be upregulated after the injury and to promote regeneration of tubular epithelial cells.[81]

THERAPEUTIC STRATEGIES TO AMELIORATE ENDOTHELIAL DYSFUNCTION

Sir William Osler opined "The physics of a man's circulation are the physics of the waterworks of the town in which he lives, but once out of gear, you cannot apply the same rules for the repair of the one as of the other." Indeed, this calls for an in-depth understanding of the metabolic abnormalities associated with the affected endothelium, a field of knowledge that still remains in its infancy. Although the functional abnormalities have been elucidated, the molecular basis for developing endothelial dysfunction in CKD still remains obscure. The first glimpses on proteomic and metabolomic disparities between normal and dysfunctional endothelium, as detailed above, constitute the backbone for the rational design of therapeutic strategies. Some well-established, traditional therapeutic interventions are considered.[82]

Inhibitors of Angiotensin-2 Action

One of the mainstay therapies directed to slow the progression of CKD, ACEIs and ARBs, exert their action through inhibition of NADPH oxidase, preservation of eNOS function and bradykinin levels, thus improving EC dysfunction.

HMG-CoA Reductase Inhibitors

Statins elicit their effect on EC by reducing oxidative stress and improving eNOS function, independent of their lipid-lowering effects.[82,92]

PPAR-α Agonists

Fibrates improve endothelial cell function *via* reduction of oxidative stress and NF-kB activation.[93]

Antioxidants

Tempol and ebselen protect the endothelium by preventing eNOS uncoupling, thus restoring endothelial functions. A synthetic triterpenoid, bardoxolone methyl, an activator of the antioxidant Keap1-Nrf2 pathway, has been advocated as a potential therapeutic agent restoring endothelial dysfunction[83] and improving renal function in CKD patients with type 2 diabetes.[84] Yet, the study of more than 2000 patients with type 2 diabetes and stage 4 CKD showed no benefit of bardoxolone methyl therapy over placebo.[85] A possible therapeutic role of an endogenous antioxidant, lipoic acid, in vascular and renal protection against elevated levels of

angiotensin II-induced injury has been demonstrated in transgenic rats harboring human renin and angiotensinogen genes.[86]

Several well-rationalized experimental strategies for vascular protection have emerged. These are briefly noted below.

mTOR Inhibitor

Rapamycin may improve endothelial dysfunction by preventing SIPS of EC.[94]

Activators of Sirtuins

Resveratrol and newly developed analogues should have a place in the prevention of endothelial cell senescence and the restoration of metabolic abnormalities. Based on earlier studies of sirtuin 1 activation by resveratrol, a number of small-molecule SIRT1 activators have been synthesized and are being currently tested.[87] Sirtuin-activating compounds (STACs) exert their effect by allosteric activation of this deacetylase. Three generations of STACs include, in addition to resveratrol, quercetin and butein (first generation), SRT 1720, 1460, and 2183 (second generation), and STAC-5, -9, and -10 (third generation), all extending lifespan and/or health-span in preclinical settings. These compounds are presently undergoing clinical trials. Dietary restriction, which induces SIRT1, acts *via* mTOR signaling and nicotine amide dinucleotide (NAD)−dependent pathways accompanied by a shift toward oxidative metabolism,[88] both representing novel modes of rejuvenation therapy.

NAD+ is a cofactor for activation of several sirtuins. NAD+ bioavailability is reduced in disease states and aging.[89] A precursor of NAD+, nicotinamide, is being evaluated as a therapy to correct NAD+ deficiency and improve sirtuin activity.

Glutamine Supplementation

Glutamine supplementation remains in experimental stages.[54]

Suppression of the JNK Pathway

Suppression of the JNK pathway, which prevents vascular dysfunction, can be achieved through activation of adenosine monophosphate kinase by chronic pretreatment with 5-aminoimidazole-4-carboxamide 1-β-D-ribofuranoside, acadesine, N^1-(β-D-Ribofuranosyl)-5-aminoimidazole-4-carboxamide (ICAR) or metformin.[90] Their effect is mediated *via* activation of PGC-1α and improved mitochondrial biogenesis and cytoprotection, leading to attenuation of oxidative stress−induced endothelial injury.

Activation of Endothelin Type B Receptors

Endothelin type B receptors, expressed predominantly by EC, mediate activation of endothelial nitric oxide synthase. Intrarenal infusion of these receptors in sarafotoxin 6c insulinopenic streptozotocin-injected rats improved renal hemodynamics.[91]

SUMMARY

Endothelium-dependent pathways of fibrogenesis play critical roles in the maintenance and progression of CKD. The mechanics of the process involve microvascular rarefaction, which itself is a result of the confluence of a multitude of pathogenic factors, such as Endo-MT, SIPS and associated abnormal secretory profiles, impaired angiogenesis and curtailed regeneration of obliterated microvascular beds, an aberrant secretome of dysfunctional EC, and enhanced degradation of endothelial glycocalyx. Strategies to alleviate endothelial dysfunction and improve the renal microcirculation must be tested in animal studies and clinical trials. Although the accumulated knowledge leaves no doubt regarding the participation of the endothelium in the pathogenesis of CKD, there remains a long translational journey to use these findings to improve outcomes in patients.

QUESTIONS AND ANSWERS

Question 1

A 25-year-old prima para is followed in the outpatient clinic. Until the present visit all physiological and laboratory data were within the normal range. She is in the third trimester of pregnancy. Her blood pressure is found to be elevated at 158/95 mm Hg. Dipstick of her urine shows 2+ protein. Her BUN and S[Cr] are in the upper normal range, as is her uric acid level. She denies any recent intercurrent infections. You strongly suspect development of preeclampsia. Being aware of the role played by vascular endothelium in this syndrome, you ask yourself: What are the mediators of preeclampsia?

A. Increased serum concentration of the soluble Flt-1
B. Increased serum concentration of VEGF
C. Decreased serum concentration of ADMA
D. All of the above

Answer: A

Choices B and C are incorrect because the opposite occurs in preeclampsia: decreased levels of VEGF and increased levels of ADMA. Therefore, Choice D is automatically eliminated. The only correct choice is A, as the cleavage of Flt-1 receptor on EC and elevated levels of its soluble fragment are characteristic findings in preeclampsia, as well as other chronic kidney diseases.

Question 2

A 59-year-old truck driver is seen by you in the outpatient clinic. He has been referred by his family physician, who on a routine check-up found elevated blood pressure and proteinuria. During your examination and analysis of the laboratory data you come across S[Cr] of 5.3 mg/dL. You immediately perform a renal ultrasound and find that both kidneys are shrunken to 7.9 cm in length. Since you are well aware of the endothelial contribution to nephrosclerosis, you ask yourself: What are the known endothelium-dependent mediator(s) of fibrosis?

A. Activation of matrix metalloproteinases
B. Inhibition of tissue inhibitor of matrix metalloproteinase-1 (TIMP-1)
C. Epithelial−mesenchymal transition (EMT)
D. Endo-MT

Answer: D

Choices A and B are incorrect because neither activation of MMPs nor inhibition of TIMP-1, which also results in the activation of MMPs, could be considered mechanisms of fibrosis. EMT has been proposed as a mechanism of fibrosis; however, this choice is incorrect because it is not an endothelium-dependent mediator of fibrosis. Hence, the only correct choice is D—Endo-MT.

Question 3

Considering lymphatic EC, which of the following statements is correct?

A. Terminal lymphatic capillaries are blind-ended
B. VEGF-C is the main growth factor for lymphatic endothelium
C. Dysfunctional lymphatic EC in the vascular wall contribute to progression of atherosclerosis
D. All of the above

Answer: D

Although our knowledge of lymphatic endothelial cells in general and renal lymphatics in particular is rather scanty, all three statements are correct. The answer is D.

Question 4

A 63-year-old woman with CKD and eGFR of 45 mL/min/1.73 m^2 is admitted to the hospital with chest pain and T-wave inversions on ECG. Having controlled her chest pain and while you are waiting for the results of biomarker tests, you search through your memory for established relations between CKD and cardiovascular disease (CVD). Which of the following statements is correct?

A. Endothelial cell dysfunction is in part responsible not only for the progression of CKD but also for the increased cardiovascular morbidity and mortality in CKD patients compared to the general population without kidney disease
B. The main therapies for endothelial cell dysfunction include statins, ACEIs, ARBs, and PPAR-alpha agonists
C. Exercise and calorie restriction regimens may improve endothelial function
D. All of the above

Answer: D

You are aware of the fact that stage 3 CKD is associated with a dramatic increase in cardiovascular death. Endothelial cell dysfunction is a nearly constant companion of CKD. This makes choice A a correct one. Indeed, the therapeutic modalities mentioned in choice B are correct and new modalities are on the way. This shows choice B is also correct. There is a plethora of data obtained in humans with endothelial cell dysfunction, as diagnosed using impaired endothelium-dependent vasorelaxation, elevation in levels of markers

of chronic inflammation and oxidative stress, which demonstrate beneficial effects of exercise and caloric restriction on dysfunctional endothelium. Hence, your choice of C is also correct. Having correctly answered all three choices, you have logically selected as the best answer choice D—all of the above.

Question 5

Which of these statements correctly characterize renal glomerular EC?

A. They are fenestrated
B. They are coated with glycocalyx, removal of which can lead to albuminuria
C. EC and podocytes form a functional unit
D. All of the above

Answer: D

EC of glomeruli and peritubular capillaries are fenestrated, as are EC in endocrine glands or sinusoidal cells in the liver. Therefore, Answer A is correct. Indeed, EC are coated with glycocalyx, and its removal from glomerular EC leads to albuminuria. This makes Answer B correct. Glomerular EC and podocytes, together with the glomerular basement membrane, represent a glomerular filtration unit. Damage to any portion of this unit leads to dysfunction of the other components. For this reason Answer C is also correct. Having correctly answered all three choices, you have necessarily selected as the best answer choice D—all of the above.

CHAPTER

23

Cardiovascular Disease and Chronic Kidney Disease

[a]Einstein Medical Center, Philadelphia, PA, United States; [b]Sidney Kimmel College of Thomas Jefferson University, Philadelphia, PA, United States; [c]Baylor University Medical Center, Dallas, TX, United States; [d]Baylor Heart and Vascular Institute, Dallas, TX, United States; [e]Baylor Jack and Jane Hamilton Heart and Vascular Hospital, Dallas, TX, United States

Abstract

Cardiovascular disease (CVD) is a major cause of morbidity and mortality in patients with chronic kidney disease (CKD). The various phenotypes of cardiovascular disease including heart failure, ischemic heart disease, valvopathies, and arrhythmias are all represented with high disease burden in patients with CKD. Several traditional and nontraditional vascular risk factors are operational in the pathogenesis of cardiovascular disease in this population. Despite the well-known risk of cardiovascular disease, patients with CKD tend to be excluded from major cardiovascular outcome trials. Therefore there is less-robust available evidence on how to deliver optimal medical and procedural therapies for CVD in the CKD population. CKD patients also present with atypical symptom profiles and receive less aggressive goal–directed medical therapies for CVD compared to patients without CKD. Therapeutic effects of medical therapies as well as procedural interventions tend to be associated with higher complication rates related to the brittle bleeding–clotting paradigm in CKD, altered pharmacotherapeutics of drugs, and high vascular calcific burden. There is an urgent need to prioritize the inclusion of patients with CKD in cardiovascular trials, as well as to implement efforts to deliver cohesive care *via* multidisciplinary cardio-renal team models to achieve optimal long-term outcomes and CVD reduction in this vulnerable patient population.

INTRODUCTION

Chronic kidney disease (CKD) is a global public health problem with increasing disease burden, poor outcomes, and higher costs in the US and worldwide.[1] According to the US Renal Data System, the overall prevalence of CKD in the US was 14.8% in 2011–2014 with high rates of diabetes, hypertension, and self-reported cardiovascular disease (CVD) in this population.[1] The classification of CKD as outlined in the clinical practice guidelines of the National Kidney Foundation in 2002 with the subsequent update from the Kidney Disease: Improving Global Outcomes (KDIGO) in 2012 stratifies the severity of CKD by estimated glomerular filtration rate (eGFR) and the degree of microalbuminuria. CKD (as defined by a eGFR <60 mL/min/1.73 m^2 for at least 3 months, or presence of markers of kidney damage such as a spot albumin:creatinine ratio $\geq$30 mg/g or structural abnormalities) is a well-recognized independent risk factor for the development of CVD.[2] The risk of CVD mirrors the degree of decline in eGFR, as well as the degree of albuminuria.[3] The 1998 National Kidney Foundation Task Force on Cardiovascular Disease in Chronic Kidney Disease as well as the KDIGO Clinical Practice Guideline on CKD in 2012 emphasized that patients with underlying CKD should be considered in the "highest risk group" and at "increased risk" for CVD, respectively.[4,5] The elevated risk of CVD in CKD represents the interplay of several "traditional" risk factors such as those in the Framingham Heart Study as well as "nontraditional" risk factors such uremia, oxidative stress, abnormalities in bone mineral metabolism, and chronic inflammation that are hallmarks of the CKD milieu.[2] The elevated risk of CVD extends across the spectrum of nondialytic CKD, maintenance dialysis as well as after kidney transplantation, with the risk of developing a major adverse cardiovascular event (MACE) in patients with CKD exceeding the likelihood of needing renal replacement therapy (RRT).[6] This chapter will focus on the pathophysiology, diagnosis, and management of CVD in patients with

Chronic Renal Disease, Second Edition

CKD (not treated with dialysis or transplantation) considering the following major phenotypes: heart failure (HF), atherosclerotic cardiovascular disease (ASCVD), valvular heart disease, and arrhythmias.

HEART FAILURE IN CKD

Pathophysiology and Diagnosis of Heart Failure in Chronic Kidney Disease

As early as in 1836, Richard Bright described cardiac structural alterations in patients with kidney disease, establishing the concept of a "cardio-renal" axis, reminiscent of the type 4 cardio-renal syndrome (CRS) phenotype defined by the Acute Dialysis Quality Initiative in a more contemporary context.[7] (Table 23.1). Left ventricular hypertrophy (LVH) is the principal myocardial structural perturbation in CKD. A cross-sectional echocardiographic study of 3487 patients in the Chronic Renal Insufficiency Cohort reported prevalence rates of LVH of 32%, 48%, 57%, and 75% for eGFR categories >60, 45−59, 30−44, and <30 mL/min/1.73 m^2, respectively.[8] There is strong evidence that abnormalities of LV structure, function, and the development of myocardial fibrosis are present in early stages of CKD, prompting the term CKD-associated cardiomyopathy instead of "uremic cardiomyopathy".[9] The increase in myocardial fibrotic tissue impairs LV contractility in three ways: increase in the collagen type I: III ratio enhances ventricular stiffness; changes in collagen alignment relative to cardiomyocytes impairs diastolic relaxation, leading to exercise intolerance, and ultimately to HF and arrhythmias; and with increasing thickness, there is a reduced capillary density and impaired oxygen delivery, particularly in regions distant from the epicardium and endocardium.[9] The burden of LVH and concomitant myocardial fibrosis through the various stages of CKD form the common basis for the development of HF, in conjunction with preexisting vascular risk factors and the neuro-humoral-inflammatory pathways activated in CKD/type 4 CRS.

TABLE 23.1 Description of the Clinical Phenotypes of the Cardio-Renal Syndromes as Outlined by the Acute Dialysis Quality Initiative (ADQI)

Phenotype	Nomenclature	Description	Clinical Examples
Type 1 CRS	Acute cardio-renal syndrome *Worsening kidney function in the setting of high dose loop diuretics in acute heart failure	Heart failure resulting in AKI *May represent a functional elevation of kidney biomarkers such as S[Cr] or Cystatin C, and not true acute kidney injury	ACS resulting in cardiogenic shock and AKI, AHF resulting in AKI *Appropriately decongested patients with Type 1 CRS with an asymptomatic elevation of S[Cr], which meets criteria for AKI, with negative renal tubular injury biomarkers.
Type 2 CRS	Chronic cardio-renal syndrome **Worsening kidney function in the setting of use of goal directed therapies in heart failure	Chronic heart failure resulting in CKD **May represent appropriate reduction in GFR from effective reduction of FF without affecting RBF	Chronic heart failure **Asymptomatic elevation in S[Cr] seen in stable and compensated chronic heart failure with the use of RAASi
Type 3 CRS	Acute reno-cardiac syndrome	AKI resulting in acute heart failure	Heart failure in the setting of AKI from volume overload, inflammatory surge, and metabolic disturbances in uremia.
Type 4 CRS	Chronic reno-cardiac syndrome	CKD resulting in chronic heart failure	LVH and heart failure from CKD associated cardiomyopathy
Type 5 CRS	Secondary cardio-renal syndrome	Acute or chronic systemic process resulting in concomitant heart and kidney failure	Sepsis, cirrhosis, preeclampsia, Fabry's disease

ACS, acute coronary syndrome; *AHF*, acute heart failure; *AKI*, acute kidney injury; *CKD*, chronic kidney disease; *CRS*, cardio-renal syndrome; *FF*, filtration fraction; *GFR*, glomerular filtration rate; *LVH*, left ventricular hypertrophy; *RBF*, renal blood flow.

** Refers to "pseudo" AKI or "functional" changes in S[Cr] or serum Cystatin C in the setting of high dose loop diuretics in acute heart failure that may not represent "true renal tubular injury despite meeting accepted definitions of AKI.(Not included in original ADQI classification of CRS). Furthur reading: Ahmad T, Jackson K, Rao VS, et al. Worsening renal function in acute heart failure patients undergoing aggressive diuresis is not associated with tubular injury.* Circulation *2018.*

*** Not included in original ADQI classification but represents a common phenotype of functional kidney injury by AKI definition/criteria when using goal directed medical therapies in heart failure.*

The risk factors associated with LVH and myocardial fibrosis in patients with CKD-associated cardiomyopathy are divided into three categories: preload-dependent factors (volume overload), afterload-dependent factors (pressure overload), and nonhemodynamic factors associated with CKD (cardiomyopathy).[10] Preload-related factors involve expansion of intravascular volume, anemia, and high-flow arteriovenous fistulae created for vascular access for hemodialysis. Afterload-related factors include systemic arterial resistance (systolic and diastolic hypertension) and decreased large-vessel compliance (vascular calcification), resulting in myocardial cell thickening and concentric LV remodeling. Activation of the intracardiac renin–angiotensin aldosterone system (RAAS) seems to be critically involved in this pathway, but angiotensin II and aldosterone can also be involved in myocardial cell hypertrophy and fibrosis, independent of afterload.

Nonhemodynamic factors involved in the pathophysiology of LVH and myocardial fibrosis in CKD include persistent activation of the RAAS, elevated parathyroid hormone levels, activation of the mammalian target of rapamycin pathway, and the fibroblast growth factor (FGF) family.[11] The FGFs are a family of peptides with broad biologic functions that include the regulation of growth and differentiation of cardiac myocytes. In contrast to other members of the FGF family, FGF-23 has unique paracrine functions in the kidney, which facilitate phosphate excretion by blocking the synthesis of vitamin D_3 and inhibition of phosphate reabsorption in the proximal nephron. The independent association between elevated FGF-23 levels and LVH in a racially diverse CKD cohort, as well as the *klotho* independent causal role of FGF-23 in LVH in rat cardiomyocytes was demonstrated elegantly by Faul et al. in the FGF receptor-dependent activation of the calcineurin–NFAT signaling pathway.[12] Galectin-3 (a member of the β-galactoside–binding lectin family that is synthesized by macrophages) can also bind directly to cardiac fibroblasts and reduces LV function through an increase in collagen production.[13] Finally, there are emerging data on the cross talk between cardiac and kidney dendritic cells that play a central role in innate and adaptive immune responses in the context of chronic CRS.[14] The pathophysiological aspects of cardio-renal cross talk in patients with type 4 CRS are illustrated in Figure 23.1.[15]

The diagnosis of HF requires the presence of clinical signs and symptoms along with evidence of a structural or functional cardiac abnormality, several of which can pose diagnostic dilemmas in the setting of CKD. Given the frequent coexistence of renal impairment along with HF, it is important to distinguish long-term decline in eGFR from CKD progression (type 4 CRS) from short-term fluctuations in renal function in the context of decompensated type 1 CRS and/or its targeted therapies. Similarly, making the clinical distinction between type 2 CRS and type 4 CRS can be challenging as patients will inevitably "switch" from a subacute to a chronic CRS phenotype with progression of kidney disease. The use of renal and cardiac biomarkers, noninvasive imaging modalities, and a careful temporal assessment of evidence of cardiac and kidney end organ involvement will help establish the diagnosis of HF in CKD.

The 2017 ACC/AHA/HFSA Focused Update of the 2013 ACCF/AHA Guideline for the Management of Heart Failure reiterated the existing 1A recommendation for the use of BNP and its inactive cleavage protein N terminal pro B type natriuretic peptide (pro BNP) in the diagnosis/exclusion of HF, as well as establishing prognosis and quantifying severity in acute and chronic HF.[16] Patients with CKD have higher baseline BNP levels compared to matched patients with normal renal function, due to impaired renal clearance (more notably with NT-pro BNP) as well as chronic pressure/volume overload and CKD-associated cardiomyopathy.[17] Other biomarkers such as suppressor of tumorigenicity 2 (ST2) (a decoy protein produced by the endothelial cells lining the left ventricle and aortic outflow tract in response to biomechanical strain) and galectin-3 may offer incremental value to natriuretic peptides levels in predicting HF-related deaths and hospitalizations.[18]

Uremic cardiomyopathy evolves through the course of progression of CKD, with subtle alterations in cardiac structure occurring even before clinically significant decline in renal function occurs.[9] Speckle echocardiography with strain analysis allows a more detailed evaluation of myocardial systolic function in the setting of normal left ventricular ejection fraction (LVEF) and may have additive value over echocardiographic assessment of LVEF in uremic cardiomyopathy (type 4 CRS)[19] (Figure 23.2). In a study of 40 controls and 90 patients with CKD across a range of eGFR, LV longitudinal systolic strain, early, and late diastolic strain rates were significantly reduced in CKD patients ($-16.9 \pm 3.8\%$, $1.6 \pm 0.5\%$, and $1.3 \pm 0.4\%$ in CKD vs. $-22.5 \pm 0.6\%$, $2.3 \pm 0.2\%$, and $1.9 \pm 0.1\%$ in controls, $p < 0.001$ for all), despite over-all preservation of ejection fraction.[20] Early attempts to characterize and quantify myocardial fibrosis in end-stage renal-disease (ESRD) using gadolinium enhanced cardiac MRI described a high prevalence of "late gadolinium enhancement" characteristic of coronary artery disease (CAD), but also described a noninfarct pattern typical of more diffuse fibrosis.[9] The limitations to the use of gadolinium in advanced CKD (due to the risk of nephrogenic systemic fibrosis) were overcome in two recent studies that described prolonged native T1 relaxation time and abnormal global

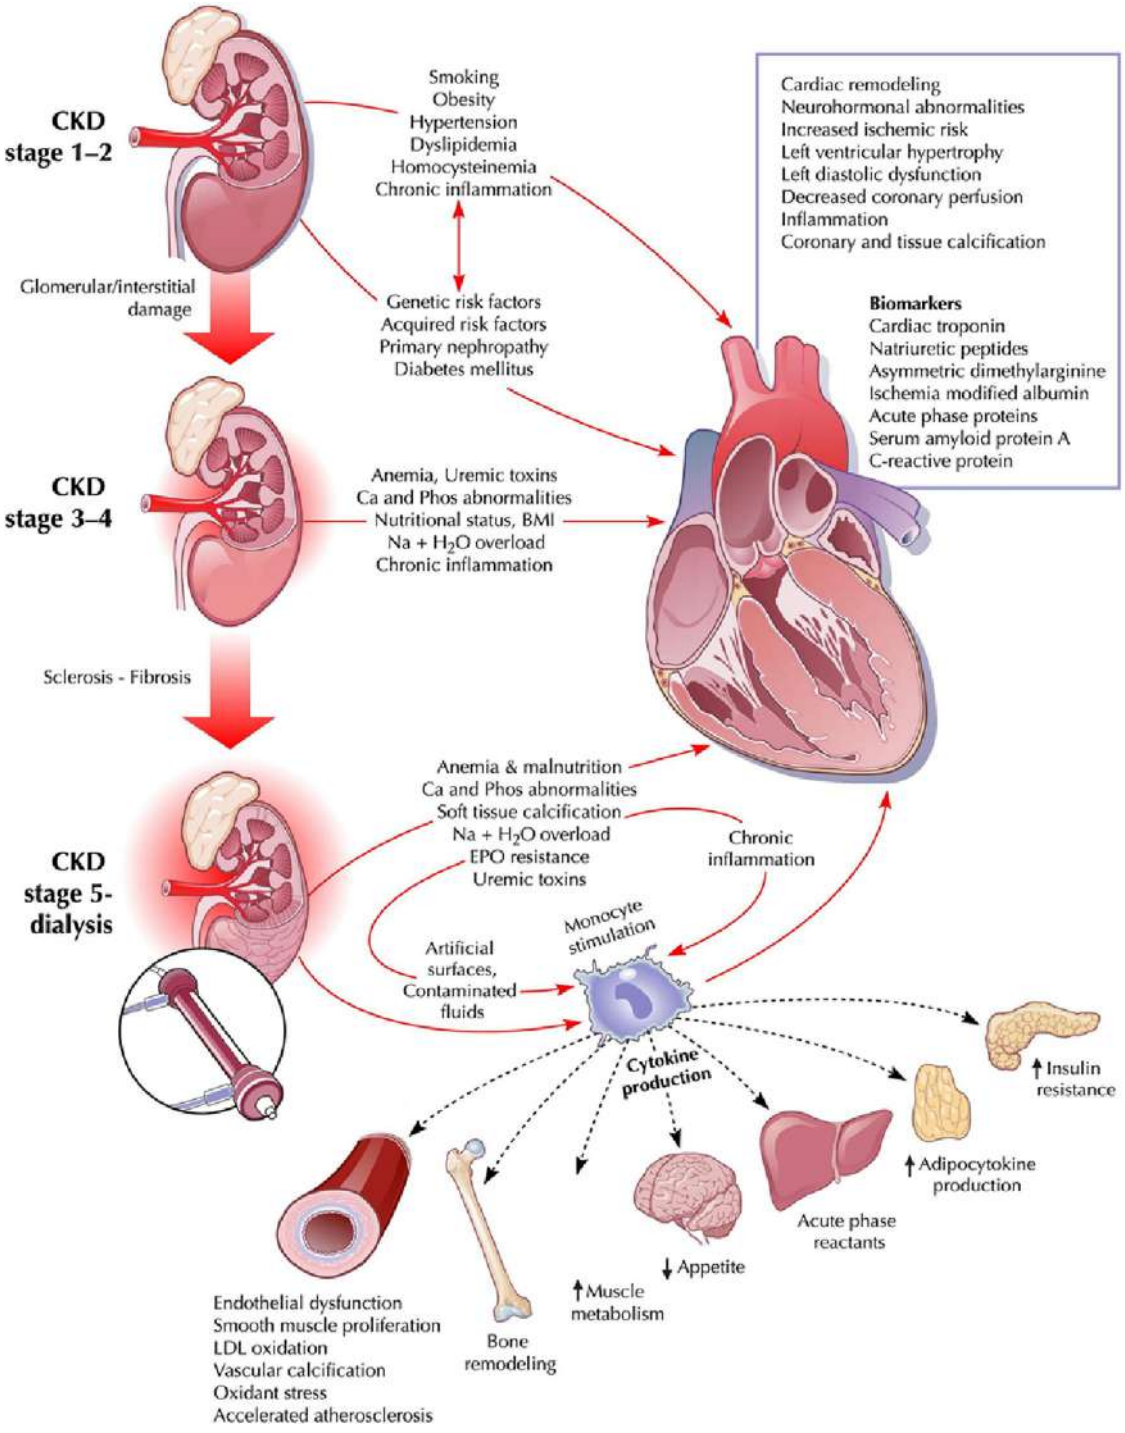

FIGURE 23.1 Pathophysiological interactions between heart and kidney in type 4 cardio-renal syndrome (CRS) or "chronic reno-cardiac syndrome" (for example, chronic glomerular disease contributing to decreased cardiac function, cardiac hypertrophy, or increased risk of adverse cardiovascular events). *BMI*, body mass index; *EPO*, erythropoietin; *LDL*, low-density lipoprotein. *Figure reproduced with permission from reference 15.*

longitudinal strain in prevalent hemodialysis patients with preserved EF compared to controls.[21,22] These advances will help further our understanding of the nuances of CKD-associated cardiomyopathy and its progression in future studies.

Management Strategies in Patients with Heart Failure with Chronic Kidney Disease

Despite the significant burden of HF in CKD, high-quality data from randomized controlled trials (RCTs)

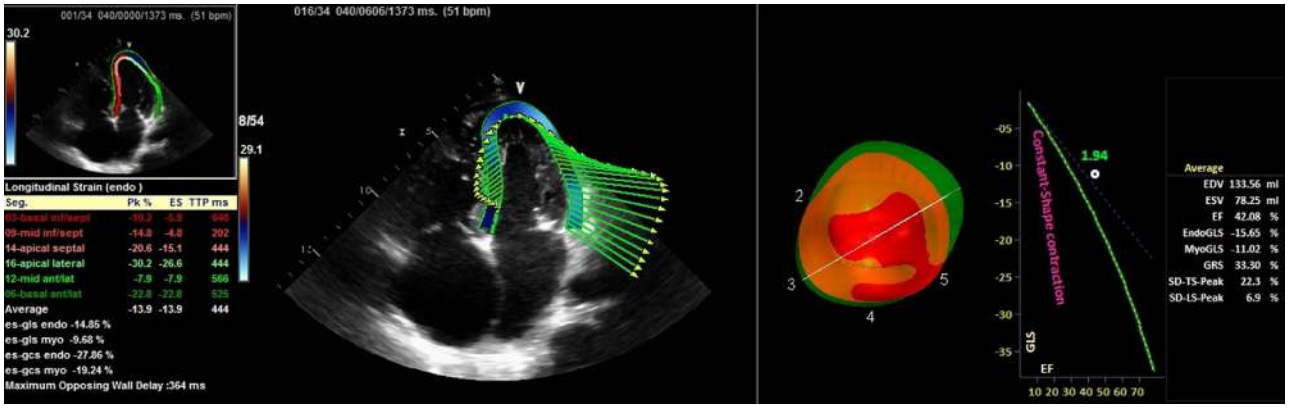

FIGURE 23.2 The panel shows a 2D speckle tracking echocardiographic measurement of global longitudinal strain in apical 4-chamber view in a patient with heart failure with preserved ejection fraction with CKD with eGFR of 40 mL/min/1.73 m^2. On the left is a segmental strain distribution with the mid- to basal inferior septal segments with reduced strain (−14.8% and −10.2%). The mid anterolateral area also exhibited reduced strain (−7.9%). The image on the far right shows the average global longitudinal strain from three views (4 chamber, 2 chamber, and 3 chamber) which is reduced (−15.65%) compared to the normal value that is equal to or more negative than −18%.

evaluating delivering goal directed medical therapies for HF are notably lacking in patients with CKD. Patients with advanced CKD and HF are less likely to receive certain therapies that are used in the general HF population.[23] The cornerstones of HF therapies including preload and afterload reduction, treatment of myocardial ischemia and related structural causes of worsening HF, inhibition of the sympathetic nervous system, and RAAS modification apply to patients with CKD as well as HF. The use of sodium restriction and diuretics to maintain volume control, despite being central to the management of HF with CKD, has not been confirmed in RCT settings with hard cardiovascular endpoint benefits in CKD patients. Diuretic therapy in patients with HF and CKD is characterized by the need for higher drug doses to achieve intended targets. Loop diuretics are more effective with advanced CKD (eGFR <30 cc/min/1.73 m^2) compared to thiazide-type diuretics. Diuretic resistance, defined as the attenuation of the maximal diuretic effect that ultimately limits sodium and chloride excretion, is encountered more frequently in HF with CKD. CKD patients with diuretic resistance have increased risk of worsening renal function, rehospitalizations for HF, and mortality.[24] Diminished nephron mass, acute and chronic diuretic "braking," distal tubular hypertrophy from chronic diuretic use, and persistent RAAS activation are some of the factors underlying diuretic resistance in patients with HF and CKD.[25] Frequent and escalated diuretic dosing, consistent with CKD stage, use of longer acting loop diuretics such as torsemide, reduction of neurohumoral activation by avoidance of chloride depletion, and optimizing RAAS hyperactivity may help circumvent some of these factors in HF with CKD.[26,27] Whether the concept of diuretic synergy (use of a distal diuretic to augment furosemide-mediated sodium excretion) can be used effectively in patients with HF and CKD is uncertain. A large-scale randomized clinical trial of thiazide-type diuretics as an adjunct to furosemide in HF/CRS/CKD is lacking; however, the ATHENA-HF trial (Efficacy and Safety of Spironolactone in Acute Heart Failure) tested spironolactone, a potassium sparing diuretic that targets another hypertrophied downstream nephron segment, against placebo. Investigators did not demonstrate significant clinical benefit.[28] Finally, novel drug delivery routes, such as subcutaneous administration of furosemide, are being developed and may offer promise in reducing the burden of HF-related hospitalizations.[29] Their impact on HF with CKD at this time is, however, unknown.

Goal directed medical therapeutic drug classes in HF include beta adrenergic receptor blockers (BB), angiotensin converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARB), mineralocorticoid receptor antagonists, vasodilator therapies hydralazine/isosorbide dinitrate), ivabradine, digitalis glycosides, and cardiac resynchronization therapy/implantable defibrillator therapy (CRT/ICD). Data are also evolving from major cardiovascular outcomes trials on the role of the novel antidiabetic agents such as sodium glucose cotransporter 2 inhibitors (SGLT2i) and glucagon like receptor 1 agonists (GLP1-RA) with respect to reduction in cardiovascular deaths and HF-related hospitalizations, including in patients with mild to moderate CKD. Relevant information on graded evidence levels in HF are available in the 2017 ACC/AHA/HFSA Focused Update of the 2013 ACCF/AHA Guideline for the Management of Heart Failure,[16] and outlines of pharmacotherapies and their risk/benefit profiles with respect to HF and CKD are summarized by Covic and Damman et al.[30,31] Figure 23.3 **(Panels A and B)** depicts relative strengths of evidence for these goal directed

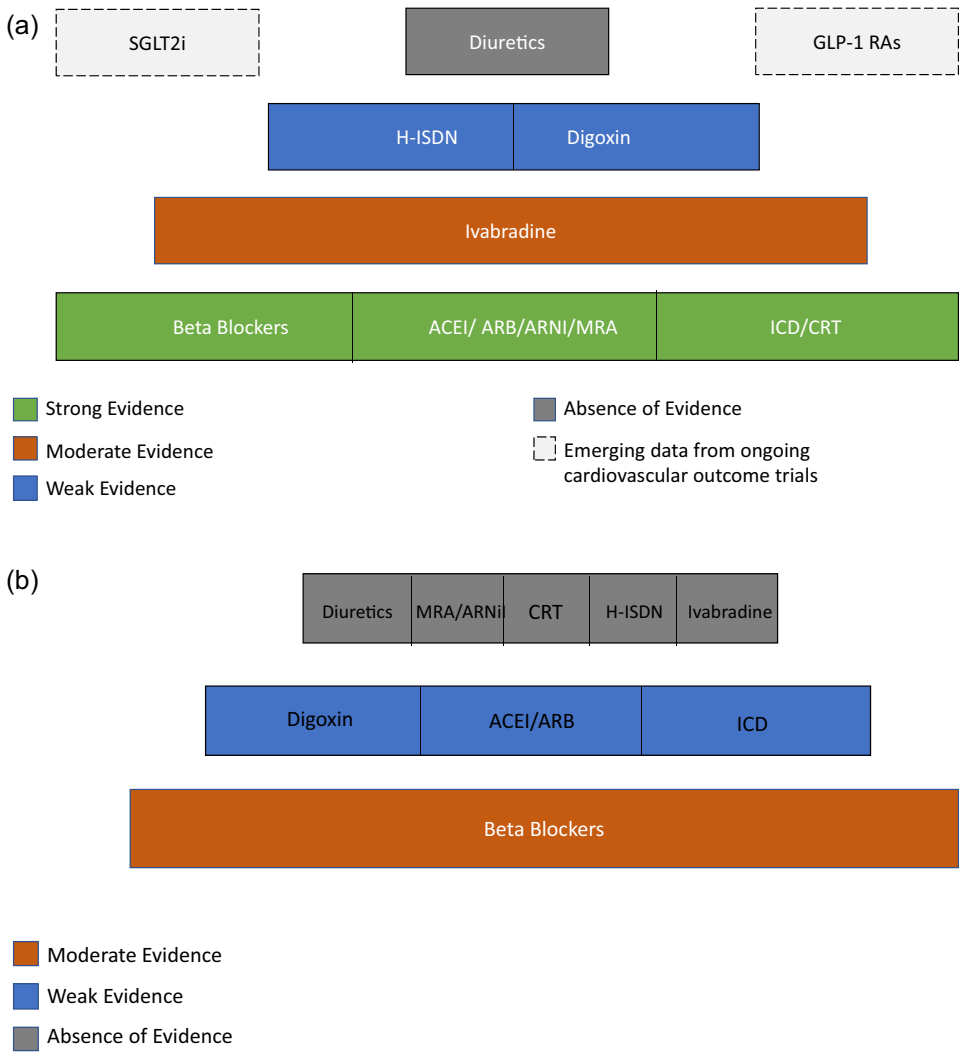

FIGURE 23.3 **Panel A** shows the relative strengths of evidence (ungraded) for goal directed medical therapies for heart failure in patients with underlying stage 1–3 CKD. **Panel B** shows the relative strengths of evidence (ungraded) for goal directed medical therapies for heart failure in patients with stage 4–5 CKD. Both panels exclude data in patients treated with dialysis and kidney transplant recipients. *ACEi*, angiotensin converting enzyme inhibitors; *ARB*, angiotensin receptor blockers; *ARNi*, angiotensin receptor blocker/neprilysin inhibitors; *CRT*, cardiac resynchronization therapy; *GLP 1 RA*, glucagon-like peptide 1 receptor agonist; *H-ISDN*, hydralazine-isosorbide dinitrate; *ICD*, implantable cardiac defibrillators; *MRA*, mineralocorticoid receptor antagonists; *SGLT2i*, sodium glucose cotransporter 2 inhibitors.

therapies in HF with respect to the different stages of CKD (excluding dialysis and transplantation).

ATHEROSCLEROTIC CARDIOVASCULAR DISEASE IN CHRONIC KIDNEY DISEASE

Pathophysiology and Risk Factors

Patients with CKD exhibit high disease burden from ASCVD, including CAD as well as peripheral arterial disease. Atheromatous plaques, the *sine qua non* of this phenotype of CVD, are quantitatively similar to those found in patients without CKD as shown in autopsy studies.[32] However, the plaques are more calcified with abundance of hydroxyapatite, i.e. calcium phosphate) with significant intimal and medial calcification in CKD compared to those without CKD.[33] The presence of CKD, independent of other CVD risk factors, appears to accelerate the atherosclerotic process including the recruitment of monocytes, upregulation of adhesion molecules, ingress of monocytes and conversion to macrophages and foam cells, mobilization of vascular smooth muscle cells, breakdown of the elastic lamina, and development of an atheroma, which expands both toward the lumen and outward toward the adventitium.[34] In addition, CKD has a significant influence on calcification in atherosclerosis. The majority of anatomic and visible calcium by imaging in atherosclerosis is the result of osteoblastic conversion of smooth muscle cells,

and the deposition of calcium hydroxyapatite crystals in the extracellular matrix.[35] Phosphate appears to be an important stimulator of the vascular smooth muscle cells to both undergo osteoblastic deposition and deposit calcium, and it may represent a major influence on the development of the disproportionately calcified lesions seen in CKD.[35,36] Finally, angiographic evidence of CAD in CKD (eGFR <60 cc/min/1.73 m^2) has demonstrated higher rates of triple vessel disease or left main disease as reported in the CKD subset of the Clinical Outcomes Utilizing Revascularization and Drug Evaluation (COURAGE) trial as well as in other databases.[37,38] Although these studies do not report the etiology of CKD or degree of albuminuria, the strong correlation between decreased eGFR and clinicopathological evidence of ASCVD reinforces the designation of CKD as an ASCVD equivalent.

Stable Ischemic Artery Disease and Acute Coronary Syndromes: Diagnostic Strategies

Currently available tools for the diagnosis of ASCVD including clinical symptoms, electrocardiogram, and cardiac stress testing are overall less reliable in the CKD population.[39] In a study evaluating the occurrence of chest pain or related symptoms (arm or jaw pain) during total balloon occlusion of an epicardial coronary artery with plaque, 48% and 50% of patients with eGFR 30–59 mL/min/1.73 m^2 and <30 mL/min/1.73 m^2, respectively, experienced no pain on occlusion, compared with 20.6% and 28.2% of patients with eGFR >90 mL/min/1.73 m^2 and 60–89 mL/min/1.73 m^2, respectively (χ^2 test for trend $p = 0.004$).[40] Coronary calcification seen on computed tomographic studies is a proxy for a greater burden of atherosclerosis, reduced vascular compliance, and more mature and stable plaques and not a passive process of calcification such as Mönckeberg's sclerosis. When the coronary calcium score (either volumetric or Agatston) is >400 units, then the probability of at least one significant ($>70\%$) lesion resulting in reduced myocardial blood flow with stress is $>80\%$. Thus, if a calcium score is known at the time of evaluation and the score is >400, further functional testing is reasonable.[41]

Despite the higher burden of CAD risk factors in CKD, the overall performance of cardiac stress testing in this population is suboptimal. A meta-analysis of cardiac stress testing performance (primarily dobutamine stress echocardiography and myocardial perfusion scintigraphy) identified a median sensitivity of 69% and specificity of 80% for myocardial perfusion scintigraphy, and median sensitivity of 80% and specificity of 89% for dobutamine stress echocardiography.[42] This translates to a higher proportion of both false-positive stress tests as well as false-negative stress tests. LVH, balanced ischemia due to multivessel disease, increased baseline coronary flow reserve, and baseline ECG abnormalities resulting in high interobserver variability are some of the factors that contribute to the lower accuracy of stress testing in CKD.[43] An overview of the utility of select diagnostic tests for CVD in CKD with emphasis on CAD is presented in Table 23.2.[41] There is no clear cut indication to evaluate asymptomatic patients with screening stress tests or other imaging modalities. The exception to this situation is the preoperative cardiac workup of the kidney transplant recipient (which is beyond the scope of this chapter). Such approaches are outlined in detail in the ACCF/AHA Scientific Statement on the preoperative workup of the potential kidney and liver transplant recipient.[44]

As CKD stage worsens, patients are more likely to present with acute coronary syndrome (ACS) than stable ischemic heart disease (SIHD).[45] McCullough et al. demonstrated that patients with CKD presenting to the emergency room with chest pain had a 40% risk of MI, HF, or death.[46] Patients with CKD presenting with ACS tend to have more extensive CAD, higher risk for reinfarction, HF, and death. Paradoxically the presentation tends to be more atypical with delayed initial presentation, with a lesser likelihood of receiving evidence-based therapies for ACS compared to patients without CKD.[47] The severity of CKD correlates with both short-term and long-term outcomes with ACS.[48] In addition to symptoms of ACS, physical findings, and electrocardiographic evaluation, cardiac biomarkers of injury play a critical role in the diagnostic algorithm for ACS as well as for prognostication. In CKD, baseline elevations in cardiac troponins can reflect myocardial damage, decreased renal clearance, skeletal muscle expression of cardiac specific isotopes, and metabolic abnormalities. Thus, in a patient with CKD and suspected ACS, baseline cardiac troponin levels of >99 percentile values for the general population are a common finding. The characteristic rise and fall of these biomarkers must be accompanied by at least one other piece of supportive evidence, including new ST–T wave changes or left bundle branch block, signs and symptoms consistent with ischemia, new myocardial wall motion abnormalities, the presence of thrombus on coronary angiography, or supportive autopsy findings to make a diagnosis.[49]

Management Strategies for Stable Ischemic Heart Disease in Chronic Kidney Disease

The evidence-based approach to the medical management of SIHD and ACS in patients with CKD is limited by the underrepresentation of this population in major

TABLE 23.2 Overview of Select Diagnostic Tests for Cardiovascular Disease in CKD

Test	Comment
12-lead electrocardiogram	Should be done yearly, evaluates baseline rhythm, presence of Q-waves, chamber enlargements, left ventricular hypertrophy
Functional imaging Exercise stress echocardiography Exercise stress nuclear scintigraphy (Tc-99 sestamibi or Tl-201) Pharmacologic stress imaging (regadenoson, dobutamine, adenosine, dipyridamole)	Evaluates exercise-related functional status with >10 metabolic equivalents of work being excellent prognosis; imaging identifies fixed and reversible ischemia; large zones of reversible ischemia call for anti-ischemic therapy and additional evaluation usually with angiography; stress echocardiography gives all the baseline information of resting echocardiography in addition to the evaluation of reversible ischemia
Cardiac computed tomographic angiography	Appropriate for the evaluation of chest pain with an uninterpretable stress test; not appropriate for patients with established CAD or ESRD; generates calcium score, can evaluate degree of lumen stenosis if calcification is not severe; normal result has excellent negative predictive value for cardiac events; calcium score >400 usually indicates severe disease on invasive angiography, while score of 0 portends excellent prognosis
Coronary angiography Left ventriculography	Definitive diagnosis of coronary luminal obstruction, left ventricular function, and opportunity for *ad hoc* PCI
Resting echocardiography	Test of choice to evaluate diastolic and systolic function, valve disease
24-hour Holter monitor	Records all beats over 24 hours, calculates mean atrial and premature beats per hour (>10 abnormal), identifies ST segment shifts, identifies asymptomatic arrhythmias
Cardiac event monitor	Worn for prolonged periods, patient activates device to record symptomatic arrhythmias
Insertable loop recorder	Subcutaneous, pectoral placement of device that records patient and device-detected arrhythmias for approximately 2 years

CAD, coronary artery disease; *ESRD*, end-stage renal disease; *PCI*, percutaneous coronary intervention; *Tc*, technetium; *Tl*, thallium.
Reproduced with permission from reference 41.

cardiovascular outcome trials (CVOTs), despite the higher baseline risk for CAD in CKD. Charytan et al. analyzed 86 large cardiovascular trials on 5 different types of therapies for CAD.[50] 75% of these trials excluded patients with CKD, and over 80% excluded subjects on dialysis. Baseline renal function was reported only in 7% of study participants. This key factor may contribute to the "therapeutic nihilism" seen in the management of CAD in CKD, in addition to the fear of causing harm (such as with antiplatelet agents or RAAS inhibitors) and the inaccurate extrapolation of data in the non-CKD patients to those with CKD.

Blood Pressure Targets

Blood pressure (BP) optimization in subjects with CKD at elevated CVD risk or with established CVD has been a moving target, with potentially conflicting data in different subpopulations (diabetic vs. nondiabetics). The Systolic Hypertension Intervention Trial (SPRINT) demonstrated benefits with intensive BP control (SBP <120 mm Hg) in nondiabetic hypertensives at high cardiovascular risk, including in its CKD subset (about 28% of participants).[51] However, the trial also reported higher rates of hypoperfusion-related serious adverse outcomes, such as AKI, syncope, and hypotension, and was limited in long-term follow-up due to premature termination of the trial after analyses of the primary outcome exceeded the monitoring boundary at two consecutive time points. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial (with less representation of CKD), in contrast, showed no benefits with a similar intensive BP reduction target in diabetics with established or high risk for CVD.[52] Beddhu et al. reported on a comparative analysis of incident CKD in the SPRINT and ACCORD trials, which showed the intensive BP target group in ACCORD experienced the highest rates of incident CKD.[53] These observations may be explained in the context of the known effects of intensive BP lowering with impaired renal blood flow autoregulation in subjects with preexisting hypertension and CKD, thus increasing the potential risk of renal hypoperfusion–related AKI, which may serve as a springboard for future CKD.[54] Finally, Malhotra et al. demonstrated an overall reduction in all-cause mortality in a meta-analysis of 18 trials looking at standard vs. intensive BP control, in subjects with stages 3–5 CKD.[55] The 2017 ACCF/AHA guidelines for management of hypertension target a SBP >130 mm Hg for treatment in CKD with ACEI/ARB being the drugs of choice in patients with albuminuria.

Statin Therapy

3-Hydroxy-3 methyl-glutaryl-coenzyme A reductase inhibitors (statins) have been studied in the CKD population in three high-quality RCTs: the Die Deutsche Diabetes Dialysis (4D) trial,[56] An Assessment of Survival and Cardiovascular Events (AURORA) trial,[57] and the Study of Heart and Renal Protection (SHARP) trial.[58] The use of statins in patients with end-stage renal disease accrued no benefits toward primary or secondary prevention of the composite cardiovascular outcomes. In the SHARP trial, the combination of simvastatin and ezetimibe in patients with CKD (including those treated with dialysis) reduced major atherosclerotic events by 17% but did not reduce overall mortality. A meta-analysis of 38 trials comparing statins vs. placebo or no treatment suggested benefits in patients with moderate CKD not requiring dialysis.[59] Given the reduction in nonfatal cardiovascular events and the lack of significant harm from statins in these trials, the KDIGO lipid guidelines recommend therapy in all patients with CKD >50 years and with high ASCVD risk in the age group of 18–49 years.[60]

Antiplatelet Agents

Patients with CKD represent both extremes of the bleeding-clotting paradigm. Baseline higher levels of platelet reactivity in patients with reduced GFR has been demonstrated,[61] as well as less robust reduction in platelet reactivity in response to P2Y12 inhibitors, such as clopidogrel in patients with CKD or proteinuria.[62] This may be a contributory factor to in-stent thrombosis, which is a bigger concern in patients with CKD than in those without CKD. The role of aspirin is limited to prevention of MI in patients with CKD, with no effect on mortality.[63,64] At this time, there are limited data on the efficacy of the newer P2Y12 inhibitors in CKD and ESRD.

Myocardial Revascularization for Stable Ischemic Heart Disease in CKD Patients

The only true randomized trial comparing medical therapy vs. revascularization of SIHD in CKD was performed by Manske et al. in 1992, which was stopped after enrollment of 26 subjects due to excessive rates of the primary outcome (unstable angina, MI, or cardiac death) in the medically managed group. This must be interpreted in the context of "optimal medical therapy" for CAD being limited to aspirin and calcium channel blockers at that time. After this, no prospective RCTs have addressed this question with the current therapeutic armamentarium available for the medical management of CAD in patients with CKD. A *post hoc* analyses of 320 subjects from COURAGE with eGFR<60 cc/min/1.73 m^2 demonstrated no differences in rates of death and MI between the medically managed group and the revascularization group. The Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) showed that an initial revascularization strategy with percutaneous coronary interventions (PCI) or coronary artery bypass grafting (CABG) vs. medical management in SIHD was not superior regarding reduction in all-cause mortality or MI. However, S[Cr] >2 mg/dL was an exclusion criteria for this trial, and no formal results are available on comparative strategies and outcomes from BARI 2D in CKD. Thus, at this time, robust evidence in favor of revascularization for SIHD in CKD does not exist, but other important conclusions can be made from available observational data, as well as from *post hoc* analyses of RCTs. Drug-eluting stents may offer superior outcomes compared to bare metal stents in patients with SIHD and CKD.[65] Patients with triple vessel disease or on maintenance dialysis may benefit from CABG, especially when complete revascularization cannot be achieved with PCI, regarding long-term outcomes.[66,67] Finally, "zero contrast" PCI techniques in patients with advanced CKD afford renoprotection and reduction of contrast-induced AKI rates even in patients with advanced predialysis CKD.[68,69]

Management of Acute Coronary Syndromes in Chronic Kidney Disease

Patients with CKD presenting with an ST elevation myocardial infarction (STEMI) should undergo primary PCI with stenting within 90 minutes (door to balloon time). Treatment patterns for STEMI in CKD are characterized by delayed therapy due to difficulty with recognition of the condition and confusion regarding the risks and benefits of treatment. Newsome et al. found that of 109,169 Medicare patients with MI, fewer patients with kidney disease received thrombolytic therapy, and those with the worst kidney disease (S[Cr] >1.6 mg/dL) waited the longest for therapy. There are no formal dose adjustment recommendations for the use of streptokinase, alteplase, reteplase, or tenecteplase in patients with CKD.[49] After reperfusion, medical management of STEMI is similar to that of patients with non-ST elevation myocardial infarction (NSTEMI). Once a patient with suspected unstable angina or NSTEMI is diagnosed, standard medical therapy should include aspirin, a beta adrenergic receptor blocker, anticoagulant therapy, possibly a glycoprotein IIb/IIIa antagonist, and a thienopyridine, unless a specific contraindication exists.[49]

Mild to moderate CKD is considered a risk for major complications in patients with unstable angina or

NSTEMI, and an early invasive strategy is preferred to conservative medical management. Although patients with predialysis CKD are less likely to be offered coronary angiography in the setting of ACS, they benefit from revascularization with improved long-term survival.[70] The Swedish Web System for Enhancement and Development of Evidence-Based Care in Heart Disease Evaluated According to Recommended Therapies (SWEDEHEART) reported in 23,262 cases of NSTEMI that the utilization of coronary angiography and revascularization decreased with declining eGFR.[71] In SWEDEHEART, the benefits of an early invasive strategy on 1-year mortality confirmed in patients with mild and moderate CKD were not observed in patients on dialysis, likely due to several other competing factors in patients on dialysis that increase mortality risk. A detailed summary by Narala et al. highlights the benefits, hazards, drug dosing, and caveats with the management of SIHD and ACS in CKD to assist with clinical decision-making in this population.[49]

Valvular Heart Disease in Chronic Kidney Disease

The two most common forms of cardiac valvular disease in CKD are aortic valve calcification and sclerosis, and mitral annular calcification (MAC). In CKD, there is a graded relationship between progressive decline in eGFR and the prevalence of calcification, hospitalizations, cardiovascular events, and death[72] (Figure 23.4). Complications associated with valvular calcification include thromboembolic phenomenon, arrhythmias, and stenosis-related symptoms. Patients with CKD and aortic stenosis (AS) are considered "rapid progressors" with annual reduction in aortic valve area being around $0.23\ cm^2$/year compared to the typical $0.05–0.1\ cm^2$/year in patients without CKD.[73] Valve replacement is the only therapy shown to have survival benefit in AS regardless of underlying CKD. The two main treatment options for aortic valve replacement are surgical (SAVR) vs. transcatheter aortic valve replacement (TAVR). CKD is a risk factor for increased 30-day mortality and a greater than 50% increase in median post SAVR mortality long term.[74] Higher complication rates with SAVR in CKD result from the technical challenges associated with high valvular and vascular calcific burden and bleeding risk, resulting in increased hospital length of stay as well as ICU duration.[75] The less-invasive TAVR is an available therapeutic option in patients with high surgical risk and CKD. However, underlying CKD is associated with higher incidence of MACEs (composite of death, myocardial infarction, or stroke), net adverse cardiovascular events (composite of MACEs, major bleeding, or vascular complications), and pacemaker implantation, compared with patients without CKD.[76] In another analysis, in additional to higher mortality rates, the risk of AKI and needing dialysis were higher in subjects with underlying CKD.[77] Finally, a recent meta-analysis of TAVR outcomes in CKD reported an increased short-term and long-term mortality risk in high-risk surgical patients undergoing TAVR with underlying CKD. This association was not seen in low/intermediate-risk patients with CKD undergoing TAVRs.[78] Given the high-risk patient profile and

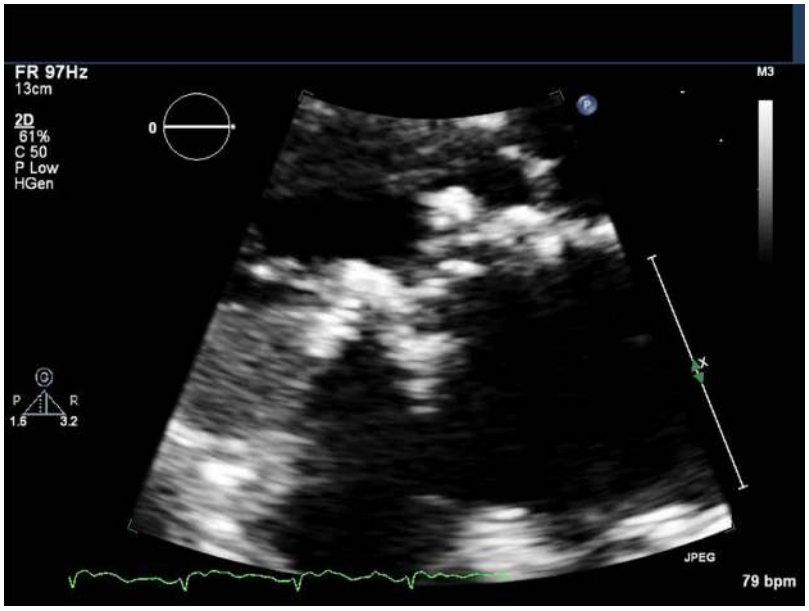

FIGURE 23.4 Parasternal long-axis view on 2-D echocardiography of a patient with stage 5 CKD (not on dialysis) with a severely calcified bioprosthetic mitral valve 6 months after valve replacement.

complexity of planned valvular procedures in patients with CKD, clinical decision-making on valve replacement choice/techniques must be conducted with a multidisciplinary heart–kidney team to achieve optimal outcomes.

Mitral stenosis and/or regurgitation can occur secondary to MAC and may require surgical or percutaneous (Mitra Clip or transcatheter mitral valve replacement) interventions. Patients with CKD undergoing Mitra Clip (placement of a stitch between the anterior and posterior leaflet, producing a double orifice valve and reducing the effective orifice area) are more likely to be male, older, and have higher preprocedural STS and EuroScores.[79] Also, patients with CKD, especially with eGFR <30 mL/min/1.73 m^2, require a higher number of postprocedure blood transfusions or experience major bleeding. Irrespective of underlying CKD status, effective reduction of mitral regurgitation can lead to improvement in renal function, with documented reductions in diuretic use and improvements in LA and LV volumes and LV dimensions in patients with CKD at 1 year follow-up.[79] This is likely from the favorable impact of reduction of valvular leak on myocardial mechanics and hemodynamic/neurohumoral changes with decompensated CRS. Further research needs to be done to enhance clinical utility.

Arrhythmias and Chronic Kidney Disease

Patients with CKD are predisposed to heart rhythm disorders, including atrial fibrillation (AF)/atrial flutter, supraventricular tachycardias, ventricular arrhythmias, and sudden cardiac death (SCD). Although treatment options including drugs, devices, and procedural therapies are available, their use in the setting of CKD is limited by paucity of high-quality data. AF is the most common sustained arrhythmia and has a high prevalence in CKD. Consequences of AF in CKD include elevated stroke risk, increased risk of progressive CKD/ESRD, and death.[80–82] Among stroke prediction risk scores, the CHA_2DS_2-VASc score remains the most commonly recommended score for risk stratification. Observational data show a treatment threshold of CHA_2DS_2-VASc ≥ 2 is associated with benefit from oral anticoagulation therapy, including in CKD.[83]

Large RCTs have demonstrated that novel oral anticoagulants (NOACs) are noninferior to warfarin among patients with estimated creatinine clearance (eCrCl) of 30–50 mL/min, with significant reductions in the risk of intracranial hemorrhage.[84] However, the lack of head to head comparisons of these drugs in CKD precludes any recommendations of an individual drug. Among patients with creatinine clearance between 25 and 50 mL/min, treatment with apixaban and edoxaban resulted in significantly fewer major bleeding events compared with warfarin.[85] In patients with eGFR<30 cc/min/1.73 m^2 and in patients treated with dialysis, there is insufficient high-quality evidence on the safety and efficacy of anticoagulation for stroke prevention in AF, with conflicting results reported from large observational cohort studies.[86,87] Anticoagulation-related nephropathy may cause episodes of intraglomerular hemorrhage and accelerate decline in renal function and dialysis dependence.[88] The US Food and Drug Administration recently approved the use of apixaban 5 mg twice daily, rivaroxaban 15 mg daily in CKD 5 and ESRD and dabigatran 75 mg orally twice daily for CrCl 15–30 mL/min based on single/limited dose pharmacokinetic and pharmacodynamic data. The recent KDIGO controversies conference on CKD and arrhythmias suggested consideration of the lower dose of apixaban 2.5 mg orally twice daily in CKD 5 and ESRD patients to reduce bleeding risk until clinical safety data are available, an approach supported by a recent pharmacokinetic study comparing the two doses.[84] Ongoing and future randomized trials addressing the need and choice of drugs for safety and efficacy for stroke prevention in AF and CKD, will help determine best clinical practices to reduce stroke burden in this population.[89]

The burden of SCD is high in patients with CKD (fourfold increase with eGFR <60 cc/min/1.73 m^2) and increases further with transition to ESRD.[90] Although traditional risk factors such as reduced ejection fraction and atherosclerotic CAD are associated with SCD in CKD, they do not fully account for the high incidence of SCD seen in this population. Factors specific to the CKD milieu such as hyperkalemia and the malnutrition–inflammation complex may also contribute to this elevated risk.[91] Given the high prevalence of CKD in patients with HF and vice versa, implantable device therapy is part of the therapeutic armamentarium in this population. Although the benefits of placement of implantable cardioverter–defibrillators (ICDs) in patients with HF meeting select criteria are well established in the general population,[92] conflicting data exist regarding the benefits in patients with HF and CKD. Pun et al. reported on outcomes with ICDs for primary prevention in CKD in a meta-analysis of three primary prevention ICD RCTs that had data available on renal function: The Multicenter Automatic Defibrillator Implantation Trial I (MADIT-I), MADIT-II, and the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT).[93] ICDs were associated with survival benefit in patients with GFR >60 cc/min (adjusted HR, 0.49; 95% posterior credible interval, 0.24–0.95). This was not the case with patients with GFR <60 cc/min (aHR, 0.80; PCI, 0.40–1.53), wherein eGFR did not modify the association between ICDs and

rehospitalizations. In contrast, the DANISH trial (Danish study to assess the efficacy of ICDs in patients with non-ischemic systolic HF on mortality) showed that prophylactic ICD implantation in HFrEF not caused by CAD had no impact on mortality from any cause, including patients with CKD.[94] Subcutaneous defibrillators offer an attractive alternative to ICDs and pilot data on safety and efficacy exists in patients with ESRD.[95,96] Similarly, benefits from CRT are attenuated in the presence of underlying CKD.[97] However, improvements in EF, reduction in mitral regurgitation, and eGFR in mild to moderate CKD have been reported in *post hoc* analyses of The Multicenter InSync Randomized Clinical Evaluation study.[98] Given that patients with advanced CKD are routinely excluded from major cardiovascular therapy trials, and the lack of robust data on survival benefits, decisions to use device-based therapies for primary prevention in advanced CKD and ESRD must consider patient comorbidities, frailty, and quality of life to balance the risk–benefit profiles including higher infection rates, bleeding, central venous stenosis, and tricuspid regurgitation with specific devices.

CONCLUSIONS AND FUTURE DIRECTIONS

Patients with CKD experience unacceptably high rates of CVD, including all its phenotypes. Paradoxically, CKD remains an exclusion criterion for most major cardiovascular trials, thus leaving several key questions regarding the diagnosis and management of CVD in CKD unanswered. Ongoing major RCTs such as the International Study of Comparative Health Effectiveness with Medical and Invasive Approaches–Chronic Kidney Disease trial (ISCHEMIA-CKD, NCT01985360) and the Trial to Evaluate Anticoagulation in Hemodialysis patients with Atrial Fibrillation (RENAL-AF, NCT02942407) will help shed light on key clinical questions pertaining to the cardiovascular care of the patient with CKD. The introduction of clinically meaningful composite cardio-renal outcomes such as Major Adverse Renal Cardiovascular Events (composite of myocardial infarction, need for RRT stroke, HF, hospitalizations for cardiac reasons, hospitalization for renal reasons, and death)[99] will allow the clinical consequences of CVD and CKD, and the effects of different interventions to be defined more accurately. There is an urgent need for dedicated "cardio-renal" interdisciplinary teams that will spearhead early identification of patients with complex CVD and CKD, and jointly manage appropriate clinical interventions across inpatient and outpatient settings (Figure 23.5). This collaboration would also oversee cross training among nephrology and cardiology fellows, and nursing and allied health care providers in both specialties, to foster a deeper understanding of the intricacies of cardio-renal cross talk.[100] These measures will help reduce the disease burden of CVD with CKD in a clinically effective and cost-favorable manner.

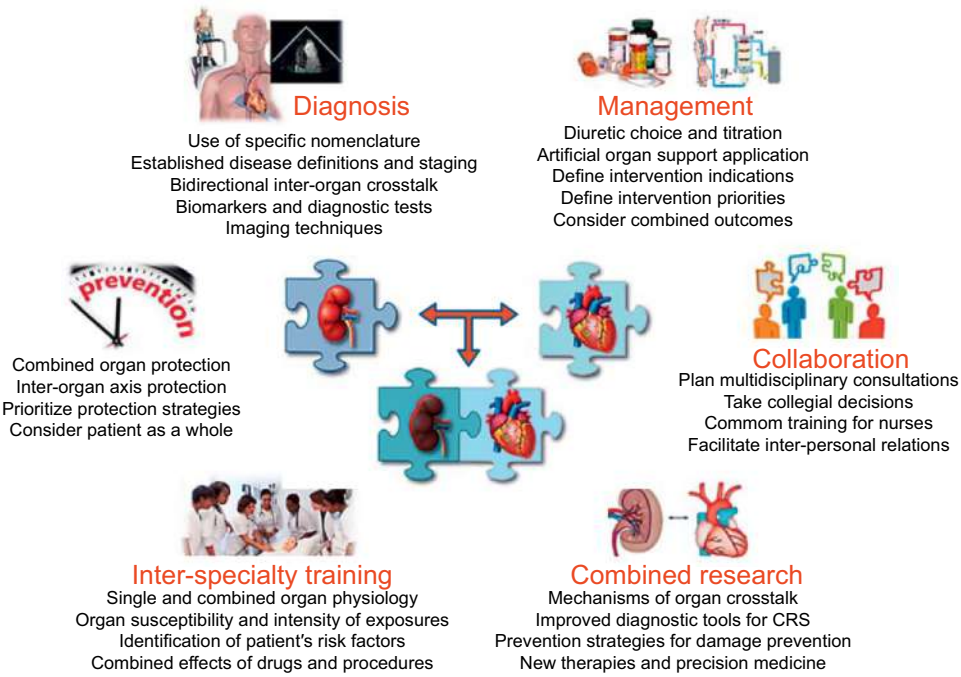

FIGURE 23.5 A model for a multidisciplinary cardio-renal team that would spearhead joint clinical decision-making, educational pathways, and research collaborative efforts in cardio-renal medicine. *Reproduced with permission from reference 100.*

QUESTIONS AND ANSWERS

Question 1

The spectrum of structural, neuro-hormonal, and biochemical cardiovascular changes seen in patients with chronic kidney disease represent the following phenotype of cardio-renal syndrome as described by the Acute Dialysis Quality Initiative:

A. Type 1 cardio-renal syndrome
B. Type 2 cardio-renal syndrome
C. Type 3 cardio-renal syndrome
D. Type 4 cardio-renal syndrome
E. Type 5 cardio-renal syndrome

Answer: D

Type 4 cardio-renal syndrome reflects the chronic structural changes seen in cardio-vascular disease in the backdrop of chronic kidney disease. This phenotype is also represented by the changes seen in neuro-hormonal modulators of the sympathetic nervous system, renin angiotensin aldosterone system, inflammatory markers, disorders of bone and mineral metabolism, iron deficiency, and anemia.

Question 2

The following classes of pharmacotherapies show evidence from high-quality randomized controlled trials in heart failure with/without kidney disease **except**:

A. Beta adrenergic receptor blockers
B. Angiotensin converting enzyme inhibitors/ angiotensin receptor blockers
C. Mineralocorticoid receptor antagonists
D. Diuretics
E. Ivabradine

Answer: D

Of all the above classes of pharmacotherapies that are part of goal directed medical therapy in heart failure with/without kidney disease, diuretics are the one class of drugs that are used for decongestion and heart failure–related symptom relief in the absence of a randomized controlled trial testing the benefits of this form of therapy toward hard clinical endpoints. Despite this, diuretics remain a cornerstone for therapy in heart failure, and novel approaches to management of diuretic efficiency and diuretic resistance are being tested in ongoing trials.

Question 3

The following are causes of diuretic resistance in heart failure **except**:

A. Distal tubular remodeling from chronic diuretic exposure
B. Activation of the sympathetic nervous system and renin angiotensin aldosterone axis
C. Chronic kidney disease
D. Impaired drug absorption
E. Diuretic "braking"

Answer: C

Of all the potential causes for diuretic resistance in a patient with heart failure, chronic kidney disease *per se* is not a cause, with the exception of very advanced predialytic kidney disease. The other causes listed factor into the phenomenon of diuretic resistance, and are potentially correctable based on the underlying etiology such as switching to intravenous loop diuretics (and more recently, subcutaneous loop diuretic administration), use of longer acting loop diuretics such as torsemide for more predictable therapeutic concentrations, combining loop diuretics with a distal diuretic such as the thiazide class of drugs, and more frequent dosing in subjects with kidney disease. Diuretic resistance in addition to impairing efforts at decongestion in acute heart failure is also independently associated with worse outcomes, including all cause mortality.

Question 4

The following would be considered true in patients with ACS with underlying chronic kidney disease:

A. Patients present with higher rates of chest pain and typical symptoms as they have higher cardiovascular disease burden because of their chronic kidney disease
B. Patients with chronic kidney disease receive delayed goal directed therapy for ACSs given their concomitant chronic kidney disease
C. The presence of advanced chronic kidney disease precludes prompt revascularization in ACS as the renal risks outweigh the benefits
D. A baseline elevation in cardiac troponins is diagnostic of ACS in chronic kidney disease
E. Major cardiovascular trials routinely include patients with advanced chronic kidney disease given the high-risk population they represent.

Answer: B

Despite the well-known elevated risk for cardiovascular disease in chronic kidney disease including ischemic heart disease, patients presenting with ACSs in this population are underdiagnosed and undertreated. Part of this may be related to the atypical symptoms of ischemia seen in patients with chronic kidney disease, concerns of "harm" by using standard goal directed therapies for ACSs in this population, and the lack of high-quality data specific to patients with chronic kidney disease on optimal medical and

revascularization therapies and their delivery in patients with kidney disease. Patients with chronic kidney disease benefit from prompt and appropriate revascularization and medical therapies for ACSs, and the presence of kidney disease should not preclude evidence-based best medical practice therapies.

Question 5

The sodium glucose cotransporter 2 inhibitors (SGLT2i) have been shown to have significant risk reduction for cardiovascular and renal endpoints in major cardiovascular outcomes trials. Which of the following statements about this class of drugs is **false**?

A. The separation of Kaplan Meier outcome curves between treatment and placebo groups in cardiovascular outcomes trials in diabetics occurred early (around 3 months) into the trials
B. These drugs are effective in advanced chronic kidney disease
C. No differences were noted in cardiovascular trials of SGLT2i for acute kidney injury rates between drug and placebo arms
D. BP control was noted to be better in patients on SGLT2i in randomized controlled trials
E. SGLT2i activates tubulo-glomerular feedback due to higher sodium delivery to the macula densa and thus reduces intraglomerular pressures.

Answer: B

The SGLT2i represent a major class of novel antidiabetic therapies that have shown major cardiovascular and renal risk reduction in CVOTs. Targeted effects from blocking SGLT2 cotransporter of the proximal tubule include natriuresis, activation of tubule-glomerular feedback, and reduction of hyperfiltration injury. Two major CVOTs: EMPAREG OUTCOME and the CANVAS programs demonstrated significant cardiovascular risk reduction with empagliflozin and canagliflozin, respectively. In addition, *post hoc* analyses of EMPAREG OUTCOME showed reduction in the prespecified renal composite secondary outcome, and the CANVAS program showed possible benefits with reduction in albuminuria and the trial's prespecified renal endpoint. Although these benefits have also been demonstrated in mild to moderate CKD, this class of drugs is less effective with advanced CKD based on its mechanism of action. The early separation of Kaplan Meier outcome curves in these trials alludes toward nonatherosclerotic mechanisms of cardiovascular benefits, including reduction in heart failure hospitalization and cardiovascular deaths. Ongoing CVOTs involving several drugs in this class will help delineate the cardiovascular and renal benefits of these drugs in a more precise fashion.

Question 6

The following is **true** about patients with cardiovascular and kidney disease:

A. These patients represent an undertreated and vulnerable group when compared to the general population
B. Cardio-renal care is usually a seamless transition across health care settings and health care providers
C. Palliation has a limited role in patients with cardio-renal disease
D. High-quality data from randomized trials are used to devise best clinical practices in patients with cardiovascular and kidney disease
E. Awareness of the dual burden of cardiovascular and kidney disease is high in the lay population

Answer: A

Patients with the dual burden of cardiovascular and kidney disease represent an underserved and vulnerable population. Outcomes related to cardiovascular disease phenotypes such as heart failure and ischemia tend to be worse with chronic kidney disease, and complications from medical and interventional therapies tend to be higher. The lack of high-quality evidence and the perception of potential "harm" in this population results in some degree of therapeutic nihilism when approaching cardiovascular disease in patients with kidney disease. Despite the complexity and overall poor quality of life in patients with advanced cardiovascular and kidney disease, palliative care is an under-utilized resource in this field. Awareness of the role of kidney disease as a cardiovascular equivalent and the dual disease burden of cardiovascular and kidney disease is overall low in the lay population. Future studies and trials in the cardio-renal sphere will help define best practices, goals, and educational pathways in this field.

Inflammation in Chronic Kidney Disease

Dominic S. Raj[a], *Roberto Pecoits-Filho*[b], *Paul L. Kimmel*[a]

[a]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States; [b]School of Medicine, Pontificia Universidade Catolica do Parana, Curitiba, Brazil

Abstract

Systemic low-grade inflammation is common in patients with chronic kidney disease (CKD). The prevalence of signs of inflammation are inversely related to the level of kidney function and positively associated with the magnitude of proteinuria. Cytokines and acute-phase proteins are key mediators as well as markers of inflammation. The etiology of inflammation in CKD is multifactorial. Comorbidities such as older age, minority race, and the presence of diabetes are independent predictors of inflammation in CKD patients. Endotoxin translocation across the gut and damage/danger-associated molecular patterns may contribute to excess inflammation in CKD. Dysregulated immune responses and the resultant inflammation are mediators and/or catalysts in the progression of renal disease, pathogenesis of cardiovascular disease, and the development of insulin resistance, protein energy wasting, anemia, and abnormal bone-mineral metabolism in patients with CKD. Progress in treatment of inflammation in patients with CKD is hampered by the complexity of the molecular pathways related to inflammation and the essential nature of some of these signaling mechanisms for cell/organism survival. However, a number of novel treatment strategies to attenuate inflammation in CKD are currently being explored.

INTRODUCTION

The word inflammation derives from the Latin term "inflammare," meaning to set on fire. Inflammation is part of the complex biological response of vascular tissue to injury, infection, ischemia, and autoimmune diseases.[1] Within physiological limits, the inflammatory response enables removal of the inciting agent and initiates healing. Inability to eliminate the insulting event and/or separate the inflammatory processes leads to a chronic inflammatory state with undesirable systemic consequences.[2] Persistent, low-grade systemic inflammation is common in chronic kidney disease (CKD) and is closely linked to adverse outcomes.[3,4]

SCOPE OF THE PROBLEM

Prevalence of Inflammation in CKD

The other face of immunity is inflammation, especially when the immune response is unregulated and misdirected. Kimmel et al. reported that adequate T-cell function is associated with improved survival in patients with end-stage renal disease (ESRD) and elevated levels of proinflammatory cytokines are associated with higher mortality.[4] Another study showed that there were no major differences in circulating cytokine levels between long-term dialysis patients and those not yet dialyzed, suggesting uremia *per se* contributes to the inflammatory state.[5] The Chronic Renal Insufficiency Cohort (CRIC) study showed that 86% of participants with CKD have some evidence of inflammation, as defined by increased circulating levels of inflammatory biomarkers.[3] However, only about 12% of the study population exhibited profound elevation in markers of inflammation, a finding not different from that reported by Kimmel et al. in ESRD patients[6] (Figure 24.1). Gupta et al. demonstrated that plasma levels of proinflammatory cytokines and positive acute-phase proteins were higher in subjects with lower levels of kidney function.[3] Furthermore, within each level of estimated glomerular filtration rate (eGFR), the magnitude of proteinuria was associated with a higher level of inflammatory biomarkers[3] (Figure 24.2).

Determinants of Inflammation

A number of demographic features such as older age, male gender, obesity, and low socioeconomic status

were associated with higher level of inflammation in patients without CKD.[7] Chronic subclinical inflammation in the elderly population is attributed to an imbalance between inflammatory and antiinflammatory networks.[8] Patients with type 2 diabetes mellitus have elevation in Th17 and Th1 cellular subsets and a reduction in the Treg subset, explaining the inflammation noted in this patient population.[9] Furthermore, inflammation predicts incident diabetes as well as diabetes-related complications.[10] The CRIC study demonstrated increasing age, minority race, and presence of diabetes are associated with increased level of inflammation at each level of eGFR[3] (Figure 24.3).

Genetics of Inflammation

Stimulation of human blood samples with bacterial lipopolysaccharide (LPS) results in large interindividual variations in production of cytokines, suggesting a genetic component related to the inflammatory response. Thus, differences in inflammatory responses between populations may be due to variations in genes

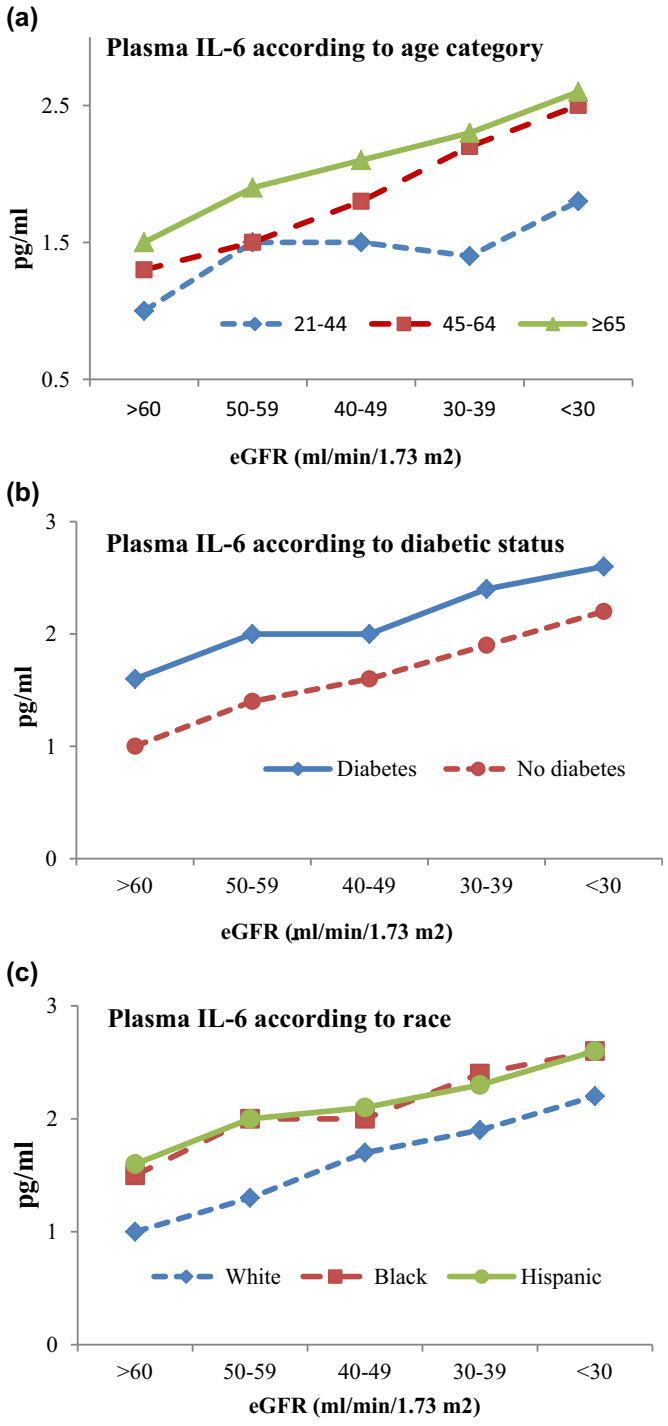

FIGURE 24.3 Association of inflammation with age, diabetes, and race in CKD. *Data from the Chronic Renal Insufficiency Cohort (CRIC) study.*

regulating inflammatory pathways. Using a relaxed linear separability model, Luttropp et al. showed the presence of inflammation in CKD patients, defined by circulating high sensitivity C-reactive protein (hsCRP), is linked to genetic variations.[11] Ness et al.[12] reported African Americans have an increased frequency of alleles related to increased production of proinflammatory cytokines, but this finding has not been confirmed by others.[13] Environmental factors and behavioral patterns may modify the inflammatory response.

Epigenetics refers to a heritable change in the pattern of gene expression mediated by mechanisms specifically not due to alterations in primary nucleotide sequences.[14] The epigenome is the interface of genetics and environment, where the plasticity of the epigenetic code modifies the rigid genetic code to determine final phenotypes. Epigenetic regulation of cytokines and transcription factors is important in directing lineage differentiation of Th1 and Th2, as well as Tregs, which play a role in determining the immune response.[15] Epigenetic effects seem to allow dividing immune cells to imprint, signaling events that allow immune cells to mount appropriate immune responses.

PATHOPHYSIOLOGY OF INFLAMMATION IN CKD

Mediators of Inflammation

The inflammatory state is generally characterized by activation of an array of soluble factors such as cytokines and chemokines.[2] Cytokines are secreted polypeptides that orchestrate the inflammatory response through autocrine, paracrine, and endocrine mechanisms. Chemokines are chemotactic cytokines, which control the attraction of leukocytes and mononuclear cells to sites of injury. These biomolecules may be broadly classified as pro- and antiinflammatory and also as ones involved in acute and chronic phases of inflammation. However, cytokines are pleiotropic in their actions, with considerable redundancy between their functions. Cytokines exhibit interactive cascades, in which they induce or repress their own synthesis, as well as that of other cytokines and cytokine receptors[2] (Figure 24.4). Circulating cytokine receptors may provide additional information regarding the state of inflammation because they generally have a longer half-life than the cytokines themselves and therefore exhibit more constant levels over time. The interleukin (IL)-1Ra binds to IL-1 receptors and blocks the activity of IL-1 and a soluble form of the p55 tumor necrosis factor (TNF) receptor (TNFsRp55) binds and neutralizes TNF.[2] Pereira et al. showed that plasma levels of IL-1Ra and TNF inhibitor TNFsRp55 are significantly higher in patients with CKD.[5] They also noted that hemodialysis patients with higher endotoxin-stimulated IL-1Ra synthesis had a higher rate of cardiovascular (CV) events.[16] Representative cytokines and their clinical significance are described in Table 24.1.

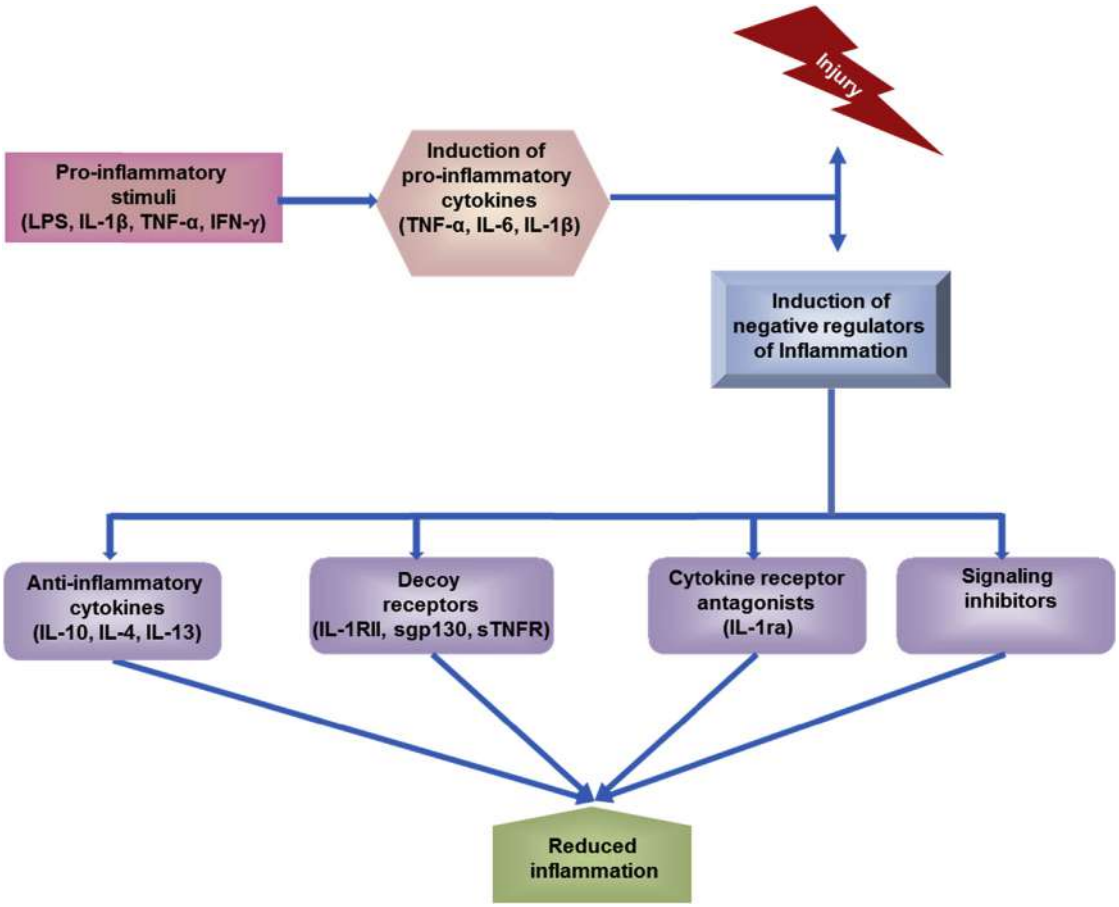

FIGURE 24.4 Cytokines are important modulators of immunoregulation, hematopoiesis, and the inflammatory cascade. These biomolecules act as a highly complex and coordinated network. There is considerable overlap and redundancy between the functions of individual cytokines. Cytokines induce or repress their own synthesis and that of other cytokines. The function of one cytokine is often modified or substituted by another's. The balance between pro- and antiinflammatory cytokines determines whether the intensity of inflammatory response is within physiological limits or in the pathologic range.

An important component of the inflammatory cascade is the acute-phase response, which is a nonspecific physiological response to diverse forms of systemic and local insults. Under the influence of cytokines, originating from the site of injury, the synthesis of positive acute-phase proteins is upregulated, and negative acute-phase proteins are downregulated, principally in hepatocytes.[17] Acute-phase proteins include complement components, antiproteases, and transport proteins, as well as proteins involved in coagulation and fibrinolytic systems. Many of the acute-phase proteins (such as CRP and ferritin) augment the inflammatory response, whereas others have an attenuating effect (e.g. albumin and hepcidin). The causes and mechanisms of downregulation of negative acute-phase protein synthesis are unknown, but this may be because resources need to be redirected toward synthesis of positive acute proteins that are required for survival in times of stress.

Etiology of Inflammation

The mechanisms underlying unprovoked inflammation in CKD are under intense investigation. Elevated plasma cytokine levels in CKD patients could be a consequence of decreased elimination and/or increased generation. Although most of the circulating cytokines are secreted from activated macrophages and lymphocytes, adipocytes and skeletal muscle are also possible sources.[18,19] It has been estimated that skeletal muscle contributes to about 12% and adipose tissue to about 10–35% of the circulating IL-6 level in patients with and without kidney disease.[20,21] Arteriovenous balance studies have shown that there is increased efflux of proinflammatory cytokines from the skeletal muscle of ESRD patients.[19,22] Preliminary findings from the CRIC study show that body fat mass as well as muscle mass are associated with circulating levels of several cytokines.[23] Myeloperoxidase (MPO) is secreted during

TABLE 24.1 Mediators and Markers of Inflammation in Chronic Kidney Disease (CKD)

Biomarker	Study Population	Remark
C-reactive protein (CRP)	CRP is a member of the pentraxin family of innate immune response proteins synthesized by the liver.	Extensively studied in patients with and without kidney disease. Associated with all cause and cardiovascular mortality, atherosclerosis, protein energy wasting, and erythropoietin resistance.
Fibrinogen	Soluble glycoprotein found in the plasma, synthesized by the liver.	Plays a vital role inflammation, atherogenesis, and thrombogenesis. Predictor of mortality in CKD.[154]
Serum amyloid A protein	Acute-phase protein synthesized by the liver.	Serves as an autocrine factor to influence vascular smooth muscle cells and platelet aggregation.[155]
IL-6	IL-6 acts *via* a receptor complex consisting of the cognate IL-6 receptor (IL-6R) and glycoprotein 130 (gp130 or IL6-ST). Signal activation necessitates association of IL-6 with gp130. The antiinflammatory activities of IL-6 are mediated by gp130, whereas its proinflammatory responses are mediated by trans-signaling through the soluble IL-6 receptor.[156,157]	Elevated IL-6 levels have been linked to malnutrition,[158] atherosclerosis,[159] and CV and all-cause mortality in patients with kidney disease.[4,160]
IL-1 family	The IL-1 family consists of two proinflammatory cytokines, IL-1α and IL-1β, and a naturally occurring antiinflammatory agent, the IL-1Ra.	Plasma IL-1 and IL-1Ra have been shown to predict cardiovascular outcomes and mortality in end-stage renal disease (ESRD) patients.[4,16,96,161]
IL-10	The principal function of IL-10 is to limit and ultimately terminate inflammatory signals.	The IL-10 low producer genotype (-1082 AA) is associated with increased CV mortality in ESRD patients,[162] and lower Karnofsky Index and nutritional indices.[163]
TNF-α	Produced primarily by macrophages and acts through two distinct cell surface receptors of 55 kDa (TNF-R1) and 75 kDa (TNF-R2). Activates NFkB and MAP kinase pathways and induces apoptosis.	Increased TNF-α levels are associated with metabolic syndrome, CVD, congestive heart failure, progression of CKD, and mortality.[4,164–166]
Soluble TNF-like weak inducer of apoptosis (sTWEAK)	Member of the TNF superfamily.	Elevated sTWEAK and IL-6 plasma concentrations are associated with mortality in HD patients.[167]
TGF-β	TGF-β has antiatherogenic, antiinflammatory, and profibrotic properties.[168,169]	Overproduction of TGF-β has been linked to hypertension, left ventricular hypertrophy, vascular remodeling, and renal fibrosis.
High mobility group box chromosomal protein-1(HMGB1)	HMGB1 is a nuclear protein that binds DNA, stabilizes nucleosomes, and facilitates gene transcription. It is a late-phase cytokine, which contributes to chronic inflammation.	HMGB1 levels correlate with GFR and markers of inflammation and malnutrition.[170]
Myeloperoxidase (MPO)	MPO is an enzyme stored in azurophilic granules of polymorphonuclear neutrophils and macrophages and released into extracellular fluid in the setting of inflammatory process.	Plasma MPO levels are elevated in patients with coronary artery disease, congestive heart failure, and are important predictors of cardiovascular events in the general population.[24,171,172] Associated with risk of death in ESRD patients.[25]
Endotoxin and soluble CD14	Endotoxin is a biologically active substance produced by bacteria, which consists of lipopolysaccharide. Endotoxin provokes an array of host responses by binding to the CD14 receptor.[173]	Abundant experimental and clinical evidence indicates that subclinical endotoxemia is involved in the pathogenesis of atherosclerosis.[174,175] Elevated soluble (s)CD14 level is associated with protein energy wasting and death in ESRD patients.[34,127]

activation of neutrophils, which plays an important role in the defense of the organism. Enhanced MPO generation is one of the major oxidative stress pathways in CKD, and a risk factor for vascular disease.[24,25]

Other potential causes of inflammation in CKD include chronic subclinical infections,[26] volume overload,[27] increased oxidative stress,[28] sympathetic overactivity,[29] poor nutrition, and vitamin D deficiency.[30] The gut microbial flora is quantitatively and qualitatively abnormal in patients with kidney disease compared with healthy subjects.[31–33] Endotoxin translocation across the gut could be one of the important causes of inflammation in CKD patients.[34] Uremic toxins cause dysfunction of both granulocytic and monocytic cell lines and should also be considered a major cause of inflammation. Among circulating monocytes, subpopulations with proinflammatory characteristics are expanded in patients with CKD. Several uremic toxins act as ligands in activation of Toll-like receptors, which are involved in the innate immune response and recognition of LPS.[35]

DAMPs and PAMPs

Accelerated cellular aging and augmented apoptosis are common in CKD. Damaged or dying cells release endogenous molecules called damage/danger-associated molecular patterns (DAMPs).[36] These molecules activate the immune system in a manner similar to pathogen-associated molecular patterns (PAMPs) molecules released by pathogenic bacteria or viruses (Figure 24.5). Many DAMPs released during renal injury are capable of activating inflammasomes, which are components of the innate immune system.[37] The inflammasome is a complex of proteins in the cytoplasm that is triggered by infectious or sterile injuries.[38] Proinflammatory mediators interact with innate danger-signaling platforms. NACHT, LRR, and PYD domains-containing protein 3 (NLRP3) play a critical role in the pathophysiology of kidney diseases.[39] Thus, release of endogenous molecules from dying cells may lead to activation of innate immunity and downstream inflammation.

Resolution of Inflammation

Chronic, dysregulated inflammation is associated with several human diseases. The inflammatory response is counterbalanced by the release of "stop signals," which serve to attenuate an excess inflammatory response and to restore functional homeostasis.[40] During this highly regulated active process, synthesis of proinflammatory mediators is halted, preventing further leukocyte influx into tissue. Immune cells are cleared from tissue either by reentry into the systemic circulation or by apoptosis or necrosis. Recent evidence suggests that this process also promotes interaction between the innate and adaptive immune systems leading to immune tolerance.[41] The resolution of inflammation is governed by several factors which include chemical mediators (lipoxins, resolvins, protectins, and maresins), gases (hydrogen sulfide, nitric oxide, and low-dose carbon monoxide), and proteins (annexin A1 and galectin-1).[40,42,43] Kourtzelis et al. identified a new member of the group of proteins, developmental endothelial locus-1 (DEL-1), which governs the resolution response.[44] Endothelial cell–derived DEL-1 reduces neutrophil infiltration into tissues. Macrophage-derived DEL-1 facilitates efferocytosis through an α vβ 3-mediated response and

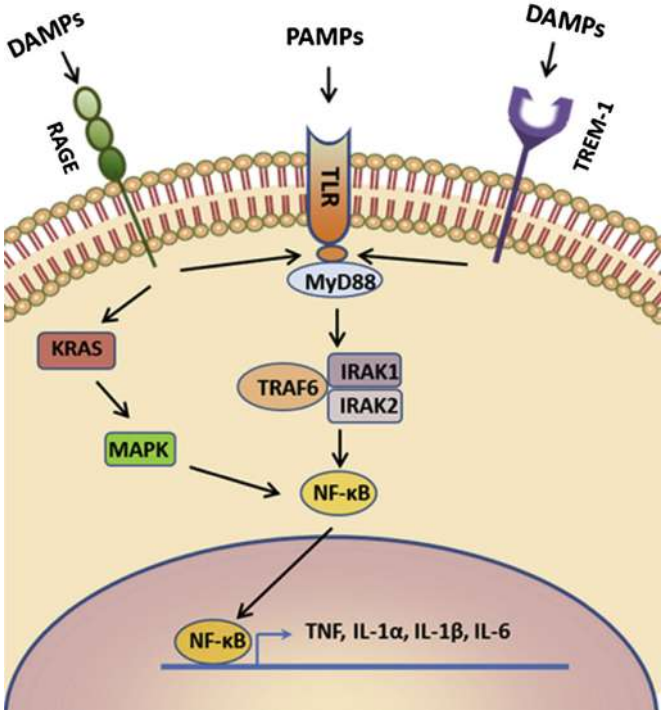

FIGURE 24.5 Mediation of pathogen-specific immune response by pathogen-associated molecular patterns (*PAMPs*) and pattern recognition receptors (*PRRs*). *PRRs* are essential for initiating immune defenses against invading pathogens. However, they also contribute to persistent and systemic inflammation. Heat shock proteins, fibrinogen, fibronectin, hyaluran, and high mobility group box-1 (*HMGB-1*) have been defined as danger-associated molecular patterns (*DAMPs*). Toll-like receptors (*TLRs*) are involved in the recognition of these endogenous or harmful self-antigens, which are released during noninfectious injury, suggesting their function may not be restricted to the recognition of extrinsic pathogens. RAGE, receptor for advanced glycation end products; TREM-1, triggering receptor expressed on myeloid cells-1; MyD88, myeloid differentiation factor 88; KRAS, Kirsten rat sarcoma viral oncogene homolog; MAPK, mitogen-activated protein kinase; TRAF6, tumor necrosis factor receptor-associated factor 6; IRAK1/IRAK2, IL-1 receptor-associated kinase 1 and 4; NFκB, nuclear factor-κB.

activates lipid X receptors and transforming growth factor (TGF)-β to promote a tissue reparative macrophage phenotype transformation.[44] Understanding the cellular pathways by which inflammation is resolved can open new opportunities to pharmacologically enhance the processes. Several promising proresolution therapeutic strategies have been tested in animal models with the potential for translation to human applications in the future.[41]

DIAGNOSIS OF INFLAMMATION

Utility of Inflammatory Biomarkers

Although the importance of inflammation in CKD is undisputed, there is no consensus regarding the index biomolecules to be used to identify inflamed subjects with CKD or regarding the appropriate threshold levels of inflammatory markers. Investigators have proposed different biomarkers and different circulating levels, largely based on mean values noted in CKD patients and/or correlations with clinical outcomes. Although the concentrations of proinflammatory cytokines, antiinflammatory cytokines, and acute-phase proteins show a tendency to increase together, there is discordance in the rate and magnitude of the increase of individual molecules involved in the inflammation cascade.[1] Thus, it may be important to integrate information from multiple biomarkers to describe the prevailing inflammatory state. Raj and associates computed a composite score ranging from 0 to 5 based on elevated levels of selected cytokines and acute-phase proteins (CRP, fibrinogen, IL-6, TNF-α, and IL-1β). They showed the score was inversely related to eGFR and positively related to albuminuria in a large cohort of CKD patients with a wide range of kidney function.[3] Zoccali showed an inflammation score composed of CRP, IL-6, IL-1β, IL-18, and TNF-α predicts death no better than IL-6 in patients with ESRD.[45] Thus, the utility of composite inflammation scores needs further validation.

There is substantial intraindividual variation in circulating cytokines levels over time, rendering the validity of a single measurement of cytokines in predicting clinical outcomes tenuous. Preliminary findings suggest that a single baseline measure accurately reflects healthy individuals' inflammatory status over a four- to six-month period.[46] Another study showed that despite variability over time, baseline CRP level correlated with time-averaged CRP and the individual median of serial CRP values in ESRD patients.[47] Thus, single baseline measurements are adequate, but multiple measurements may be better for predicting outcome or response to interventions.

Is CRP an Ideal Biomarker of Inflammation in CKD?

CRP belongs to the pentraxin family of calcium-dependent ligand-binding plasma proteins. It derives its name from its ability to precipitate the C-polysaccharide of *Streptococcus pneumonia.* Circulating CRP is produced primarily by hepatocytes under transcriptional control by IL-6.[48] In response to an inciting stimulus, CRP synthesis is rapidly initiated, with the serum concentration peak occurring in about 48 hours. The median concentration of CRP is 0.8 mg/L in healthy subjects, the 90th percentile is 3.0 mg/L, and the 99th percentile is 10 mg/L.[49] CRP binds to phosphocholine residues and also to a variety of autologous and extrinsic ligands and aggregates the molecules exhibiting these ligands, leading to activation of the complement cascade.[50] CRP is a highly stable analyte in serum or plasma, which can be measured with ease in a reproducible manner. CRP level is a nonspecific measure of inflammation that may be useful for screening and monitoring response to treatment. It has also emerged as an independent risk factor for adverse outcomes in diverse clinical settings. None of the other upstream mediators or downstream effectors of inflammation, including other acute-phase reactants, have such desirable characteristics, rendering CRP the most commonly used measure of inflammation.

Consequences of Inflammation

Even minor decreases in kidney function are associated with an increased risk for all-cause and CV death. Abundant evidence has accrued showing inflammation is a mediator of adverse outcomes in patients with CKD.[51–53] Inflammation could be a by-product of the original insult and thus an innocent bystander rather than a prime mover. Others claim that inflammation is a partner in crime. CKD complications linked to inflammation are depicted in Figure 24.6.

Progression of CKD

Regardless of initial causes, progressive CKD often results in glomerulosclerosis and/or tubulointerstitial fibrosis, characterized by widespread tissue scarring leading to ESRD. A variety of cytokines, chemokines, and growth factors act in concert to create an imbalance in matrix formation and degradation, leading to overall accumulation of extracellular matrix and eventually glomerulosclerosis and interstitial fibrosis.[54–59] Expression of IL-1, IL-6, IL-10, and IL-1 receptor antagonist and TGF-β have been reported in experimental and human renal diseases.[60–64] In the kidney, cytokines induce resident cells to proliferate,[65] promote aberrant

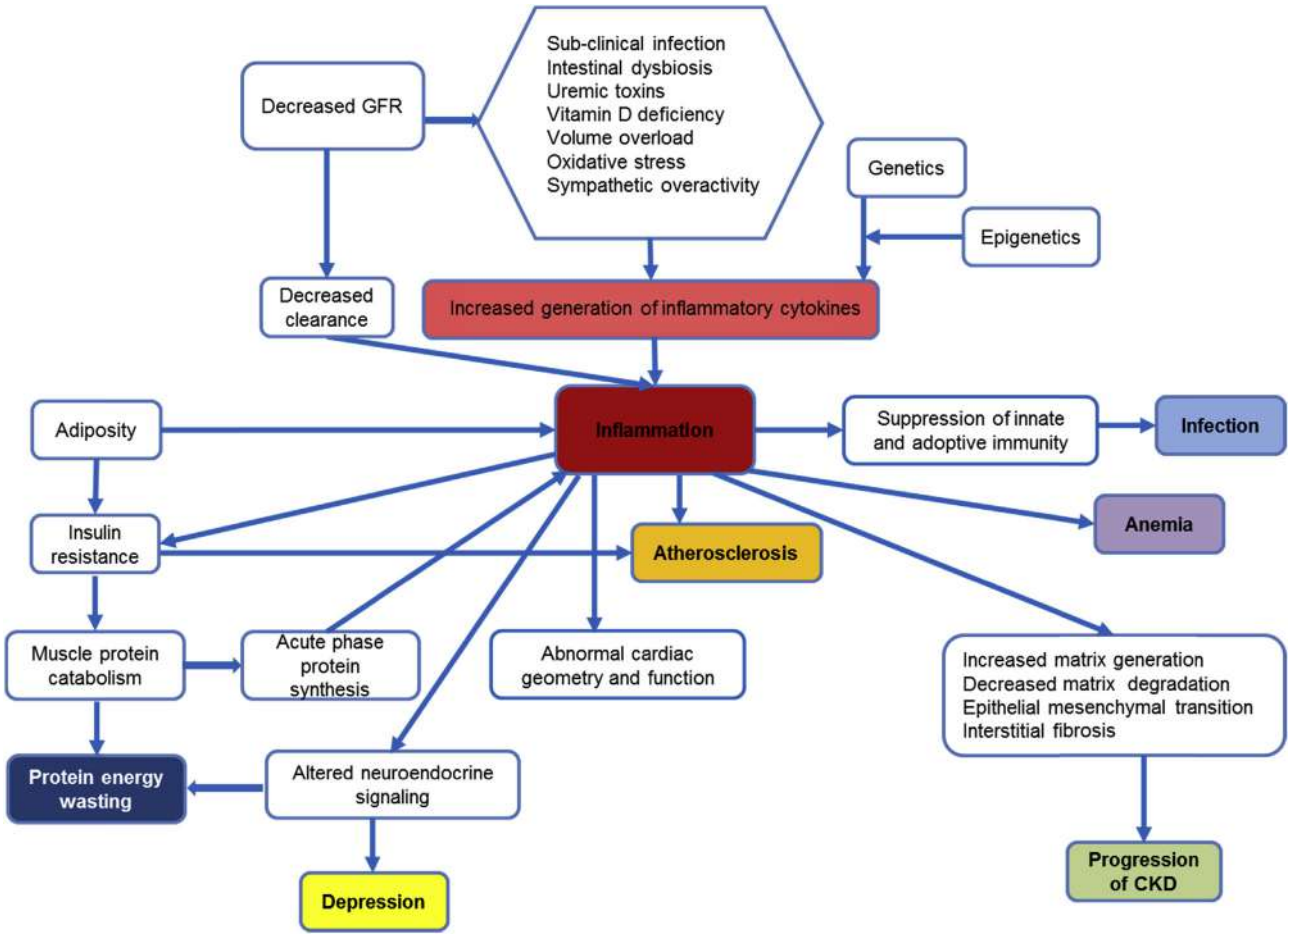

FIGURE 24.6 Inflammation in chronic kidney disease (CKD): causes and consequences. Inflammation is the result of multiple mechanisms inherent to CKD, including comorbidities such as adiposity, increased levels of inflammatory cytokines, and uremic toxicity. In turn, inflammation may increase the rate of CKD progression and cause infection, anemia, CVD, and depression.

matrix metabolism,[66,67] incite procoagulant endothelial activity,[68] generate reactive oxygen/nitrogen species,[69] and activate expression of adhesion receptors,[70] bioactive lipids,[71] and metalloproteinases.[72–75] Cytokine expression in the kidney release into the renal vein as well as excretion in the urine are increased in patients with glomerular disease.[76–79] Preliminary evidence indicates that urinary cytokine levels may be an indicator of severity and progression of renal disease.[77,78,80] Findings from the CRIC study show elevated plasma levels of fibrinogen and TNF-α and decreased serum albumin (S[Alb]) are associated with rapid loss of kidney function in patients with CKD after adjusting for traditional risk factors.[81] TNFR-1 is expressed on the cell surface of glomeruli and by the peritubular capillary endothelium of the kidney. In the Multi-Ethnic Study of Atherosclerosis study participants, elevated serum sTNFR-1 concentrations were associated with faster declines in eGFR, independent of traditional risk factors for kidney disease progression.[82] In a cross-sectional study in Japanese patients with T2D and eGFR $\geq$30 mL/min/1.73 m^2, circulating TNF-related inflammatory biomarkers (TNFα, progranulin, TNFR1, and TNFR2) were associated with albuminuria.[83]

During disease more than 30% of fibroblasts originate from tubular epithelia at the site of injury, through the process of epithelial mesenchymal transition, although such notions are controversial.[84,85] This molecular reprogramming of the cell is regulated, at least in part, by the profibrotic cytokine TGF-β. Renal arteriovenous balance studies indicate that TGF-β is released from the kidney of patients with diabetes.[78] In a population-based study of predominantly White subjects, TNF-receptor 2, WBC count, and IL-6 levels were associated with risk of developing CKD.[86] Similarly, in patients with type 2 diabetes mellitus, elevated concentrations of circulating TNF receptors at baseline are strong predictors of subsequent progression to ESRD.[58]

Hypertension and Inflammation

The roles of immune dysregulation and inflammation in the pathogenesis of hypertension have been investigated for decades. Virtually every cell type involved in innate and adaptive immunity has been implicated in the pathogenesis of hypertension. RAG1$^{-/-}$ mice, which lack both T and B cells, exhibit blunted hypertensive response to Ang II infusion, which is restored by adoptive transfer of T cells.[87] Interestingly, CD8+ T cells express the mineralocorticoid receptor, which plays a role in systemic hypertension.[88] Arterial wall inflammation is present in patients with CKD even in the absence of atherosclerosis.[89] Excess extracellular sodium activates antigen-presenting dendritic cells *via* immunogenic isolevuglandin-protein, which, in turn, promotes hypertension.[90] Proinflammatory cytokines are associated with arterial stiffness in CRIC study participants.[91] Thus, the prevalence and severity of hypertension in CKD could be related to inflammation.

Progression of Cardiovascular Disease

Atherosclerosis is described as an indolent, fibroproliferative disease fueled by chronic inflammation.[92] Immune cells dominate the atherosclerotic lesion and exhibit evidence of activation. The underlying mechanism for "accelerated atherosclerosis" in CKD may be related to chronic inflammation. Several cross-sectional studies suggest the Framingham risk equation is insufficient to capture the extent of CVD risk in CKD patients, highlighting the importance of novel risk factors such as inflammation in this population. Epidemiologic and clinical studies demonstrate strong and consistent relationships between markers of inflammation and risk for CV events in the general population and in patients with CKD.[93] Elevated CRP levels were associated with increased risk for all cause and CV mortality in Modification of Diet in Renal Disease study participants.[53] Abundant evidence from clinical studies and laboratory-based investigations suggest that abnormal cardiac geometry and function are related to inflammation in subjects with and without kidney disease.[51,94,95] Amdur et al. reported that inflammatory biomarkers and kidney function are independently associated with incident atherosclerotic vascular disease events and death in CKD patients.[96] They further showed that traditional CV risk estimates could be improved by adding measures of kidney function and markers of inflammation to traditional risk factors in evaluations.

Protein Energy Wasting

Protein energy wasting, or its extreme form, cachexia, is a maladaptive metabolic state common in inflammatory conditions, in which lean body mass is wasted, but the fat depot is relatively underutilized. Cytokines regulate neuroendocrine signaling and promote muscle wasting to sustain acute-phase protein synthesis in hemodialysis patients.[97] As a reflection of the trend in the US population, there is an epidemic of obesity among CKD patients.[98] Adiposity is associated with inflammation in the general population as well as in CKD patients. Results from the CRIC study show that fat mass and muscle mass are positively associated with hsCRP, fibrinogen, IL-1, IL-1RA, and IL-6 levels.[23] One standard deviation increases in fat and muscle mass were associated with 36% and 26% increases in log transformed hsCRP. The association between inflammation and fat mass was stronger in Caucasian than African-American patients with CKD, suggesting that abundant energy depot in conjunction with decreased burden of inflammation may explain the survival advantage observed in African Americans treated with maintenance hemodialysis.

Insulin Resistance

Epidemiologic studies show insulin resistance is a risk factor for CKD.[99] Chronic inflammation is a common feature of the metabolic syndrome and insulin resistance. Cytokines activate a number of intracellular serine/threonine kinases, including the inhibitor κB kinase (IKK) complex, a regulator of the NF-κB pathway, an important second messenger system in inflammatory cytokine signaling. The IKK complex and TNF-α activated JNK may be involved in the pathogenesis of insulin resistance.[100,101]

Anemia of CKD

Anemia is common in CKD patients. Epidemiologic studies show inflammation is an important predictor of hemoglobin variability and erythropoietin (EPO) hyporesponse in ESRD patients.[102,103] Goicoechea and associates demonstrated that EPO resistance is associated with elevated circulating levels of IL-6 and TNF-α.[104] Anemia in CKD may be related to true or functional deficiency of iron and EPO. The latter has been attributed to inflammation. Hepcidin, a 25-amino acid peptide, is produced predominantly by hepatocytes under the influence of IL-6. As the key regulator of transmembrane iron transport, hepcidin controls the absorption of iron in the intestine, the mobilization of iron from hepatic stores, and iron recycling by macrophages.[105] Furthermore, certain proinflammatory cytokines may suppress erythroid progenitor cell proliferation and inhibit EPO production.[106]

Infection and Inflammation in CKD

It has long been suspected that subclinical infections may be one of the underlying causes of inflammation in CKD. Paradoxically, systemic inflammation coexists with a state of acquired immunodeficiency in patients with CKD, predisposing to infections.[107] Persistent infection/inflammation could induce counterregulatory mechanisms that suppress innate and adaptive immunity in CKD.[108] Thus, chronic inflammation could predispose to infection, leading to a vicious cycle with poor outcomes in CKD patients.

Inflammation and Depression

The cytokine theory of depression assumes that inflammatory cytokines can trigger depression by acting on the central nervous system.[109,110] Studies in subjects without CKD have implicated TNF-α, IL-2, and IL-6 in the pathogenesis of depression. Small studies in CKD patients confirm such associations,[111] although the findings are controversial.[110]

TREATMENT OF INFLAMMATION IN CKD

A number of intervention studies targeting established risk factors for mortality in CKD have not yielded the anticipated positive results. Such negative studies could be due to the fact that inflammation in CKD has a competing and possibly overwhelming effect on outcomes, rendering these interventions ineffective.[112,113] Preliminary evidence indicates that targeting a single component of the inflammatory cascade is not sufficient in complex diseases and requires the use of broad immnomodulation therapy.[114] Alternatively, the redundancy and pleiotropy of the cytokine system renders a nontoxic intervention, a difficult proposition.

There are at least three potential therapeutic approaches using inflammation as a target that may result in clinical benefits in CKD patients: pharmacological manipulation of cell responses, reduction of the source of ligands, and direct antiinflammatory therapies. There are an increasing number of studies analyzing the potential impact of these strategies.

Targeting Inflammation Through Pharmacological Manipulation of Inflammatory Cell Responses

Renin–angiotensin system blockers, with antiinflammatory activity, have been tested in clinical trials in the dialysis population. The results of a randomized trial using fosinopril showed a slight benefit of this agent in comparison to placebo.[115] In another randomized trial with a small number of patients, candesartan significantly reduced CV events and mortality in patients treated with chronic maintenance hemodialysis.[116] Suzuki et al.[117] showed treatment with an angiotensin receptor blocker was independently associated with reduced fatal and nonfatal cardiovascular disease (CVD) events in a hemodialysis population, although this analysis may be limited because of the small sample size.

Statins are another drug class with antiinflammatory actions.[118] In observational studies, patients treated with statins had lower mortality than non-statin-using hemodialysis patients.[119] These results have not been uniformly confirmed by randomized controlled trials in ESRD hemodialysis patients.[120] Although treatment with rosuvastatin had no significant effect on the composite primary endpoint of death from CV causes, nonfatal myocardial infarction, or nonfatal stroke, there was a reduction in mean level of plasma CRP in treated hemodialysis patients.[120] Inflammation at baseline was one of the most important risk factors for mortality.[120]

Inflammation is linked to oxidative stress, and antioxidants may be interesting drugs for antiinflammatory therapeutic interventions. One trial investigated the effect of high-dose vitamin E supplementation on CVD outcomes in hemodialysis patients with preexisting CVD.[121] After a median follow-up of 519 days, the use of vitamin E was associated with reduced CVD endpoints and myocardial infarctions.[121] In a randomized controlled trial, treatment with N-acetylcysteine, an antioxidant, reduced CV events and mortality in hemodialysis patients.[122]

Circulating levels of 25-hydroxyvitamin D3 and 1,25-dihydroxyvitamin D3 can potentially influence the activity of many tissues and cells,[30] including cardiomyocytes, active T and B lymphocytes, and mononuclear and endothelial cells. In observational studies, dialysis patients treated with activated vitamin D and analogs have a survival advantage, perhaps related to the systemic activation of vitamin D receptors, acting as a negative endocrine regulator of renin–angiotensin synthesis and inflammation, thus reducing CV complications.[123] However, in a randomized controlled trial involving 227 patients with CKD, paricalcitrol failed to alter left ventricular mass index or improve diastolic function.[124] The Japan Dialysis Active Vitamin D study, a randomized, open-label multicenter study of 1289 hemodialysis patients without secondary hyperparathyroidism concluded oral alfacalcidol did not reduce the risk of a composite measure of fatal and nonfatal CV events.[125] Whether the results of this study are also applicable to patients with secondary hyperparathyroidism remains uncertain.[126]

Targeting Inflammation Through Reduction of Source of Ligands

Subclinical endotoxemia is associated with inflammation, protein energy wasting, and mortality in ESRD patients.[34,127] The human gut harbors 10^{14} bacteria and endotoxemia resulting from gut microbial imbalance, termed dysbiosis, could promote inflammation. Thus, restoration of gut-microbial symbiosis may have a number of potential benefits in ESRD patients. Prebiotics are nondigestible food ingredients that selectively stimulate growth and/or activity of beneficial bacteria in the colon. Preliminary evidence indicates the prebiotic oligofructose-enriched inulin (p-inulin) may reduce endotoxin generation, attenuate inflammation, and improve metabolic function in patients without kidney disease.[128,129]

Although the drug had been created to be used as a phosphate binder, sevelamer hydrochloride showed a potential endotoxin-binding effect in the intestinal lumen, reducing systemic inflammation in an experimental model.[130] Other potential pleiotropic effects of sevelamer that could have CV impact include a lipid-lowering action and reduction in CRP levels.[131,132] Stinghen et al.[133] demonstrated that sevelamer treatment leads to a decrease in CRP levels accompanied by a parallel decrease in endotoxemia in hemodialysis patients.

Periodontal disease, an occult source of inflammation, is associated with CVD.[134] CKD patients with moderate-to-severe disease compared with those with mild or no periodontal disease had higher risk of death from CV causes.[135] Intervention trials to determine if treating periodontitis (and other hidden infections) reduces CVD mortality in CKD patients would shed light in this important area.

Direct Antiinflammatory Therapies

Pentoxifylline (PTX) is a nonselective inhibitor of cyclic-3′, 5′-phosphodiesterase (PDE). Inhibition of PDE has been shown to reduce *de novo* synthesis and tissue accumulation of proinflammatory cytokines.[136] Treatment with PTX has been shown to reduce proteinuria in patients with diabetic nephropathy and glomerular diseases.[137,138] PTX slows the progression of atherosclerosis and modifies plaque morphology in patients with type 1 diabetes.[139]

Pirfenidone (5-methyl-1-phenyl-2-(1H)-pyridone) is an antifibrotic drug that reduces TGF-β2 protein levels and reverses extracellular matrix accumulation. It has been shown to slow the progression of renal disease in animal models[140] as well as in clinical studies.[141] In a double-blind randomized controlled study, Sharma et al.[142] showed pirfenidone preserves renal function in patients with diabetic nephropathy. In this study, 77 subjects with diabetic nephropathy were randomized to escalating doses of pirfenidone (1200 mg/day and 2400 mg/day) or placebo. A significant number of subjects in the high dose group dropped out of the study. Among the 52 subjects who completed the study, the mean eGFR increased in the pirfenidone 1200 mg/day group, whereas the eGFR decreased in the placebo group. Pirfenidone has also been shown to improve cardiac geometry and vascular biology. Although a promising antifibrotic agent, it has a number of adverse effects and is generally not well tolerated.[143]

Tocilizumab, a humanized mouse antihuman IL-6 receptor antibody, inhibits IL-6 activity by competing for both the membrane-bound and soluble types of IL-6 receptors.[144] Preliminary findings indicate that it may be effective in the management of glomerular disease.[145] Its potential benefit in the management of anemia of CKD and CVD in patients with CKD is a fertile area for research. Treatment with etanercept, a TNF-receptor antagonist, did not have a significant effect on CRP or IL-6 but had positive effect on S[Alb] and prealbumin in hemodialysis patients.[146]

Anakinra is a nonglycosylated, recombinant form of human IL-1Ra that, like endogenous IL-1Ra, competitively inhibits IL-1 by binding the IL-1 type I receptor. In a pilot study, Hung et al. showed Anakinra reduced markers of inflammation and increased prealbumin concentrations in patients treated with hemodialysis.[147] Furthermore, an IL-1 beta receptor antagonist has been shown to improve coronary flow, left ventricular function, and endothelial function in patients with rheumatoid arthritis.[148] In a double-blind trial, 42 adult patients with stages 3−4 CKD were randomized to treatment with an IL-1 trap, rilonacept, or placebo. Rilonacept therapy improved brachial artery flow-mediated dilation and reduced systemic inflammation in patients with CKD.[149] Preliminary results from the Canakinumab Anti-inflammatory Thrombosis Outcome Study suggest that major atherosclerotic CV events were reduced with IL-1β inhibition with canakinumab in patients with moderate CKD (HR 0.82; 95% CI: 0.68−1.00, $p = 0.05$) and in those with normal kidney function (HR 0.86; 95% CI: 0.77−0.97, $p = 0.012$).[150]

An emerging therapeutic option is to directly use nanotechnology-based drug delivery systems. Various nanosized materials are currently being developed, including micelles, liposomes, polymeric nanoparticles, dendrimers, carbon nanotubes, and metallic nanoparticles. The inflammatory milieu enhances incorporation of nanosized materials into mononuclear phagocytic systems for delivery to the target organ.[151]

Bardoxolone methyl is an inducer of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) pathway, which can suppress oxidative stress and inflammation. Initial reports showed bardoxolone methyl treatment was

TABLE 24.2 Important Issues to be Considered in the Management of Inflammation in Chronic Kidney Disease (CKD)

How should the intensity of inflammation in CKD patients be assessed?
What are the therapeutic targets for reduction of inflammation?
What is the level to which the inflammation could be reduced without compromising its physiological function?
Should specific molecules be targeted or is a broad nonspecific approach appropriate?

associated with improvement in eGFR in patients with advanced CKD and type 2 diabetes.[152] The bardoxolone methyl Evaluation in Patients with Chronic Kidney Disease and T2DM: The Occurrence of Renal Events (BEACON) trial, however, was terminated because of excess mortality in the treatment arm.[153] Thus, it is important to navigate through the maze of inflammatory pathways while selecting the target, with careful assessment of clinical risk.

CONCLUSION

Our understanding of the causes and consequences of inflammation has certainly expanded considerably, but the science is still evolving rapidly, constantly revealing new molecules and novel pathways. Besides contributing to the progression of renal disease, inflammation is now recognized as a potential catalyst that may accelerate kidney disease complications. Lack of clear understanding has hampered our progress in the management of uremia-associated inflammation, but we have made considerable strides during the last two decades. Challenges and questions still remaining to be addressed are listed in Table 24.2. While investigators are seeking answers, a number of drugs that target inflammation are in development, and small studies have reported some encouraging results.

QUESTIONS AND ANSWERS

Question 1

A 52-year-old African-American man with CKD was seen in the nephrology clinic. He complained of fatigue and diffuse joint pain. He denied any urinary symptoms. On physical examination, he was afebrile; his blood pressure was 154/98 mm Hg with a pulse rate of 78 beats per minute. Oral cavity was normal. No lymphadenopathy was noted nor was there any focus of infection. His current medications include amlodipine 10 mg/day, asprin 75 mg daily, and a multivitamin.

The following laboratory investigations were obtained:

WBC 4.7, neutrophils 31%, hemoglobin 9.8 g/dL
Albuminuria by spot urine albumin:creatinine ratio (UACR): 3.1 g/day
BUN: 32 mg/dL
Serum creatinine (S[Cr]): 2.5 mg/dL
Glucose: 289 mg/dL.
HbAIC: 9%
hsCRP 4.5 mg/L

Which one of these statements is true?

A. Stable patients with CKD who are not yet on dialysis do not have elevated CRP
B. A single measurement of CRP has no clinical significance. Multiple measurements are required to determine the level of inflammation in a given patient
C. The contribution of traditional risk factors for inflammation such as age, sex, obesity, and diabetic status are minimal and attenuated by the presence of CKD
D. Proteinuria is an independent predictor of inflammation

Answer: D[3]

A is not correct. Plasma levels of cytokines are not significantly different in dialysis patients and CKD patients not yet on dialysis.[5]

B is not true. CRP levels fluctuate over time, but baseline CRP levels correlate with time-averaged CRP measurements and the median of serial CRP values in patients with kidney disease.[47]

C is not true. Older age, male sex, obesity, and diabetic status are associated with inflammation in patients with CKD.[3]

Question 2

The same patient returns for a follow-up visit six months later. His blood pressure remains elevated at 158/94 mm Hg. Laboratory investigations showed WBC 4.2, hemoglobin 9.7 g/dL. Total cholesterol 230 mg/dL, BUN 30 mg/dL, S[Cr] 2.8 mg/dL, K+ 3.4 mEq/dL, HCO3- 21 mEq/L, Ca++ 9.6 mg/dL, PO_4 5.2 mg/dL, hsCRP 5.2 mg/L. Albuminuria by spot UACR suggests urinary losses of 3.4 g/day

Choose the most appropriate response

A. Lisinopril will not reduce albuminuria and preserve GFR in this patient
B. Besides a cardioprotective effect, statins therapy may reduce inflammation in this patient
C. Sevelamer has no advantage over calcium-based phosphate binders in reducing systemic inflammation in CKD patients
D. Pirfenidone will be an established adjunct therapy, which should be considered in this patient, to slow the progression of CKD

Answer: B

B is correct. Treatment with statins reduces CRP and proinflammatory cytokine levels in patients with and without CKD.[176]

A is not correct. Preliminary evidence indicates that ACE inhibitor treatment is associated with reduction in markers of inflammation.[177,178]

C is not correct. Treatment with sevelamer hydrochloride lowers circulating biomarkers of inflammation in patients with CKD.

D is not correct. Studies in human subjects and animal models suggest that pirfenidone has antifibrotic properties, but it has a number of adverse effects precluding clinical use.

Question 3

The patient subsequently underwent angioplasty with stent placement for acute myocardial infarction. He was started on atorvastatin 40 mg/day and metoprolol 50 mg twice daily. Laboratory investigation showed WBC 4.4, hemoglobin 9.7 g/dL. Total cholesterol 170 mg/dL. BUN 34 mg/dL, S[Cr] increased to 3.1 mg/dL, hsCRP 4.9 mg/L, S[Alb] decreased to 3.1 g/dL. Fibrinogen was 4 g/L.

Which of the following statements is correct?

A. Augmented inflammation in CKD contributes to accelerated atherogenesis in CKD
B. S[Alb] is a marker of nutrition. Nutrient supplementation alone is sufficient to improve the level of S[Alb] in this patient
C. In CKD patients, cytokines are derived exclusively from macrophages and adipocytes
D. Excess inflammation is this patient is due to decreased clearance of cytokines. There is insufficient evidence that cytokines contribute to the progression of CKD beyond traditional risk factors

Answer: A

A is correct. In an analysis that applied the Framingham risk equation to a population with CKD, the predicted CVD risk was similar to and not substantially higher than that of the general population,[179] leading to the speculation that traditional risk factors may have a qualitatively and quantitatively different risk relationship with CVD in CKD patients compared with the general population. Several studies have demonstrated a relationship between chronic inflammation and presence of atherosclerosis and CV mortality in patients with CKD and ESRD.[52,180]

B is not correct. In addition to being nutritionally modulated, albumin is also a negative acute-phase protein. Ballmer et al.[181] showed that proinflammatory cytokines stimulated total liver protein synthesis, but decreased albumin synthesis rate and also inhibited nutrient-induced increases in albumin synthesis

C is not correct. Human skeletal muscle cells have the ability to express a variety of cytokines, including IL-6.[19,182] Muscle-derived IL-6 functions as an exocrine hormone, exerting its effect on the liver and adipose tissue.[183]

D is not correct. Cytokine production by mononuclear cells in undialyzed CKD patients and in patients treated with maintenance hemodialysis is increased.[184] There is evidence that many inflammatory cytokines and chemokines play significant roles in the progression of CKD. They may be potential therapeutic targets.

Question 4

The patient returned after 3 months and had no specific complaints except fatigue. On examination he appeared pale. His blood pressure was 138/74 mm Hg. Laboratory investigations showed WBC 4.2, hemoglobin 7.9 g/dL. Total cholesterol 130 mg/dL. BUN 34 mg/dL, S[Cr] 3.4 mg/dL, hsCRP 5.2 mg/L. He had hypochromic microcytic anemia. Iron profile and PTH were appropriate.

Which of the statement is true?

A. The primary function of hepcidin is host defense against infection
B. This patient will show a robust response to erythropoiesis-stimulating agents
C. With EPO therapy, the patient will effectively utilize iron for hematopoiesis
D. Reducing inflammation will improve EPO hyporesponsiveness in this patient

Answer: D

D is correct. Reducing inflammation (such as removal of a rejected kidney allograft[185] or nonfunctioning arteriovenous grafts with occult infection[186]) and treatment directed toward reducing inflammation improve response to EPO therapy.

A is not correct. In addition to its antimicrobial properties, hepcidin is the main regulator of iron metabolism and controls both the amount of dietary iron absorbed in the duodenum and iron release by reticuloendothelial cells. Elevated serum hepcidin levels in CKD may contribute to the development and severity of anemia and to resistance to erythropoiesis-stimulating agents.

B is not correct. EPO resistance is manifested in the presence of elevated cytokines and positive acute-phase response.[178]

C is not correct. There is a functional iron deficiency in patients with CKD. Iron is not effectively utilized for hematopoiesis.

Abstract

Several genes associated with the development of chronic glomerular and tubulointerstitial kidney diseases have been detected. Recent developments include an improved understanding of potential mechanisms involved in nondiabetic glomerulosclerosis, including apolipoprotein L1 gene (*APOL1*)-associated nephropathy, as well as autosomal dominant tubulointerstitial kidney disease. The identification of genes associated with diabetic kidney disease has proven more challenging. Nephropathy susceptibility genes are changing the classification of common complex kidney diseases, offering new insights into pathogenesis and providing hope for novel treatments. This chapter reviews genetic associations and mechanisms of injury in diabetic and nondiabetic glomerular and tubulointerstitial kidney diseases.

INTRODUCTION

The past decade has seen advances in the identification of genes associated with chronic kidney disease (CKD) and improved methodologies for detecting associated gene variants. Linkage analyses useful for detecting genomic regions coinherited with a trait in families, genome-wide association studies (GWAS), and candidate gene association studies capable of detecting common variants in unrelated cases and controls samples, and admixture mapping (useful for detecting associated variants more common in one ancestral population of admixed groups) have all been performed in CKD. Major breakthroughs include the identification of a newly recognized spectrum of nondiabetic apolipoprotein L1 gene (*APOL1*)-associated nephropathy, untangling of structural and signaling pathways involved in maintaining the delicate glomerular filtration barrier critical for preventing glomerulosclerosis, and identification of mutations producing rare interstitial kidney diseases. Nephropathy susceptibility genes have altered the classification of common complex kidney disease, offer new insights in pathogenesis, and provide hope for novel treatments.

STEROID-RESISTANT NEPHROTIC SYNDROME

Nephrotic syndrome (NS) is characterized by proteinuria caused by disruption of the glomerular filtration barrier. Approximately 10%–20% of affected children and 40% of affected adults exhibit steroid-resistant nephrotic syndrome (SRNS).[1] This disorder manifests histologically as focal segmental glomerulosclerosis (FSGS) or as the early-onset developmental variant "diffuse mesangial sclerosis" (DMS). These histologic variants may progress to end-stage renal disease (ESRD). A mutation in the nephrin gene (*NPHS1*) was the first to be reported to cause early-onset NS.[2] Since then, mutations in more than 50 genes causing FSGS have been identified. The rate of mutation detection is inversely correlated with age. Approximately 30% detection rates are seen in individuals with SRNS less than 25 years old.[1] Mutations in genes with recessive inheritance (e.g., *NPHS1*, *LAMB2*, and *PLCEI*) usually manifest as SRNS in early childhood with DMS.

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00025-5

Mutations in other genes with recessive inheritance (podocin or *NPHS2*) or genes with dominant inheritance (e.g., *ACTN4*, *TRPC6*, *INF2*, *ANLN*, and *ARHGAP24*) lead to late childhood/adult-onset SRNS with FSGS. The sole exception is dominant *WT1* mutations presenting in early childhood.[1] Notably, the inheritance mode of R229Q in *NPHS2* deviates from the classic autosomal recessive paradigm. This mutation is innocuous in homozygotes and only pathogenic when associated with another specific C-terminal *NPHS2* mutation (compound heterozygous), exerting a dominant-negative effect through altered dimerization and mislocalization of the protein.[3]

Some mutations causing NS manifest a heterogeneous syndromic phenotype. The best example is *WT1*, where mutations in the KTS domain (deletion of lysine−threonine−serine) cause Frasier syndrome with streak gonads and pseudohermaphroditism and harbor increased risk for gonadoblastoma in XY phenotypic females or lead to isolated NS in XX phenotypic females. In contrast, missense mutations can cause Denys−Drash syndrome with pseudohermaphroditism and Wilms tumor or isolated NS.[1]

The proteins encoded by the NS-causing genes have coalesced to complexes and cellular pathways in podocytes, including podocyte slit membrane components (*NPHS1*, *NPHS2*, *CD2AP*, *PLCE1*), laminin/integrin signaling components (*LAMB2* and *ITGA3*), actin-binding proteins (*ACTN4*, *INF2*, *MYO1E*, and *ANLN*), Rho-like small GTPase regulatory cluster (*RHO/RAC/CDC42*, *ARHGAP24*, *ARHGDIA*, *KANK1*, 2, and 4, *FAT1*, *MAGI2*, *TNS2*, *DLC1*, *CDK20*, *ITSN1*, *ITSN2*), lysosomal proteins (lysosomal integral membrane protein type-2, encoded by *SCARB2*), calcium signaling (*TRPC6*), transcription factors (*WT1*, *LMX1B*, and *SMARCAL1*), proteins of coenzyme Q10 biosynthesis (*COQ2*, *COQ6*, *PDSS2*, and *ADCK4*), and nuclear pore complex components (*NUP93/107/205* and *EXPORTIN5*).[1,4,5]

Although the majority of patients with NS and monogenic mutations rarely respond to steroid treatment or immunomodulation, exceptions exist. Steroid-sensitive nephrotic syndrome (SSNS) caused by mutations in the *EMP2* gene can respond to glucocorticoids.[1] The absence of *EMP2* upregulates caveolin-1 in podocytes, and this phenotype is ameliorated by glucocorticoid therapy.[6] Furthermore, NS due to mutations in *PLCE1*, *NUP93*, *TRPC6*, or regulators of Rho-like GTPase may partially respond to steroid or cyclosporine A treatment.[1,4,5] Therefore, resistance and sensitivity to steroid and calcineurin inhibitors represent a phenotypic spectrum of FSGS, reflecting the pleiotropic effects of the medications on podocyte biology.

In the case of mutations in genes encoding proteins essential for coenzyme Q10 biosynthesis in SRNS (*COQ2*, *COQ6*, *ADCK4*, or *PDSS2*), treatment with coenzyme Q10 may be warranted.[1] Eplerenone may also ameliorate NS in individuals harboring *ARHGDIA* mutations through modulation of Rac I−mineralocorticoid interactions.[1,4,5,7]

Mutations in genes that lead to clinical phenocopies of SRNS, such as cystinosis, hyperoxaluria, or Fabry's disease, can also require specific therapy. Although these disorders may present with proteinuria, edema, and CKD, mutations in these genes would be missed in panel sequencing because they are not canonical NS genes. The ability to detect mutations in genes that represent phenocopies of NS is an advantage of whole exome sequencing.[7] Patients with monogenic forms of FSGS known to confer resistance to immune modulation therapy should avoid unnecessary immune-modulating therapy.[1] Appropriate selection and counseling of potential living-related kidney donors should be based on causative mutations, especially in families harboring a dominant mutation with variable penetrance.[1,7] Mutations associated with kidney disease recurrence following kidney transplantation due to antibody formation (e.g., mutations leading to the absence of nephrin, which can trigger antibody formation against the "neoantigen" nephrin in the allograft) should be identified to direct immunomodulatory therapy that may ameliorate recurrence.[8]

CKD affects approximately 10% of the population worldwide. Heritability of impaired kidney function in the general population is estimated to range between 29% and 46%.[9] GWAS investigate the contribution of multiple common gene variants to CKD, each with a potentially small effect. In contrast to candidate gene studies, GWAS offer an unbiased hypothesis-free approach with the potential to identify novel therapeutic targets. The Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium provided the basis for the first CKD GWAS meta-analysis that identified several CKD-associated single-nucleotide polymorphisms (SNPs) for the estimated glomerular filtration rate (eGFR) computed using serum creatinine concentration (S[Cr]) [eGFRcrea] and cystatin C levels [eGFRcys]).[10] The three most significant SNPs were located near or within genes encoding for the uromodulin/Tamm−Horsfall protein (*UMOD*), shroom family member 3 (*SHROOM3*), and stanniocalcin-1(*STC1*).[10] Subsequent GWAS have been conducted on the CKDGen Consortium including 16 population-based cohorts joined to the CHARGE Consortium,[11] as well as European and cross-ethnic cohorts.[12] These GWAS expanded the spectrum of CKD-associated

variants. More than 50% of associated SNPs shared effects across all ethnicities.[12,13] Cohorts that examined CKD progression or ESRD discovered fewer associated variants due to the reduced power of dichotomous disease traits versus continuous clinical measures.

The CKD-associated SNPs shared several common pathways including kidney development and nephrogenesis (*ALMS1*, *VEGFA*, and *DACH1*), podocyte function and glomerular filtration barrier formation (*DAB2* and *VEGFA*), angiogenesis (*VEGFA*), solute transport (*SLC7A9* and *SLC34A1*), kidney metabolism (*PRKAG2*, *GCKR*, and *LASS2*), primary cilia function (*ALMS1, GCKR/IFT172, PARD3B*), drugs and toxin metabolism (*NAT8*), and ion channels (*KCNQ1)*.[11–14] Some loci are located near genes causing monogenic kidney diseases, such as autosomal dominant tubulointerstitial kidney disease or ADTKD (*UMOD*), nephrolithiasis (*SLC7A9*), phosphaturia (*SLC34A1*), tubular dysfunction (*SLC7A9* and *DAB2*), cystinuria (*SLC7A9*), ciliopathies (*ALMS1*), and congenital kidney disease (*DACH1*).[11,12] This suggests that rare disruptive mutations in genes causing monogenic kidney diseases are at the extreme of a continuum with common regulatory variants in these genes that elicit subtler effects on kidney function. Many variants are located at regulatory regions, specifically enhancer regions that control the expression of multiple genes in kidney tissues[12,14,15] (also called expression quantitative trait loci [eQTL]). The majority of these are enriched for pathways important in kidney development, transmembrane transporter activity, kidney structure, regulation of glucose metabolism, and lysosomal proteins.[12,14,15]

A GWAS meta-analysis for the urine albumin:creatinine ratio (UACR) combined data from >80,000 individuals in the international CKDGen and CARe Consortia, including populations of European and African descent. The authors identified a common missense variant (allele frequency 0.1 in the general population) in the cubilin gene (*CUBN*) associated with UACR and incident microalbuminuria, but not eGFR.[16] The association was also significant in diabetic patients from the Diabetes Control and Complications Trial and Epidemiology of Diabetes Interventions and Complications.[16] Cubilin mediates reuptake of filtered albumin in the proximal tubule. The involvement of this variant in albuminuria is further supported by the fact that rare *CUBN* mutations can cause Imerslund–Gräsbeck syndrome, resulting in megaloblastic anemia with varying degrees of proteinuria.

Coupling genomics and metabolomics in genome-wide association analyses of metabolites can illuminate mechanisms underlying CKD progression. It may be difficult, however, to discriminate between causality versus consequence of CKD.[17] Moreover, even an extremely high correlation between an eQTL and a GWAS signal does not establish causality and requires functional studies to determine the biologic significance of discovered variants. In this regard, the *UMOD* locus stands out by virtue of cell biology studies, animal models, and data from human populations. These studies provide evidence that common eGFR-associated GWAS variants upstream of *UMOD* induce salt-sensitive hypertension and kidney disease by increasing renal uromodulin expression, leading to increased activation of the sodium cotransporter NKCC2 (Table 25.1).[18] Individuals with the genetic *UMOD* risk variant have higher Tamm–Horsfall protein concentrations in their urine and are at increased CKD risk.[19] The role of *UMOD* as causal mediator in CKD has also been demonstrated by a Mendelian randomization approach.[20]

Similarly, *SHROOM3* function was characterized in various experimental models. SHROOM3 participates in maintaining the glomerular filtration barrier in rat models of kidney disease and zebrafish (Table 25.1).[21] Additionally, *SHROOM3* null mice show glomerular abnormalities and podocyte pathology, and heterozygous mice develop adult-onset glomerulosclerosis.[22] In spite of these findings suggesting a loss-of-function mechanism, significantly elevated *SHROOM3* expression in kidney allografts homozygous for the CKD risk SNP (rs17319721) was correlated with increasing allograft fibrosis and reduced posttransplant eGFR.[23] SHROOM3 expression is enhanced by rs17319721, functioning by a cis-acting element with specific TCF7L2-dependent enhancer binding β-catenin and facilitating TGF-β downstream profibrotic pathways.[23] Prokop et al. demonstrated that rs17319721 increased transcription of the *SHROOM3* short isoform in the kidney with altered binding of TCF7L2.[24] Further studies are required to explore the biologic mechanism of this intronic variant. Table 25.1 lists additional variants whose causality in CKD have been partially validated.[13,15,25,26]

Although large sample sizes are required for the detection of variants associated with a heterogenous kidney phenotype such as CKD, identification of variants associated with well-defined kidney disease phenotypes can be achieved with moderately sized cohorts. Genetic variants in the phospholipase A2 receptor 1 gene (*PLA2R1*) and *HLA-DQA1/HLA-DQB1* locus were identified by GWAS in European patient/control cohorts with membranous nephropathy (MN).[27] The odds ratio for the homozygous risk genotype for HLA-DQA1 was 20.2 (95% confidence interval [CI], 5.5 to 74.4) and for *PLA2R1* was 4.2 (95% CI, 2.4 to 7.5). Moreover, the odds ratios were additive, with each additional copy of the risk allele at either locus being 78.5, compared to individuals homozygous for the protective genotype at both loci. Follow-up clinical studies

TABLE 25.1 List of Gene Variants With Potential Roles in Chronic Kidney Disease (CKD)

Gene	GWAS Allele	Chr	Organism/Model	Genetic Manipulation	Experimental Results	Other Supportive Findings	References
UROMODULIN	rs4293393	16	Mice	Transgenic mice	Salt-sensitive hypertension. Age-dependent renal lesions similar to elderly individuals homozygous for UMOD promoter risk variants. Uromodulin causes hypertension by activation of the renal sodium cotransporter NKCC2	Carriers of UMOD promoter risk variants have higher UMOD expression in kidney and urine versus carriers of protective haplotype. Pharmacological inhibition of NKCC2 more effective in lowering blood pressure in hypertensive patients homozygous for UMOD promoter risk variants than others	18,19
SHROOM3	No specific SNP examined	4	Rat	Congenic rat introgression of Brown Norway rat Shroom3 gene onto fawn-hooded hypertensive (FHH) rat genetic background; 13 protein coding variants in the SHROOM3 gene	Improvement of glomerular function		21
	rs181194611-rare coding variant-P1244L	4	Zebrafish	Knockdown and rescue	Wild-type SHROOM3a allele, not FHH SHROOM3 allele or P1244L mRNA, rescued glomerular defects induced by knockdown of endogenous SHROOM3	P1224L attenuates the interaction of SHROOM3 with 14-3-3, suggesting alterations to the Hippo pathway, a known mediator of CKD	21,24
	rs17319721	4	Podocytes and HEK293T	CRISPR/Cas9 to generate the homozygous A allele	Disrupted allele binding to transcription factor TCF7L2 in podocyte cell nuclear extracts and altered transcription levels of SHROOM3 short isoform in cultured cells		24
	No specific SNP examined	4	Mice	Knockdown of SHROOM3	Impaired kidney development and morphology Abrogation of interstitial fibrosis in mice with unilateral ureteric obstruction	Rs7319721 allele in donors correlated with increased SHROOM3 expression in allografts, and with fibrosis and decreased kidney function. rs17319721 functions as a cis-acting expression quantitative trait locus of SHROOM3 that facilitates TGF-B1 signaling	22,23

KCNQ1	No specific SNP examined	11	Zebrafish	Knockdown	Abnormal kidney development		13
CDH23	No specific SNP examined	10	Zebrafish	Knockdown	Severe edema 72h after gentamicin compared with controls; no gross renal abnormalities before gentamicin		25
GALNT11	No specific SNP examined	7	Zebrafish	Knockdown	Severe edema 72h after gentamicin compared with controls; no gross renal abnormalities before gentamicin		25
ACP1	No specific SNP examined	2	Zebrafish	Knockdown	Altered glomerular gene expression and renal tubule morphology in the embryonic kidney; impaired kidney function		26
S0S2	No specific SNP examined	14	Zebrafish	Knockdown	Altered glomerular gene expression and renal tubule morphology in the embryonic kidney; impaired kidney function		26
MANBA	No specific SNP examined	4	Zebrafish	Knockdown	Renal tubule defects and pericardial edema	The expression of MANBA was significantly lower in kidneys of subjects with risk alleles	15

GWAS, genome-wide association studies; *SNP*, single-nucleotide polymorphism.

demonstrated that 73% of individuals carrying these susceptibility genotypes had anti-PLA2R antibodies, whereas antibodies were absent in carriers of protective genotypes.[12] In addition, immunosuppressive therapy was more effective in patients carrying the combined susceptibility genotype, likely by decreasing anti-PLA2R levels.[12] Cui et al. investigated the HLA class II gene profile in Chinese MN patients and controls.[28] *DRB1*1501* and *DRB1*0301* were independent risk alleles for MN and associated with circulating anti-PLA2R antibodies. Strong gene−gene interactions were identified between rs4664308(A) (top intronic SNP within *PLA2R1*) and *HLA-DRB1*1501/DRB1*0301*. Structural models identified specific amino acids in these HLA loci that facilitate interactions with T-cell epitopes of PLA2R and thereby enhance antibody production, thus translating the GWAS findings to an immunologic mechanism.[28]

SSNS accounts for 80% of cases of childhood NS. Gbadegesin et al. reported association of an *HLA-DQA1* (rs1129740) risk allele with SSNS in children of South Asian and European ancestry.[29] A trans-ethnic GWAS discovered three independent risk SNPs for pediatric SSNS.[30] Two were located in noncoding regions in *HLA-DQB1* and *HLA-DRB1* and the third in the 3′ untranslated region of the butyrophilin like-2 gene (*BTNL2*) within introns of *HCG23* and *LOC101929163* (long noncoding RNA). Increased burden of risk alleles across independent loci was associated with higher odds of SSNS, younger age at onset and increased odds of complete remission. Reassuringly, one of the leading SNPs (rs1063348) was in strong linkage disequilibrium with the SNPs identified by Gbadegesin et al.[29] and was associated with decreased HLA transcript expression across tissues, including glomeruli.[30] These studies establish SSNS as another primary glomerular disease caused by genetic susceptibility that leads to immune dysregulation.

Immunoglobulin A nephropathy (IgAN) is the most common glomerulonephritis worldwide. IgAN is most prevalent in East Asians, less frequent in individuals of European ancestry, and relatively rare in individuals of African ancestry. Although most cases are sporadic, familial aggregation of biopsy-proven IgAN is widely recognized.[31] GWAS in European, Han Chinese, and Asian cohorts identified multiple IgAN susceptibility loci.[31−33] Implicated pathways include antigen processing and presentation (*HLA-DQB1*, *DRB1*, and *DQA1* loci on chromosome 6p21), mucosal immunity and maintenance of the intestinal mucosal barrier, activation of mucosal IgA production, NF-κB signaling and defense against intracellular pathogens (chromosomes 22q12 *LIF, OSM, HORMAD2, MTMR3* loci, 8p23 *alpha-DEFENSIN* locus, 17p13 *TNFSF13* locus, 6p21 *PSMB9/TAP1* locus, 1p13 *VAV3* locus, 9q34 *CARD9* locus, 16p11 *ITGAM-ITGAX* locus, 3q27 *ST6GAL1* locus, 8q22.3 *ODF1-KLF10*, and 11p11 *ACCS* locus), and the alternative complement pathway (chromosome 1q32 complement factor H [*CFH/CFHR*] locus).[31−33] GWAS findings generated new insights into the pathogenesis of IgAN, highlighting a common role for the intestinal immune response and the alternative complement pathway. A genetic risk score has been developed, explaining nearly 5% of disease variance. The polygenic score paralleled the known East−West gradient in disease risk (Asian > Northern Europe > African ancestry population) and was similar to other autoimmune diseases correlated with North−South risk. One standard deviation increase in score was associated with nearly 50% increase in disease risk, translating into a fivefold increase in risk between individuals from the extremes of the risk score distribution and strongly correlated with distance from the African continent and disease prevalence.[31] Moreover, the cumulative effect of multiple genic risk loci was correlated with age at diagnosis, specifically after ancestry adjustment.[32] Risk variants at 3q27 and 11p11 also show strong association with mRNA expression levels of *ITGAX, ITGAM, ACCS, EXT2,* and *ST6GAL1* in peripheral blood cells, whereas allele frequencies of the risk variants within *ST6GAL1*, *ACCS*, and *DEFENSIN* correlate with geographical variation in IgAN prevalence.[33] This suggests that many common risk alleles influence IgAN through effects on regulation of gene expression.

Some GWAS findings provide insights from an evolutionary perspective. For example, the lead *UMOD* risk variant (allele T at rs4293393) associated with CKD and hypertension is the ancestral allele. Its prevalence ranges from 70% to 80% in Africans and Europeans to 90% in East Asians. The ancestral allele shows a global correlation with bacterial diversity (the Human Genome Diversity Project) and the prevalence of antibiotic resistance to gram-negative uropathogens.[19] High urinary levels of uromodulin are associated with lower risk for urinary tract infection (UTI) in older adults from the Cardiovascular Health Study, independent of traditional risk factors. These studies suggest that the ancestral *UMOD* allele has been kept at a high frequency due to its protective effect against UTI, which mainly affects young women and has important fitness and reproductive consequences.[19]

Regarding geospatial correlations in IgAN, Kiryluk et al. elegantly demonstrated a strong association of the IgAN genetic risk score with local pathogen diversity.[32] In the final combined model, only helminth diversity and geographical location were independently associated with the IgAN genetic risk score. This suggests that helminth infection serves as a potential source of selective pressure that has shaped the genetic diversity at IgAN risk loci.[32]

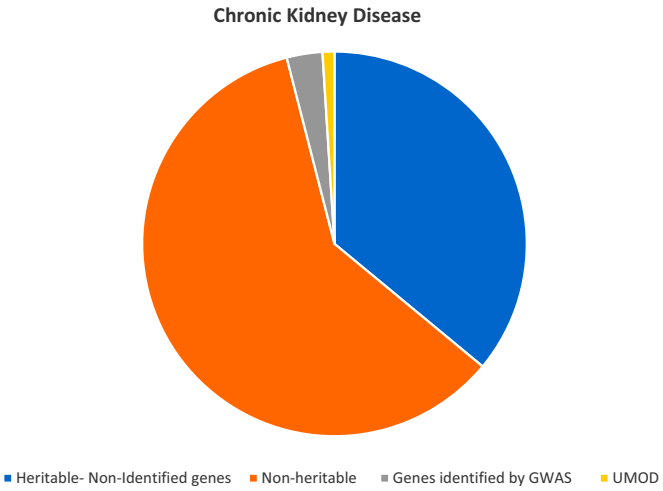

FIGURE 25.1 Heritability of glomerular filtration rate. Heritability of impaired kidney function in the general population ranges between 29% and 46% (*blue*, *yellow* and *gray*). The identified variants by genome-wide association studies explain less than 4% of the eGFRcrea variance (*gray* and *yellow*), including *UMOD* that explains approximately 1% (*yellow*). There is an unexplained gap of nonidentified genes termed the "missing heritability" (*blue*).

Notwithstanding these discoveries, identified variants in CKD GWAS explain <4% of eGFRcrea variance.[19,34] The small effect size leaves an unexplained gap that has been termed "missing heritability" (Figure 25.1).[26,34] Therefore, questions persist related to the extent by which genetic variation currently undetectable through GWAS (e.g., rare variants and non-SNP variants), as well as gene–environment interactions, explains missing heritability.

APOLIPOPROTEIN L1 GENE (*APOL1*)-ASSOCIATED NONDIABETIC KIDNEY DISEASE

Approximately 50% of patients with advanced renal disease have nondiabetic forms of nephropathy.[35] Disease etiologies were often unknown, as renal biopsies are performed mainly in patients with nephrotic syndrome or heavy proteinuria. Those with isolated hematuria or low level proteinuria were deemed less likely to have a treatable lesion identified on biopsy, beyond the usual supportive measures of controlling blood pressure and lipids and use of renin–angiotensin–aldosterone system (RAAS) blockade. Renal diagnoses in the absence of histology were most often ascribed to the effects of essential hypertension in those with low to absent proteinuria or IgAN or familial hematuria in those with isolated hematuria.

TABLE 25.2 Apolipoprotein L1 (*APOL1*)-Associated Forms of Nephropathy in African Ancestry Populations

Idiopathic focal segmental glomerulosclerosis (FSGS)
Solidified glomerulosclerosis with interstitial fibrosis and vascular injury (historically termed hypertension-attributed nephrosclerosis)
HIV-associated nephropathy and other forms of collapsing glomerulopathy
Sickle cell disease-associated nephropathy
Lupus nephritis-associated kidney disease
Shorter renal allograft survival in recipients of *APOL1* high-risk genotype deceased donor kidneys
Nephropathy in living kidney donors with *APOL1* high-risk genotypes

A paradigm shift occurred in 2010 with demonstration that the complex disorders idiopathic FSGS, focal global glomerulosclerosis (FGGS) with interstitial scarring and vascular changes (previously labeled "hypertension-attributed nephrosclerosis"), and human immunodeficiency virus-associated nephropathy (HIVAN) were strongly associated with two coding variants in the *APOL1* gene on chromosome 22q13 in patients of African ancestry.[36,37] Individuals inheriting two *APOL1* nephropathy risk variants (G1: nonsynonymous coding variant 342G:384M and G2: 6 bp deletion) have impressive 29-89-, 17-, and 7.3-fold increases in risk for HIVAN, FSGS, and nondiabetic (hypertension-attributed nephrosclerosis) ESRD, respectively. Odds ratios of this magnitude had not been seen before in complex disorders. Development of nephropathy in patients with sickle cell disease and progressive lupus nephritis (LN) were subsequently found to reside within the *APOL1* disease spectrum (Table 25.2).[38]

The *APOL1* discovery explained the marked familial aggregation of ESRD in African American families, with disparate causes of ESRD.[39] More than 30% of incident African American patients with ESRD had close relatives already receiving renal replacement therapy (RRT), excluding families with Mendelian disorders such as polycystic kidney disease.[40] Far greater numbers had relatives with CKD not yet undergoing RRT. Familial clustering of ESRD is present, albeit weaker in European Americans. Importantly, aggregation of different types of CKD was often observed in African American families. This is in dramatic contrast to other populations groups, where one type of kidney disease (e.g., IgAN or diabetic kidney disease [DKD]) clusters in families. Together, these findings supported the existence of an overarching kidney failure susceptibility gene in African American families, with multiple potential inciting events (such as the presence of antinuclear antibodies or HIV infection) that could trigger progressive kidney failure.[39]

The *APOL1* encodes APOL1, a secretory protein that associates with trypanosome lytic factor in plasma.[41] Selection for *APOL1* renal-risk variants confers ability to kill *Trypanosoma brucei rhodesiense*, a parasite causing African sleeping sickness.[36] This spectrum of kidney disorders is of great public health and personal importance. Population ancestry differences in *APOL1* allele frequency explain the excess risk of nondiabetic ESRD in African Americans, relative to European Americans, as well as the poorer allograft survival of deceased donor kidneys transplanted from donors of African ancestry.[42] The mechanisms whereby *APOL1* gene renal-risk variants lead to podocyte loss and clinically evident nephropathy remain unknown. APOL1 exhibits homology with the bacterial colicin family of toxic proteins that possess pore-forming capability.[43] APOL1 G1 and G2 nephropathy risk-variant proteins are toxic to (or form ion channels for cations or anions) in cell membranes and membrane-bound organelles.[44,45] Mitochondrial dysfunction with energy depletion appears to be an early manifestation of *APOL1*-associated renal injury and can result from damage to the mitochondrial membrane.[46,47] Other potential mechanisms of renal cell injury reported in animal and cell-based models of *APOL1*-associated nephropathy include defective endocytic fusion with lysosomes altering intracellular trafficking,[48–50] autophagic cell death,[51] and intracellular potassium depletion with secondary activation of stress kinases.[45] A single mechanism of renal injury has not been seen in all disease models. It is uncertain how closely transgenic and *in vitro* models reproduce the human condition.

Experiments in transgenic mice expressing the *APOL1* G0 (wild type) variant, and the G1 and G2 renal-risk variants in podocytes and renal tubule cells, reveal that expression of only the renal-risk variants in podocytes led to albuminuria and podocyte loss.[48,52] This study demonstrated that *APOL1* renal-risk variants cause kidney disease and are not simply disease-associated. In contrast, plasma *APOL1* protein concentrations are not associated with presence (vs. absence) of nephropathy.[53,54] Presence of two *APOL1* renal-risk variants in kidney donors, but not kidney transplant recipients, is associated with more rapid failure of the transplanted kidney and a higher risk for post-donation kidney disease in living kidney donors.[54,55] These studies support intrinsic renal expression of *APOL1*, not circulating APOL1 protein, as important in the pathogenesis of nephropathy.

APOL1 nephropathy variants are present in approximately 52% of African Americans; 13% of whom possess two renal-risk variants and are at increased risk for kidney disease.[36] These frequencies are higher in people from West Africa.[56] G1 and G2 risk variants are virtually absent in Asians, Europeans, and non-admixed Hispanic populations, suggesting relatively recent origin (<10,000 years ago), after early humans departed the African continent. Importantly, approximately 20% of individuals possessing two *APOL1* renal-risk variants will develop nephropathy, and only a minority of kidneys transplanted from *APOL1* high-risk donors fail shortly after transplantation. These findings suggest that requisite gene–gene or gene–environment interactions are necessary for development of kidney disease.[57] *APOL1*-associated nephropathy in individuals with low levels of proteinuria appears resistant to treatment with RAAS blockade or aggressively lowering blood pressure, although these therapies are often indicated in affected patients to reduce the risk of cardiovascular complications.[58]

HIV infection is a major environmental trigger for *APOL1*-associated kidney disease, with a population attributable risk of 70%. This means that 7 of 10 cases of HIVAN would not develop in the absence of the G1 and G2 *APOL1* variants.[59] The kidney serves as a reservoir for HIV replication, and HIV infection produces the highest attack rates of nephropathy among genetically susceptible hosts. Approximately half of patients with untreated HIV infection and two *APOL1* nephropathy variants develop nephropathy.[60] Aberrant replacement of partially differentiated podocytes develops in HIVAN, and renal histology reveals the most aggressive form of FSGS, the collapsing variant. Individuals with these risk variants but without HIV infection develop different renal histologic patterns of FSGS, solidified glomerulosclerosis with interstitial fibrosis and vascular changes, whereas others develop nonspecific FSGS variants. It has been proposed that different second hits likely determine the final renal histopathologic lesion in the spectrum. Solidified glomerulosclerosis has the lowest levels of proteinuria and slowest rate of loss of kidney function, whereas FSGS nonspecific variants appear to have intermediate degrees of proteinuria and rates of nephropathy progression relative to HIVAN and other forms of collapsing glomerulopathy.[61]

Based on this paradigm, there is reason for optimism. Rates of HIVAN have fallen dramatically with the introduction of highly active antiretroviral therapy (HAART).[35] This supports the concept that successful treatment of an environmental exposure can prevent kidney disease in those at high genetic risk. In this sense, HAART can be viewed as a novel treatment for kidney disease, whereas conventional therapies (i.e., blood pressure control and RAAS inhibitors) failed to reliably halt the progression of *APOL1*-associated nephropathy in cases with hypertension-attributed kidney disease,

predominantly solidified glomerulosclerosis, in the National Institute of Health-Sponsored African American Study of Kidney Disease and Hypertension (AASK).[58,62] In contrast to HIVAN, the inciting cause(s) of solidified glomerulosclerosis remain unknown.

As HIV infection is a modifiable risk factor for nephropathy, non-HIV viral infections were sought to identify other pathogens potentially influencing risk of kidney disease *via* interaction with *APOL1*. *APOL1* genotypes and presence of urine JC polyoma virus (JCV) were assessed for their joint impact on parameters of kidney disease phenotypes in first-degree relatives of African Americans with nondiabetic nephropathy.[63] Adjusting for family age at start of ESRD, sex and ancestry, an additive model testing for presence of urinary JCV genomic DNA and *APOL1* genotype (recessive) were *negatively* associated with high cystatin C concentration ($p = 0.006$), albuminuria ($p = 0.0002$), and presence of nephropathy based on low estimated eGFR or albuminuria ($p = 0.000017$). Thus, African Americans at risk for kidney disease based on two *APOL1* risk variants and with JC viruria had a *lower* prevalence of kidney disease. Similar results have been observed in nondiabetic African Americans without *APOL1*-mediated kidney diseases, suggesting that urinary tract JCV replication may be a marker for reduced host immune system activation and lower risk of renal fibrosis.[64] Additional work is being done to detect modifiable environmental factors that modulate risk of *APOL1*-associated nephropathy. Elevated levels of soluble urinary plasminogen activator receptor (suPAR) have been reported to interact with *APOL1* risk genotypes and contribute to kidney disease.[65]

Several genes and genomic regions have been reported to interact with *APOL1* (gene−gene interactions) to alter the risk for nondiabetic ESRD, including *NPHS2* (podocin), *SDCCAG8* (serologically defined colon cancer antigen 8), *BMP4* (bone morphogenetic protein 4), *GSTM1* (glutathione-*S*-transferase-μ1), and *UBD* (ubiquitin D or FAT10).[57,66,67] However, a recent GWAS in 4306 African Americans (2650 with nondiabetic ESRD; 1656 nonnephropathy controls) failed to identify significant genome-wide associations with ESRD beyond *APOL1*.[68] In addition, no SNP showed significant genome-wide evidence of interaction with *APOL1*. Thus, although variants with small individual effects likely exist, results from a large GWAS in African American nondiabetic ESRD suggest that *APOL1*−environment interactions may be of greater clinical importance in triggering nephropathy than *APOL1* interactions with other genes and SNPs.

APOL1 appears to impact CKD progression to ESRD more strongly than the initiation of nephropathy. This concept is based on weaker association with mild renal phenotypes (albuminuria and slightly reduced GFR) compared to ESRD.[56,58,69,70] The longitudinal AASK, Chronic Renal Insufficiency Cohort, and Coronary Artery Risk Development in Young Adults studies strongly support *APOL1* playing a predominant role in the progression of albuminuria and kidney disease.[71,72]

In the future, there will likely be benefits to screening potential living and deceased kidney donors for *APOL1* renal-risk variants. *APOL1* risk genotypes in deceased organ donors have been associated with shorter renal allograft survival in retrospective studies.[42,55,73] A multivariate analysis in 1153 kidney transplants from 624 unique African-American deceased kidney donors revealed that donor *APOL1* genotypes had similar (or stronger) effects on the time to renal allograft failure than did the degree of match for human leukocyte antigens (HLA), cold ischemia time, recipient sensitization based on panel reactive antibodies, expanded (vs. standard) criteria donors, and donor or recipient age.[55] Of great concern are the potential effects of *APOL1* renal-risk genotypes in healthy living African American kidney donors. Doshi et al. examined post-donation kidney health in 136 African American living kidney donors with median 12 year follow-up. Fourteen percent (19/136) had two *APOL1* renal-risk variants.[74] Living kidney donors with high-risk *APOL1* genotypes had significantly faster rates of decline in eGFR compared to those with low-risk genotypes. In addition, 67% of *APOL1* high-risk donors had a follow-up eGFR $<60\ mL/min/1.73\ m^2$ versus 36% of *APOL1* low-risk donors ($p < 0.01$) and 11% developed ESRD compared with 0% of low-risk donors ($p = 0.02$). Case reports document that recipients of kidneys from living donors with *APOL1* renal-risk genotypes can develop proteinuric FSGS with subsequent loss of the graft. The National Institutes of Health recently initiated the "*APOL1* Long-term Kidney Transplant Outcomes Network" (APOLLO) to prospectively assess effects of *APOL1* in kidney transplantation. APOLLO results have the potential to optimize the allocation of kidneys from deceased African American donors, reduce rates of organ discard, and maximize safety after living kidney donation in populations with recent African ancestry.[75,76] Hence, *APOL1* genotypic data will likely alter the clinical practice of transplant medicine, as the search for a cure in *APOL1*-associated nephropathy continues.

INHERITED TUBULOINTERSTITIAL NEPHROPATHIES

Rather than primarily affecting glomerular or excretory function, a variety of inherited disorders involve dysfunction of one or more segments of the renal tubule downstream of the glomerulus. These disorders cause

specific physiological disturbances that may or may not also be associated with CKD and anatomical abnormalities (e.g., cysts). Those that classically lead to CKD are discussed below. Typically, the primary defect is in only one cell type or nephron segment, and this "geography" is how such disorders are typically classified, when understood (Table 25.3). The downstream consequence and final common pathway is interstitial fibrosis with ensuing CKD.

Tubulointerstitial nephropathies can also be considered from a mechanistic perspective. Although disease-causing mutations may result in complete failure of transcription and thus loss of function because of RNA instability or failure to translate the encoded protein, many others will result in structurally and/or functionally abnormal proteins. Such mutated proteins may be either misfolded and therefore intracellularly retained or, because of disturbed protein–protein interactions be intracellularly misrouted, reach the "wrong" domain of the polarized plasma membrane, be prematurely internalized, or not be retrieved from the cell surface for appropriate disposal.

ADTKD is a classic protein misfolding disorder. Newly synthesized proteins are normally assembled in the endoplasmic reticulum (ER), where a quality control and degradation system ensures that only properly folded and assembled proteins pass through the Golgi apparatus before being directed to their final cellular destination.[77] If proteins fail to assume their correct structure and are unfolded or misfolded because of amino acid alterations consequent on specific mutations, they are retained in the ER by the association of chaperone molecules and become destined for ubiquitination and degradation by the 26S proteasome. The ER retains mutant proteins in many diseases. Loss of function can manifest as intracellular accumulation of abnormal protein that should have been delivered to the cell surface. This has been documented in ADTKD.

Until recently, a variety of disease names and overlapping phenotypes caused confusion among clinicians and geneticists concerning these disorders. The relevant genes are *UMOD, MUC1, REN,* and *HNF1b*. *REN*-associated disease is the rarest. A 2015 KDIGO conference stated "Multiple names have been proposed for these disorders, including Medullary Cystic Kidney Disease (MCKD) type 2, Familial Juvenile Hyperuricemic Nephropathy (FJHN), or Uromodulin-Associated Kidney Disease (UAKD) for *UMOD*-related diseases, and MCKD type 1 for the disease caused by *MUC1* mutations.[78] The multiplicity of these terms, and the fact that cysts are not pathognomonic, creates confusion. [We] propose adoption of a new terminology for this group of diseases using the term 'Autosomal Dominant Tubulointerstitial Kidney Disease' (ADTKD) appended by a gene-based sub-classification, and suggest diagnostic criteria. Implementation of these recommendations is anticipated to facilitate recognition and characterization of these monogenic diseases."

Typically, ADTKD presents with early-onset renal impairment and relentless progressive renal shrinkage due to fibrosis. Hyperuricemia is usually (but not always) present, gout is seen in about 67%, diabetes mellitus may be present, and sometimes impaired urinary concentrating capacity is detected.[79] Urinalysis reveals bland sediment and only modest proteinuria. It was thought that reduced urate excretion was a defining feature, but it is not always present.[80] Some forms of ADTKD are associated with medullary cysts, and this led to misdiagnosis as nephronophthisis. The hallmark of these disorders is interstitial fibrosis on biopsy, out of proportion with the degree of renal impairment and often with secondary glomerulosclerosis.

A family history should be sought but is often unclear. From the genotype–phenotype perspective, *REN* mutations are particularly associated with anemia, *HNF1β* with hypomagnesemia, and *HNF1β* and *MUC1* with prominence of cysts. In patients with *UMOD* mutations, radiographic evidence of renal cysts is only found in approximately 33%.[81] Although none of the causative genes encode uric acid transporters, anecdotes suggest that allopurinol therapy may delay ESRD. However, there is no proven disease-modifying therapy beyond blood pressure control.[79]

UMOD encodes uromodulin (UMOD, Tamm–Horsfall protein), the most abundant protein in normal human urine and the major component of urinary casts. Uromodulin is secreted into the urine solely by cells of the thick ascending limb, is heavily glycosylated, and has a variety of proposed functions including protecting epithelial integrity in the loop of Henle and bladder, modulating inflammatory responses *via* cytokine binding, inhibiting calcium oxalate crystal aggregation (although it is notable that ADTKD is *not* associated with stone formation), and preventing urinary infections. Its primary function remains under debate.[82]

All known *UMOD* mutations alter protein structure, as its sequence is rich in highly conserved cysteine residues, particularly in exons 4/5 leading to a high degree of intramolecular cross-linkage. The majority of *UMOD* mutations are missense involving exon 4, with others in exons 3/5/7/8, most involving a cysteine residue. One recurrent insertion–deletion mutation replaces five amino acids with four novel ones.[83] Some mutations correlate with age at ESRD onset.[84]

Mutated UMOD polymerizes within the ER, leading to cellular stress and apoptosis.[85] The mechanism of interstitial fibrosis is not well understood but could potentially include mis-secretion basolaterally or triggering of local inflammatory responses.[86] As with other dominantly inherited disorders, knocking out *UMOD* in

mice does not reproduce the human phenotype. Rather, evidence from transgenic models supports that misfolding delays intracellular trafficking of wild-type protein, i.e., a dominant-negative effect of heterozygous mutations.[87]

In *MUC1*-associated ADTKD, mutations involve insertion of a single cytosine in the terminal portion of a canonical 60-mer repeat in the encoded protein Mucin-1.[88] This produces a frameshift leading to the protein lacking several important domains. For technical reasons, these mutations are often impossible to identify, but immunohistological methods for diagnosis have recently been developed.[89]

Mucin-1 differs from UMOD in being a transmembrane glycoprotein expressed more broadly, including in the distal convoluted tubule. It is thought to play a role in cell adhesion, recognition, and/or cytoprotection.[90] As with UMOD, mutant MUC1 is improperly processed, and intracellular trafficking is delayed. Knockout mice have an essentially normal phenotype, again consistent with a dominant-negative mechanism.

Positional cloning identified the renin gene *REN* as mutated and segregating with disease in three families with AD progressive renal failure and a phenotype consistent with MCKD, including hyperuricemia.[91] Anemia in affected children is erythropoietin-responsive, and hyperkalemia may be present, both consistent with impaired renin activity. *REN* mutations are either deletion or substitution of a single leucine residue in the signal sequence for renin, which leads to failure of secretion, with evidence of activated ER stress. It is hypothesized that this produces accelerated apoptosis in juxtaglomerular apparatus cells, with impaired development and nephron loss.

Finally, some families with an apparent *UMOD/MUC1* phenotype harbor mutations in the HNF1β gene.[92] HNF1β is a transcription factor with a wide variety of target genes. A recent study showed ablation of *HNF1β* in renal epithelial cells led to epithelial–mesenchymal transition and aberrant TGF-*β* signaling with resultant renal fibrosis.[93]

Abnormalities of membrane transporter disposal also result in disease. Liddle syndrome is an autosomal dominant form of secondary hypertension, in which elevated blood pressure may be evident from childhood.[94] Hypertensive end-organ damage is frequent if untreated. Its genetic basis and physiology were revealed after one of Liddle's original kindred developed ESRD. A strong family history of premature death from cardiovascular or kidney disease is typical.[95] Liddle's patients behaved as if they had primary hyperaldosteronism with volume expansion, high-normal sodium, and hypokalemic metabolic alkalosis. Measured aldosterone and plasma renin activity, however, were markedly suppressed.

Liddle's syndrome is associated with mutations of either the beta or gamma subunit of the epithelial sodium channel (ENaC), which mainly affect the C-terminus, and lead to high constitutive levels of ENaC activity.[96] The normal C-termini of ENaC subunits contain motifs recognized by the ubiquitylation machinery responsible for internalizing the protein and targeting it for disposal. Compromised integrity of this domain leads to an apparent gain of function because too many ENaC trimers become stuck in the apical collecting duct plasma membrane.[97] This accounts for increased sodium absorption in the cortical collecting duct and hypertension with physiologically appropriate reductions in renin and aldosterone. Blood pressure reduction and normalization of plasma potassium levels can be achieved using amiloride or triamterene, but not spironolactone. An important cofactor is concomitant restriction of dietary sodium, because the drugs compete with sodium for binding to ENaC.

Disorders of intracellular protein misrouting include Dent disease (DD) and Lowe syndrome. DD and the

oculocerebrorenal syndrome of Lowe (LS) are X-linked recessive disorders with closely overlapping renal phenotypes, characterized by proximal tubulopathy with low molecular weight proteinuria and aminoaciduria, albuminuria, variable urinary losses of glucose and phosphate, hypercalciuria, renal stones, nephrocalcinosis, and progressive CKD.[98] They differ in LS having additional severely disabling extra-renal features (cataracts, other eye disorders leading to blindness, mental retardation, muscular hypotonia, and other neurologic disturbances) and renal tubular acidosis.

About 60% of cases of DD are associated with mutations in the *CLCN5* gene encoding a voltage-gated chloride transporter (CLC5) expressed in the proximal tubule, medullary thick ascending limb, and intercalated cells of the collecting tubule. LS is consistently associated with *OCRL1* mutations encoding phosphatidylinositol-4,5-bisphosphate-5-phosphatase. Approximately 15% of patients with clinical DD have mutations in the Lowe *OCRL1* gene, and some have mild extra-renal abnormalities. Both proteins participate in pathways affecting trafficking of membrane proteins. Both are found on endosomes and OCRL1 in the *trans*-Golgi network (TGN). Loss of function results in defective endosomal recycling and/or abnormal TGN function, particularly in the proximal tubule.[99]

Cystinosis resides in the lysosomal storage disorder family. It is characterized by an accumulation of cystine within all organs, as a result of a deletion or mutation in *CTNS*, which encodes the widely expressed lysosomal cystine transporter, cystinosin.[100] Although there are milder forms, children with infantile cystinosis appear normal at birth, but demonstrate failure to thrive at less than 1 year, with proximal tubular dysfunction followed by rickets. Renal insufficiency is inevitable before teenage years, if untreated, and at a median 20 years when therapy with cysteamine is initiated early. Deposition of cystine crystals in the cornea occurs early, causing photophobia and painful corneal erosions. In the second to third decades, hypothyroidism, hypogonadism, diabetes, myopathy, and central nervous system deterioration are often observed.

Cystinosin is required to clear cystine (released from the hydrolytic cleavage of peptides) from lysosomes into the cytosol. Cystinosin contains a classic tyrosine-based lysosomal targeting signal (GYDQL) in its C-terminal tail. Unusually, mutation analysis revealed a novel second signal, the core of which is YFPQA situated in the fifth loop of the protein. Alterations within either domain result in misdirection of cystinosin to the plasma membrane.[100] Thus, cystinosis may arise either because cystinosin is absent or nonfunctional (e.g., with truncation mutations) or because it cannot traffic normally to the lysosome, as reported in missense mutations in the fifth loop or C-terminal truncations.[101,102]

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis is a very rare autosomal recessive condition characterized by progressive renal failure often evident in childhood, with nephrocalcinosis, hypomagnesemia with renal magnesium wasting, kidney stones, UTI, and in some cases ophthalmologic abnormalities such as severe myopia, macular colobomas, horizontal nystagmus, and chorioretinitis.[103] Positional cloning led to the identification of the paracellin-1 (claudin 16) gene on chromosome 3q as causative.[104] Subsequently, another family member, claudin 19, was found to be mutated in patients with ocular abnormalities.[105] Claudins are expressed at the tight junction between cells of the medullary thick ascending limb and are important in maintaining selectivity of paracellular cation transport, facilitating the reabsorptive movement of magnesium and calcium driven by positive luminal potential. Mutations drive the protein away from tight junctions, in one case to lysosomes[106] and in another transiently to the plasma membrane until internalized.[107]

Distal renal tubular acidosis (dRTA) is a disease of defective urinary acidification, caused by dysfunction of intercalated cells (α-IC) in the collecting system. It is characterized by hyperchloremic hypokalemic metabolic acidosis with reduced urinary citrate excretion, metabolic bone disease, hypercalciuria, and nephrocalcinosis and/or nephrolithiasis, often with progressive CKD. Of the inherited forms (much rarer than acquired), autosomal dominant dRTA (ddRTA) generally presents later, and less severely than the recessive form.[108] Recessive dRTA is often associated with progressive and irreversible sensorineural hearing loss. Treatment for all forms of dRTA is alkali replacement, which corrects most biochemical abnormalities but does not improve hearing.

In the α-IC, protons are secreted into the urine by apical H^+ATPases, coupled to the reclamation of bicarbonate across the basolateral plasma membrane *via* the Cl-bicarbonate exchanger, AE1. Although recessive disease is heterogeneous, and accounted for by loss-of-function mutations in one of the apical H^+ATPase subunits, mutations in *SLC4A1* encoding AE1 are the only genetic cause of ddRTA reported to date.

Autosomal ddRTA is unlikely to result from simple haploinsufficiency, because AE1 mutations causing the autosomal dominant erythrocyte diseases hereditary spherocytosis and ovalocytosis (the red cell being the other site of expression of AE1) are not associated with defects in urine acidification. Second, dRTA-associated AE1 mutations demonstrate near-normal anion exchange function when expressed in *Xenopus* oocytes. Examination of missense mutations and an 11-amino acid truncation at the C-terminus, R901X, have demonstrated that while some mutants are retained intracellularly, others lose their normal basolateral localization

and end up partly or wholly at the apical surface by acquiring a novel targeting motif.[109,110] Mislocalization is predicted to disturb voltage locally and disrupt vectorial proton and bicarbonate transport. Further studies have shown that loss of C-terminal interactions with GAPDH and the sodium pump cause loss of AE1 retention at the cell surface.[111,112]

Type I primary hyperoxaluria (PH) is a rare autosomal recessive disorder characterized by high urinary oxalate excretion, progressive bilateral calcium oxalate stone formation, nephrocalcinosis, and progressive CKD by adulthood.[113] PH is primarily a liver disease, caused by functional defects of the liver enzyme alanine–glyoxylate aminotransferase (AGT). Catabolism of glyoxylate to glycine fails, leading to overuse of the alternate pathway by which oxalate is produced. The kidney is the only excretory pathway for oxalate, which cannot be further metabolized. Therapy with pyridoxine, phosphates, magnesium, and citrate has proven helpful.[113] Extra-renal oxalate deposits occur in later stages, including in cardiovascular tissues, bone, and retinae. AGT normally resides in peroxisomes. In some patients, mutations in the *AGT* gene on chromosome 2 do not cause loss of the protein, but instead result in mistargeting to the mitochondria, a highly unusual mechanism of disease.[114]

Approaches to diagnosis and therapy include careful phenotypic and biochemical assessments. These are important in narrowing the likely differential diagnosis in tubule–interstitial nephropathies. Clinical mutation analysis is increasingly available for many of the affected genes.

Unless noted, no specific therapy exists for many of these disorders. Treatment is conservative, focusing on control of hypertension and hyperuricemia, repletion of vitamin D, limiting salt (other than in salt-wasting disorders), and supplementing electrolyte deficiencies. Apart from hyperoxaluria (where combined liver–kidney transplantation is required), they do not recur in renal transplants, because they are inherent to the recipient kidneys.

DIABETIC KIDNEY DISEASE

DKD is a common microvascular complication of type 1 (T1D) and type 2 diabetes (T2D), leading to increased morbidity and premature mortality. The etiology of DKD is multifactorial, including an inherent genetic component supported by the familial aggregation of DKD and related intermediate phenotypes across European American, African American, Asian, and Pima Indian populations. In addition, there is a markedly higher risk for developing disease among certain racial and ethnic groups. These observations suggest the presence of genetic variation underlying the etiology of DKD.

Early reports attempting to decipher the genetic architecture of DKD focused on candidate gene studies and the assessment of SNPs, typically coding mutations which have an increased likelihood of being functionally implicated in disease, residing in genes with a plausible physiological role in disease. Among loci evaluated, the angiotensin-converting enzyme (*ACE*), aldo-keto reductase family 1 member B (*AKR1B1*), and ectonucleotide pyrophosphatase/phosphodiesterase one genes (*ENPP1*) have been implicated in DKD in individuals with T1D and T2D. ACE is part of the renin–angiotensin system and regulates blood pressure and hemodynamics. The genetic association observed resides with an insertion/deletion of a 287 base pair *alu* repeat sequence,[115] with the deletion associated with higher ACE activity thus hypothesized to alter renal hemodynamics.[116] AKR1B1 is part of the aldose reductase pathway. Among variants associated with DKD, a dinucleotide repeat upstream of the transcription start site has been shown to impact expression of AKR1B1, leading to its association with disease.[117] ENPP1, also referred to as plasma cell membrane glycoprotein (PC-1), plays a role in insulin resistance, through blockade of the tyrosine kinase activity of the insulin receptor with a substitution at amino acid 121 influencing protein–protein interactions and providing biological plausibility for involvement.[118] The apolipoprotein E (*APOE*) and peroxisome proliferator-activated receptor gamma genes (*PPARG*) have been associated with DKD in those with T2D. APOE plays a central role in lipid and lipoprotein metabolism, although the mechanism conferring risk of DKD remains controversial. PPARG affects renal hemodynamics and water and sodium transport. Although numerous candidate gene studies have been published, results have been largely inconsistent.[119] Among the limitations of this approach are a relatively naïve understanding of the pathophysiology, selection of a modest number of genetic variants which fail to comprehensively capture variation at the locus, and relatively small numbers of cases and controls which adversely impacts study power. Despite these limitations, individual candidate gene studies can contribute to larger, well-powered meta-analyses in an effort to identify and validate loci which contribute to DKD. The major advantage of the meta-analysis approach is an increase in sample size, thereby increasing study power to detect genetic associations of more nominal effect. This approach has been applied to DKD.[120] In a comprehensive review of the literature, 671 studies investigating DKD were identified with a subsequent meta-analysis identifying 21 variants significantly associated with DKD. Among the most significant findings, *ACE* was associated with disease among

patients with T1D and T2D and was the most intensively studied gene for DKD. Specific to T1D, the findings also highlighted *AKR1B1*, erythropoietin (*EPO*), and heparan sulfate proteoglycan 2 genes (*HSPG2*). Specific to T2D, additional loci included the *APOE* and carnosine dipeptidase 1 genes (*CNDP1*). Despite new insights, this methodological advance has the same limitations as candidate gene studies. In addition, these studies are negatively impacted by publication bias, which may overestimate the effect size and may also yield false negative associations owing to phenotypic heterogeneity as a result of imprecise phenotypic characterization among study participants.

In an effort to provide more comprehensive coverage of the genome in a pathophysiology agnostic manner, linkage studies of DKD have been explored. Linkage studies rely on clustering of affected individuals within families to examine cosegregation of the phenotype with regions of the genome. Through interrogation of genetic variation, typically microsatellite markers evenly spaced across the genome, regions of the genome which are coinherited with disease across generations can be identified. The first linkage analysis for DKD was performed among Pima Indian sibling pairs, where DKD was defined as the presence of overt proteinuria and/or macroalbuminuria in the setting of T2D.[121] The strongest linkage signal observed was at 7q32.3−33 with significant linkage at two microsatellite markers, log of the odds (LOD) score of 2.04, spanning 4.9 cM (approximately, 4.9 Mb). Among the genes with a plausible biological role were aldose reductase (*ALDR1*), T-cell receptor β-chain (*TCRBC*), and constitutive endothelial nitric oxide synthase genes (*NOS*). More contemporary linkage studies have extended the evaluation of linkage peaks and identified positional candidate genes for evaluation. The most notable example is a linkage analysis in Turkish kindred and Pima Indian families which identified a linkage peak on 18q22.3−23 with a LOD score of 6.6 spanning 8.5 cM (approximately, 2.9 Mb).[122] Among the positional candidate genes, the carnosinase genes, *CNDP1* and *CNDP2*, were identified as positional candidates related to their role in inhibition of oxidative stress and advanced glycation end products, thus, protecting against the adverse effects of hyperglycemia.[123] Among variants analyzed, a trinucleotide repeat in exon 2 of *CNDP1* was significantly associated with DKD and replicated in European Americans.[124] The allelic form containing five leucine repeats, referred to as CNDP1 Mannheim, was observed with increased frequency among controls and associated with lower serum carnosinase concentration, which is hypothesized to result in higher levels of carnosine.

More recent linkage scans for DKD have focused on quantitative intermediate phenotypes, e.g., eGFR and albuminuria, in an attempt to dissect the heterogeneous phenotype of DKD.[125−127] Results from linkage analysis require further investigation as they often span on the order of megabases. In such cases, positional candidate gene studies are required. The utility and significance of linkage analysis for DKD remains unclear, with identification of relatively few genetic determinants. The major advantage of family-based approaches such as linkage analysis is minimization of population stratification or systematic differences in allele frequencies among subpopulations. Thus, as an alternative application, family-based studies may be well-suited for the study of rare genetic variation derived from next generation sequencing studies, as the family-based design will enrich these variants beyond frequencies observed in the general population.

GWAS comprehensively interrogate the entire genome, with less reliance on family-based recruitment. These studies can be extended through imputation, a statistical methodology which estimates ungenotyped variation through the use of reference populations with extensive genetic data. The search for genetic susceptibility loci for DKD using the GWAS approach was first performed in a Japanese patient population with T2D.[128] Through the gene-based analysis of 80,000 SNPs, a variant in intron 18 of the engulfment and cell motility 1 gene (*ELMO1*) was identified for association with DKD. Interestingly, although ELMO1 plays a role in promotion of phagocytosis and cell migration, there was no prior evidence for a role in DKD. Among the pathophysiological phenotypes, expression of *ELMO1* was increased under hyperglycemic conditions, which may result in excess accumulation of extracellular matrix proteins and lead to development and progression of DKD.

An early GWAS for T1D-associated DKD was performed in the Genetics of Kidneys in Diabetes (GoKinD) cohort.[129] Although not meeting strict evidence for statistical significance, this analysis in 820 cases and 885 controls genotyped for 360,000 SNPs identified the 4.1 protein ezrin, radixin, moesin (FERM) domain containing 3 (*FRMD3*) and cysteinyl-tRNA synthetase genes (*CARS*) as putative DKD susceptibility genes with replication in an independent cohort. The cohort was subsequently leveraged for a large-scale meta-analysis composed of three existing collections with 6691 participants as part of the GEnetics of Nephropathy: an International Effort (GENIE) consortium.[130] Using GWAS with imputation, GENIE evaluated ∼2.4 million SNPs and identified two variants associated with ESRD: a SNP in the AF4/FMR2 family, member 3 gene (*AFF3*) and an intergenic SNP on 15q26 located between RGM domain family, member A (*RGMA*), and multiple C2 domains, transmembrane 2 genes (*MCTP2*). Extension of this work under the auspices of the SUrrogate markers for Micro- and Macrovascular hard endpoints

for Innovative diabetes Tools (SUMMIT) Consortium amassed 12,540 individuals with GWAS and imputation, but failed to identify genetic variants reaching stringent levels of statistical significance despite adequate study power, i.e., 80% power to detect a variant with a MAF>10% and an allelic odds ratio (OR) $\geq$1.55.[131] However, investigators did establish the narrow-sense heritability, i.e. phenotypic variance explained by genome-wide SNPs, of DKD in the setting of T1D at 35%. The genetic similarity calculated from array-based data used to estimate this narrow-sense heritability is broadly similar to earlier estimates from family-based studies.[132]

In an effort to further expand sample size, researchers investigating the genetic architecture of DKD in the setting of T2D have undertaken meta-analyses combining DKD in T1D and T2D to identify similar and distinct genetic features of these diseases. Using data from 6335 individuals with T2D, researchers established the narrow-sense heritability of DKD at 8%. In comparison to estimates derived from DKD in patients with T1D, these estimates strongly parallel the genetic basis of the diabetes phenotype. To investigate the genetic basis of DKD and related phenotypes, analysis included up to 40,340 subjects with diabetes (18,582 with DKD) for association of greater than nine million variants from GWAS with imputation. Although this study represents the largest study of the genetic basis of DKD for patients with T2D, there were no significant genetic associations for DKD following replication analysis. However, a novel locus, the gamma-aminobutyric acid receptor subunit rho-1 gene (*GABRR1*), was associated with microalbuminuria. *GABRR1* gene expression is upregulated in kidney biopsies from DKD subjects supporting a role in disease. This locus was not associated with DKD in subjects with T1D. With its focus on European and Asian populations, a potential limitation of this study was failure to include ethnic minority samples with increased incidence and prevalence of T2D, such as African Americans. Relative to European Americans, African Americans are more often affected by T2D and proteinuric kidney diseases such as FSGS. Although inclusion of these populations may increase study size and ultimately power to detect more modest genetic effects, improved phenotypic precision coupled with ascertainment of controls that lack clinical symptoms at advanced age would still be required.

Progress in identifying the genetic architecture underlying DKD has been arduous, with the realization that a single locus of large effect does not exist. A general consensus is that DKD is a polygenic disorder with multiple genetic loci, each contributing a modest effect. Beyond statistical implication of genetic variation for susceptibility to DKD, further work will be needed to identify the causal variant as comprehensive approaches relying on linkage analysis identify broad genomic regions, and array-based technologies capture only common variation representative of the regional genetic landscape. Thus, there is an increasing need for next generation sequence analysis of participants coupled with detailed phenotypic evaluation. To better dissect the heterogeneous disorder DKD, clinicians and researchers need to identify novel disease biomarkers beyond clinically used measures such as eGFR, albuminuria, blood urea nitrogen, uric acid, and S[Cr] to facilitate earlier diagnosis and establish novel therapeutic interventions.

A relatively new area of exploration to identify putative biomarkers is metabolomics. Metabolites are small molecule intermediates produced by metabolic processes within the cell. For research targeted to identify predictive biomarkers, metabolomic assessment of serum or urine represent appropriate, easily obtainable biologically relevant samples. For DKD in the setting of T1D[133] and T2D,[134] these types of studies are still in the early stages. Coupling these findings with existing genetic linkage and association approaches will provide a systematic approach to gain insight into the genetic modulation of relevant pathways and identify genetic susceptibility markers.

CONCLUSIONS

This chapter highlights recent breakthroughs in the genetic underpinning of rare Mendelian nephropathies and more common forms of kidney disease. Advances have been made in nondiabetic kidney disease, particularly FSGS, nonspecific forms of glomerulosclerosis, and tubulointerstitial kidney diseases. In comparison, genetic developments in DKD have lagged. Large meta-analyses reveal that kidney disease in patients with diabetes is polygenic. Although DKD associates with multiple genes, each appears to have a relatively small effect. Environmental factors including hyperglycemia play important roles in susceptibility to DKD.

These laboratory discoveries have led to advances in patient care. Select genetic forms of FSGS have been shown to respond to medical therapy, and *APOL1* genotyping may improve outcomes in kidney transplantation. Finally, novel therapies targeting the *APOL1* gene are under development to prevent kidney disease in populations with recent African ancestry. The genetics revolution has been of great benefit to the field of nephrology. It will help patients with and at risk for CKD.

QUESTIONS AND ANSWERS

Question 1

A 32-year-old European man presents with subacute onset of NS with hypertension. His S[Cr] is 1.05 mg/dL (preserved kidney function), and he denies a family history of kidney disease. Physical exam reveals a blood pressure of 150/98 mm Hg and is otherwise unremarkable except for 2 + ankle edema bilaterally. He receives a statin and ACE inhibitor. A kidney biopsy displays FSGS with "not otherwise specified" lesion. Which of the following is the most appropriate approach to evaluation and treatment?

A. Consider immunosuppressive therapy because screening for mutations in adults with sporadic FSGS is not indicated
B. Test for mutations in the *INF2* (inverted formin-2) gene
C. Test for mutations in the *NPHS2* (podocin) gene, especially its p.R229Q variant
D. Test for mutations in the *APOL1*
E. Test for mutations in the *TRPC6* (transient receptor potential cation channel, subfamily 6) gene

Answer: A

Adults with European ancestry who have sporadic or nonfamilial forms of FSGS are highly unlikely to have causative mutations detected. Although screening for the p.R229Q variant in the *NPHS2* (podocin) gene can be considered for family planning purposes, few such mutations will be detected in settings such as this. Podocin mutations are common causes of childhood SRNS with autosomal recessive inheritance. The specific *NPHS2* variant p.R229Q variant is permissive, allowing adults to develop disease with only one *NPHS2* disease-associated variant. Although mutations in *INF2* and *TRPC6* cause adult FSGS, this is relevant in autosomal dominant forms of disease, and this patient lacked a family history of nephropathy. *APOL1* mutations are common causes of idiopathic FSGS in individuals of African ancestry.[135]

Question 2

Which of the following gene mutations is the most common cause of nonsyndromic (renal-limited) steroid resistant nephrotic syndrome (SRNS) in children less than 5 years of age?

A. Nephrin gene (*NPHS1*)
B. Inverted formin-2 gene (*INF2*) gene
C. Podocin (*NPHS2*) gene
D. Phospholipase C, epsilon 1 gene (*PLCE1*)
E. Wilms tumor 1 gene (*WT1*)

Answer C

Autosomal recessive mutations in the podocin (*NPHS2*) gene are the most common cause of autosomal recessive SRNS in infants and children and can be identified in sporadic and familial cases of SRNS. Based on this, *NPHS2* should be the first gene assessed in these cases. Autosomal recessive mutations in the *PLCE1* and *NPHS1* genes are less often detected—but can be assessed if risk variants in *NPHS2* are absent. *WT1* mutations typically cause syndromic (nonrenal limited) kidney diseases such as Denys–Drash and Frasier syndrome, and they are inherited in an autosomal dominant pattern.[136]

Question 3

Which statement regarding chronic kidney disease in hypertensive African Americans who lack diabetes mellitus and have less than 1 gm proteinuria per day is true?

A. The most common lesion on a kidney biopsy is FSGS, collapsing variant
B. Aggressive treatment of hypertension to <120/80 mm Hg using ACE inhibitors reliably halts the progression of nephropathy
C. Progression of kidney disease commonly relates to possessing two renal-risk variants in the *APOL1* inherited in an autosomal recessive inheritance pattern
D. Renal arteriolar narrowing and hyalinosis are rarely present

Answer: C

Kidney biopsies in hypertensive, nondiabetic African Americans with low level proteinuria reveal FGGS with interstitial fibrosis and small vessel arteriolar changes. The arteriolar lesions do not correlate with systemic blood pressure. Subnephrotic forms of FSGS may also be observed; however, collapsing lesions are uncommon. Results of the NIH AASK study revealed that nearly 60% of participants treated with ACE inhibitors to low blood pressure targets still reached the composite endpoint of ESRD, doubling of S[Cr], or death after 10-year follow-up. In contrast to blood pressure target or class of antihypertensive medication, presence of two *APOL1* renal-risk variants predicted progression of kidney failure. This study demonstrates that this type of kidney disease in African Americans is not likely caused

by high blood pressure but resides in the spectrum of *APOL1*-associated nephropathy.[58]

Question 4

Mutations in which of the following genes does not cause ADTKD?

A. Uromodulin (*UMOD*)
B. Mucin-1 (*MUC1*)
C. Claudin 16 (*CLDN16*)
D. Renin (*REN*)
E. HNF1 Homeobox B (*HNF1β*)

Answer: C

Mutations in the claudin 16 gene (also called paracellin-1) lead to the rare syndrome "familial hypomagnesemia and nephrocalcinosis". In contrast, mutations in *UMOD*, *MUC1*, *REN*, and *HNF1β* associate with ADTKD. Many patients have hyperuricemia and gout; anemia can be seen with *REN* mutations and hypomagnesemia with *HNF1β* mutations.[78]

Question 5

Liddle's syndrome is caused by mutations in the beta or gamma subunits of the *ENaC* gene. Affected patients display all of the following except:

A. Hypertension with plasma volume expansion
B. Loss-of-function mutations in ENaC with urinary sodium wasting
C. Gain-of-function mutations in ENaC with sodium retention
D. Low or undetectable plasma renin and aldosterone levels
E. Improvement in hypertension with amiloride or triamterene

Answer: B

Liddle's syndrome is associated with mutations of either the beta or gamma subunit of the ENaC; these produce high constitutive levels of ENaC activity. This leads to an apparent gain of function and accounts for increased sodium absorption in the cortical collecting duct and hypertension with physiologically appropriate reductions in renin and aldosterone. Effective blood pressure reduction and normalization of plasma potassium in patients with this syndrome can be achieved using amiloride or triamterene (not spironolactone) with concomitant dietary sodium restriction. Salt restriction is critical because these drugs compete with sodium for binding to ENaC.[96]

Question 6

Which of the following statements is true regarding genetic factors in DKD?

A. Polymorphisms in the *ACE* gene contribute to the majority of cases
B. Family-based linkage studies reveal that a trinucleotide repeat sequence in the carnosinase 1 gene (*CNDP1*) cause most cases of kidney disease in patients with type 2 diabetes mellitus
C. A single locus of large effect has not been identified
D. DKD is a polygenic disorder (multiple genes contribute to risk), whereas environmental factors including hyperglycemia play a minor role

Answer: C

Progress in identifying the genetic architecture underlying DKD has been difficult with realization that one locus of large effect does not exist. DKD is a polygenic disorder with multiple genetic loci, each contributing modest effect. To better dissect the heterogeneous disorder DKD, clinicians and researchers need to identify novel disease biomarkers beyond clinically used measures such as eGFR, albuminuria, blood urea nitrogen, uric acid, and S[Cr] to facilitate earlier diagnosis and establish novel therapeutic interventions.[137]

CHAPTER

Acute Kidney Injury and Chronic Kidney Disease

Matthew T. James[a], *Lakhmir S. Chawla*[b,c,d], *Paul L. Kimmel*[c]

[a]Department of Medicine, Cumming School of Medicine, University of Calgary, Calgary, AB, Canada; [b]Department of Anesthesiology and Critical Care Medicine, George Washington University Medical Center, Washington, DC, United States; [c]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States; [d]University California of San Diego, San Diego, CA, United States

Abstract

Previous conventional wisdom suggested patients who survived an episode of acute kidney injury (AKI) fully recovered renal function. AKI and chronic kidney disease (CKD) have been traditionally approached as separate clinical syndromes, mainly distinguished by criteria based on timing and duration of reduced kidney function. However, recent research demonstrates that AKI and CKD are closely related. CKD is an important risk factor for the development of AKI. In turn, AKI is associated with the development of CKD and progression of preexisting CKD in significant numbers of patients. Both AKI and CKD are associated with increased morbidity and mortality, particularly when they are seen in combination, including increased risks of major adverse cardiovascular events.

AKI and CKD may be better considered as interconnected syndromes, rather than two disparate entities. This knowledge has implications for the longitudinal care of survivors of AKI and patients with CKD. Interventions that target the AKI to CKD continuum may improve outcomes of patients with kidney disease, although strong evidence identifying strategies that improve outcomes remains lacking. Improved strategies for identification of patients at risk could inform the design of clinical trials, but well-designed RCTs are needed to determine effective interventions and best care practices to mitigate the pathways of AKI to CKD and to ameliorate its progression.

INTRODUCTION

Medical teaching has traditionally divided pathophysiology of disease into organ systems, and within these, into syndromic approaches.[1,2] For more than a half century, nephrologists have taught limited and separate modules pertaining to acute renal failure (ARF) and chronic renal disease to medical students. Over the last 15 years, in part to facilitate clinical recognition and research, conceptual definitions of chronic kidney disease (CKD)[3] and acute kidney injury (AKI)[4,5] have been developed and refined, categorizing disease states and stages according to measures based on long-term level and acute changes in S[Cr]. AKI is currently defined by decline in kidney function over one week or less, whereas CKD is defined as alterations of kidney function and structure for more than 3 months.[6,7]

Previous conventional wisdom suggested favorable long-term outcomes of patients with ARF, and acute tubular necrosis (ATN) in particular, if recovery occurred during hospitalization. In 1952, Lowe reported creatinine clearances ranging from 65.3 to 99 mL/min in a subset of 14 of 40 patients with oliguria or anuria and a diagnosis of ATN when followed 228 days to 2.9 years.[8] Most of the values for creatinine clearance one to three years after the ATN episode remained below normal. Premorbid levels of renal function were not recorded. Lowe concluded "… once recovery has been made from the acute episode of ATN, a favorable prognosis can be given… the levels of renal function attained are compatible with normal expectation of life, although the renal reserve is diminished." Finkenstaedt and Merrill described long-term outcomes of 16 patients with ARF who did not have cardiovascular disease (CVD) or kidney disease before the acute episode.[9] In these patients as well, "clearance values obtained for the majority of the patients fell below the lower limit of normal." Inulin clearances ranged from 35 to 120 mL/min/1.73 m^2 at 1 to 76 months after the episode of ARF. Three

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00026-7

of the patients had long-term values of inulin clearance less than or equal to 63 mL/min/1.73 m^2. The lessons of these small seminal papers published in the Lancet and the New England Journal of Medicine regarding long-term outcomes of ATN more than a half century ago have been forgotten or misinterpreted.[1]

Recent evidence, however, from large well-designed observational studies shows a substantial proportion of patients with AKI, even those without a history of previous renal disease, progress to high stage CKD,[1,2,10] and that AKI is an independent prognostic factor for the progressive loss of renal function in patients with CKD.[1,10–12] Although the antecedents and clinical correlates of ARF have been known for many years, in the era of CKD and AKI classifications, CKD has emerged as the preeminent risk factor for AKI.[1,2,13,14] Since 2007, the concept of AKI has been generally accepted by the kidney research and clinical communities.[3,5] Several observational studies have documented ominous outcomes associated with small increases in S[Cr] in populations. Concepts and definitions of AKI (Table 26.1) demonstrate numerous similarities to those of CKD.[1,3,7,15,16]

The public health impact of the long-term outcomes of AKI is significant. AKI is associated with significant morbidity and mortality, and the incidence of AKI has nearly doubled over the past two decades.[17,18] AKI is common, morbid, deadly, and costly.[4] AKI has been linked with the development of subsequent CVD, CKD, and end-stage renal disease (ESRD) and is associated with high costs of care.[1,2,10,18–20] Secular trends suggest that while the incidence of AKI has increased, early mortality from AKI has diminished in high-income countries. As a result, the number of survivors who may live with sequelae of CKD has increased over time.[20–22]

The annual incidence of AKI has been estimated as approximately 2100 per million population.[23,24] Given the population of the developed world, there are projected to be over 2 million cases of AKI yearly, with an expected 1.5 million AKI survivors.[24,25] Of these patients, more than 15% of those without preexisting CKD will progress to advanced stage CKD within 24 months, resulting in an incidence of more than 300,000 cases of advanced CKD a year.[24,25] Furthermore, episodes of AKI that are superimposed on CKD may hasten the progression to ESRD of additional patients with established CKD.[20] These estimates demonstrate the significant population attributable risk of CKD associated with AKI. Given the higher incidence of AKI in older populations, the projected incidence of CKD and ESRD related to AKI is expected to increase.[15,18,24,26]

Observational studies show a large proportion of patients with AKI, even in the absence of concurrent or preexisting CKD, progress to advanced stages of CKD, even if not treated with RRT during the index hospitalization.

Given the relationships between AKI and incident CKD, progression of preexisting CKD, increased risk of entry into ESRD programs, and higher mortality,[1,2,20,27,28] AKI and CKD can be considered parts of an interdigitated syndrome (Figure 26.1). The individual components, AKI and CKD, differ in presentation both temporally and clinically. AKI involves rapid changes in glomerular filtration rate (GFR), while CKD is usually characterized by slowly progressive decline in GFR. Patients with AKI are at high risk of developing CKD, even when GFR recovers after the initial episode. Patients with CKD remain at risk for developing episodes of AKI, which may further contribute to progression toward kidney failure.[1,2,14] The individual components of the syndrome and their combination are common and associated with adverse long-term outcomes. This syndrome can be expanded to include patients with acute kidney diseases and disorders when alterations in kidney function or structure are present for less than 3 months, which includes patients who do and do not strictly meet AKI criteria but also have similar relationships with increased risks of CKD and ESRD.[7,29] CKD, however, is the obverse face of the AKI coin. For patients with reduced GFR, AKI and CKD are the twin prognostic profiles of Janus, the two-faced Roman god of doorways, beginnings and endings.

Specific populations of immune cells including subpopulations of macrophages and T cells
Dietary sodium and protein intake

FGF-23, fibroblast growth factor 23; *PTH*, parathyroid hormone.

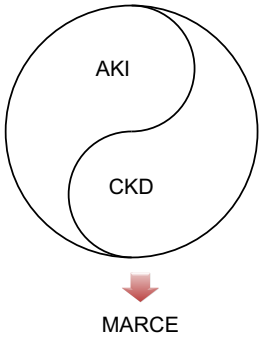

FIGURE 26.1 AKI and CKD are interconnected syndromes. AKI patients are at risk for developing long-term decrements in GFR, even if full recovery occurs after an episode. CKD patients are at the highest risk of developing AKI. Patients with AKI and CKD are at risk for developing major adverse renal and cardiovascular events (MARCE). *AKI*, acute kidney injury; *CKD*, chronic kidney disease; *MARCE*, major adverse renal and cardiovascular events.

AKI AND DEVELOPMENT OF CKD, END-STAGE RENAL DISEASE, AND CARDIOVASCULAR EVENTS

Several retrospective studies have characterized the relationship between AKI and development of CKD. In an important early study, Vikse and colleagues showed the rate of entry into ESRD programs was 3.7 per 100,000 women per year, but women with a diagnosis of preeclampsia had a relative risk of ESRD that was 3.2- to 15-fold higher.[30] Ishani et al. showed, in a retrospective, observational study of Medicare patients, with follow-up of two years, that a coded diagnosis of ARF was associated with a 13-fold increase in the risk of development of ESRD compared with hospitalized patients without such a diagnosis. Patients who had a diagnosis of both ARF and CKD had a 40-fold increased risk of entering the ESRD program compared with patients without either diagnosis, and their ESRD risk was almost five times as great as those with a diagnosis of CKD in the absence of AKI.[20] The mortality rate for patients with a diagnosis of ARF was 57.7%, twice as high as that of comparable patients without a diagnosis of ARF. Patients who had diagnostic coding related both to ARF and CKD had a mortality rate 18% higher than those with only an ARF diagnosis, 70% higher than those with CKD alone, and 2.4-fold higher than those without either diagnosis. Newsome et al. showed similar increases in both ESRD and mortality among patients with acute myocardial infarction (MI) who sustained small increases in S[Cr].[31] Lo et al. found, after controlling for potential confounders such as presence of diabetes mellitus and baseline level of estimated GFR (eGFR), that AKI necessitating dialysis was independently associated with an almost 30-fold increase in the risk of developing subsequent stage 4 or 5 CKD, and a more than doubled risk of death.[28] Bucaloiu et al.[11] showed, using propensity score matching techniques, an approximately 50% increased risk in mortality of patients with AKI, but without concomitant CKD, as well as an almost doubled risk of developing incident CKD in the Geisinger Health System in Pennsylvania. A strength of the study was the ability to ascertain information regarding urinary protein excretion, when present in the medical record. Of note, almost three quarters of the AKI patients only had stage 1 disease, by Acute Kidney Injury Network criteria, and the duration of AKI was less than 24 hours. Hsu et al. showed AKI had an incrementally adverse effect on patients with preexisting CKD in a cohort of patients from the Kaiser Permanente dataset. Compared with patients who had CKD and did not experience AKI, those who had AKI superimposed on CKD had a 30% higher long-term risk of death or ESRD.[32] Wald et al. showed, in an administrative database study of a Canadian population of patients who required dialysis during hospitalization, but survived free of dialysis for at least a month after hospital discharge, that the group had a threefold increased risk of ESRD compared with the control group.[27] In a cohort of Canadian patients identified from a prospective cardiac catheterization registration, patients who exhibited laboratory evidence of AKI following coronary angiography were at particular risk for subsequent loss of renal function and ESRD.[14]

Amdur and colleagues examined the long-term risk of patients diagnosed with ATN, as well as ARF, in the US Veterans Administration health system.[24] Progression of loss of renal function in patients with ATN who did not have preexisting, concomitant CKD to stage 4 CKD or higher was similar to those who were diagnosed with CKD at study baseline. CKD and ATN patients had similar mortality, which was higher than that of the control group, which was comprised of patients with the serious hospital diagnoses of MI or pneumonia, acutely ill patients with a substantial burden of CVD and cardiovascular risk factors. Patients with ATN had approximately six times the risk of developing CKD compared with the control group, whereas those with ARF had a fourfold increase in risk. Approximately 20% of patients with a diagnosis of ATN, without preexisting CKD, entered stage 4 CKD after a follow-up of more than six years. More than 13% of patients with a diagnosis of ARF, without preexisting CKD, developed stage 4 CKD during the study observation period. The risk of developing stage 4 CKD in patients with a diagnosis of ATN or ARF was 5.6 and more than 3-fold greater, respectively, than that of a control group of hospitalized patients with MI or pneumonia.

Nineteen retrospective cohort studies have characterized the relationships between AKI, based on the KDIGO criteria, and the risks of CKD and ESRD. Based

on meta-analyses of these data, AKI carries an over twofold increased risk of new or progressive CKD (17.8 vs. 7.6 cases per 100 person-years for those with vs. without AKI) and an over fourfold increased risk of ESRD (0.47 vs. 0.08 cases per 100 person-years for those with vs. without AKI). More severe AKI stages are consistently associated with higher risks for both outcomes. These findings have recently been confirmed in a multicenter prospective study from the US. The Assessment Serial Evaluation and Subsequent Sequelae (ASSESS) AKI study compared outcomes following discharge of patients with AKI and matched hospitalized patients without AKI. Importantly, this study employed protocolized follow-up measurements of eGFR and proteinuria to ascertain CKD in a consistent manner during follow-up.[33,34] The ASSESS AKI study reported that AKI was associated with an over threefold higher adjusted rate of development of CKD incidence and an over twofold higher adjusted rate of CKD progression.

The risk of development of CKD and progression of CKD to and development of ESRD is enhanced after AKI, but is also negatively affected by the increased severity of and number of episodes of AKI.[10,35,36] Risk factors that have been identified for developing CKD following AKI include older age, presence of a diagnosis of diabetes mellitus, heart failure, the magnitude of increase in S[Cr], provision of dialysis, lower baseline eGFR, level of RIFLE score, albuminuria, and hypoalbuminemia (Table 26.2).[36,37] These findings have been confirmed in a systematic review, demonstrating an almost ninefold increased risk of developing CKD for patients with AKI, a threefold increased risk of developing ESRD, and a doubled risk of death.[10] The study suggested increased risks of developing CKD and ESRD associated with severity of AKI as well.[10] Table 26.2 outlines factors which may be associated with long-term outcomes in patients after an episode of AKI.

Degree of early recovery of kidney function
Lack of follow-up by physicians
Genetic susceptibility

Several large observational cohort studies show patients who survive an AKI episode are at high risk for both progression to CKD and increased cardiovascular events.[14,19,38] In a cohort of patients who received coronary angiography in Alberta Canada, AKI was independently associated with subsequent hospitalizations for heart failure and MI.[14] In an analysis of the Veterans Administration hospital database, after a median follow-up of 1.4 years (interquartile range 0.5–3.4 years), patients with a diagnosis of ARF or with AKI had a cumulative incidence of major renal and cardiovascular events 37% higher than that of a comparison group of patients with a diagnosis of MI.[19] More than 60% of patients with AKI had a major cardiovascular or kidney event during follow-up (Figure 26.1). The highest risk of death, kidney, and cardiovascular events was observed in patients with AKI and MI. In a meta-analysis of six studies with a minimum follow-up of 6 months, Odutayo et al. found AKI was associated with an approximately 86% higher risk of cardiovascular mortality, and 38% higher risk of a major cardiovascular event.[39] Go et al. found that, among hospitalized patients from Kaiser Permanente in California, 20% of patients with AKI experienced a cardiovascular event in the year after hospital discharge, and that individuals with AKI were at 18% higher adjusted risk of developing acute coronary syndrome, peripheral arterial disease, ischemic stroke, or heart failure.[40] However, AKI was most strongly and significantly associated with a 44% increased risk of heart failure, without significantly increased risks of atherosclerotic disease following adjustment. The prospective ASSESS AKI study showed similar findings when cardiovascular events following hospitalization were clinically adjudicated, with significantly higher adjusted risks of heart failure, but not major atherosclerotic events identified among those with AKI.[33,34]

AKI AS A SYNERGISTIC COMPLICATION OF PROGRESSION OF CKD

Patients with AKI superimposed on preexisting CKD present special challenges to clinicians and researchers.[41] Analyses of repeated measures of kidney function suggest trajectories of CKD progression may include AKI episodes, but in a complex manner which makes analyses of the data problematic, and the formulation of definitive conclusions challenging.[2,42,43] O'Hare and colleagues identified four distinct trajectories of eGFR in patients with CKD during the two years before onset of ESRD. The trajectories included relatively stable courses, progressive loss of renal function, and both aggressive and catastrophic decreases in GFR. Patients with more aggressive progression to ESRD were more likely to have been hospitalized and to have had a diagnosis of AKI.[43]

CKD is the most important risk factor for the development of AKI, and patients with CKD appear uniquely susceptible to the development of AKI.[1,2,14,16] This was illustrated in a large cohort study from Alberta, Canada, that included almost 1 million participants with outpatient eGFR and albuminuria measurements to characterize their CKD stage. The risk of hospitalization with AKI was shown to increase progressively with both lower eGFR and greater albuminuria.[44] The importance of CKD as a predictor of AKI is also apparent from the development of clinical risk scores for AKI after cardiac surgery and cardiac catheterization.[45–47] Most risk scores for AKI include a history of CKD or baseline eGFR among the strongest predictors. More recently, some have also identified albuminuria as an additional independent predictor of AKI in multivariable models.

Mechanisms by which patients with CKD may be at risk for developing transient decreases of renal function include failure of autoregulation, abnormal vasodilatation, lack of renal reserve, failure of adequate renal tubular mechanisms to reabsorb water and sodium, frequent hospitalizations with the potential for iatrogenic mishaps or exposure to nephrotoxins, treatment to achieve diuresis leading to volume depletion, susceptibility to effects of antihypertensives, overvigorous medication, the use of RAAS blockers, nephrotoxins, and age-related physiologic changes.[1,2,14,16,26,48] Patients with congestive heart failure or those with cardiorenal syndrome would seem to be intrinsically at increased risk because of their decreased renal function, even in the absence of laboratory evaluations which suggest the presence of CKD.[49–51] Some data suggest, however, the uremic milieu might be associated with protective factors, such as antiinflammatory responses that modify factors associated with progression of kidney disease.[52]

Of note, the data linking small changes in S[Cr] with adverse outcomes may have potential significance apart from traditional notions of disease states such as ATN, acute interstitial nephritis (AIN), acute glomerulonephritis, or renal vascular disease.[15] If such findings are confirmed in prospective studies, the implication is that patients who experience changes in cardiac hemodynamics, such as those with congestive heart failure or one of the cardiorenal syndromes, may represent a population at risk, but not necessarily from kidney dysfunction as a prime determinant. In addition, commonly employed therapeutic maneuvers, theoretically applied by extrapolating from findings from RCTs conducted in patients with CKD, such as diuretic therapy, interventions to control level of blood pressure, salt restriction, and intervention with agents which affect the RAAS may have unintended adverse consequences in patients with AKI and CKD. The ramifications, especially regarding patients with prerenal hemodynamics, are wide-ranging. Although the clinical paradigm of "acute on chronic" kidney disease has been well-appreciated, it is only recently that observational data (frequently from administrative sources) have been effectively used to study such patients. The nephrology community's therapeutic approach to patients with simultaneous AKI and CKD is limited to anecdotal approaches. In addition, whether temporal sequence (such as whether AKI preceded CKD or CKD was complicated by AKI) is associated with outcomes in patients with coexisting CKD and AKI is unknown.

Although the large number of observational studies linking episodes of AKI to the development and progression of CKD has established consistent relationships, causal links cannot be inferred by these study designs. Observational studies, particularly those using administrative databases or conducted retrospectively, are subject to errors associated with confounding and selection bias.[1,2,12,14,53] Findings linking small changes in S[Cr] to adverse outcomes may be affected by the clinical circumstances associated with receiving multiple laboratory tests, such as site of care, and linkages may be missed in those patients who do not have systematic or frequent ascertainment of S[Cr]. The assessment of renal disease using administrative data often does not have the granularity necessary to assess specific laboratory findings. The prospect of underestimation of the scope of the clinical problem is magnified when mild abnormalities, such as failure to maximally concentrate or acidify urine, in the presence or absence of a specific stressor, are considered as measures of CKD or tubular dysfunction.

Only an RCT designed to test whether an intervention decreases the incidence of CKD or progressive loss of renal function after an episode of AKI can achieve a definitive conclusion regarding causality. In one of the few studies to explore this question, a randomized clinical trial testing off-pump vs. on-pump coronary artery bypass grafting surgery showed off-pump surgery reduced the incidence of AKI by 17%. There was no difference detected between the treatment groups in the risk of a 20% decline in renal function one year later in this trial.[54] A lack of other effective early interventions for prevention and treatment of AKI has limited opportunities to further test causal pathways between AKI and long-term outcomes, and inferences continue to be drawn from several sets of extant data.[2,53,55]

Children usually do not have underlying comorbidities associated with risk for AKI or CKD, such as diabetes mellitus or hypertension. Several studies show children who sustain an episode of AKI develop signs of CKD, such as hypertension, decreased GFR, and urinary abnormalities, in the absence of comorbidities characterizing the adult population.[56–58] In analyses in adult populations, when variation in the presence of

comorbidities is considered, AKI emerges as an independent risk factor for the development of CKD, progressive loss of renal function, and development of ESRD. The severity of AKI has been associated with the development of adverse outcomes.[10,36,59] Finally, the number and severity of episodes of AKI has been linked to adverse outcomes.[35]

MECHANISMS ASSOCIATED WITH PROGRESSIVE RENAL INJURY

The long-term course after an episode of AKI is presumably determined by the extent of the decrement in GFR, the reversibility of the injury, and the temporal balance between effective and maladaptive repair mechanisms (Figure 26.2, Table 26.3).[1,16] Although the mechanisms underlying progression of renal dysfunction in humans are incompletely understood, and are primarily derived from studies in animals and model systems, rather than from individual level clinical findings, data from animal studies delineate a number of possible mechanisms.

Neugarten and Baldwin and colleagues first proposed that progression of chronic disease might occur by processes independent of the original pathology or injury, originally in glomerular diseases.[60] The group showed evidence of renal dysfunction, consisting of incident hypertension, proteinuria, and hematuria, in addition to change in renal function characterized the long-term course of patients who recovered from an episode of poststreptococcal glomerulonephritis.[61] They subsequently expanded these notions to patients with other glomerular diseases, and with decrements in renal function nonspecifically.[62] These metrics are used today in analyses of CKD in children.

A variety of mechanisms associated with progressive injury in AKI patients is similar to that proposed for progression in CKD (Table 26.1, Table 26.3).[1,2,16] These include the effects of systemic and intrarenal hypertension and hyperfiltration, tubular hypertrophy and atrophy, tubulointerstitial fibrosis, progressive glomerular sclerosis, arteriosclerosis, and disordered physiologic, humoral, and biochemical responses associated with CKD (such as PTH, FGF-23, inflammation, and hyperphosphatemia [Table 26.1]). In addition, endothelial injury, as part of tubular interstitial injury, and vascular dropout may set up vicious cycles of hypoxia and ischemia, in turn affecting renal cellular function (Table 26.3).[63] The state of the interstitium has been known to be associated with long-term outcomes in many glomerular and tubular diseases for many years.[64]

AKI has been associated with interstitial infiltration, mediated by chemokines, resulting in an influx of macrophages, T cells, and neutrophils (Table 26.1).[65,66] Such cellular responses can culminate in facilitation of repair and regenerative mechanisms, or might be associated with maladaptive responses such as enhancing fibrosis, or interfering with cellular responses. Studies have assessed the roles of arrest of the normal cell cycle, and epigenetic changes within renal epithelial and interstitial cells. These processes might be exacerbated by diets rich in sodium and protein (Table 26.3).[2,67,68]

A balance of injury and restorative factors underlies outcomes for the kidneys in patients with AKI and

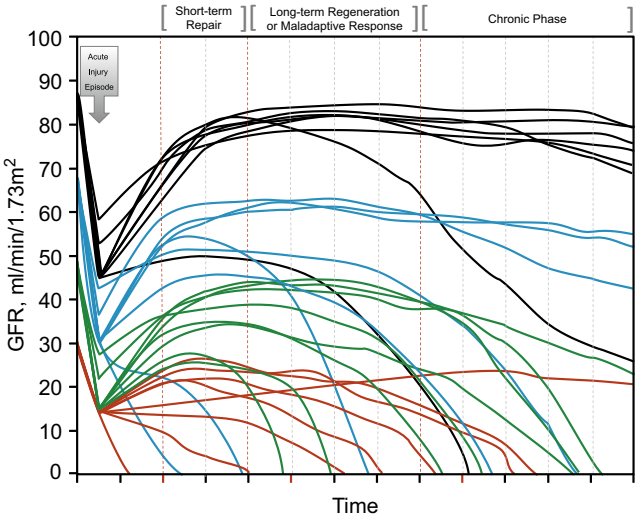

FIGURE 26.2 Renal functional changes after AKI. Previous investigators have outlined possible courses of AKI over time: complete resolution of renal functional decline, rapid, irreversible progression to ESRD, and intermediate long-term courses with progressive decline or maintenance of renal function. Findings from the African-American Study of Kidney Disease and Hypertension (AASK study) suggest the individual trajectories of renal functional changes over time in CKD patients are not simple linear slope relationships interrupted by the steep, rapid sloped declines of AKI, but are rather complicated higher order curves which render modeling difficult. The severity of injury and, most importantly, the baseline level of function at the beginning of the AKI episode, likely determine the long-term course. The Y axis depicts the range of GFR, and the X axis time, in months and years. Different colors indicate different individual patients, with similar GFR before the beginning of an episode of AKI. The time frame for the AKI episode is illustrated with an arrow. The individual lines indicate distinct patients, with varying changes in GFR over time after an episode of AKI. Dotted lines indicate repair and long-term regenerative phases. The scope of outcomes however theoretically includes the entire range of the GFR (right margin, Y axis). Responses after AKI and during the subsequent course of disease may vary over several phases, which may differ between patients in timing: repair and regeneration and chronic maladaptive periods. Individual factors such as age, genetic susceptibilities, the robust nature of repair and regenerative processes compared to those associated with fibrosis, and prescribed therapy may change the slope of decline differentially during the phases. Repetitive episodes of AKI during the course of illness in patients with diminished GFR will make analyses more difficult.

TABLE 26.3 Selected Putative AKI-Specific Factors Related to Progressive Loss of Renal Function

Specific populations of immune cells including subpopulations of macrophages and T cells

CKD, or the combination of the two entities (Table 26.3).[2] It may also be that repetitive insults play meaningful roles.[16,69] Various mediators (such as p21) have been outlined as protective factors in AKI, but may be contributors to ongoing fibrosis, inflammation, and CKD, depending on temporal regulation and expression.[1,2,16] Other factors associated with long-term outcomes after an episode of AKI include failed differentiation, and sustained proinflammatory profibrotic signaling, progressive capillary loss, and endothelial−mesenchymal transformation, G2 M cell cycle block, and epigenetic changes.[1,2,16] Hypoxia-inducible factor-1-α (HIF-1-α) has been outlined as a protective factor in AKI but may be a contributor to CKD.[16] Heme oxygenase-1 protects against acute insults, but also suppresses inflammation. Complex interactions between heme oxygenase and TGF-β1, over time, in specific cell subsets, may have ameliorative or maladaptive consequences.[16,69,70] The lack of kidney tissue from patients with AKI and suitable controls has been identified as a barrier to enhancing our understanding of factors associated with outcomes in patients with AKI.[2,71] The National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) supports the Assessment, Serial Evaluation and Subsequent Sequelae of AKI (ASSESS AKI) study, which prospectively evaluated long-term outcomes of hospitalized patients, with and without CKD, after an episode of AKI, to determine the natural history of AKI and delineate risk factors for progression and development of complications, including CVD. This study also prospectively collected biological samples that will aid future evaluation of associations between selected biomarkers and long-term outcomes.[33]

CLINICAL CONSIDERATIONS

Few patients with AKI receive follow-up after hospital discharge, by generalists, cardiologists, or nephrologists.[1,72,73] Siew et al. demonstrated a low rate of referral of patients with AKI to nephrologists after hospital discharge in the Veterans Administration system.[73] Severity of renal disease did not affect referral rates. A survey study of Canadian nephrologists suggested a substantial gap between the opinions of nephrologists regarding patients who should receive follow-up and actual processes of nephrology care after hospitalization with AKI.[74] Both patients and healthcare providers have described important challenges to care after a hospitalization with AKI, which may affect health outcomes.[75,76]

Despite the relationships between AKI and CKD, not all survivors of AKI go on to develop CKD. However, identification of patients at high risk of CKD following AKI could be used to target specialized care to individuals at greater risk. A predictive model for progression of AKI to stage 4 or 5 CKD was developed in over 14,000 survivors of an AKI hospitalization with a baseline eGFR >45 mL/min/1.73 m^2 from Alberta, Canada. The model was validated in over 2700 patients from Ontario, Canada.[37] Six independent variables associated with advanced CKD following AKI hospitalization were combined in the model: older age, female sex, higher baseline S[Cr], albuminuria, greater severity of AKI, and higher S[Cr] at the time of discharge. A multivariable model based on these predictors was well-calibrated and achieved good discrimination for predicting advanced CKD in the external validation cohort. This model could be used at the time of hospital discharge to identify patients at high risk warranting specialized follow-up after AKI.

We suggest patients with AKI at risk of developing CKD following discharge from the hospital should have periodic assessment of renal function and urinary albumin:creatinine ratio (UACR), to assess prognosis and outcome. Patients at high risk or who sustain severe or persistent decrements in renal function should have follow-up with a nephrologist.[2]

How to treat patients who have survived an AKI episode whether or not they have CKD is unclear.[1,2] Care for patients without preexisting CKD, who sustained an episode of AKI, should include avoidance of nephrotoxic medications, which may include nonsteroidal antiinflammatory drugs (NSAIDs) and contrast agents.[2] However, because of lack of appropriate studies, we do not know whether current practices employed in CKD care slow or worsen the progression of renal disease in patients, with or without CKD, who

survive an episode of AKI.[1,2] Addressing factors associated with poor outcomes in CKD patients, by treating hypertension, and optimizing diabetes care would seem to be useful, but the efficacy and safety of these interventions in patients after an episode of AKI is unknown.[2] For example, more intensive blood pressure lowering resulted in more frequent episodes of AKI in the Systolic Blood Pressure Intervention (SPRINT) Trial,[77] and patients with diabetes who develop AKI have been reported to be at higher subsequent risk of hypoglycemia, particularly when they experienced partial or no recovery of kidney function.[78] Use of RAAS blockers has been associated with lower mortality after AKI but may carry an increased risk of renal complications, including hospitalization for hyperkalemia or recurrence of AKI, suggesting cautious monitoring is warranted in this setting.[79] Low sodium diets and other dietary interventions should be evaluated in such patients. Patients who have had an episode of AKI superimposed on CKD, a common clinical occurrence, should be followed by nephrologists to ensure optimal care.

FUTURE DIRECTIONS

Although recent studies have focused on outcomes based on KDIGO AKI definitions, and changes in S [Cr], several areas need emphasis in future research. Little is known from prospective observational data regarding the long-term course of ATN. It is important that the long-term consequences of AKI be delineated in patients with specific renal diseases, such as ATN, or AIN, as well as prerenal azotemia, and renal vascular disease. The setting in which AKI occurs may be critical to outcome. We know little specifically about AKI which occurs in intensive care unit settings.[80] Although sepsis is understood to be an important common etiologic factor in the development of AKI, relatively little is known about patients who develop AKI after sepsis.[2,16,80–82] In addition, the elderly are particularly susceptible to the development of AKI.[1,26,80]

Finally, only recently have we begun to investigate the long-term sequelae of pediatric and neonatal AKI as well as AKI in low- and middle-income countries.[57,71,83] Studies in children with AKI are particularly important regarding the scope of the problem of CKD in the US and worldwide. If AKI is associated with even small changes in renal function, and the development of chronic disease is dependent, at least in part on time, perinatal status, developmental stage, early nutritional experiences, and absence of diagnostic and therapeutic services, the potential for children with serious illness in the neonatal period or in early life to develop CKD, which is unnoticed until adulthood, perhaps first during a physical examination for the military, an occupational-associated insurance evaluation or a medical encounter for acute illness or traumatic episode, is enormous. If AKI is fundamentally associated with the development of CKD, it is imperative that we understand the course of events in children who survive AKI and come to medical attention in adolescence or young adulthood.

Biomarkers have been sought to predict the susceptibility to AKI, the course of the disease, and progression of CKD.[84–86] It will be important to validate fit-for-purpose biomarkers to predict long-term outcomes of patients with AKI, in the presence or absence of CKD, to determine both prognosis, and therapeutic response to interventions.

Nephrologists caring for patients with AKI, and with AKI superimposed on CKD, urgently need evidence from well-designed, controlled clinical trials to guide the therapy of their patients.[2,82,87] However, initial evaluations suggest therapeutic trials will need to be large and costly, and prevention trials must include very large numbers of participants.[87] The NIDDK has held workshops to facilitate design of clinical trials for AKI patients.[87] Designs considered included prevention trials, trials in specific patient populations, such as those with sepsis, or hospitalized in an intensive care setting, and evaluation of the challenges encountered in developing new therapeutics. The most recent workshop discussed mechanisms that drive susceptibility to future CKD and cardiovascular events and characterized key knowledge gaps to facilitate new strategies to improve clinical outcomes of patients with AKI after hospitalization.[88]

The NIDDK has also sought suggestions regarding research in the field through an electronic medium, the Kidney Research National Dialogue.[71] Responses encompassed developing clinical trial tools, including refining proteomic and metabolomic approaches to diagnosis and prognosis, improving AKI patient phenotyping, including complex clinical, environmental and pharmacologic interactions, determining genetic links with disease susceptibility and outcomes, assessing, characterizing, and validating fit-for-purpose biomarkers in observational and clinical trial settings, focusing on the interplay between repair and regenerative processes in association with mechanisms engendering fibrotic responses, developing better and more clinically relevant animal models, enhancing the evaluation of human renal tissue samples, building public/private partnerships, including academia, regulatory agencies and industry, and performing longitudinal studies.[71] Attention to the AKI stage, setting, and characteristics of the patient population will be critical for research resulting in the improvement of outcomes for patients with AKI in the presence and absence of CKD due to a variety of causes.

CONCLUSIONS

AKI and CKD are interconnected syndromes. To care for patients, nephrologists, pediatricians, internists, critical care specialists, and public health professionals, as well as policy makers, must appreciate the individual components of the syndrome, as well as their combined nature. Identification and implementation of effective interventions and models of care for patients with AKI, CKD, and AKI superimposed on CKD will be necessary to decrease the progression of CKD, and the incidence of ESRD, as well as the incidence and progression of CVD. More knowledge is needed regarding the interplay of AKI and CKD in distinct populations, in particular clinical settings. Like Janus, the two-profiled Roman god, we must evaluate AKI and CKD simultaneously in research, as well as in past and present studies, to advance the care and outcomes of patients with this complex interdigitated syndrome of decrement in renal function.

QUESTIONS AND ANSWERS

Question 1

A 58-year-old man underwent coronary artery bypass surgery. Postoperatively he developed AKI. He was treated with HD over a two week period. S[Cr] on discharge was 1.2 mg/dL.

Which ONE of the following statements in NOT TRUE regarding his future risk?

A. He is at higher risk of developing CVD
B. He is at higher risk of developing ESRD
C. He is at higher risk of developing advanced stage CKD
D. He is at higher risk of developing a malignancy

Answer: D

There is no evidence that he is at higher risk of developing a malignancy making Answer D not true and the correct answer to this question. AKI has been linked with the development of subsequent CVD, CKD, and ESRD making Answers A, B, and C true.[1,10,18–20]

Question 2

A 63-year-old woman with normal kidney function is admitted with sepsis secondary to a urinary tract infection. She developed AKI during the hospitalization but recovered kidney function and did not require treatment with HD.

Which ONE of the following is true regarding her subsequent hospital course?

A. She is NOT at higher risk of developing advanced stage CKD because there was no preexisting CKD before her episode of AKI
B. She is NOT at higher risk of developing advanced stage CKD because her AKI episode did not require dialysis
C. She has a higher mortality risk secondary to developing AKI
D. She is NOT at higher risk of developing CVD

Answer: C

Answer C is true and the correct answer to this question. AKI leads to new CKD, progression of preexisting CKD, increased risk of entry into ESRD programs, and worsened mortality.[1,20,27,28] Observational studies show a large proportion of patients with AKI, even in the absence of concurrent or preexisting CKD, progress to advanced stages of CKD, even if not treated with RRT during the index hospitalization, therefore Answers A and B are not true.[1,10,24,28,32] Several large observational cohorts show patients who survive an AKI episode are at risk for both progression to CKD and increased cardiovascular events making Answer D not true.[14,25,38]

Question 3

Which of the following clinical factors are associated with poor long-term outcomes of AKI?

A. Level of initial kidney function
B. Extent and severity of AKI
C. Older age
D. Lack of follow-up by physicians
E. All of the above

Answer: E

All of these factors are associated with poor renal outcomes following an episode of AKI. See Table 26.3 for a more comprehensive list.

Question 4

Which of the following factors places CKD patients at higher risk for developing AKI?

A. Failure of autoregulation
B. Abnormal vasodilatory responses
C. Lack of renal reserve
D. Failure of renal tubular mechanisms to reabsorb sodium and water
E. All of the above

Answer: E

All of these factors place CKD patients at higher risk for developing AKI. In addition, frequent hospitalizations with the potential for iatrogenic mishaps or exposure to nephrotoxins, treatment to achieve volume depletion, susceptibility to the use of antihypertensives, overvigorous medication, the use of RAAS blockers, the use of nephrotoxins, and age-related physiologic changes also increase the risk of developing AKI.[1,16,26,48]

Question 5

Which of the following factors have been proposed as factors associated with progressive loss of renal function following AKI?

A. Tubulointerstitial fibrosis
B. Progressive glomerular sclerosis
C. Endothelial injury and vascular dropout
D. Tubular hypertrophy and atrophy
E. All of the above

Answer: E

All of these factors have been associated with progressive loss of renal function following AKI. See Table 26.1 for a comprehensive list of factors.

Question 6

A 47-year-old man is discharged after a prolonged hospitalization for sepsis following an episode of severe pancreatitis. Baseline S[Cr] was 1.1 mg/dL. He required three weeks of treatment with HD and eventually recovered kidney function. Discharge S[Cr] was 2.1 mg/dL.

Which ONE of the following should be part of his post discharge management?

A. No renal follow-up is necessary because he is recovering from his episode of AKI and no longer requires dialysis
B. Renal follow-up is needed to monitor his renal recovery
C. The patient should be seen one year following discharge to recheck S[Cr]
D. It is safe to use NSAIDs because he has recovered renal function

Answer: B

Answer B is correct. We suggest patients discharged from the hospital should have periodic assessment of renal function and UACR, to assess prognosis and outcome. Patients with severe decrement in renal function should have follow-up by a nephrologist, therefore Answer A is incorrect. Answer C is incorrect because one year follow-up is too late to assess his course. Answer D is incorrect as he has not fully recovered kidney function and is at higher risk for rehospitalization with recurrent AKI, which could result from NSAID use.

CHAPTER

Psychosocial Issues in Chronic Kidney Disease Patients

Daniel Cukor[a], *Nisha Ver Halen*[b], *Paul L. Kimmel*[c]

[a]Behavioral Health, The Rogosin Institute, New York, NY, United States; [b]Center for Integrative Health and Wellbeing, Weil Cornell Medicine, New York, NY, United States; [c]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States

Abstract

The mental health needs of patients with chronic kidney disease (CKD) are reviewed with particular emphasis on the roles of depression, quality of life, and adherence. We also review the likely precipitating factors and effects of each of these psychological phenomena, including a discussion of some of the health disparities in the psychological presentations of CKD patients. Identification of depression in patients with renal disease is improving, but intervention strategies and research are greatly needed. Biopsychosocial formulation and intervention would provide better overall medical care to patients with CKD.

INTRODUCTION

The psychological response to the diagnosis and continued demands of chronic kidney disease (CKD) are variable but largely understudied. The course, prognosis, and symptom burden of a medical illness alter patients' responses. Beyond medical and illness factors, the psychological landscape of individuals also shapes the patient's perception of his or her ability to cope with the disease. Past psychiatric history, level of social support, understanding of the disease, and characteristics of relationships with physicians all play roles in determining how the CKD patient will adjust. Research on psychological influences on CKD course is still underdeveloped. We review the existing scientific literature regarding psychosocial challenges in CKD patients, concentrating on the roles of comorbid psychopathology, adherence to medical prescription, and perception of quality of life (QOL).

PSYCHOPATHOLOGY

Psychosocial functioning can affect medical outcomes. We propose a general heuristic of the path from CKD to consequent negative health outcomes (Figure 27.1). In the model, the CKD patient can enter a cycle of increased symptom burden, depression, and social strain, which can lead to a second cycle of decreased compliance, increased illness activity, and feeling worse. This second cycle can cause further complications and contribute to continuing decline in kidney function.

Depression

Both depression and poor QOL have been associated with increased morbidity and mortality in patients with end-stage renal disease (ESRD).[1–3] However, the prevalence and long-term effects of psychological comorbidities that develop in earlier stages of CKD have been understudied.

Depression Measurement

The identification of depression in patients with CKD is complicated by the substantial overlap between the symptoms of the affective disorder and those of uremia.[4–6] Careful attention to the etiology, nature, and timing of the presentation is required. There is similarity between the uremic symptoms of encephalopathy, anorexia, sleep apnea, and neuropathic pain and the psychomotor changes, weight and appetite changes, sleep difficulties, and aches and pains associated with depression.

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00027-9

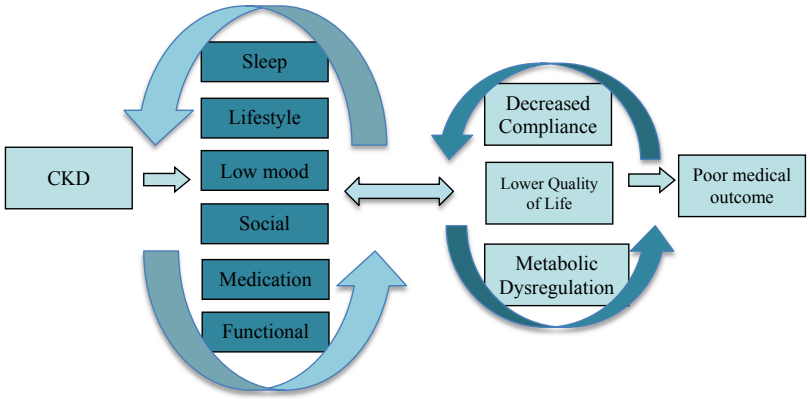

FIGURE 27.1 Suggested pathways of psychosocial variables leading chronic kidney disease (CKD) to increased negative medical outcomes. The vicious cycle between symptoms of illness, depression, and social strain lead to a second cycle of decreased compliance, increased illness activity, and feeling worse. These cycles then lead to worsened health outcomes.

Another challenge to the identification of depression in patients with medical illness is the lack of a standard measurement tool. A variety of psychological measures have been used to measure depression in CKD patients, but the validity and reliability of these measures in this population are not well studied. The field still needs to arrive at a consensus regarding the appropriate screening and diagnostic tools for the broad population of patients with kidney disease. Evaluation of the appropriate cutoff scores for these measures is warranted, as the prognostic value of these measures has yet to be determined in CKD samples. Furthermore, the sensitivity of these measures to track depression over time or illness course is still unclear.[7]

Prevalence of Depression in CKD

Depression has been identified as a prominent psychological issue facing patients with ESRD, with studies reporting prevalence rates of approximately 20%.[5–15] Far less is known about rates of depressive affect and major depressive disorder in patients with CKD prior to starting renal replacement therapy (RRT). Early stages of CKD are often not associated with symptoms. Only after a severe decrease in GFR does the symptom burden of CKD increase, at which point symptoms of depression may be more likely to emerge. In a study of male Veterans, Hedayati et al.[15] reported that 21% of the sample had a lifetime history of a major depressive episode, using the Mini International Neuropsychiatric Interview (MINI). The prevalence of depression did not vary according to stage of CKD. In a large multicenter cohort of African Americans with hypertensive CKD, 26% of participants were found to have elevated depressive affect, measured by the Beck Depression Inventory (BDI)-II using a threshold score of >14.[16] In our study of 70 Black CKD patients, we found the rate of depression to be 30%, using the BDI self-report scale.[17]

Effects of Depression in CKD

CKD patients who are also depressed are at risk for consequences that may affect the course of disease progression. We found that baseline depression scores predicted eGFR at 6 months in a study of CKD patients.[17] These results were confirmed using a regression model, even after controlling for baseline eGFR and presence of hypertension and diabetes. Another longitudinal study examined depression as a predictor of adverse outcomes in patients with CKD.[18] Patients with a major depressive episode were 1.86 times more likely to experience an adverse outcome within 1 year. Although this study highlights the important predictive role of depression, it was limited to psychiatric diagnosis in a select population of Veterans, for a limited duration (1 year). Kellerman et al.[19] found that depressive affect predicted mortality in CKD patients over a 7-year follow-up, as measured in a population of predominantly White males, but like all the studies mentioned, it was limited to a single psychological variable. In a large cohort of Veterans, depression in late-stage CKD was associated with a 6% increase in mortality after transition to ESRD.[20] Depression has also been found to be associated with other physical health outcomes, such as prevalence of pain, sexual dysfunction, and sleep disturbance in patients with CKD.[21]

The impact of the treatment of depression on other outcome variables has not been well studied. In fact, a recent randomized controlled trial did not demonstrate improved depression response to sertraline vs. placebo in patients with CKD.[22]

Investigators have examined the association between depression and health outcomes in ethnic minority groups.[16,23] In a large multicenter cohort of African Americans with hypertensive CKD, Fischer et al. found elevated depressive affect was associated with greater incidence of cardiovascular death or hospitalization.[16]

A second study, a cross-sectional analysis of 3853 Hispanic and non-Hispanic patients with CKD, revealed elevated depressive affect was associated with lower eGFR and higher levels of proteinuria.[23]

The relationship between depression, CKD, and cognitive decline requires further investigation. Kurella et al.[24] assessed cognitive functioning in a sample of 80 CKD patients not requiring dialysis and 80 ESRD patients receiving maintenance hemodialysis. An association between stage of CKD and degree of cognitive impairment was found on measures of mental status, executive functioning, and verbal memory. Similarly, Elias et al.[25] found an association between CKD severity and cognitive impairment. CKD patients with lower renal function as well as those with higher S [Cr] demonstrated decreased performance on visual spatial processing, attention, and planning abilities. In examining 2800 SPRINT-MIND participants, an association was detected between both lower eGFR and higher urine albumin:creatinine ratio and poorer global cognitive functioning. Cerebrovascular disease may be a key link between CKD and extent of cognitive impairment.[26]

Other Psychopathology

A number of other psychiatric disorders can either develop or manifest during the course of CKD. Nephrologists are increasingly called on to serve their patients' mental health needs or coordinate psychiatric consultation. There is little research on the effect an anxiety disorder, personality disorder, or substance abuse disorder might have on CKD course or treatment.

There is a small but developing literature on anxiety disorders and their effect in CKD patients. A review of 55 studies that examined anxiety symptoms in ESRD patients revealed an average prevalence rate of 38% with levels for individual studies ranging from 12% to 52%.[27] Anxiety in CKD and ESRD patients has been associated with decreased QOL, with specific reductions in ratings of emotional wellbeing, burden of kidney disease, quality of social interaction, and even general health.[28–33] There are few treatment studies of anxiety disorders in nondialysis CKD patients.

Treatment options for CKD patients with psychiatric disorders include psychotherapy, particularly cognitive behavioral therapy, and pharmacologic agents similar to those used in the general patient population. However, treatment of psychological disease in the ESRD population presents unique challenges. Careful consideration of medication dose adjustments for level of GFR must be addressed each time pharmacologic therapy is considered in a CKD patient. The challenges of treating anxiety in CKD patients should not limit use of appropriate therapy.

There is increasing evidence in the ESRD literature that psychiatric disorders should be evaluated and followed, as they may have a significant impact on outcome.[34,35] This emerging evidence is leading to an acceptance that a focus on the emotional needs of the patient should be included in the provision of comprehensive medical care to the CKD patient.

QUALITY OF LIFE

Treatment of CKD has evolved to entail more than mere survival and extension of life, and includes maintenance of wellbeing.[36,37] Though prolonging life remains an essential goal of treatment, physicians are additionally examining how CKD impacts patients' daily living and functioning. Preserving the patients' sense of wellbeing, or their QOL, is an essential component of medical treatment for CKD.

Quality of Life Definitions

The World Health Organization defines QOL as an "individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns."[38] Essentially, QOL is an expansive, multidimensional concept that includes one's subjective appraisal of the "goodness" of various aspects of life.[39] Measuring this construct of subjective wellbeing requires an assessment of pleasant and unpleasant affect, general life satisfaction, and satisfaction in various domains including work, family, leisure, health, and finances.[39]

Health-related quality of life (HRQOL) is a somewhat narrower construct, often looked at within the chronic disease literature, that focuses on health concerns and demands.[40] HRQOL refers to quality of life issues that are related to health or illness. The concept of HRQOL has evolved from the World Health Organization's definition of health as more than the lack of disease or sickness, including total physical, mental, and social wellbeing.[41] HRQOL is defined as one's perception of the effect of disease and its treatment across physical, psychological, and social areas of functioning and wellbeing.[40] HRQOL is measured using both general multidimensional assessments, which allow comparison across diseases, and disease-specific multidimensional assessments, which allow specific examination of characteristics common to specific diseases or populations.[40] The SF-36 is a commonly used generic survey that has been deployed in a variety of disease populations.[42,43] This assessment examines health status over the past 4 weeks within eight domains including physical function, role limitations caused by physical problems,

pain, general health, vitality/energy, social function, mental health, and role limitations caused by mental health. The Kidney Disease Quality of Life Instrument (KDQOL) is a commonly used disease-specific self-administered survey designed specifically for patients with kidney disease.[44–47]

Threats to Quality of Life

A substantial amount of research indicates ESRD patients experience impaired QOL.[1,42,48–53] Generally, it appears the HRQOL of ESRD patients treated with dialysis is worse than the general population and patients with kidney transplants.[37,42,45] Although few studies have examined HRQOL in CKD patients in earlier stages not on RRT, age, frailty, symptom burden, and treatment frequency may all be important predictors of diminished QOL. Some findings suggest that even in early stages of CKD, impairments in QOL are exhibited across stages and over time.

There are conflicting results concerning whether QOL impairments occur progressively across CKD stages. Although one study showed progressive impairments in all dimensions of HRQOL across renal function levels and CKD stages, another study did not demonstrate such a progressive decrease in HRQOL throughout CKD stages.[40,50] Other studies show a relationship of HRQOL to mortality, but not disease progression.[53] Nevertheless, studies clearly demonstrate a significant drop in QOL within CKD stages 1–3 in both physical and mental health dimensions. Patients in CKD stages 2 and 3 exhibited significantly lower scores on HRQOL dimensions compared to matched controls.[40] It appears the HRQOL of CKD patients can be affected by a variety of different factors across multiple domains.

Medical Factors

Several medical factors specific to CKD, and CKD-related comorbidities and risk factors, have been implicated as negatively affecting QOL. A recent study found C-reactive protein (CRP) and cardiovascular disease (CVD) were the most important predictors of poor QOL in 535 patients with CKD stages 2–5, followed by reduced GFR and diabetes.[40] One study of 155 predialysis patients (CKD stages 1 through 5) and 36 dialysis patients found the presence of three or more comorbidities had a negative impact on the physical functioning, physical role functioning, and the physical component summary scores of the SF-36.[40] Numerous studies have also found anemia is a central predictor of QOL and that treatment of anemia for CKD patients can lead to positive changes in perception of QOL.[36,42,47] A study of 81 CKD patients not on dialysis found that improvements in hemoglobin were associated with statistically significant and clinically meaningful HRQOL increases in physical activity, vitality, and fatigue.[54] Hypertension, which commonly occurs with CKD, may also reduce HRQOL.[55]

Psychological and Subjective Factors

Renal functional decrements and medical factors are not the sole determinants of perception of impaired QOL in CKD patients. Several studies delineate a relationship between pain, physical activity, sleep, and perception of QOL in the CKD population.[21] Ninety-two predialysis patients with CKD exhibited a significant association between poor sleep and poor QOL and between pain and lower QOL. There were no significant differences in perception of pain or sleep disturbance between these CKD patients and a comparison group of 61 general medical outpatients without renal disease.[21] Regardless of whether the amount of pain and sleep disturbance in patients with CKD is unique or similar to individuals suffering from other chronic illnesses, it is important to assess such factors when evaluating QOL in this patient population.[56] Another study found that in 79 predialysis patients with stages 3 and 4 CKD and 19 dialysis patients, higher emotionally defensive coping was associated with a lower score on the mental component summary of the SF-36 and with the physical component summary, indicating coping strategies can have varying effects on the different dimensions of HRQOL.[57] Though research specifically examining the effect of depression on QOL in early stage CKD patients is lacking, one cross-sectional study of advanced CKD (stages 4 and 5) and ESRD patients revealed depression was strongly correlated with the mental component summary of the SF-36.[58] Coping and illness perception are important ways of measuring people's response to their illness and may well lead to targeted psychological interventions in the future.[59]

Sociodemographic Factors

A cross-sectional study of 155 predialysis patients and 36 dialysis patients noted that more sociodemographic factors, such as age, ethnicity, gender, professional activity, education, and income, were associated with decreased perception of QOL compared to physical factors.[56] One large-scale, longitudinal study revealed early-stage CKD patients who were female and/or over the age of 65 had worse perception of QOL.[36]

ADHERENCE

Treatment for CKD requires adherence to a complex medical prescription including dietary, medication, and behavioral regimens. To slow the progression of

kidney disease, patients must work with their physicians to develop a treatment plan. Diabetes and high blood pressure are the two most common causes of CKD. Hypertension and diabetes are responsible for approximately two-thirds of all cases of ESRD and a substantial proportion of patients with CKD.[60] For patients with diabetes and/or hypertension, treatment involves taking prescribed medication, as well as making significant lifestyle changes, including substantive changes in diet. CKD patients should also attend appointments with nephrologists and in some cases follow recommendations for surgical procedures.

Medical Prescription

Treatment of diabetes mellitus and/or hypertension often involves taking medication, and the medication regimen may be complex, including multiple drugs. There are three ways in which a patient may be nonadherent to medication.[61] The first is through nonfulfillment, whereby the patient may accept a prescription from the physician but then fail to fill it in a timely manner, or at all. In a second form of nonadherence, nonpersistence, patients may initially comply with the prescription but over time cease to take the medication for various reasons. Finally, patients may have difficulty taking medication at the correct dosage or time, known as nonconforming.

Dietary changes are prescribed with the goal of preserving existing kidney function and delaying onset of later stages of CKD. Dietary changes include limiting protein intake to reduce kidney burden, decreasing sodium intake to control high blood pressure, decreasing phosphate intake, and managing blood glucose levels in diabetic patients. Exercise recommendations for the CKD patient typically involve increasing aerobic activity. CKD patients who regularly exercise show improvements in physical fitness, walking capacity, cardiovascular health, and perception of QOL.[62]

CKD patients must attend regular follow-up visits with a nephrologist to monitor progression of the disease. Given that many CKD patients manage multiple comorbid illnesses, these appointments may add to the perceived burden of illness. In the later stages of CKD, the patient and physician must begin to prepare for RRT. Access placement represents a time of increased stress for patients with CKD.[63,64] One study found that this stage of illness was associated with the highest levels of depression, measured by the BDI.[64] Increased stress burden coupled with elevated depressive affect could affect adherence to prescription for access placement.

Evidence of Nonadherence

Research on adherence in CKD has largely been limited to the study of ESRD patients. More recently, studies have begun to examine medication nonadherence in patients with earlier stages of CKD. Data from the REGARDS (Reasons for Geographic and Racial Differences in Stroke) study indicated that in a sample of approximately 4000 patients with CKD using antihypertensive medications, 27.7% of participants indicated that they had forgotten to take their medication, 4.4% reported being careless about taking medication, 5.7% reported not taking medication when they felt better, and 4.2% missed taking medications when feeling sick. In this study CKD and non-CKD patients reported similarly poor adherence to antihypertensive medication.[65] In a longitudinal study of medication adherence, researchers in Brazil used self-reported pill counts and questionnaires to assess adherence in 149 patients with CKD for 1 year. At baseline 17.4% of patients were found to be nonadherent, and this number increased to 26.8% at 1-year follow-up.[66]

Another study examined a large cohort of patients who presented at the Cincinnati Veterans Administration Medical Center for ambulatory care.[67] Researchers examined patterns and effects of antihypertensive medication adherence in 7227 patients with CKD (GFR less than 60 mL/min/1.73 m^2 during the 2-year study period). Unlike studies that used self-report to measure adherence, this study calculated medication adherence using the Medication Possession Ratio (MPR), derived from prescription information included in the Veteran's Administration medical database. MPR was defined as actual treatment days divided by total possible treatment days (truncated for the study period or death). An MPR of less than 0.80 constituted poor medication adherence. Approximately one-third of patients with CKD had poor medication adherence. MPR declined along with renal function and with increase in number of medications.[67] Vupputuri et al.[68] also assessed MPR in patients with CKD taking antihypertensive medication. In a sample of 3077 patients, 22.6% and 8.9%, respectively, had low and very low medication adherence.

Barriers to Adherence

There are numerous factors that make adhering to the medication, dietary, and behavioral treatments for CKD challenging. Polypharmacy and regimen complexity are two significant obstacles to medication adherence in patients managing chronic illnesses including CKD.[66,67] Polypharmacy and regimen

complexity may present particular challenges for elderly patients who may have concurrent cognitive decline.

Barriers to adherence have been separated into three categories: patient factors, physician factors, and system factors. Patient factors are individual-level variables that may affect a patient's thoughts and behaviors associated with treatment adherence. Depression and medical illness can interfere with adherence by reducing motivation and energy to engage in healthy behaviors, obtain social support, take medications, attend appointments, and plan for future treatment.[11,17,34] Difficulties with memory and concentration can present a significant obstacle to compliance with drug therapy. Health beliefs regarding the prioritization of illnesses and effectiveness of treatment can also affect adherence behaviors, particularly for patients taking many medications with side effects. In a qualitative study of older adults with CKD, interviews revealed that patients prioritize medications based on perceptions of the salience of a particular condition and revealed a discordance between patients' beliefs about medication and conventional medical opinion.[69] Cultural associations with particular foods may make it difficult for some CKD patients to abstain from meals high in protein or sodium.

Physicians play an important role in determining patient adherence to treatment. The physician–patient relationship has been identified as an important predictor of treatment adherence across various chronic illnesses.[70] Patients dealing with other illnesses as well as CKD must learn about each of these conditions to successfully manage their health. The nephrology team is responsible for providing education about course of illness, treatment options, and effects of nonadherence. The team should be sensitive to the impact that the information and recommendations may have on patients' lifestyles. Ethnic differences between patient and physician can serve as a barrier to participation and effective communication.[71–73] Open and culturally sensitive communication with the patient will inform the physician about relevant individual-level factors that may interfere with adherence. Physicians should be cognizant of these factors when developing a treatment plan with the patient.

Systemic factors are variables that are typically outside the control of both the patient and the physician, and present potential obstacles to treatment adherence. Of primary importance for many is the issue of cost of medications, hospitalizations, and physician visits. Pharmacotherapy for psychiatric as well as medical illness may be costly and can influence patient prioritization of medications. Access to care can also be a challenge for disabled patients or those living in particular geographic regions.

Effects of Nonadherence

Poor adherence to medication regimens accounts for substantial worsening of disease, death, and increased healthcare costs in the US.[74–77] Although there is limited literature about the specific effects of treatment nonadherence on CKD outcomes, there is overwhelming evidence that uncontrolled diabetes and hypertension are associated with progression of CKD. Schmitt et al.[67] found patients with poor adherence were 23% more likely to remain hypertensive over a 2-year observation period, controlling for age, renal function, and comorbid illness. Vupputuri et al.[68] showed poor medication adherence was consistently associated with uncontrolled hypertension. Tangkiatkumjai[75] showed that nonadherence to antihypertensive medication in patients with CKD was associated with more rapid disease progression.

MENTAL HEALTH DISPARITIES

In the general population the prevalence, persistence, and impact of depression appear to vary by race. Williams et al.[78] conducted a national survey of 6082 African American, Caribbean Black, and non-Hispanic White participants and found that lifetime prevalence of major depressive disorder was highest for Whites. Chronicity and severity of depression, however, were greater for both Black groups. Furthermore, depression was more likely to be untreated in African Americans and Caribbean Blacks.[78,79] In two studies, the impact of elevated depressive affect in hypertensive CKD in the African–American Study of Kidney Disease and Hypertension (AASK) Cohort Study was investigated. In the first study,[16] baseline data were analyzed. Among 628 subjects, 166 had scores over 14 on the BDI, but only 34 were prescribed antidepressant medication. Although there was no direct relationship between depression scores and GFR, a relationship was found with unemployment, lower income, and lower QOL and satisfaction with life scales. In a further analysis that included a 5-year observation period, Cox regression analyses were used to relate cardiovascular and renal outcomes to baseline BDI scores.[56] Forty-two percent of the sample ($n = 628$) had BDI-II scores of 11 or more, and 26% had a score above 14. During a 5-year follow-up, the cumulative incidence of cardiovascular death/hospitalization was significantly greater for participants with baseline BDI-II scores of 11 or more compared with those with scores less than 11.

Fischer et al.[23] examined data from the Chronic Renal Insufficiency Cohort (CRIC) and Hispanic-CRIC (H-CRIC) studies. CRIC enrolled Hispanics and non-Hispanics at seven centers, and H-CRIC enrolled

Hispanics at the University of Illinois. Twenty-seven percent of participants (n = 3853) had evidence of elevated depressive symptoms (greater than 11 on BDI). Only 31% of those with elevated depressive symptoms were taking antidepressants. They found a relationship between the prevalence of elevated depressive symptoms and level of kidney function. Decreased eGFR was associated with a greater risk for elevated depressive affect. In regression analyses, BDI score, Hispanic ethnicity, non-Hispanic Black race, and higher urine albumin levels were each associated with decreased odds of antidepressant use. Women had greater odds of antidepressant use.

Although more research on the mental health disparities within CKD are urgently needed, certain points are clear.[80] Elevated depressive symptoms are common in individuals with CKD. Individuals of racial and ethnic minority background and CKD have a substantial burden of elevated depressive symptoms. In general, depression treatment utilization is low and appears to be lower for men, Hispanics and Blacks.

CONCLUSIONS

CKD by definition is a chronic and often progressive disease. Patients' psychological functioning, ability to cope, perception of social support, and resources may well predict their reaction to the diagnosis and acceptance of the illness. Depression is the most common psychiatric disorder in patients with CKD. Although the identification of depression can be complicated by overlapping CKD symptoms, screening may be warranted. Untreated depression is a risk factor for progressive CKD and possibly mortality. Depression is also associated with decreased QOL. Beyond depression, QOL for CKD patients can be negatively affected by several medical and psychological factors, some of which may be modifiable.

As physicians' treatment goals increasingly embrace a biopsychosocial perspective, more intervention trials aimed at improving mental health and QOL of CKD patients will be needed. As treatment for CKD requires dietary, medication, and behavioral adherence, the factors that predict and explain patient nonadherence warrant further investigation.

There may be meaningful mental health disparities in CKD patients, with rates of psychopathology being higher in some minority groups. As minority populations are overrepresented among CKD patients, they form an important group for assessment and treatment. The formal study of the psychosocial needs of CKD patients is still in its early stage of development, and there are many important questions still unanswered. What is clear, however, is that the psychosocial needs of the CKD patient can be substantial, and quality medical care should attempt to identify and address those needs.
