Urine microscopy: no cells, casts, crystals, or other abnormalities

Which one of the following is correct regarding the assessment and treatment of her albuminuria?

A. Increasing lisinopril dose to 60 mg daily will further reduce albuminuria and blood pressure
B. Addition of spironolactone to reduce albuminuria will likely increase S[K] to >6.0 mEq/L and is therefore contraindicated
C. The increased albuminuria does not predict further progression of her CKD toward ESRD so does not need to be treated
D. Albuminuria can vary especially with swings in glycemic control. ACR should be rechecked before making a therapeutic change
E. An increase in hydrochlorothiazide dose to 50 mg daily will improve blood pressure and albuminuria

Answer: D

Exercise, infection, fever, congestive heart failure, marked hyperglycemia, and marked hypertension may each cause increases in urinary albumin excretion. Thus, if albuminuria increases rapidly since the last check, these potentially confounding factors should be corrected if present and the urine albumin:creatinine (or protein:creatinine) level should be rechecked before committing a nonhypertensive patient to an additional medication.

Increasing lisinopril above 40 mg daily does not result in improved proteinuria or blood pressure control in type 1 diabetic patients[128]; hence Answer **A** is incorrect.

Addition of spironolactone can cause a further increase in S[K] in diabetic patients with CKD treated with either an ACEI or an ARB, but this increase is usually <0.5 mEq/L. In two RCTs in patients with diabetic nephropathy, S[K] increased no more than 0.8 mEq/L after add-on spironolactone therapy for up to 52 weeks.[84] Hence, Answer **B** is incorrect.

If validated and persistent, the increased albuminuria in this patient would be associated with a greater risk of progression to ESRD, so Answer **C** is incorrect.

Hydrochlorothiazide at doses above 25 mg has little increased efficacy on blood pressure control and does not directly improve albuminuria, so Answer **E** is incorrect.

Abstract

The prevalence of chronic kidney disease (CKD) in human immunodeficiency virus (HIV)-infected patients has increased over the past two decades. Renal biopsy series show a variety of lesions associated with CKD in this patient population, including HIV-associated nephropathy (HIVAN), HIV-associated immune complex renal disease (HIVICD), thrombotic microangiopathy (TMA), tubulointerstitial renal diseases including some related to combination antiretroviral therapy (cART), diabetic nephropathy, arterionephrosclerosis, and diseases related to coinfection with hepatitis B and C virus. Screening for renal disease is recommended in all patients with newly diagnosed HIV infection. Approximately 10–15% of all HIV-infected patients have microalbuminuria. Estimating equations for glomerular filtration rate (GFR) have not been widely validated in patients with HIV infection. Serum creatinine concentration-based GFR estimating equations including the Chronic Kidney Disease Epidemiology Collaboration and Modification of Diet in Renal Disease may have limited utility in patients with HIV infection who have decreased muscle mass, but equations are being evaluated in this population. Therapy for CKD in the setting of HIV infection focuses on reducing viral replication, and control of traditional risk factors for CKD progression, including hypertension, hyperglycemia, and hyperlipidemia. Use of cART may slow CKD progression, especially in patients with renal disease manifesting as classic HIVAN. Renin-angiotensin-aldosterone system inhibitors should be employed in all patients with proteinuria and CKD unless a contradiction exits, such as hyperkalemia. *APOL1* genetic variants contribute to HIV nephropathy, but at this time do not influence choice of therapy. Future studies should focus on optimal screening tools to facilitate early detection of CKD in this patient population.

INTRODUCTION

Combination antiretroviral therapy (cART) has revolutionized the outcomes of human immunodeficiency virus (HIV)-infected patients over the past two decades.[1–5] As patients with HIV infection life expectancies continue to rise, the prevalence of comorbid conditions including diabetes, hypertension, and chronic kidney disease (CKD) has also increased.[5–9] HIV-associated renal diseases are the third most common cause of end-stage renal disease (ESRD) among black patients between the ages of 20 and 64 years of age.[3,10,11] 10–15% of HIV-infected patients are estimated to have CKD or proteinuria.[12–14] While HIV-associated nephropathy (HIVAN), a form of collapsing focal segmental glomerulosclerosis (FSGS), remains the most common cause of renal failure among HIV-infected African Americans, other forms of HIV-associated renal disease are increasingly recognized and may be more common in whites and individuals of other ethnicities.[4,15,16] In addition to HIVAN, the effects of HIV infection on the kidney are also manifested by a number of renal syndromes (Table 52.1), including acute kidney injury (AKI), immune complex-mediated forms of glomerulonephritis, tubulointerstitial renal injury (especially related to particular forms of cART), TMA, and fluid, electrolyte, and acid-base abnormalities.[15–19] The relationship between HIV infection and the development of CKD and strategies for the screening, diagnosis, and management of CKD in HIV-infected patients are evolving.

HISTORY

The first cases of HIV infection were reported in 1981 by the Center for Diseases Control. The initial association between HIV infection and kidney injury was made in 1984 based on case reports from Miami, Florida, and New York City.[20,21] These urban medical centers reported HIV-infected patients with proteinuria and rapid progression to ESRD within 2–4 months. Although the report from SUNY Downstate emphasized the presence of a single diagnosis, the study from the University of Miami highlighted a spectrum of renal diseases, including mesangial lesions and glomerulosclerosis, as well as immune complex-associated renal diseases. In both studies, patients were recognized to have a distinct clinical syndrome now termed HIVAN, characterized by collapsing FSGS, or collapsing glomerulopathy, which is one of the most common renal histologic lesions seen in biopsy series of HIV-infected patients, particularly when modern cART is not used. It has subsequently been recognized that other forms of renal disease may exist in association with HIV infection, including HIV-associated immune complex kidney disease (HIVICD).[4,5,15–18] The emergence of cART and its associated metabolic side effects is changing the epidemiology of renal biopsy studies in the setting of HIV infection to include other classic forms of CKD including diabetic nephropathy, arterionephrosclerosis, diseases related to coinfection with hepatitis B and C viruses (HBV and HCV), and other tubulointerstitial renal processes that at times may be related to a unique nephrotoxicity of cART.[22]

RENAL SYNDROMES THAT CAUSE CKD IN HIV-INFECTED PATIENTS

Acute Kidney Injury

HIV-infected patients are at increased risk for the occurrence of AKI,[23] which is a major risk factor for the development of CKD.[19,24,25] HIV-infected patients who are hospitalized with AKI have a significantly higher likelihood of progression to ESRD.[23,25] HIV-infected patients with dialysis-dependent AKI have an approximately 20-fold higher likelihood of developing ESRD.[25] Prompt diagnosis and treatment of AKI in this high-risk patient population is essential.

The causes of AKI in HIV-infected patients are similar to those encountered in the general patient population, with prerenal azotemia and acute tubular necrosis (ATN) being the most frequent etiologies.[19] HIV-infected patients are at risk for volume depletion related to superimposed gastrointestinal illnesses and poor oral intake.[19,23] Obstructive etiologies of AKI related to HIV infection include retroperitoneal lymphadenopathy from lymphomas and crystal nephropathies secondary to use of indinavir, sulfadiazine, and acyclovir causing renal tubular obstruction.[19,26] In addition to ATN, other intrinsic etiologies of AKI in the setting of HIV infection include nephrotoxic acute renal tubular injury and acute interstitial nephritis (AIN), possibly related to cART and the antimicrobials used to treat opportunistic infections. HIV infection, particularly when CD4 counts are very low, has also been associated with TMA requiring plasma exchange.[19,26] HIV is directly myotoxic and has been associated with increased risk for rhabdomyolysis.[19,26] HIVAN, HIVICD, and other forms of tubulointerstitial renal disease, including nephropathies related to cART, may be associated with either AKI or CKD.

HIV-Associated Nephropathy

Clinical Presentation and Therapy

HIVAN remains one of the most prevalent forms of renal disease associated with this viral infection. HIVAN is especially common among individuals of African descent. There is an underlying genetic predisposition leading to this strong association in people of African descent. It has become apparent that this genetic susceptibility is largely explained by genetic variants in the *APOL1* on chromosome 22, encoding apolipoprotein L1. The *APOL1* gene family underwent rapid evolution in primates, probably due to the roles that the encoded proteins play in innate immunity. ApoL1 is present in plasma, where it is a component of HDL, and acts to kill *Trypanosoma brucei brucei* (which causes sleeping sickness in cattle, which lack APOL1). *T. b. rhodesiense* evolved the serum resistance antigen, which binds and inactivates APOL1, preventing trypanosomal killing. Two APOL1 variants, termed G1 and G2, have the ability to kill T. *b. rhodesiense*, and these genetic variants have reached high prevalence, particularly in West Africa. These variants are strongly associated with development of specific forms of CKD, generally acting in a recessive fashion (e.g. genotypes G1/G1, G2/G2, or G1/G2). The odds ratio for those with two *APOL1* risk alleles is 17 for primary FSGS and 29 in US studies

and 89 in a study from South Africa for HIVAN.[5,27–29] Approximately three quarters of both groups carry two *APOL1* risk alleles.[27,28] *APOL1* risk alleles are also associated with hypertension-attributed arterionephrosclerosis.[29]

It appears that with the advent of cART, kidney disease in those with two *APOL1* risk alleles may have shifted from HIVAN to FSGS and hypertensive arterionephrosclerosis. The mechanism by which *APOL1* risk alleles affect glomerular function, and presumably disturb podocyte biology, is the focus of considerable attention. Emerging evidence suggests APOL1 variants may injure podocytes *via* alterations in membrane ion flux, dysregulation of endolysosomal, mitochondrial and autophagic function, and increase in recruitment of cellular inflammatory pathways.[5]

HIVAN is characterized by glomerular collapse and marked hypertrophy of visceral epithelial cells (Figure 52.1). These cells were once considered to be dysregulated podocytes, but it is now apparent that these cells mostly likely derive from parietal epithelial cells.[30] The mechanisms responsible for their excess proliferation and failure to undergo differentiation into podocytes are unknown. Other characteristic features of HIVAN include microcystic tubular changes with proteinaceous casts and occasional tubuloreticular inclusions within the glomerular endothelial cells seen on electron microscopic examination (Figure 52.2).[10,11] Clinical characteristics of patients with this condition include proteinuria, often in the nephrotic range, and reduction in glomerular filtration rate (GFR). Edema may be less common than in other forms of nephrotic syndrome, due to an underlying salt wasting nephropathy, tubular dysfunction, or malnutrition. Enlarged and echogenic kidneys may be detected by renal ultrasound. A renal biopsy is required to make a diagnosis of HIVAN.[31] HIV-infected patients with renal disease who do not undergo a renal biopsy may be inappropriately labeled with this diagnosis. Several renal biopsy series confirm that a variety of renal histologic diagnoses exist in association with HIV infection.[5,16,18]

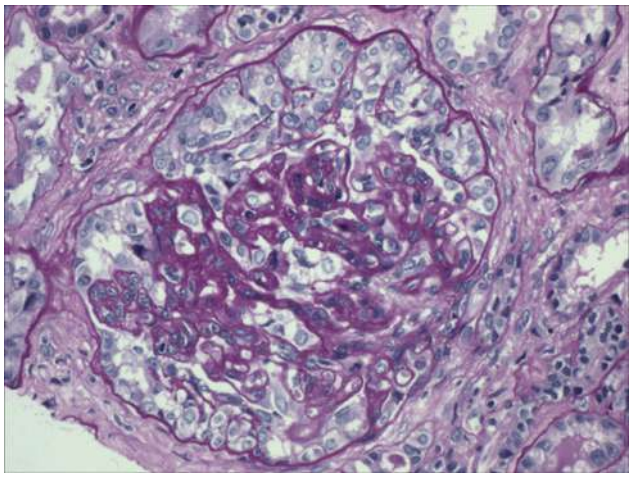

FIGURE 52.1 Light microscopy in HIV-associated nephropathy: a glomerulus from a patient with HIV infection and collapsing focal segmental glomerulosclerosis. The glomerular tufts are collapsed and Bowman's space is filled by proliferating parietal epithelial cells (periodic acid Schiff, magnification ×200).

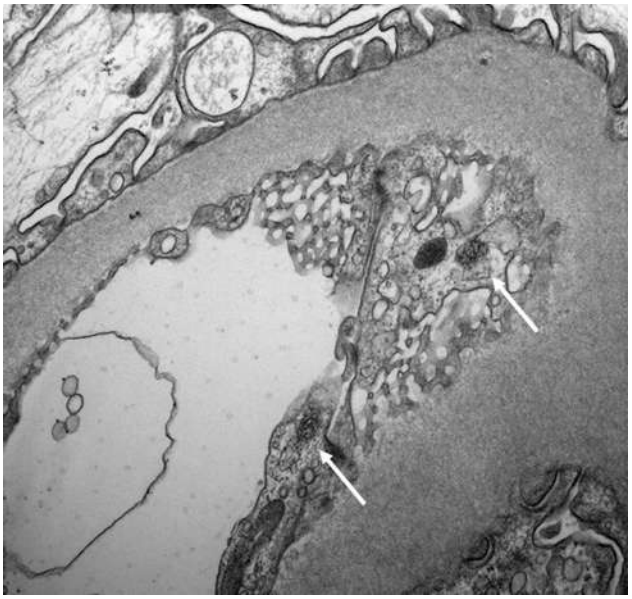

FIGURE 52.2 Electron microscopy in HIV-associated nephropathy: a glomerulus with tubuloreticular inclusion bodies (*arrows*) within the glomerular endothelial cell (magnification ×12,000).

cART remains the cornerstone of treatment for HIVAN, and HIVAN is an indication to start antiretroviral therapy.[2,7,10,11,32] cART may slow the progression of HIVAN to ESRD,[10,11] although this hypothesis has not been tested in randomized controlled trials. There are also data that earlier initiation of cART in HIV-infected patients improves renal outcomes. Case reports have shown improvement in GFR and regression of characteristic HIVAN pathologic features with initiation of cART.[33,34] General therapies to slow progression of CKD also apply in this condition. Blood pressure control with use of renin–angiotensin–aldosterone system (RAAS) inhibitors should be encouraged where clinically appropriate, coupled with dietary sodium restriction and judicious use of diuretics, including thiazides, both of which potentiate antifibrotic effects of RAAS antagonism.[35–37] The target blood pressure in this patient population has not been established, but aiming for BP less than 130/80 mm Hg seems reasonable while awaiting the results of randomized clinical trials. There are also limited data supporting a role for corticosteroids in the treatment of HIVAN.[38] However, caution should be applied particularly in this immunocompromised patient population.

Pathogenesis

HIVAN is characterized by loss of differentiated podocytes and repopulation of that niche by proliferating parietal epithelial cells. It appears that viral factors and host factors are both required for the development of disease. The HIV-1 genes Nef and Vpr[39,40] are each sufficient to induce podocyte injury and glomerulosclerosis when expressed in the podocytes of transgenic mice. The molecular pathways by which these genes act have been only partly unraveled. The *APOL1* genetic variants appear to be required, or at least strongly facilitate HIV infection to damage podocytes and promote aberrant parietal cell repopulation of the glomerular tuft. HIV-1 nucleic acid is present in dysmorphic visceral epithelial cells and tubular epithelial cells, the principal sites of pathologic change in HIVAN. The precise role that *APOL1* plays in the development of HIVAN is an active area of research. The genetic effect is strongly recessive, which is most commonly associated with loss-of-function mutations. On the other hand, several lines of evidence suggest that APOL1 may not play a critical role in podocyte biology, which would argue against a loss-of-function mutation. Therefore, it may be that the mutations confer a gain in function. In support of this hypothesis, in the setting of HIV infection, a single APOL1 risk allele is sufficient to increase risk for HIVAN in some populations.[41]

HIV-Associated Immune Complex Renal Disease

Clinical Presentation and Therapy

Approximately half of HIV-infected patients with CKD who undergo a renal biopsy have a diagnosis other than HIVAN.[18,42] In many of these cases, a form of HIVICD is identified. Patients typically present with active urine sediment, reduced renal function, hypertension, and proteinuria. There may also be serologic evidence of immune complex activity with hypocomplementemia.

There are a variety of renal histologic lesions that may be associated with HIVICD, including IgA nephropathy, lupus-like glomerulonephritis with "full-house immunofluorescence," (Figures 52.3 and 52.4), postinfectious glomerulonephritis with diffuse endocapillary proliferation, mesangioproliferative (Figures 52.5 and 52.6), and membranoproliferative glomerulonephritis, membranous nephropathy, cryoglobulinemic glomerulonephritis, and fibrillary/immunotactoid glomerulopathies.[15–18,43] One study has advocated excluding IgA nephropathy in the setting of HIV from the HIVICD group of diseases based on differing outcomes.[44] A recent KDIGO report suggested dropping the term HIVICD altogether and replacing it with each immune complex-associated disease followed by "in the setting of HIV." The rationale is the heterogeneous nature of these diseases and the uncertainty regarding causal associations with HIV infection in most cases.[18,45]

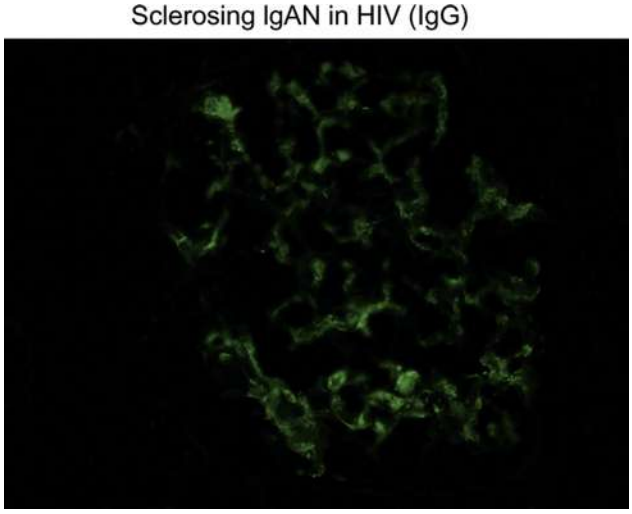

FIGURE 52.3 Immunofluorescence in HIV-associated immune complex renal disease: a glomerulus from a patient with HIV infection and IgA nephropathy showing mesangial deposits of IgG with codominant deposition of IgA (not pictured) (intensity 2+; scale trace through 3+, magnification ×400).

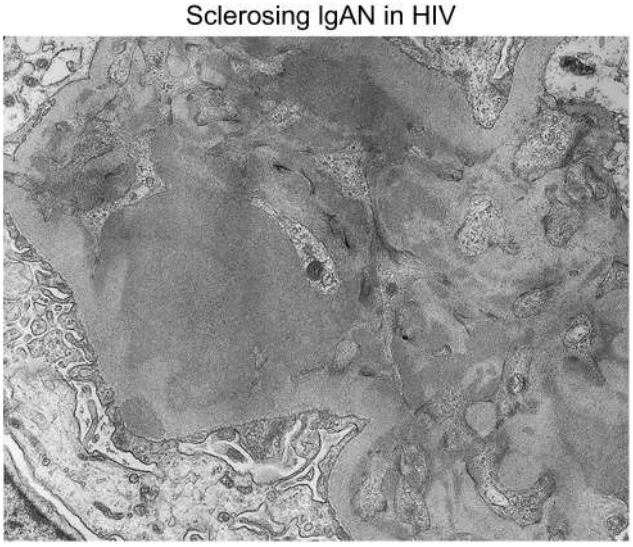

FIGURE 52.4 Electron microscopy in HIV-associated immune complex renal disease: a glomerulus from a patient with HIV infection and IgA nephropathy showing mesangial deposits (magnification ×7000).

Unlike classic HIVAN, it is not clear whether HIVICD progression is slowed with cART. An observational study of patients with HIVAN and other non-HIVAN lesions failed to show an effect of cART to slow the progression of renal disease in HIV-infected patients without HIVAN.[16] A nested case-control study of 751

HIV-positive patients from Baltimore confirmed the results of the previous study. Foy et al.[46] showed that use of cART did not reduce the incidence of ESRD secondary to HIVICD. Although immunosuppressive therapies are frequently considered in the treatment of immune complex renal disease, extreme caution should be used in HIV-infected patients given their immunocompromised state. The risks and benefits of immunomodulatory therapy should be carefully balanced before initiation of immunosuppression.[5,17,18]

Patients with HIVICD may be coinfected with other pathogens including HBV and HCV. The immune complex renal disease may improve following antiviral therapy for hepatitis.[17,18] Immunotherapy including steroids may also promote increased viral replication. Therefore, patients with HIVICD should be screened for coexistent hepatitis infection before proceeding with additional therapeutic options.[17] As with other forms of CKD, optimization of blood pressure control with antagonists of the RAAS should be instituted when clinically feasible.

Pathogenesis

Polyclonal hypergammaglobulinemia frequently occurs in the setting of HIV infection.[17] This predisposes to the development of circulating immune complexes. Kimmel et al. demonstrated that circulating immune deposits, made up of HIV antigens and antibodies directed against them, can lead to glomerulonephritis,[15,17,18,47] directly linking the infection with the renal disease in a causal pathway in some cases. Research techniques are necessary to directly link HIV infection with a particular glomerular disease in individual cases. The relationship between IgA nephropathy and HIV infection appears to be particularly compelling. There may be "passive trapping" of immune complexes containing HIV antigen in renal tissue.[4,15,17,18,47] There may also be "*in situ*" immune complex deposition with preformed antibodies in the circulation binding to HIV antigens on glomerular cells.[4,15,17,47] It is unclear whether the "passive trapping" or "*in situ*" mechanism of immune complex deposition plays the predominate role in HIVICD.[17,18] As with other forms of glomerulonephritis, cellular mediated immune injury may also lead to progressive disease.[15,17,47]

Thrombotic Microangiopathy and HIV Infection

The prevalence of TMA in the setting of HIV infection has decreased since the introduction of cART.[5,48–50] TMA is a histologic pattern seen in a variety of diseases, including thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), disorders of complement regulatory proteins (atypical HUS), disseminated intravascular coagulation, malignant hypertension, and antiphospholipid antibody syndrome. TMA is clinically characterized by the presence of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency. Neurologic deficits and fever may also occur. TMA is more likely to be seen in patients with advanced HIV infection, including those with low CD4 counts and high HIV viral loads.[48]

Risk factors for endothelial injury leading to TMA in HIV-infected patients include the direct cytopathic effects of HIV or associated opportunistic infectious agents, antiretroviral medications, or other comorbid conditions including malignancy.[4] The HIV p24 antigen has been isolated from endothelial cells in patients with TTP and HIV infection.[51] The HIV envelope protein gp120 can increase a procoagulant factor in arterial smooth cells potentially leading to TMA.[52] The von Willebrand factor cleaving protease ADAMTS 13 may be deficient in the TMA associated with HIV infection.[53,54] TMA may present as AKI or a recurrent subacute disease that can ultimately lead to CKD.

On renal biopsy, the microscopic features of TMA are often subtle and sparse. They include fragmented red cells within hilar arterioles, microthrombi within glomerular capillaries, and less often fibrinoid necrosis of arterial walls. The presence of specific microscopic features is not a reliable way to differentiate between the underlying disease processes.[55]

Treatment options for patients with HIV-associated TMA include antiretroviral therapy, plasma exchange, and possibly eculizumab.[4,5] If the disease is refractory, immunosuppression should be considered only after carefully balancing the risks and benefits in this immunocompromised patient population. There have been mixed results regarding the effects of immunomodulatory agents on HIV-associated TMA, which includes corticosteroids, immunoglobulin infusions, rituximab, and splenectomy.[4] Randomized controlled clinical trials have not been performed to determine which therapy leads to the best clinical outcomes in this patient population.

Tubulointerstitial Renal Diseases and HIV Infection

The impact of HIV infection on the kidney is not limited to glomerular diseases. It is increasingly recognized that a distinct subset of patients have AKI and CKD secondary to tubulointerstitial nephritis (TIN).[22] Parkhie et al.[56] showed that 11% of 262 HIV-infected patients who underwent renal biopsy had AKI secondary to AIN. TIN was also found in 26.6% of HIV-infected patients who underwent a renal biopsy from a single center in Paris, France.[22] These results highlight the importance of obtaining a renal histologic diagnosis whenever possible, especially when the clinical history does not match that usually associated with the development of classic HIVAN. As in the general population, TIN in the setting of HIV infection may be secondary to medications, autoimmune diseases, infections, or idiopathic causes.

cART Nephropathy

cART has become a major cause of tubular and interstitial renal injury in HIV-infected patients.[2,5,22] Tenofovir, a nucleotide reverse transcriptase inhibitor (NRTI), a commonly prescribed primary treatment of HIV infection, is associated with nephrotoxicity.[5] Tenofovir has two formulations: the older formulation tenofovir disoproxil fumarate (TDF) and a newer formulation tenofovir alafenamide (TAF). The latter is believed to have less nephrotoxic potential.[5,57] Following metabolism of TDF by gut and serum esterases, tenofovir is taken up by the basolateral membrane of the proximal tubular cell through organic anion transporter proteins-1 and 3 (OAT 1,3) and is secreted into the tubular lumen of the nephron through a multidrug-resistant protein-4 (MRP4).[5,58,59] Tenofovir may accumulate in the proximal tubule, damaging mitochondria or interfering with the function of tubular cell proteins, leading to the development of Fanconi syndrome, followed in some cases by AKI, often due to ATN. Risk factors for tenofovir-associated renal injury include presence of preexisting CKD, polymorphisms in the ABCC2 gene (which encodes for the proximal tubule apical membrane channel MRP2), increased age, and decreased body mass index.[60,61] There may also be an increased risk of nephrotoxicity in patients taking protease inhibitors concomitantly with tenofovir.[62,63] TAF is absorbed intact through the gut and is taken up by peripheral blood mononuclear cells. Plasma tenofovir levels are significantly lower following TAF administration compared with the older formulation TDF.[5] In contrast to tenofovir, TAF is not a substrate for OAT1 and OAT3, which likely contributes to the decreased nephrotoxicity seen with this newer formulation of the drug.[5]

Clinical characteristics of tenofovir nephrotoxicity are initially those of a classic proximal tubulopathy, with hypophosphatemia, normoglycemic glycosuria, hypouricemia, a nongap metabolic acidosis, and proteinuria.[64] Dysfunction may progress to a form of nephrogenic diabetic insipidus and ATN from diffuse renal tubular injury. The characteristic finding on renal biopsy is the presence of enlarged, distorted mitochondria seen ultrastructurally in proximal tubular cells. Over the long-term, there are mixed results regarding the risk of CKD in HIV-infected patients treated with tenofovir.[2] If Fanconi syndrome or ATN is recognized early, the medication can often be discontinued before significant irreversible renal injury occurs. However, AKI is an important risk factor for CKD. Therefore, it is postulated that therapy with tenofovir can lead to the development of CKD.

Two studies evaluated the long-term impact of chronic tenofovir use on the average decline in estimated GFR (eGFR). In two separate cohorts, there was no significant difference in the median eGFR decline in HIV-infected patients who received tenofovir-based cART compared with those on a cART regimen lacking tenofovir.[65,66] However, several more recent studies have contradicted these initial results.[67,68] HIV-infected patients taking tenofovir enrolled in the Johns Hopkins clinical cohort had a significantly greater decrease in renal function over three years of follow-up compared with patients not on tenofovir-based therapy.[67] A study from the San Francisco Veterans Administration Medical Center[68] of 10,841 HIV-infected patients also showed an increased risk for CKD in patients with prolonged exposure to tenofovir. The disparate results are likely related to differences in study designs and characteristics of the patient populations among the various cohorts.[69]

There are other antiretroviral therapies with nephrotoxic potential. Indinavir is associated with intratubular crystalline precipitation leading to acute renal tubular injury, but this drug is no longer commonly used.[2] Atazanavir has also been associated with the development of nephrolithiasis, crystalluria, and granulomatous interstitial nephritis.[2,5] Several forms of cART have also been associated with interstitial nephritis and the presence of CKD.[22,64]

A number of antiretroviral therapies including the protease inhibitors have metabolic effects which increase the likelihood of diabetes, hyperlipidemia, and hypertension in HIV-infected patients.[2] Increasingly, diabetic nephropathy and hypertensive arterionephrosclerosis are recognized as causes of CKD in HIV-infected patients. The causal implications of the concordance of the two diseases are unknown.

Other Causes of Tubulointerstitial Nephritis

While medications are a common cause of TIN in HIV-infected patients and in the general population, other etiologies unique to HIV infection should be considered. Patients with HIV infection may develop immune reconstitution inflammatory syndrome and diffuse infiltrative lymphocytosis syndrome which are both associated with a form of TIN.[5,19] These may require treatment with corticosteroids. Opportunistic infections related to the immunocompromised state, such as CMV infection and other bacterial infections, may lead to a form of TIN.[19]

EPIDEMIOLOGY OF CKD IN PATIENTS WITH HIV INFECTION

In seven studies carried out between 1994 and 2011, a consistent rate of microalbuminuria of 10–15% was found.[5,70] One study, involving three urine samples collected over 6–9 months, found a rate of 14%, using the geometric mean of the samples to diagnose period microalbuminuria.[70] The negative predictive value of a single sample for microalbuminuria was 98%, whereas the positive predictive value was only 74%. Thus, for periodic screening, a single negative test suffices, but positive tests should be repeated. The implications of microalbuminuria in this population are uncertain, but likely causes include glomerulopathy, tubulopathy, and metabolic syndrome, although febrile proteinuria is also a possibility.[71]

Between 2 and 10% of HIV-infected patients also have a reduction in eGFR.[13,14,72,73] The presence of proteinuria and reduced eGFR is associated with increased mortality in HIV-infected patients.[74,75] Therefore, close attention should be paid to HIV-infected patients with manifestations of CKD. Potential risk factors for CKD in this patient population include older age, black race, diabetes mellitus, hypertension, low CD4 cell count, increased HIV viral load, coinfection with HBV and HCV, and previous episodes of AKI.[73]

SCREENING FOR CKD IN HIV-INFECTED PATIENTS

Screening for CKD remains essential in this patient population. Detection of CKD involves assessment for proteinuria and albuminuria, review of the urine microscopy, and estimation of the GFR. Guidelines from the Infectious Diseases Society of America recommend checking renal function and screening for proteinuria in all patients with newly diagnosed HIV infection.[7] There was initial concern that GFR estimating equations were not adequately validated in HIV-positive patients.[76] However, more recent studies have validated the use of the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation in HIV-infected patients with utilization of cystatin C in those individuals with severely reduced muscle mass.[5,77,78]

Proteinuria is one of the main indicators of renal injury and is frequently present in screening tests of HIV-infected patients. Proteinuria may be screened using urine dipsticks, or spot urine protein or albumin: creatinine ratios (UPCRs or UACRs). A study of 166 HIV-infected patients compared the utility of urine dipstick testing vs. spot UPCRs to assess for proteinuria.[79] Approximately 20% of patients with proteinuria ranging from 300 to 999 mg/g creatinine were not detected by urine dipstick testing.[79] Therefore, UACRs or UPCRs may be preferred as screening tools to detect clinically significant proteinuria. KDIGO guidelines advocate use of UACRs in the staging of patients with CKD.[45,80]

Cystatin C is increasingly being used to estimate GFR in patients with CKD, especially in those individuals with borderline low eGFR using the creatinine-based CKD-EPI and Modification of Diet in Renal Disease equations. This cystin-protease inhibitor has the advantage of being constantly produced by all nucleated cells, is not affected by muscle mass, is freely filtered at the glomerulus, and is fully reabsorbed and catabolized in the renal tubules.[73] However, inflammation is known to affect circulating cystatin C levels.[73] This is particularly relevant in patients with chronic infections such as HIV where inflammation may have a significant effect on cystatin C levels. Additional studies are needed to validate the use of cystatin C estimating equations in the setting of HIV infection. In the interim, use of S [Cr]-based estimating equations, such as CKD-EPI, remains the first approach to screening of patients with CKD and HIV infection.[5,73,77,78]

Other potential biomarkers of renal injury in HIV-infected patients are being studied, including neutrophil gelatin-associated lipocalin, kidney injury marker-1, interleukin-18 (IL-18), asymmetric dimethylarginine, and liver-type fatty acid-binding protein.[73,81] Urinary markers of tubular injury may also be useful in the early detection of cART nephrotoxicity, including *N*-acetyl-β-D-glucosaminidase, β2 microglobulin, and α1 microglobulin.[69,73] In light of the lack of clarity regarding the clinical utility of these evaluations, additional studies of these biomarkers are necessary before their potential use in clinical settings can be assessed.

TREATMENT OF CHRONIC KIDNEY DISEASE IN HIV-INFECTED PATIENTS

Early identification of CKD remains essential in all patients including those infected with HIV. Therapy for CKD in this patient population presents unique considerations, especially with respect to the multitude of antiretroviral medications and their potential for nephrotoxicity.[82] Close consultation with infectious disease and nephrology specialists as part of a multidisciplinary team is essential in the treatment of HIV-infected patients. Renal and hepatic function should always be considered in prescribing and dose calculation of cART.

Biopsy-proven HIVAN is an indication for initiation of cART regardless of the absolute CD4 cell count and HIV PCR viral load.[83] Other potential treatment options for HIVAN include use of RAAS inhibitors and corticosteroids.[38,82] As with other forms of CKD, treatment of coexisting comorbid conditions including hypertension and diabetes may be important in slowing progression.

Hypertension is present in approximately 12–20% of HIV-infected patients.[84] Extrapolating from the literature in the general population, target blood pressure in HIV-positive patients with CKD should typically be <130/80 mm Hg, especially in those with significant proteinuria.[7,82] How more recent study results might affect these recommendations in patients with CKD and HIV infection is unclear. Glycemic control should include a target HbA1c less than 7%. Another treatment consideration is controlling hyperlipidemia. Caution is necessary in HIV-infected patients treated concomitantly with statins and protease inhibitors, due to a common metabolism through the cytochrome P450 hepatic enzyme system. Patients coinfected with HBV and HCV should be considered for antiviral therapy.[82,85–87]

KIDNEY TRANSPLANTATION FOR HIV PATIENTS

Kidney transplantation has become an option for HIV-infected patients with CKD. Acute rejection rates are somewhat higher than in other recipients,[88,89] but medium-term patient survival falls between that of the general kidney transplant population and that of recipients greater than 64 years of age.[88] It is important to select appropriate candidates for kidney transplantation. Those with detectable plasma HIV RNA, CD4 count <100 cells/μL, malignancy, and opportunistic infection are excluded. Immunosuppressive strategies have generally involved an IL-2-inhibitor (basiliximab) for induction (avoiding T-cell depleting agents), followed by triple therapy with prednisone, a calcineurin inhibitor (or sirolimus), and mycophenolate mofetil.[90] Multiple drug interactions between these immunosuppressive agents and cART, as well as antihypertensive agents and antibiotics that may be required, pose a challenge and require pharmacologic expertise and therapeutic drug monitoring. The rate of malignancy may be higher in patients with HIV infection and a kidney transplant. Therefore, cancer surveillance is recommended. When HIV-infected patients receive HIV-negative kidneys, the transplanted kidney can be infected with HIV even when plasma HIV RNA remains undetectable.[91] In some cases, HIV RNA was present in podocytes and tubular epithelial cells and those with podocyte infection had faster functional decline after transplant.[91] Organs from deceased HIV-positive individuals can be transplanted into HIV-positive individuals in the US under a research program sponsored by the HIV Organ Policy Equity Act.[5,92] This approach was pioneered in South Africa, where a report of 14 subjects suggested that plasma HIV viral levels remain suppressed following successful kidney transplantation.[93–96]

CONCLUSION

The widespread use of cART has dramatically decreased the mortality and improved the clinical outcomes of HIV-infected patients. The success of cART has led to an increase in the prevalence of chronic medical conditions including CKD in HIV-infected patients. The range of diseases known to cause CKD in the setting of HIV infection includes but is not limited to HIVAN, HIVICD, TMA, TIN (including cART-related nephropathy), as well as renal diseases associated with diabetes, hypertension, and coinfection with HCV and HBV. The metabolic consequences of chronic cART are increasing the rates of diabetes, hypertension, and hyperlipidemia in HIV-positive patients, which will likely further add to the CKD burden in this patient population. Additional clinical studies are needed to determine the optimal approach to diagnose and treat CKD in HIV-infected patients. Early screening for CKD in HIV patients is important to ensure prompt diagnosis and therapy.

QUESTIONS AND ANSWERS

Question 1

A 44-year-old African-American man with a history of HIV infection, CD4 count 200 cells/μL, and viral load 4,000,000 copies/mL presents for initial evaluation of proteinuria. His primary care physician did a 24-hour urine collection which showed 5 g of proteinuria. His S[Cr] is 1.6 mg/dL and blood urea nitrogen is 20 mg/dL. His S[Cr] was 1.5 mg/dL four months ago. A complete blood count was within normal limits. You ordered a renal ultrasound which showed 14 cm echogenic kidneys bilaterally. Urine sediment was bland with no cellular casts visualized. A renal biopsy was performed. Which of the following lesions is most likely to be found on the biopsy?

A. TMA
B. HIV-associated immune complex kidney disease
C. Collapsing FSGS with microcystic tubular dilatation
D. TIN
E. ATN

Answer: C

This patient's clinical presentation is most consistent with HIVAN with nephrotic-range proteinuria, reduced eGFR, and enlarged echogenic kidneys. HIVAN is also more common in individuals of African descent. The bland urine sediment is not consistent with HIVICD. The normal complete blood count does not support a diagnosis of TMA. The nephrotic-range proteinuria suggests a glomerulopathy rather than a tubular or interstitial renal disease process.[2–5]

Question 2

A 44-year-old Caucasian man with a history of HIV infection, a CD4 count 450 cells/μL, and viral load undetectable on chronic cART, as well as HCV infection (viral load 1,000,000 copies/mL), presents to your office for initial evaluation of subnephrotic proteinuria and microscopic hematuria. His S[Cr] is 1.2 mg/dL and was previously 0.9 mg/dL six months ago. A complete blood count was normal. Urinalysis showed 3+ protein/3+ blood/trace leukocyte esterase, 10–20 RBC/hpf, and 10-20 WBC/hpf, with rare red blood cell casts. Complement C3 and C4 are reduced. You order a renal biopsy. Which of the following is the most likely diagnosis?

A. HIVAN
B. HIVICD
C. TIN
D. ATN
E. TMA

Answer: B

This patient has an active urine sediment and hypocomplementemia, which is consistent with immune complex renal disease. In the classic clinical presentation of HIVAN, patients often have nephrotic-range proteinuria. In addition, HIVAN tends to be more common in individuals of African descent. The patient is also coinfected with HCV which may make immune complex renal disease more likely. The incidence of HIVICD compared with HIVAN in renal biopsy series is increasing perhaps due to the more common treatment of HIV-infected patients earlier in the course of disease, with cART.[5,15–17]

Question 3

A 45-year-old African-American man with a history of HIV infection not on cART, CD4 count 50 cells/μL, and viral load 2,000,000 copies/mL presents to the emergency room with headache and altered mental status. He is found to have a S[Cr] of 4.5 mg/dL and BUN 54 mg/dL. His hemoglobin was 8.4 g/dL and platelet count 75,000. Haptoglobin is undetectable and LDH is 1200. His urinalysis showed 2+ protein, 3+ blood/negative leukocyte esterase. Microscopy revealed 10–20 RBC/hpf, 0–3 WBC/hpf, and no cellular casts visualized. There is no baseline S[Cr]. A renal ultrasound showed 12 cm kidneys bilaterally with normal cortical echogenicity. Which of the following is the most likely etiology of the patient's renal disease?

A. ATN
B. TIN
C. IgA nephropathy secondary to HIV infection
D. Lupus-like glomerulonephritis
E. TMA

Answer: E

This patient exhibits a classic presentation for TMA with thrombocytopenia, microangiopathic hemolytic anemia, renal failure, and altered mental status. The other answer choices do not fit this patient's clinical history.[4,5,48]

Question 4

A 47-year-old man with HIV CD4 count 350/μL and viral load 3000 copies/mL on cART presents to your office for initial evaluation of proteinuria. You perform chemistries which are notable for a S[Cr] of 1.4 mg/dL (previously 0.8 mg/dL nine months ago), BUN 24 mg/dL, glucose 100 mg/dL, HCO_3 18 mEq/L, uric acid 2.1 mg/dL, and phosphate 2.0 mg/dL. His urinalysis shows 2+ protein, 2+ blood, positive glucose, negative leukocytes, and urine pH 6.5. Which of the following would most likely explain the above disorder?

A. cART nephropathy
B. HIVAN
C. HIVICD
D. TMA
E. AKI

Answer: A

This patient has the classic presentation of a proximal tubulopathy from presumed tenofovir nephrotoxicity with normoglycemic glycosuria, hypouricemia, hypophosphatemia, bicarbonaturia (alkaline urine pH), and renal insufficiency. The other answer choices are not consistent with this clinical presentation.[5,59–63]

Question 5

A 49-year-old woman with CKD secondary to biopsy-proven HIVAN diagnosed four years ago, last CD4 count 300 μL, and HIV viral load undetectable presents to your office for management of hypertension. Her blood pressure at today's office visit is 145/95 mm Hg. Urinalysis is notable for 2+ protein and is otherwise negative. Most recent chemistries show S[Cr] 1.5 mg/dL, BUN 24 mg/dL, and potassium 4.3 mEq/L. Which of the following medications is the most appropriate first-line agent to control her hypertension?

A. Clonidine
B. Hydrochlorothiazide
C. Propranolol
D. Hydralazine
E. Ramipril

Answer: E

RAAS antagonists slow the progression of CKD. If there are no contraindications to RAAS inhibitors, these agents are the first-line antihypertensive agents in all patients with CKD and proteinuria. The other answer choices are all second-line agents that should be tried only after the dose of the ramipril has been maximized.[35–37]

Question 6

A 35-year-old African-American man with a history of HIV infection, CD4 count 500 μL, and viral load 5000 copies/mL presents to your office for initial evaluation of nephrotic-range proteinuria with a spot UPCR of 6000 mg/g creatinine. His S[Cr] is 1.6 mg/dL (S[Cr] was 1.5 mg/dL three months prior). Urinalysis revealed 4+ protein, trace blood, negative leukocytes, and negative glucose. A renal ultrasound revealed 13 cm echogenic kidneys symmetric bilaterally. A renal biopsy was performed which revealed collapsing FSGS. Which of the following would be most effective in slowing the progression of his CKD?

A. cART
B. Corticosteroids
C. Cyclosporine
D. Adrenocorticotropic hormone
E. Cyclophosphamide

Answer: A

cART would be most effective in slowing the progression of CKD secondary to HIVAN. Immunosuppression (choices B–E) should be used with extreme caution in immunocompromised patients. There are case reports of improved eGFR and regression of HIVAN lesions following initiation of cART.[5,33,34]

Abstract

Recent investigations have established the existence of robust cross talk between the liver and kidney. These bidirectional interactions mediate deleterious effects of liver disease on the development and progression of kidney disease as well as effects of kidney disease on liver injury and hepatic drug metabolism. Although the full spectrum and consequences of liver/kidney cross talk remains to be elucidated, the clinical relevance of these interactions is clear.

INTRODUCTION

The association of liver disease with immunologically mediated glomerular disease and tubulointerstitial renal injury has long been recognized (Table 53.1). However, more recently, attention has focused on the existence of bidirectional cross talk between the liver and the kidneys. It has been suggested that chronic liver disease may accelerate the progression of CKD and that CKD may accelerate the progression of chronic liver disease, as well as alter hepatic drug metabolism. The existence of cross talk between the liver and the kidney may affect therapeutic interventions directed toward slowing the progression of both liver and kidney disease and may significantly influence drug dosing in patients with combined liver and renal disease.

HEPATORENAL SYNDROME

The most dramatic manifestation of liver/kidney cross talk is the development of hepatorenal syndrome (HRS).[1–5] Our understanding of the pathogenesis of the HRS has undergone a dramatic evolution in the past decade. From its initial conception as a functional disorder mediated by systemic circulatory dysfunction accompanying decompensated liver failure, HRS has been transformed into a more complex systemic disorder characterized by systemic inflammation and multiorgan dysfunction.[1–5] In 2015, the International Club of Ascites redefined HRS to incorporate a modified version of the Kidney Disease: Improving Global Outcomes criteria for the diagnosis of acute kidney injury (AKI).[6,7] HRS-AKI was defined as AKI that developed in a patient with cirrhosis and ascites that did not respond to diuretic withdrawal and plasma expansion in the absence of shock, nephrotoxic drugs, or evidence of structural renal injury.

The classification of HRS into types 1 and 2 was not incorporated into the new definition. In earlier nomenclature, type 1 HRS was characterized by rapidly progressive renal failure, whereas type 2 HRS referred to a more indolent decline in renal function that was more moderate in severity. Type 2 HRS was characterized by refractory ascites and diuretic resistance, with an average survival of 6 months.[1,3] Type 2 HRS is now referred to as HRS-CKD.

Role of Systemic Circulatory Dysfunction in HRS

HRS-AKI has primarily been defined as a renal event; however, new insights into the pathophysiology of decompensated liver disease suggest that HRS is also an indicator of severe systemic inflammation, indolent multiorgan dysfunction, and failure of hemodynamic compensatory mechanisms. Cirrhosis is characterized by deranged liver architecture, leading to increased intrahepatic vascular resistance that in turn leads to increased portal vein pressure.[1–5] Release of systemic vasodilators, classically thought to arise as a response to portal hypertension, leads to peripheral vasodilation and decreased vascular resistance. Numerous vasodilatory agents have been proposed as pathogenetic mediators.[1–5] Decompensated cirrhosis is associated with increased endothelial cell production of nitric

TABLE 53.1 Kidney Lesions Associated with Liver Disease*

Hepatitis C	Membranoproliferative glomerulonephritis with or without cryoglobulinemia
	Membranous nephropathy
	Focal and segmental glomerulosclerosis
	Immunoglobulin A nephropathy
	Fibrillary glomerulopathy
	Immunotactoid glomerulopathy
	Thrombotic microangiopathy
	Amyloidosis
	Interstitial nephritis
	Diabetic nephropathy
Hepatitis B	Membranous nephropathy
	Immunoglobulin A nephropathy
	Membranoproliferative glomerulonephritis
	Minimal change disease
	Focal and segmental glomerulosclerosis
	Crescentic glomerulonephritis
	Polyarteritis nodosa
	Cryoglobulinemia
	Amyloidosis
Alcoholic cirrhosis	Immunoglobulin A nephropathy
	Membranoproliferative glomerulonephritis with immunoglobulin A deposition
Primary sclerosing cholangitis	Membranous nephropathy
	Membranoproliferative glomerulonephritis
	Tubulointerstitial nephritis
	Antineutrophil cytoplasmic antibody-associated vasculitis/glomerulonephritis
Primary biliary cirrhosis	Interstitial nephritis
	Membranous nephropathy
	Antineutrophil cytoplasmic antibody-associated vasculitis/glomerulonephritis
	Antiglomerular basement membrane disease
Alpha-1 antitrypsin deficiency	Membranous nephropathy
	Antiglomerular basement membrane disease

* *Cause and effect relationships have not been established in all cases.*

oxide, carbon monoxide, prostacyclin, calcitonin gene-related peptide, adrenomedullin, endocannabinoids, and plasma substance P which may contribute to arterial vasodilatation.[1–5] An increase in regional blood flow in response to portal hypertension, splanchnic vasodilation, and portosystemic shunting leads to pooling of blood in the splanchnic circulation.[1–5] The recruitment of compensatory mechanisms to maintain renal perfusion in the face of reduced effective arterial volume constitute the hallmark of HRS. These compensatory mechanisms include release of systemic vasoconstrictors, upregulation of the renin–angiotensin system, and activation of the sympathetic nervous system.

Animal models of portal vein hypertension support a direct neural connection between hepatic osmo- and baroreceptors and the kidney.[8,9] Acute induction of experimental portal hypertension activates hepatic baroreceptors, which in turn increase renal sympathetic efferent nerve activity. Activation of the renal sympathetic nervous system is associated with renal vasoconstriction and reduced renal blood flow, increased renin release, and enhanced renal tubular salt and water reabsorption.[1–5] Reduced effective circulating volume also leads to increased nonosmotic release of vasopressin and increased generation of potent vasoconstrictors, including leukotrienes and endothelin-1.[1–5] In contrast, local compensatory renal vasodilators, such as prostaglandins, are reduced.[1–5] Consistent with this scenario, an increased renal resistive index on renal Doppler ultrasonography, an index of reduced diastolic renal blood flow, predicts the subsequent development of HRS.[10–12]

Lack of cardiac compensation in response to severe systemic vasodilation worsens this cycle. In early stages of cirrhosis, increased cardiac output maintains renal perfusion.[1–5] However, in advanced cirrhosis, the ability of the heart to compensate is limited by cirrhotic cardiomyopathy and cardiac output declines. In this setting, beta blockers are deleterious to cardiac function and worsen hemodynamic dysfunction by sensitizing the sympathetic nervous system. In addition, renin–angiotensin blockade may increase renal vasoconstriction and promote AKI. Because cardiac preload may play a crucial role in cardiac function in this setting, nitrates are also contraindicated.

Hepatorenal Syndrome as a Systemic Inflammatory State

It has recently been suggested that the primary factor responsible for the release of vasodilatory mediators in HRS is increased circulating levels of cytokines and chemokines resulting from chronic inflammation associated with decompensated liver disease.[2,13] Cirrhosis is associated with increased gastrointestinal permeability, altered gastrointestinal microbiome, and translocation

of bacteria and bacterial products (pathogen-associated molecular patterns) from the gastrointestinal tract into the circulation.[2] These bacterial products, along with danger-associated molecular patterns released by apoptotic and necrotic hepatocytes, stimulate the production of proinflammatory cytokines and chemokines, reactive oxygen and nitrogen species, and activate immune cells, which in turn magnifies the proinflammatory response.[2]

Decompensated cirrhosis is associated with increased circulating levels of proinflammatory cytokines and chemokines including interleukin-6 (IL-6), IL-8, and tumor necrosis factor-alpha (TNF-α), which may contribute to renal injury.[2,5,13,14] Circulating levels of IL-6, TNF-α, and vascular cell adhesion molecules are higher in patients with cirrhosis and HRS-AKI compared with those without HRS-AKI.[5] Patients with spontaneous bacterial peritonitis and renal dysfunction have higher IL-6 and TNF-α levels than patients with spontaneous bacterial peritonitis without renal dysfunction.[14] Similarly, other investigators have correlated renal dysfunction associated with decompensated liver failure with circulating levels of IL-6, IL-8, and irreversibly oxidized nonmercaptalbumin 2.[13]

The functional nature of HRS has recently been challenged. Renal histologic injury has never been systematically excluded because careful renal biopsy studies in patients who satisfy the clinical criteria used to diagnose HRS have not been performed. Urinary biomarkers suggest tubular injury in HRS-AKI diagnosed by traditional criteria.[5,15] Pathogen-associated molecular patterns and danger-associated molecular patterns may be injurious to proximal tubule epithelial cells and downregulate mitochondrial metabolism. Lastly, it has been suggested that cholestasis, with resultant hyperbilirubinemia, may promote deposition of bilirubin in the renal tubular lumen to induce tubular obstruction and direct toxic tubular injury.[16,17] This disorder has been referred to as bile cast nephropathy.[16,17] Bile acid casts were demonstrated in 11 of 13 renal specimens obtained from patients meeting the clinical criteria for HRS.[17]

HRS-CKD

HRS-CKD is uncommon, accounting for only 5−11% of patients with cirrhosis and renal dysfunction. Treatment with intravenous albumin and terlipressin or noradrenaline can reverse HRS-CKD in more than half the cases.[18,19] However, responders experience a high relapse rate early after withdrawal of therapy. Relapse occurs in two-thirds of initial responders.[18,19] Multiple relapses in the same patient are also frequent.[18,19] It has been postulated that a persistent proinflammatory state or rebound activation of vasoconstrictor pathways are responsible for this high relapse rate.[18]

Treatment of HRS-CKD with albumin volume expansion and vasoconstrictors is controversial and is not recommended by international practice guidelines due to inconsistent outcomes data.[2,18] In a retrospective study of 56 patients with "type 2" HRS awaiting liver transplant and treated with terlipressin and albumin, no difference in pretransplantation or posttransplantation outcomes was observed between responders and nonresponders.[19] There was no difference in the mortality of wait-listed responders and nonresponders. After liver transplantation, there was no difference in estimated glomerular filtration rate (eGFR) or in the development of CKD on follow-up, ranging up to 1 year, based on response to therapy. Length of hospitalization, development of AKI, need for renal replacement therapy (RRT), and survival did not differ between responders and nonresponders. The authors suggest that the failure of therapy to improve outcomes in these patients may reflect unrecognized underlying renal parenchymal injury.

Transjugular intrahepatic portosystemic shunting as a bridge to orthotopic liver transplantation has been associated with improved renal function in patients classified as type 2 HRS.[20] European Association for the Study of the Liver Clinical Practice Guidelines state that transjugular intrahepatic portosystemic shunting "could be suggested in selected patients with HRS-NAKI."[2]

Intra-abdominal hypertension may also contribute to hemodynamic-mediated renal dysfunction in patients with decompensated cirrhosis with ascites. Clinical studies of decompensated liver disease have demonstrated correlations between intra-abdominal pressure and sodium avidity and azotemia. A reduction of intra-abdominal pressure by paracentesis is associated with an improvement in renal blood flow and urine output in patients with decompensated cirrhosis and intra-abdominal hypertension.[4,21] In a murine model of cirrhosis, increased intra-abdominal pressure was associated with renal dysfunction.[22] It is postulated that nephro-congestion leads to an increase in intratubular pressure, a reduced pressure gradient for filtration, and reduced glomerular filtration rate.

Serum creatinine concentration (S[Cr]) is a poor marker of renal disease in liver failure, frequently overestimating renal function and underestimating renal injury. Because the Model for End-Stage Liver Disease score uses S[Cr] as a marker of renal disease, the lack of sensitivity of S[Cr] for the diagnosis of CKD or AKI is highly problematic vis-a-vis allocation of donor liver organs. In patients with cirrhosis, where significant muscle atrophy, reduced hepatic conversion of creatine

into creatinine, and reduced tubular secretion of creatinine are commonplace, significant renal dysfunction may be masked by an ostensibly normal S[Cr] value.

HEPATITIS C VIRUS INFECTION

Hepatitis C virus (HCV) infection affects approximately 3.5 million Americans and over 71 million individuals worldwide.[23] The annual incidence rate in the US is estimated to be 13.9 cases per 100,000 population.[24] HCV infection is among the most common causes of liver transplantation in the US and Europe. HCV infection disproportionately affects patients with CKD and end-stage renal disease (ESRD). Among CKD patients who have never been transfused, the prevalence of HCV antibody is approximately 10-fold higher than in the blood donor population.[25] HCV infection not only represents a major cause of morbidity and mortality in the CKD population but may also independently influence the natural history of the underlying kidney disease.

Numerous investigators have suggested that HCV infection is associated with the development and accelerated progression of CKD leading to an increased risk for ESRD. Although many epidemiologic studies show an association between HCV infection and CKD, as do several meta-analyses, the results have not been entirely consistent. In fact, some studies have found a protective effect of HCV infection on CKD.

Fabrizi et al.[26] performed a meta-analysis of 40 studies, containing over 4 million patients, that used multivariate analysis to examine the association of HCV infection with CKD. An association between HCV infection and an increased incidence of CKD was demonstrated in 15 longitudinal studies containing 2,299,134 patients (295,773 of whom were HCV-infected) (HR 1.54). The diagnosis of HCV infection was based on anti-HCV seropositivity, detection of HCV RNA, or an administrative code indicating a diagnosis of HCV infection. The risk of CKD increased with aging and duration of follow-up. HCV infection was also associated with the prevalence of proteinuria in 10 cross-sectional studies containing 378,769 patients (63,365 of whom were HCV-infected) (HR 1.63). Overall, no association between HCV and an increased prevalence of CKD was observed. However, an association between HCV and an increased prevalence of CKD was demonstrable in Asian populations (HR 1.2).

A recent report by Tartof et al.[27] found that the risk of a 25% reduction in eGFR or progression to ESRD was greater in a cohort of 1603 subjects with CKD and HCV infection compared with 151,974 subjects with CKD alone.

Another meta-analysis examined the association of HCV with CKD in human immunodeficiency virus (HIV)/HCV coinfected patients.[28] An association between HCV infection and increased risk of incident CKD was demonstrated in eight longitudinal studies of 105,462 coinfected patients (HR 1.64). HCV infection was also an independent risk factor for proteinuria in six studies that included 26,835 coinfected patients (HR 1.23). In contrast, in five cross-sectional studies of 13,853 patients, the prevalence of CKD was not increased in HIV/HCV coinfected patients.

Representative of studies that reported no effect or a protective effect of HCV infection on CKD is a cohort of over 13,000 anti-HCV seropositive subjects from an urban area with a high prevalence of HIV studied by Moe at al.[29] In a cross-sectional analysis of these subjects, HCV infection was associated with a reduced prevalence of CKD compared with anti-HCV seronegative subjects. In a longitudinal analysis of a subset of over 7000 subjects without CKD followed for a median of 3.5 years, there was no difference in the incidence of CKD in adjusted analysis. In another adjusted analysis of a demographically diverse cohort of insured individuals followed for a mean of over 2 years, Asrani et al.[30] found no difference in the prevalence, incidence, or rate of progression of CKD among 13,384 HCV-infected subjects compared with 154,185 subjects without HCV infection.

HCV infection was associated with proteinuria and an increased mean eGFR, but not with CKD, among participants in the 1988–1994 and 1999–2012 National Health and Nutritional Examination Survey ($n = 33{,}729$ and 15,029, respectively).[31,32] Rogal et al.[33] followed 71,528 US veterans for a mean of 6 years. Recent HCV seroconversion was documented in 2599 of the cohort. They found that HCV-infected individuals were less likely to develop CKD, but showed no difference in the rate of progression of CKD. However, in a much larger cohort of 920,531 uninfected and 100,518 HCV-infected US Veterans, Molnar et al.[34] found an association between HCV infection and increased incidence of CKD, progressive loss of renal function, and the development of ESRD.

In adjusted analysis of HCV/HIV coinfected women, Tsui et al.[35] reported no association between HCV infection and the prevalence of CKD, but found that in those with established CKD, HCV infection was associated with accelerated progression. In a large cohort of 474,369 US Veterans (52,874 of whom were anti-HCV seropositive), Tsui et al.[36] found that although the prevalence of CKD was lower in infected patients and there was no significant difference in the rate of progression of CKD, HCV-infected patients who did progress did so at a more rapid rate, leading to a higher incidence of ESRD.

Interpretation of available clinical studies is complicated by heterogeneity in subject demographics, including differences in age, sex, ethnicity, socioeconomic status, alcohol use, angiotensin-converting enzyme inhibitor therapy, and coinfection with HIV or hepatitis B virus (HBV), and by differences in the number of treatment-naïve vs. experienced patients. Methods to identify HCV infection differ among the studies, and include detection of anti-HCV antibody, detection of HCV RNA, and use of administrative codes to diagnose HCV infection. Because only 60–70% of HCV-infected patients demonstrate chronic viremia, diagnosis of HCV infection solely by the detection of HCV RNA may miss mild cases, leading to severity bias. Errors in administrative coding may also lead to misclassification. In addition, multiple confounding factors must be considered. Patients infected with HCV are more likely to suffer from diabetes, hypertension, obesity, HIV, cirrhosis, coronary artery disease, and hyperlipidemia and to have a history of intravenous drug use. Unmeasured confounding variables represent a significant issue in analyses of these data. A longer duration of HCV infection has been associated with an increased risk of CKD.[37] In this regard, many of the cohorts that failed to demonstrate an association between HCV infection and incident CKD were followed for only 2–3 years. Patients with HCV may also receive a higher intensity of medical care with more frequent follow-up visits, leading to detection bias due to earlier detection of CKD.

The REVEAL-HCV Study Group[38] found an increased CKD prevalence in those infected with genotype 2. This observation might help explain inconsistent data regarding the association of HCV infection and CKD. Meta-analysis has shown that the pooled risk for CKD among HCV-infected cohorts is higher in Asian populations than in the US or Europe.[26] These geographic variations in CKD risk parallel the relative prevalence of the HCV genotype 2. However, another publication from the REVEAL-HCV Study Group reported that genotype 1, not genotype 2, was a strong predictor of ESRD in their cohort.[39] Numerous other investigators found no association between HCV genotype and the incidence or prevalence of CKD.[37,40] Studies seeking to establish an association between CKD and viremia in HCV-infected patients have also yielded inconsistent results.[37–43] Peters et al.[40] reported an association between HCV viremia and the incidence rate of CKD among over 8000 HIV/HCV coinfected patients. Those who cleared their viremia showed an incidence rate similar to anti-HCV seronegative patients. Similarly, a high plasma HCV RNA level was associated with the prevalence of CKD in separate cohorts of 434 and 552 anti-HCV seropositive patients, as well as with the risk of progressive CKD in a third cohort of 34,441 HIV/HCV coinfected patients.[37,38,42] However, other investigators found no relationship between viremia and the incidence, prevalence, or rate of progression of CKD.[41,44]

Numerous mechanisms have been suggested to explain the purported association of HCV with CKD. Glomerular disease is a well-described, albeit uncommon, extrahepatic manifestation of HCV infection.[45–47] A systemic immune response to HCV infection is thought to contribute to glomerular injury. Glomerular disease may be mediated by HCV-antibody immune complex deposition with or without cryoglobulin formation. Deposition of immune complexes containing viral antigens has been demonstrated in mesangial and subendothelial locations. The most common histologic pattern of glomerular injury is membranoproliferative glomerulonephritis; however, membranous glomerulopathy, focal and segmental glomerulosclerosis, IgA nephropathy, immunotactoid and fibrillary glomerulopathies, amyloidosis and thrombotic microangiopathy have been described in HCV-infected patients (Table 53.1).[45–49] The prevalence of membranoproliferative glomerulonephritis and of cryoglobulinemia in patients chronically infected with HCV, identified by administrative codes reported to the National Inpatient Sample of the Healthcare Cost and Utilization project, has been reported to be 0.38% and 0.33%, respectively.[50] Similarly, the prevalence of membranoproliferative glomerulonephritis and of cryoglobulinemia, identified by administrative codes, among 34,204 HCV-infected hospitalized US veterans was 0.36% and 0.57%, respectively.[51] Postmortem series have identified a higher prevalence of nondiabetic glomerular disease in HCV-infected subjects, ranging from 8.8 to over 50% of cases.[47,52] A series of kidney biopsies obtained from liver transplant recipients showed glomerulonephritis in over 83% of cases.[49] Perhaps the inconsistencies in these data can be reconciled by the observation that many patients with membranoproliferative glomerulonephritis documented by kidney biopsy have clinically silent renal involvement.[49]

HCV may also exert direct cytopathic effects in renal tissue.[45,46,53] HCV viral particles or antigen has been identified in glomeruli, endothelial cells, and tubules in renal biopsy specimens from HCV-infected patients.[45,46] HCV exposure has also been associated with increased expression of toll-like receptors in renal glomeruli.[54] HCV core protein also directly inhibits insulin signaling, leading to a state of insulin resistance associated with compensatory hyperinsulinemia.[45,46,55] HCV activates the mammalian target of

rapamycin/ribosomal S6 kinase signal transduction pathway, which in turn alters the function of glucose transporters, insulin receptors, and the gluconeogenesis enzyme phosphoenolpyruvate carboxykinase 2, leading to insulin resistance.[45,46,55] HCV core protein induces increased oxidative stress and induces endothelial dysfunction by decreasing endothelial nitric oxide synthase activity and nitric oxide synthesis. HCV also exerts immunomodulatory effects.[45,46,55] HCV infects peripheral dendritic cells, monocytes, and macrophages and stimulates B cells, which in turn modulates B- and T-cell function. HCV core protein increases the synthesis of proinflammatory cytokines including IL-6, C-reactive protein, and nuclear factor kappa-light-chain enhancer of activated B cells (NF-κB).[55] Other downstream effects of HCV include increased levels of insulin-like growth factor-1, transforming growth factor-beta (TGF-β), and endothelin-1, and increased angiotensin II type 1 receptor density.

Use of DAA Medications to Eradicate HCV in Patients with CKD

Newer and highly effective therapeutic strategies for treatment of HCV have had a significant impact in the CKD and ESRD populations and may play a role in the prevention of HCV-related kidney injury. In the past, interferon and ribavirin constituted the only treatment option for HCV, and outcomes were suboptimal because of adherence issues related to toxicity.[56] By far, the most serious complication was hemolytic anemia associated with ribavirin, which precluded its use in most CKD patients. Research into the HCV life cycle identified the opportunity to arrest viral replication and infectivity within hepatocytes.[57] The four types of direct acting antivirals (DAAs) that were developed include (1) NS3/4A protease inhibitors, (2) NS5A inhibitors, (3) NS5B nonnucleoside polymerase inhibitors, and (4) NS5B nucleoside polymerase inhibitors.[57] They are given for a finite duration, usually in combination, avoid the difficult adverse effects of interferon-based therapies, and are curative. HCV type 1 is most successfully treated with combination DAA therapy, with cure rates exceeding 90%.[57] Initial DAA regimens used these agents in conjunction with pegylated interferon and ribavirin. Sofosbuvir-containing regimens later supplanted these strategies, and though effective, were contraindicated in patients with a GFR less than 30 mL/min.[58] Sofosbuvir is a nucleotide prodrug inhibitor of NS5B polymerase whose active metabolite is eliminated predominantly through the kidney.[58,59] Phase 3 clinical studies examining sofosbuvir and ledpasvir combinations did not include patients with CKD.[59–61] However, sofosbuvir was subsequently found to be well tolerated and effective in patients with stages 3–5 CKD, including dialysis-dependent CKD.[58,62–66] Notwithstanding these data, FDA approval of sofosbuvir is limited to individuals with an eGFR >30 mL/min/1.73 m^2. Other regimens are now available for advanced CKD[58,62]

The C-SURFER trial was the first to examine an all oral, ribavirin-free treatment for HCV in patients with stages 4 and 5 CKD.[67] The regimen used was grazoprevir (NS 3/4A protease inhibitor) in combination with elbasvir (NS5A inhibitor). The recruited patients were infected with HCV genotype 1; 76% were dialysis-dependent. Less than 1% of the grazoprevir and elbasvir combination is excreted by the kidney and less than 5% of grazoprevir is removed by hemodialysis.[67,68] The regimen was generally well tolerated and after 12 weeks of therapy, 99% achieved a sustained virologic response (SVR).[67] In the RUBY-1 trial of 20 patients with hepatitis C infection and stage 4 CKD (14 of whom required dialysis), the combination of ombitasvir/partparevir/ritonavir and dasabuvir with or without ribavirin was examined.[69] After 12 weeks of therapy, all 20 patients had completed the trial and 18 achieved SVR. A phase 3 multicenter, open-label trial (EXPEDITION 4) evaluated a 12 week course of therapy with combination of glecaprevir (NS3/4A protease inhibitor) and pibrentasvir (NS5A inhibitor) in 104 patients infected with HCV genotypes 1, 2, 3, 4, 5, or 6 and a baseline eGFR <30 mL/min/1.73 m^2.[70] SVR was achieved in 98% of patients. The current DAA regimens approved for use in patients with advanced CKD (stages 4 and 5) include Zepatier (combination of grazoprevir and elbasvir), Viekira (combination of ombitasvir, paritaprevir, dasabuvir, and ritonavir), and Mavyret (combination of glecaprevir and pibrentasvir).

The European Association for the Study of the Liver Recommendations on Treatment of Hepatitis C, 2018 state that "All patients with HCV infection must be considered for therapy, including treatment-naïve and individuals who failed to achieve SVR after prior treatment."[71] Many commentators have suggested that patients with mild to moderate CKD are especially attractive candidates for therapy and strongly recommended universal therapy of such patients. They emphasize the potential benefits of SVR on prevention of diabetes mellitus, improvement in glycemic control and cardiovascular outcomes and amelioration of CKD progression. The purported benefits of SVR on CKD are based on an emerging body of evidence suggesting that SVR is associated with a reduced incidence and prevalence of CKD, an improvement in eGFR, a slower rate of progression of CKD, and a reduced incidence of ESRD. Although the benefit of HCV therapy and SVR on renal outcomes in HCV-associated

glomerulonephritis is well established, the effects of therapy designed to achieve SVR on renal outcomes in the broader CKD population have not been entirely consistent. Moreover, studies are often compromised by small numbers of subjects, the frequent lack of an untreated control group, and heterogeneity in treatment regimens. These studies must also be interpreted in light of the bias inherent in the selection of patients for treatment.

Feng et al.[72] performed a meta-analysis of 11 clinical trials involving 225 patients with HCV-associated glomerulonephritis treated with interferon-based antiviral therapy. They reported a 2.71 g/24 h decrease in urinary protein excretion associated with SVR. Mean S[Cr] fell by 0.23 mg/dL. Others have found that DAA therapy is associated with a full or partial remission of cryoglobulinemic glomerulonephritis in nearly two-thirds of cases.[73]

Among 12,384 Taiwanese HCV-infected patients who were treated with pegylated interferon plus ribavirin and followed for over 8 years, the multivariate-adjusted risk of ESRD, identified by administrative codes, was reduced by 85% compared with propensity score-matched untreated HCV controls.[74] Among 919 HCV-infected patients treated with an interferon-based regimen in the same Taiwanese cohort, the 7-year cumulative incidence of CKD was lower by 58% in adjusted analysis compared with propensity score-matched untreated HCV controls.[75] Similar results have been reported by other investigators using interferon-based regimens to treat HCV.[37,74,76,77] In a cross-sectional study of 552 HCV-infected patients, there was a fivefold decrease in CKD in those who were treated with an interferon-based regimen during a 7-year follow-up.[37] Among 650 HCV-infected patients treated with interferon with or without ribavirin, the failure to achieve a SVR was associated with a 2.67-fold greater risk of developing CKD.[76] Among 12,534 HCV-infected patients treated with pegylated interferon and ribavirin and followed for a mean of 3.3 years, antiviral therapy was associated with a lower risk of ESRD in adjusted analysis (HR 0.15).[74] Consistent with these observations, Park et al.[77] observed a 30% reduction in the risk of developing CKD among 55,000 newly diagnosed HCV-infected individuals treated with interferon with or without ribavirin or boceprevir, telaprevir, sofosbuvir, or simeprevir plus pegylated interferon and ribavirin or all oral therapy.

Similar benefits have been described among patients treated exclusively with DAA therapies.[58,78,79] Sise et al.[58] treated 98 HCV-infected patients with stages 1–3 CKD with a sofosbuvir-based regimen. In those with an eGFR less than 60 mL/min/1.73 m^2 at baseline, a multivariate linear regression model indicated that SVR was associated with a 9.3 mL/min/1.73 m^2 improvement in GFR over a 6-month posttreatment follow-up period. In contrast, no change in eGFR was observed in those with stage 1 or stage 2 CKD at baseline. However, this study did not include an untreated control group. Medeiros et al.[79] also observed an increase in eGFR in HCV-infected patients 1 year after treatment with a sofosbuvir-based regimen.

In contrast, other studies show no improvement in renal outcome after DAA therapy and SVR.[43,80,81] A pooled analysis of phase 3 clinical trials of therapy with ombitasvir/paritaprevir/ritonavir or dasbuvir with or without ribavirin involving 5539 genotype 1 HCV-infected patients with stages 2–5 CKD and 464 placebo-treated controls followed for 52 weeks post treatment showed no significant change in eGFR from baseline, assessed 52 weeks after therapy.[81] However, those patients with stage 1 CKD at baseline experienced a significant decline in eGFR. One year after treatment of 523 HCV-infected patients with mostly sofosbuvir-containing DAA regimens, the rate of decline in eGFR in those who achieved SVR was not different from untreated HCV-infected patients but was less than in treated patients who failed to achieve SVR.[80] Rossi et al.[43] also failed to find an association between SVR and the rate of eGFR decline in HCV/HIV coinfected patients.

First-generation DAAs have been associated with transient AKI during therapy, and in the case of telaprevir, with long-term reductions in eGFR.[82,83] Several trials of second-generation DAAs report an increased, albeit low, incidence of AKI during therapy, which may occur more frequently with sofosbuvir-containing regimens and in those with more advanced CKD at baseline.[43,84–88] However, this signal has not been observed in other trials.[58,89] The use of different criteria among various trials to define adverse renal events confounds interpretation of data. A persistent reduction in eGFR measured 12 weeks after the end of therapy with second-generation DAAs as compared with baseline values has also been reported in many studies.[85,86,90,91] Saxena et al.[84] reported AKI, identified by administrative codes, in 2% of all patients treated with a sofosbuvir-containing regimen. However, the rate of AKI rose to 15% in those with an eGFR less than 45 mL/min/1.73 m^2 at baseline. Among 43 HCV-infected patients treated with sofosbuvir-containing regimens, eGFR fell more than 6 mL/min/1.73 m^2 at the end of therapy and, in those with cirrhosis, failed to recover 24 weeks after therapy. A meta-analysis of 13 trials which included 6884 HCV-infected subjects

found that DAA therapy was associated with renal functional deterioration in those with advanced CKD at baseline.[92] In contrast, the incidence of sosofovir-induced AKI was not increased among 98 HCV-infected patients with stages 1–3 CKD at baseline who were treated with a sosofovir-based regimen.[58] Although nearly 7% of patients experienced a transient episode of AKI with full recovery of renal function, in all but one case, the investigators deemed all these episodes to be unrelated to sofosbuvir therapy.

Several studies suggest that therapy of HCV-infected liver transplant recipients with antiviral therapy has a beneficial effect on renal outcomes.[93–95] Satapathy et al.[94] treated 204 liver transplant recipients with interferon and/or DAA and followed them for a median of 5.5 years. They found an 88% lower risk of CKD, a less steep rate of decline of eGFR over time and an 85% lower risk of ESRD in treated patients. Similarly, in a study of 99 HCV-infected liver transplant recipients with stage 2 CKD at baseline who were treated with pegylated interferon and ribavirin and followed for up to 5 years, SVR was associated with a 16 mL/min/1.73 m^2 improvement in eGFR compared with nonresponders.[93] However, among 31 treated patients with stage 3 CKD at baseline, there was no difference in eGFR between responders and nonresponders.

The decision whether or not to treat an HCV-infected individual suffering from late-stage CKD with a second-generation DAA entails consideration of the individual's kidney transplantation status. Immediate therapy may be warranted in living donor kidney transplant candidates, CKD due to HCV-related glomerulonephritis or in those suffering from advanced liver disease at high risk for decompensated liver failure. However, successful treatment of an HCV-positive candidate for a deceased donor kidney may result in a substantial delay or a lost opportunity for transplantation. The wait list for a kidney harvested from a deceased HCV-positive donor is on average one year shorter, and up to several years shorter, than for a HCV-negative deceased donor, giving HCV-positive recipients a substantial advantage in securing a kidney transplant.[96] Thus, deferring DAA therapy until after kidney transplantation may result in a substantial reduction in wait time. This advantage is greater in geographic regions with a high prevalence of anti-HCV seropositive deceased kidney donors and in those regions with a long wait list. Of course, patient preference and whether or not the local kidney transplant center accepts anti-HCV seropositive deceased donor kidneys are of paramount importance. Other considerations include HIV coinfection, which may increase the risk of decompensated liver failure, dialysis vintage which determines accumulated wait time credit, the average wait time for a deceased donor kidney in the local geographic area, and the HCV genotype which determines the complexity of treatment.

HEPATITIS B VIRUS INFECTION

Controversy also surrounds the relationship between CKD and HBV infection. A meta-analysis of four longitudinal studies which included 184,937 subjects, 36,192 of whom were infected with HBV, found that HBV infection was associated with incident ESRD (HR 3.78 [1.48,6.25]) as well as incident CKD, however, the latter association did not achieve statistical significance.[97] In contrast, the meta-analysis found no relationship between HBV infection and the prevalence of CKD in seven cross-sectional or case-control studies which included 109,889 subjects, 8023 of whom were infected with HBV. The meta-analysis also found no relationship between HBV infection and the prevalence of proteinuria. More recently, several large studies have confirmed the association of HBV with CKD. Si et al.[98] found an association between HBV infection and incident CKD, identified by administrative codes, among 469,459 subjects followed for 9.1 years, of which 14,871 were seropositive for HB surface antigen. Similarly, Hong et al.[99] found an association between HBV infection and incident proteinuria, but not incident eGFR <60 mL/min/1.73 m^2, among 299,913 subjects followed for 5.6 years, of which 11,209 were seropositive for HB surface antigen. Unlike the aforementioned meta-analysis, Kim et al.[100] found an association between HBV infection and prevalent eGFR <60 mL/min/1.73 m^2 and proteinuria among 265,086 subjects, of which 10,048 were seropositive for HB surface antigen.

Many of the same limitations identified in studies of HCV infection and CKD also apply to studies that address the relationship between HBV infection and CKD. Similarly, the mechanisms invoked to explain the effects of HBV infection on the development and progression of CKD are analogous to those postulated to mediate the effects of HCV infection on CKD. Proposed mediators include enhanced oxidative stress, upregulation of inflammatory cytokines, insulin resistance, modulation of immune responses, and cytopathic effects of HBV on renal tissue.

Therapy of HBV-associated glomerulonephritis with an interferon-based regimen or with lamivudine leads to remission of proteinuria in nearly two-thirds of cases and reduces the risk of progression to ESRD.[52,101–103] Eradication of HBV infection reduced the risk of incident ESRD in a propensity-matched cohort of HBV-infected subjects with CKD.[103] On the other hand, most of the nucleos(t)ide analogs used to treat HBV infection have

been associated with deterioration of renal function, likely related to the nephrotoxicity of these agents.[104] The sole exception is tebivudine which was associated with an increase in eGFR in treated patients which persisted after 4–6 years of follow-up. The mechanisms responsible for this effect are unclear insofar as no relationship was observed between sustained viral response and the improvement in eGFR.[104]

NONALCOHOLIC FATTY LIVER DISEASE

Nonalcoholic fatty liver disease (NAFLD) represents a burgeoning public health concern of enormous importance. NAFLD is defined by the accumulation of liver fat exceeding 5% of liver weight in the absence of significant alcohol intake or other secondary causes of chronic liver disease.[105–111] NAFLD encompasses a spectrum of liver injury ranging from simple steatosis to the more severe inflammatory form, nonalcoholic steatohepatitis (NASH), and ultimately advanced fibrosis and cirrhosis.[105–111] 20–30% of the adult population of western countries are estimated to suffer from NAFLD.[105–111] The prevalence of NALFD is even greater among the obese and among diabetics. NAFLD is generally regarded as the hepatic manifestation of the metabolic syndrome.

Complex interrelationships have been proposed to explain cross talk between the liver and kidney in NAFLD. Cross talk may be mediated by the synthesis and systemic release of proinflammatory and procoagulant factors released by steatotic, necrotic, and apoptotic hepatocytes, nonparenchymal Kupffer cells and hepatic stellate cells. Cross talk may also be mediated by insulin resistance or dyslipidemia associated with NAFLD. Specifically, NAFLD has been associated with increased circulating levels of inflammatory cytokines and other inflammatory mediators (TNF-α, TGF-β, IL-6, and C-reactive protein), a procoagulant profile (increased plasminogen activator inhibitor-1, decreased tissue plasminogen activator, and decreased fibrinolytic factors), and evidence of increased oxidative stress.[105–111] Increased production of fetuin A by the liver in NAFLD promotes insulin resistance by inhibiting insulin signal transduction and by reducing adiponectin levels in adipose tissue and in plasma.[105–111] A fall in adiponectin levels reduces activation of the energy sensor, 5′ adenosine monophosphate activation protein kinase, which in turn acts to decrease insulin sensitivity and induce insulin resistance and dyslipidemia. These effects are mediated by the influx of free fatty acids into the liver to increase liver gluconeogenesis, lipogenesis, and fatty acid oxidation.[105–111] These actions promote hepatic inflammation, cell proliferation, and fibrosis. An increase in proinflammatory cytokines and a decrease in protective adipokines released from inflamed visceral adipose tissue may also contribute to both liver and kidney injury.[105–111] These metabolic alterations make the liver both a target and a contributor to a systemic inflammatory response in which the kidney is also a target. In addition, endothelial dysfunction and activation of the renin–angiotensin system have been postulated to play a role in liver-kidney cross talk in NAFLD.

Despite the elucidation of intricate pathways that might mediate liver-kidney cross talk in this disorder, the clinical data supporting the role of NAFLD in promoting CKD remains controversial. Recent studies have demonstrated an association between NAFLD and CKD which survives multivariate analysis, leading to the suggestion that NAFLD may be an independent risk factor for the development and progression of CKD.[105–111] However, NAFLD and CKD share multiple common risk factors, and both have been associated with abdominal obesity, hypertension, diabetes mellitus, dyslipidemia, and insulin resistance.[105–111] The paramount issue revolves around the role that common pathogenic mechanisms and shared risk factors play, and whether or not the purported effects of NAFLD on the progression of CKD are truly independent of these shared risk factors.

Most studies demonstrate an association between the presence and the severity of NAFLD and the risk and severity of CKD after adjusting for traditional risk factors. In these cohorts, the prevalence of CKD in patients with NAFLD ranges from 10% to 20%.[112] In addition, most liver biopsy cohorts have shown a correlation between the histologic severity of NASH and renal dysfunction.[112]

Musso et al.[112] performed a meta-analysis of 20 cross-sectional and 13 longitudinal studies that included nearly 64,000 screened individuals. Patient-level data were available in nearly half of the subjects. Prevalent CKD was over twice as common in NAFLD compared with controls, and incident CKD was 1.8 times more common in NAFLD compared with controls. The severity of NAFLD was associated with the severity of CKD. In adjusted analyses of liver biopsy studies, the presence of NASH increased the prevalence of CKD by 2.5-fold, and increased the incidence of CKD by over 2-fold compared with simple steatosis. The presence of advanced fibrosis increased the prevalence of CKD by 5.2-fold and increased the incidence of CKD by 3.3-fold compared with nonadvanced fibrosis.

Mantovani et al.[113] performed a meta-analysis of nine prospective or retrospective observational cohorts consisting of nearly 100,000 subjects followed for a mean of 5.2 years. They found that NAFLD was associated with a 40% increase in the incidence of CKD. Furthermore, increased severity of NAFLD was associated with an increased risk of developing CKD.

Newer noninvasive techniques to detect NAFLD have recently been employed to study the relationship between CKD and NAFLD. The use of transient elastography to generate a controlled attenuation parameter score to quantitate steatosis and a liver stiffness score to quantitate fibrosis led to the observation that over 85% of patients with CKD had NAFLD, and that the severity of CKD correlated with the severity of hepatic steatosis.[114] Similar findings have been reported by other investigators.[115,116]

The limitations of the studies that report an association between NAFLD and CKD are significant and arguably compromise the validity of conclusions drawn from the accumulated data. The observational nature of these studies does not allow for a conclusion of causality. Despite utilization of multivariate analysis, residual unmeasured confounding factors cannot be excluded. Studied cohorts have been heterogeneous and vary by age, ethnicity, duration of follow-up, and prevalence of diabetes and hypertension. In addition, there is heterogeneity of kidney disease outcome parameters. Most population-based cohort studies rely on liver enzyme abnormalities or ultrasound examination to diagnose NAFLD without liver biopsy confirmation. Even liver biopsy diagnosis is subject to sampling error, because NAFLD may be patchy in distribution. Moreover, cohorts that underwent liver biopsies have been small in size, generally lack a control group, and suffer from selection bias. Misclassification of NAFLD cases due to the low sensitivity of liver enzyme abnormalities and ultrasound examination may obscure relationships between NAFLD and CKD. Ultrasound-based diagnosis is subjective and qualitative in nature and in cases where less than 30% of hepatocytes are steatotic, the sensitivity is limited to 60–90%.[105–111] However, in more severe NAFLD, the sensitivity rises to 85–94% with a specificity in the mid-90s range. Use of abnormal liver enzymes as a surrogate marker for NAFLD lacks both sensitivity and specificity. In fact, liver enzyme tests may be normal in up to 50% of patients with NAFLD.[105–111]

Misclassification of CKD cases due to overestimation of kidney function in liver disease may also obscure relationships between NAFLD and CKD. The equations used to estimate GFR overestimate renal function in severe liver disease and underestimate the incidence and prevalence of CKD in this population, which may mask relationships between NAFLD and CKD. Although patients with cirrhosis were excluded from most studies, S[Cr] tends to be lower in patients with severe liver disease due to muscle wasting, reduced hepatic generation of creatinine from creatine, and increased tubular secretion of creatinine.

MECHANISMS OF KIDNEY-LIVER CROSS TALK

The existence of renal-hepatic cross talk has been clearly established in animal models of CKD. However, to what extent these experimental observations in animal models of CKD can be extrapolated to CKD in humans is not clear. Unilateral nephrectomy promotes liver injury and the development of steatohepatitis. Unilateral nephrectomy is associated with dysregulation of lipid metabolism, insulin resistance, hyperglycemia, and a redistribution of fat from adipose to nonadipose tissue.[117] There is evidence of ectopic fat deposition in the liver and kidney and increased oxidative stress and upregulation of TGF-β in both organs. These metabolic alterations are mediated by the renin–angiotensin system insofar as angiotensin-converting enzyme inhibitors reverse these effects.

Studies performed by Park et al.[118] have implicated inflammatory cytokines as the primary mediators of remote hepatic injury associated with renal disease. Bilateral nephrectomy in the rat was associated with elevated transaminase levels and hepatocellular injury characterized by apoptosis and inflammation. These distant effects on the liver were attributed to increased synthesis and release of IL-17A by intestinal Paneth cells. Increased systemic delivery of IL-17A to the liver by circulating macrophages induced hepatic neutrophil infiltration, hepatic cellular necrosis and apoptosis, transaminitis, and increased hepatic expression and release of IL-6 and TNF-α. The latter cytokines magnified tissue injury. Administration of neutralizing antibodies to IL-17A, genetic deficiency of IL-17A, or genetic or pharmacologic depletion of Paneth cells reduced hepatic injury after bilateral nephrectomy, supporting the putative role of IL-17A in mediating the remote effects of renal injury on the liver. Also of interest is the observation that bilateral nephrectomy exacerbated hepatic injury after hepatic ischemia reperfusion.

Studies by other investigators have focused on the role of oxidative stress in mediating remote hepatic injury associated with renal disease.[119–121] Following bilateral nephrectomy in rats, hepatic lipid peroxidation products increased, whereas levels of the antioxidant molecule glutathione decreased.[121] Enzyme markers of liver injury were transiently increased in association with histologic evidence of hepatic cellular injury including apoptosis, leukocyte infiltration, and vascular congestion. Levels of TNF-α and the antiinflammatory cytokine IL-10 were elevated. An important role for increased oxidant stress in mediating these remote effects on the liver was suggested by the ability of infused reduced glutathione to partially prevent hepatic injury

and blunt hepatic lipid peroxidation. An important role for increased oxidative stress in mediating kidney/liver cross talk was also demonstrated in a protein overload nephropathy model.[119,120]

HEPATIC DRUG METABOLISM

CKD alters the pharmacokinetics of over 75 drugs whose elimination depends on nonrenal, predominantly hepatic, clearance. In general, CKD is associated with reduced hepatic drug clearance, although in some cases hepatic clearance is enhanced. The magnitude of the change in hepatic drug clearance generally correlates with the degree of renal functional impairment.

Cytochrome P450 (CYP) enzymes are a superfamily of hemoproteins that play a key role in the metabolism of endogenous substrates, therapeutic agents, and environmental chemicals.[116,122–128] The CYP3 family is responsible for most CYP-mediated drug metabolism. These enzymes are present in a variety of organs but are most abundant in the liver.[116,122–128] Experimental evidence suggests CKD influences CYP-mediated hepatic drug metabolism by multiple different mechanisms: by directly inhibiting CYP enzyme activity, by influencing CYP gene transcription, and by acting at posttranslational and epigenetic levels.[116,122–128] The remote effects of CKD on CYP enzymes are likely mediated by both the accumulation of uremic toxins and by the generation of cytokine mediators.[116,122–128] Although CKD generally inhibits CYP enzyme activity and suppresses CYP protein expression, CYP inducibility is retained, with important clinical implications.[129,130]

The effect of subtotal nephrectomy on hepatic drug clearance pathways has been studied by several investigators. Leblond et al.[129,130] found a reduction in total hepatic microsomal CYP activity associated with a reduction in the protein expression of several hepatic CYP proteins. These changes paralleled a reduction in the clearance of drugs that are known substrates for these hepatic CYP enzymes. The reduction in CYP activity correlated with the severity of renal functional impairment in this as well as in other studies.[129–133] Although total hepatic microsomal CYP activity was reduced, inducibility by dexamethasone and phenobarbital was retained.[129,130] The reduction in CYP protein expression was transcriptionally mediated, as evidenced by a parallel reduction in mRNA levels. The relationship between subtotal nephrectomy and CYP activity and protein expression has been replicated by other investigators, although the pattern of CYP alterations has not been entirely consistent.[131–135]

The metabolic activity of hepatic CYP2D was assessed in an isolated rat liver preparation using a specific CYP substrate as a probe. Hepatic drug clearance declined when normal rat livers or livers from rats made uremic with uranyl nitrate were perfused with uremic blood.[136] Hepatic drug clearance was restored when livers from uremic rats were perfused with normal blood. The rapidity of onset of the effects of uremic serum suggests a direct and reversible inhibitory effect of a circulating uremic toxin on CYP enzyme activity.

Michaud et al.[137] showed that incubation of normal rat hepatocytes with serum from patients with CKD had a widespread suppressive effect on CYP enzyme activity and protein expression, and that these effects were mediated at a transcriptional level. Several small molecular weight uremic toxins have been identified that inhibit CYP activity *in vitro* at concentrations achieved in humans with CKD.[131,138] Yoshitani et al.[138] found that incubation of hepatic microsomal preparations from normal livers with uremic serum obtained from rats with bilateral ureteral ligation reduced the metabolism of a specific CYP substrate probe, and that this effect was reproduced by exposure of the microsomal preparations to the putative uremic toxin indoxyl sulfate. Barnes et al.[131] found a potent suppressive effect of several known uremic toxins on CYP activity in human liver microsomes. These data support the hypothesis that circulating uremic toxins mediate the inhibitory effects of CKD on CYP activity, protein expression, and mRNA levels. It would follow that removal of these toxins by RRT or kidney transplantation would restore hepatic drug metabolism. Several studies have demonstrated that both RRT and kidney transplantation reverse the inhibitory effects of uremic serum on the hepatic clearance of drugs that are specific substrates for hepatic CYP enzymes, as well as on hepatic CYP protein expression and mRNA levels in hepatocyte microsomal preparations and in isolated hepatocytes.[139,140]

The inhibitory factor in CKD serum has been isolated to a serum fraction that contained parathyroid hormone and proinflammatory cytokines.[137] Several investigators have suggested that proinflammatory cytokines such as IL-6, TNF-α, and NF-κB mediate the effects of CKD on CYP activity and protein expression. The NF-κB signaling pathway may be the final common pathway transducing the suppressive effects of other proinflammatory cytokines. Michaud et al.[139] proposed that the inhibitory effects of uremic human serum on CYP expression in normal rat hepatocytes were mediated by NF-κB, because inhibition of NF-κB reversed these effects. Michaud et al.[141] also suggested a prominent role for elevated parathyroid hormone levels in mediating the suppressive effects of uremic sera on CYP activity and protein synthesis and went on to hypothesize that this effect is mediated through NF-κB. The suppressive effects of serum from rats made uremic with subtotal nephrectomy on CYP protein expression, mRNA levels,

and enzyme activity in preparations of normal rat hepatocytes correlated with parathyroid levels. These effects were reversed by parathyroidectomy or depletion of parathyroid hormone by immunoadsorption and were restored by administration of exogenous parathyroid hormone. Inhibition of NF-κB prevented the effects of exogenous parathyroid hormone on CYP activity. However, other investigators failed to find a correlation between CYP activity and parathyroid hormone levels.[140]

In a subtotal nephrectomy model, Velenosi et al.[142] proposed that the effects of CKD on hepatic CYP activity, protein expression, and mRNA levels occur both at transcriptional and epigenetic levels. Several CYP isoforms are transcriptionally regulated by the nuclear receptors pregnane X receptor and hepatic nuclear factor 4α. These investigators demonstrated reduced nuclear receptor binding and decreased histone acetylation of CYP promoter regions in CKD animals. Interestingly, Gu et al.[143] have shown that the ability of TNF-α to suppress CYP3A4 is mediated by NF-κB. NF-κB prevents the association of the pregnane X receptor with the retinoid X receptor, which in turn prevents the heterodimer from binding to the promoter region of CYP3A4. Watanabe et al.[144] reported that CYP3A was downregulated in rat primary hepatoctyes by parathyroid hormone through multiple signal transduction pathways. Increased intracellular cyclic adenosine monophosphate levels led to activation of phosphatidylinositol 3-kinase-protein kinase B/protein kinase C/protein kinase A/NF-κB pathways which ultimately suppressed pregnane X receptor activity. They further demonstrated that administration of a calcimimetic partially reversed CYP inhibition in a subtotal nephrectomy model. Thus, the NF-κB pathway may be crucial to interactions between CKD and hepatic CYP activity and may represent a final common pathway for the effects of proinflammatory cytokines and PTH on CYP activity.

Using specific hepatic CYP substrates as probes to assess hepatic CYP activity in humans, investigators have confirmed that experimental observations on interactions between CKD and CYP activity translate to clinical practice.[116,122–128] Reductions in CYP activity observed in experimental models parallel increased bioavailability of numerous drugs known to be specific CYP substrates in humans with both dialysis-dependent and nondialysis-dependent CKD.[116,122–128] The magnitude of the effects of CKD on hepatic drug metabolism correlates with renal function, and the effects are reversed by RRT or kidney transplantation.

Active transport of drugs across the sinosoidal membrane of hepatocytes to access hepatic metabolic enzymes is mediated by transporters such as the organic anion transporting polypeptide family of transporters, expressed on the sinosoidal surface of hepatocytes.[116,122–128] P-glycoprotein and multidrug resistance-associated protein-2 are energy-dependent efflux transporters on the canalicular membrane of hepatocytes, responsible for extrusion of drug metabolites into bile canaliculi.[116,122–128] Drug uptake and efflux transporters regulate intracellular exposure of substrates to hepatic CYP and may be rate-limiting for hepatic drug metabolism. These transporters are also expressed on renal proximal tubules and enterocytes.[116,122–128]

Hepatic organic anion transporting polypeptide protein-mediated uptake of specific drug probes is reduced in humans with ESRD.[126] In addition, organic anion transporting polypeptide activity is inhibited *in vitro* by uremic toxins.[145] In a subtotal nephrectomy model and in *in vitro* studies of normal rat hepatocytes incubated with uremic rat serum, Naud et al.[146] showed reduced organic anion transporting polypeptide protein expression in the absence of changes in mRNA levels. However, data on the effects of CKD on P-glycoprotein and multidrug resistance-associated protein expression and mRNA levels in the subtotal nephrectomy model have been inconsistent.[146,147]

Although the majority of drug metabolized by the liver undergoes oxidation, the hepatic elimination of other drugs is mediated by conjugation reactions, including glucuronidation and acetylation, mediated by the enzyme uridine diphosphate-glucuronosyl transferase, and N-acetyl-transferase, respectively.[122,123,126,148] Using drug probes, investigators have demonstrated reduced hepatic acetylation in humans with ESRD.[122,123] Reversal of the uremic milieu by renal transplantation restores hepatic clearance of drugs whose elimination is dependent on acetylation.[122,123] Similarly, normal rat hepatocytes incubated with uremic serum from rats which had undergone subtotal nephrectomy show reduced N-acetyl-transferase activity and protein expression mediated at a transcriptional level.[148] These effects were reversed by parathyroidectomy and reproduced by incubation of rat hepatocytes with exogenous parathyroid hormone. Using drug probes, investigators have also demonstrated reduced hepatic drug glycuronidation in humans with CKD, the magnitude of which correlated with the level of renal function.[126] P-cresol, a putative uremic toxin, inhibited uridine diphosphate-glucuronosyl transferase activity in human liver microsomes.[131] However, other experimental data have yielded inconsistent results. No changes in uridine diphosphate-glucuronosyl

transferase activity or in protein expression were observed in a subtotal nephrectomy model of CKD in the rat.[149]

Adding further complexity to the situation is the fact that effects of CKD on hepatic CYP and drug transporter protein function may not necessarily translate into the change in serum drug concentration that might be expected from the observed changes in hepatic metabolism. CKD may have effects on CYP and drug transporter protein activity in the intestine or kidney than are opposite to those seen in the liver. Furthermore, CKD may have additional effects on organ perfusion, drug plasma protein binding and volume of distribution, renal clearance, and extrahepatic metabolism that offset or magnify the effects of CKD on the hepatic metabolism of a given drug. Thus, the net effect on drug pharmacokinetics is a complex interplay between all these competing or complementary actions, and further translational research will be critical.

CONCLUSIONS

Accumulating evidence derived from basic science and clinical studies supports the existence of bidirectional cross talk between the kidney and the liver. These studies suggest that chronic liver disease promotes the development and accelerates the progression of CKD, and that CKD accelerates the progression of chronic liver disease. The data are most robust for interactions between the kidney and decompensated liver disease in the context of HRS-CKD, in HCV-related liver disease and in NAFLD. Upregulation of proinflammatory cytokines plays a paramount role in mediating these interactions. CKD also alters hepatic drug metabolism *via* effects on hepatic CYPs and hepatic drug transporter proteins, mediated by the accumulation of uremic toxins and release of proinflammatory cytokines. These interactions significantly influence drug dosing in patients with combined liver and renal disease. Opportunities for future research may be directed toward enhancing our understanding of the molecular pathways that mediate liver-kidney cross talk. Elucidation of the complex interactions between the liver and kidney may lead to therapeutic interventions directed toward slowing the progression of both liver and kidney disease and may provide novel therapeutic strategies, directed primarily toward the liver, to retard the progression of CKD in patients with combined liver and kidney disease. The emergence of newer DAAs warrant a reappraisal of the effects of sustained viral remission on the progression of CKD, to better inform our therapeutic decisions in HCV-infected patients with CKD.

QUESTIONS AND ANSWERS

Question 1

A 54-year-old man infected with HCV develops the acute onset of oliguric AKI in the setting of decompensated cirrhosis which fails to respond to diuretic withdrawal or intravenous albumin infusion. Which of the following statements about the patient is most likely to be correct?

A. The renin–angiotensin system is suppressed
B. Arginine vasopressin levels are reduced
C. Nitric oxide levels are low
D. Cardiac output is reduced
E. A beneficial effect of blockade of the renin–angiotensin system is anticipated

Answer: D

Cirrhosis is characterized by deranged liver architecture leading to increased intrahepatic vascular resistance which in turn leads to increased portal vein pressure.[1–5] Release of systemic vasodilators, classically thought to arise as a response to portal hypertension, leads to peripheral vasodilation and decreased vascular resistance. The recruitment of compensatory mechanisms to maintain renal perfusion in the face of reduced effective arterial volume constitutes the hallmark of the HRS. These compensatory mechanisms include release of systemic vasoconstrictors, upregulation of the renin–angiotensin system, and activation of the sympathetic nervous system, increased nonosmotic release of vasopressin, and increased generation of potent vasoconstrictors. In early stages of cirrhosis, increased cardiac output maintains renal perfusion. However, in advanced cirrhosis, the ability of the heart to compensate is limited by cirrhotic cardiomyopathy and cardiac output declines.

Question 2

A 35-year-old woman with alcoholic cirrhosis develops the acute onset of oliguric AKI in the setting of decompensated cirrhosis which fails to respond to diuretic withdrawal or intravenous albumin infusion. Which of the following statements about the patient is most likely to be correct?

A. TNF-α levels are suppressed
B. Interleukin-6 levels are reduced
C. Urinary biomarkers of renal injury are absent
D. Circulating pathogen-associated molecular patterns are absent
E. An inflammatory state exists

Answer: E

It has recently been suggested that the primary factor responsible for the release of vasodilatory mediators in the HRS is increased circulating levels of cytokines and chemokines resulting from chronic inflammation associated with decompensated liver disease.[2,13] Cirrhosis is associated with increased gastrointestinal permeability, altered gastrointestinal microbiome, and translocation from the gastrointestinal tract of bacteria and bacterial products into the circulation. These bacterial products along with mediators released by apoptotic and necrotic hepatocytes stimulate the production of proinflammatory cytokines and chemokines, reactive oxygen species, and nitrogen species and activate immune cells. Decompensated cirrhosis is associated with increased levels of interleukin-6, interleukin-8, and TNF-α. Renal dysfunction in patients with decompensated liver failure has been correlated with circulating levels of proinflammatory cytokines.

Question 3

A 24-year-old woman with alcoholic cirrhosis develops a slowly progressive rise in the level of S[Cr] from 0.4 to 1.6 mg/dL over 3 weeks, which fails to respond to diuretic withdrawal or intravenous albumin infusion. Which of the following statements about the patient is most likely to be correct?

A. This is the most common clinical presentation of the HRS
B. This disorder is likely to show a sustained response to intravenous albumin and terlipressin
C. Post liver transplant renal outcomes are favorably influenced by therapy with intravenous albumin and terlipressin
D. This disorder is not associated with an inflammatory state
E. Even if intravenous albumin and terlipressin improve renal function in the short term, relapse is frequent

Answer: E

HRS-CKD is uncommon, accounting for only 5–11% of patients with cirrhosis and renal dysfunction. Treatment with intravenous albumin and terlipressin or noradrenaline can reverse HRS-CKD in more than half the cases.[18,19] However, responders experience a high relapse rate early after withdrawal of therapy. Relapse may occur in two-thirds of initial responders. Treatment of HRS-CKD with albumin volume expansion and vasoconstrictors is controversial and is not recommended by international practice guidelines due to inconsistent outcomes data.[2] After liver transplantation, there was no

difference in eGFR or in the development of CKD on follow-up, ranging up to 1 year, based on response to therapy.[19]

Question 4

A 69-year-old man with stage 5 chronic kidney disease is begun on therapy with warfarin, a drug that is subject to cytochrome P450 metabolism. Which of the following statements about the patient is most likely to be correct?

A. His chronic kidney disease status will have no effect on hepatic drug metabolism
B. The patient may require a lower dose of warfarin as a result of chronic kidney disease
C. Chronic kidney disease is associated with upregulation of most cytochrome P450 enzymes
D. Parathyroid hormone is not involved in cross talk between the kidney and hepatic drug metabolism
E. Chronic kidney disease does not influence gastrointestinal absorption of some drugs

Answer: B

CKD alters the pharmacokinetics of over 75 drugs whose elimination depends on nonrenal, predominantly hepatic clearance. In general, CKD is associated with reduced hepatic drug clearance, although in some cases hepatic clearance is enhanced. The magnitude of the change in hepatic drug clearance generally correlates with the degree of renal functional impairment. The remote effects of CKD on cytochrome P450 enzymes and drug transport proteins in the liver, kidney, and gastrointestinal tract are likely mediated by both the accumulation of uremic toxins including parathyroid hormone and by the generation of cytokine mediators.

Question 5

A 24-year-old HCV-infected man presents with microscopic hematuria and nephrotic syndrome. Which of the following statements about the patient is most likely to be correct?

A. Focal and segmental glomerulosclerosis is the most likely cause of nephrotic syndrome in this patient
B. Deposition of immune complexes containing viral antigens will not be demonstrated on kidney biopsy
C. HCV infection probably did not play a role in the development of glomerulonephritis in this patient
D. Interleukin-6 levels are reduced in this patient
E. Membranoproliferative glomerulonephritis is the most likely cause of nephrotic syndrome in this patient

Answer: E

Glomerular disease is a well-described extrahepatic manifestation of HCV infection.[45–47] A systemic immune response to HCV infection is thought to contribute to glomerular injury. Glomerular disease may be mediated by HCV-antibody immune complex deposition with or without cryoglobulin formation. Deposition of immune complexes containing viral antigens has been demonstrated in mesangial and subendothelial locations. The most common histologic pattern of glomerular injury is membranoproliferative glomerulonephritis; however, membranous glomerulopathy, focal and segmental glomerulosclerosis, IgA nephropathy, immunotactoid and fibrillary glomerulopathies, amyloidosis, and thrombotic microangiopathy have been described in HCV-infected patients.

Question 6

A 35-year-old HCV-infected man with stage 5 chronic kidney disease presents for antiviral therapy. Which of the following statements about the patient is most likely to be correct?

A. Sofosbuvir is approved by the Food and Drug Administration to treat this patient
B. Newer DAA agents may be expected to achieve a SVR in 25% of such cases
C. Transplantation status is not relevant to the decision whether or not to delay antiviral therapy in this patient
D. An interferon-based regimen is preferred due to the patient's age
E. A regimen containing grazoprevir and elbasvir is approved by the Food and Drug Administration to treat this patient

Answer: E

In the past, interferon and ribavirin constituted the only treatment option for HCV, and outcomes were suboptimal because of adherence issues related to toxicity.[56] Research into the HCV life cycle identified new opportunities to arrest viral replication and infectivity within hepatocytes. The four types of DAAs that were developed include (1) NS3/4A protease inhibitors, (2) NS5A inhibitors, (3) NS5B nonnucleoside polymerase inhibitors, and (4) NS5B nucleoside polymerase inhibitors.[57] They are given for a finite duration, usually in combination, avoid the difficult adverse effects of interferon-based therapies, and are curative. The current DAA regimens approved for use in patients with advanced CKD (stages 4 and 5) include Zepatier (combination of grazoprevir and elbasvir), Viekira (combination of ombitasvir, paritaprevir, dasabuvir, and ritonavir), and Mavyret

(combination of glecaprevir and pibrentasvir). FDA approval of sofosbuvir is limited to individuals with a GFR>30 mL/min/m^2. The decision whether or not to treat an HCV-infected individuals suffering from late-stage CKD with a second-generation DAA entails consideration of the individual's kidney transplantation status. Successful treatment of an HCV-positive candidate for a deceased donor kidney may result in a substantial delay or a lost opportunity for transplantation.[96]

Chronic Kidney Disease and Heart Failure—A Nephrologic Approach

Andrew A. House[a], *Claudio Ronco*[b,c], *Charles A. Herzog*[d]

[a]Division of Nephrology, Department of Medicine, Western University and London Health Sciences Centre, London, ON, Canada; [b]Università degli Studi di Padova, Padova, Italy; [c]Department of Nephrology, Dialysis and Transplantation, San Bortolo Hospital, Vicenza, Italy; [d]Division of Cardiology, Department of Medicine, Hennepin County Medical Center and University of Minnesota, Minneapolis, MN, United States

Abstract

Increasing stages of chronic kidney disease are associated with increasing incidence and prevalence of congestive heart failure. After adjustment for multiple risk factors, even modest degrees of chronic kidney disease and/or albuminuria are associated with a significant increase in the adjusted hazard ratio of incident heart failure, underscoring the important relationship between the kidneys and the heart. Evidence supports the hypothesis that chronic kidney disease, through a variety of proposed mechanisms, contributes to significant functional and structural changes to the heart culminating in the clinical phenotype we recognize as congestive heart failure. Furthermore, chronic kidney disease and heart disease commonly coexist and may have shared pathophysiology and risk factors. In this chapter, the epidemiological association between chronic kidney disease and heart failure is examined, pathophysiology is briefly reviewed, and strategies to prevent and treat heart failure in this population are presented, both from the viewpoint of improved cardiovascular outcomes, and improved renal outcomes.

BACKGROUND

Owing to the high prevalence of heart disease in patients with chronic kidney disease (CKD), nephrologists must be well versed in the recognition and management of heart disease in this population. Cardio-renal syndrome type 4, or chronic renocardiac syndrome, has been defined as "chronic abnormalities in renal function leading to cardiac disease."[1] Within this broad category of patients, who suffer an inordinate burden of excess cardiovascular events and arrhythmias,[2] there is a significant proportion with incident and prevalent heart failure. The definition and classification of cardio-renal syndromes is presented in Table 54.1.[1] The European Society for Cardiology (ESC) defines heart failure as "a clinical syndrome characterized by typical symptoms (e.g. breathlessness, ankle swelling, and fatigue) that may be accompanied by signs (e.g. elevated jugular venous pressure, pulmonary crackles, and peripheral edema) caused by a structural and/or functional cardiac abnormality, resulting in a reduced cardiac output and/or elevated intracardiac pressures at rest or during stress."[3] Within this are categories that differ significantly in terms of ejection fraction (EF), clinical phenotype, pathophysiology, and response to treatment, namely heart failure with preserved ejection fraction, ≥50% (HFpEF); reduced ejection fraction, <40% (HFrEF); and mid-range ejection fraction, 40–49% (HFmrEF).

The characterization of a patient as having cardiorenal syndrome type 4 is predicated on the ability to temporally place the kidney disease before the development of heart failure, which is not always a straightforward task. A remaining problem to be resolved is the clinical conundrum of what actually constitutes congestive heart failure in this population. For example, a patient with advanced stage 5 CKD who consumes a large helping of pepperoni pizza may develop "cardiogenic pulmonary edema" with all of the ESC clinical and radiologic stigmata of heart failure (including elevated serum natriuretic peptides), but the main cause is really circulatory congestion. Moreover, an anuric dialysis patient (who is exquisitely sensitive to alterations in interdialytic volume status), might present to the hospital after consuming said pepperoni pizza with conventionally labeled Class IV New York Heart

TABLE 54.1 Definition and Classification of the Cardio-Renal Syndromes Workgroup Statements from the Seventh ADQI Consensus Conference.

CARDIO-RENAL SYNDROMES (CRS) GENERAL DEFINITION
Disorders of the heart and kidneys whereby acute or chronic dysfunction in one organ may induce acute or chronic dysfunction of the other
ACUTE CARDIO-RENAL SYNDROME (TYPE 1)
Acute worsening of cardiac function leading to renal dysfunction
CHRONIC CARDIO-RENAL SYNDROME (TYPE 2)
Chronic abnormalities in cardiac function leading to renal dysfunction
ACUTE RENO-CARDIAC SYNDROME (TYPE 3)
Acute worsening of renal function causing cardiac dysfunction
CHRONIC RENO-CARDIAC SYNDROME (TYPE 4)
Chronic abnormalities in renal function leading to cardiac disease
SECONDARY CARDIO-RENAL SYNDROMES (TYPE 5)
Systemic conditions causing simultaneous dysfunction of the heart and kidney

Association congestive heart failure—yet following a single ultrafiltration treatment they may be reclassified as "Class I." In dialysis patients, current heart failure classification schemas are too blunt an instrument for meaningful clinical understanding of heart failure in this special group of patients.

Clearly, it is not always possible to dissect out the temporal order of advanced CKD and (clinical) heart failure. Observational studies of CKD and heart failure often assemble a cohort of patients defined by the presence of one disease and then establish the prevalence of the other. For example, the Acute Decompensated Heart Failure National Registry evaluated over 100,000 hospitalizations for decompensated heart failure for evidence of concurrent CKD,[4] whereas a landmark study of patients newly starting on dialysis examined participants for evidence of concurrent heart failure.[5,6] This naturally leads to highly disparate estimates of coexisting CKD and heart failure. For many patients presenting with both disorders, it may be difficult to determine which of the disease processes is primary, and which is secondary, or whether in fact both are the result of shared pathophysiology or risk factors (for example hypertension or diabetes mellitus). It has been suggested that the term cardio-renal syndrome type 2/4 be used,[7] as an amalgam of type 2, (chronic abnormalities in cardiac function leading to renal dysfunction[1]) and type 4. Figures 54.1 and 54.2 (from references 8,9) illustrate the great burden of cardiovascular disease (CVD) in elderly CKD patients, particularly related to congestive heart failure.

Although these distinctions may seem somewhat artificial or arbitrary, they do assist in the interpretation of epidemiological studies and have helped focus clinical and basic investigation into the pathophysiology and treatment of heart failure in patients with CKD. In this chapter, the epidemiological association between CKD and heart failure will be examined, pathophysiology will be briefly reviewed, and strategies for the prevention and treatment of heart failure in patients with CKD will be presented, both from the viewpoint of improved cardiovascular outcomes, and improved renal outcomes. At the time of writing of this chapter, there

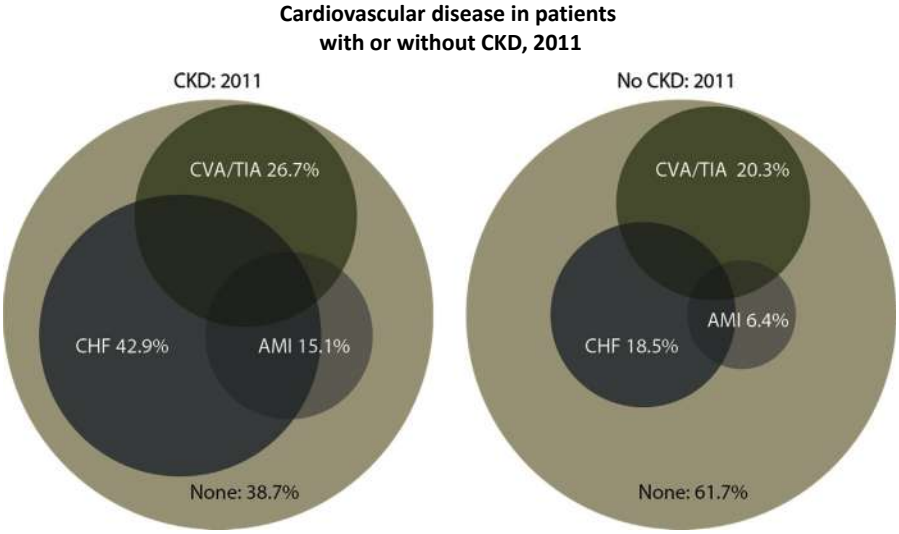

FIGURE 54.1 Cardiovascular disease burden in elderly Medicare enrollees based on presence or absence of CKD. remains a lack of any robust evidence for successfully modifying the grave outcome of HFpEF, including in the setting of CKD.[10] For this reason, discussion of prevention and treatment strategies generally refer to HFrEF, for which the strongest data are available. Although this textbook is primarily geared toward the various facets of CKD prior to reaching end-stage, there are a number of observations in dialysis patients that warrant brief discussion in this chapter.

EPIDEMIOLOGY

The independent association between CKD and the risk of CVD, events, and mortality has long been recognized. Early reports suggested that the risk associated with CKD and cardiovascular events was explained by comorbid conditions and cardiovascular risk factors.[11] As subsequent observational studies with larger numbers and greater statistical power emerged, it has become clearer that statistical adjustment for known risk factors can mitigate the association between renal function and cardiovascular events somewhat, but an independent association can be easily demonstrated. For example, a meta-analysis of nearly 1.4 million subjects found a progressive increase in all-cause mortality with declining glomerular filtration rate (GFR), and estimated relative odds of death increased in a stepwise manner to 1.9, 2.6, and 4.4 for GFR of 80, 60, and 40 mL/min respectively, compared with a reference group with GFR 100 mL/min.[12] A study by Go et al. found not only an increase in all-cause mortality but also that hospitalization for cardiovascular events, which included heart failure, coronary disease, stroke, and peripheral vascular disease, increased with each diminishing category of GFR.[13] These relationships held after sophisticated multivariable adjustment for all manner of potential confounding or influential variables. The burden of cardiovascular morbidity and mortality is particularly evident in patients with the most advanced stage of CKD, whether treated by hemodialysis, peritoneal dialysis, or kidney transplantation (Figure 54.3, from reference 8). Currently, it is believed that CVD is responsible for approximately 50% of deaths in CKD patients, regardless of age,[14] though most of these events are ischemic or arrhythmic in nature.

In the Kidney Early Evaluation Program, over 100,000 subjects screened for kidney disease self-reported the presence of a number of comorbid conditions, including congestive heart failure in 1.6% of respondents with estimated GFR >120 mL/min/1.73 m^2, increasing with every diminishing category of GFR to 14.9% for the respondents with GFR <30 mL/min/1.73 m^2.[15]

In a subset of the Chronic Renal Insufficiency Cohort Study,[16] investigators focused on 190 subjects who progressed from moderate CKD to end-stage renal disease (ESRD) and underwent serial echocardiography. Over a period of approximately 2 years where subjects progressed from advanced CKD to ESRD, there was a decrease in mean EF from 53% to 50% ($p = 0.002$), and the proportion of participants with an EF $\leq$50% increased from 29% to 48% ($p < 0.001$). During this period the frequency of self-reported congestive heart failure nearly doubled.

Lesser degrees of CKD have also been associated with development of heart failure. Investigators in the Atherosclerosis Risk in Communities (ARIC) study analyzed data from nearly 15,000 participants in a large, population-based study of adults who were followed with serial estimates of GFR.[17] Participants known to

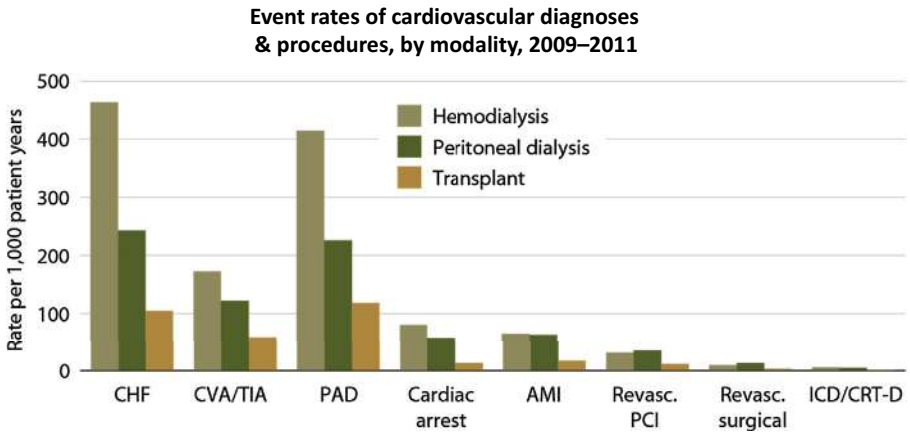

FIGURE 54.3 Rates of cardiovascular diagnoses and procedures in patients 20 years and older with end-stage renal disease treated by hemodialysis, peritoneal dialysis, or transplant. *AMI*, acute myocardial infarction; *CHF*, congestive heart failure; *CRT-D*, cardiac resynchronization therapy defibrillator; *CVA*, cerebrovascular accident; *ESRD*, end-stage renal disease; *ICD*, implantable cardiac defibrillator; *PAD*, peripheral arterial disease; *PCI*, percutaneous coronary intervention; *TIA*, transient ischemic attack. *From USRDS, reference 8.*

have preexisting heart failure were excluded, meaning that incident heart failure was captured in the analysis. They found a substantial increase in heart failure in participants with GFR <60 mL/min. Specifically, using participants with GFR ≥90 mL/min as reference, Cox proportional hazards modeling demonstrated an adjusted relative hazard of incident heart failure of 1.10 (95% CI 0.97–1.26) for participants in the range 60–89 mL/min, and 1.94 (95% CI 1.49–2.53) for participants <60 mL/min. In spite of multivariable adjustment for many known risk factors for CVD, the presence of a GFR consistent with stage 3 CKD or greater was associated with nearly a doubling in the risk of incident heart failure.

In a subsequent analysis of the ARIC study, investigators estimated GFR using not only serum creatinine concentration (S[Cr]) but also using serum cystatin C (GFRcys), and also quantified albuminuria using the albumin:creatinine ratio (ACR).[18] The addition of these biomarkers to the categorization of kidney disease strengthened the association with all-cause mortality, cardiovascular events, and incident heart failure. At every level of GFR, increasing ACR was associated with a greater adjusted hazard ratio of heart failure. Likewise within each category of ACR, decreasing GFR, particularly as estimated by cystatin C, was associated with a greater hazard of heart failure. Adjusted hazard ratios ranged from 5.6 for participants with an estimated GFRcys of 45–59 mL/min/1.73 m^2 and ACR of 30–299 mg/g to as high as 14.0 for participants with estimated GFRcys of 30–44 mL/min/1.73 m^2 and ACR ≥300 mg/g. This is illustrated graphically in Figure 54.4 (from reference 18).

These observations are all supportive of the hypothesis that CKD, through a number of posited mechanisms, can lead to significant functional and structural changes to the heart, leading eventually to the clinical phenotype of congestive heart failure. Not only is heart failure more prevalent but patients with CKD are also at higher mortality risk following the diagnosis of CVD, including heart failure. As shown in Figure 54.5 (from reference 9) there is a strong, graded relationship between heart failure mortality and CKD stage. Additional support for this association is found in a meta-analysis of 30 cohort studies comprising nearly 40,000 heart failure patients, from the Meta-Analysis Global Group in Chronic Heart Failure investigators.[19] In multivariable modeling, S[Cr] was found to be one of the five most powerful predictive variables associated with mortality, along with age, EF, New York Heart Association class, and diabetes mellitus, the association becoming evident at a S[Cr] as low as 1.25 mg/dL.

PATHOPHYSIOLOGY OF HEART FAILURE IN CKD

Various proposed mechanisms of CVD and heart failure are highlighted in Figure 54.6 (from reference 20). In brief, CKD of varying degrees can contribute to heart failure indirectly through its putative role in exacerbating ischemic heart disease, or more directly through pressure and volume overload, which increase proportionately with the decline in renal function and contribute to ventricular hypertrophy.[21] Marked hypertrophy has been shown to be highly prevalent by the time patients progress to dialysis-dependence. Ventricular hypertrophy is a frequent precursor to subsequent hospitalizations for heart failure.[22] Furthermore, the association between CKD and heart disease/heart failure may also be one of shared risk factors, such as diabetes and hypertension, or reflect widespread vascular disease and endothelial dysfunction. Pressure overload is

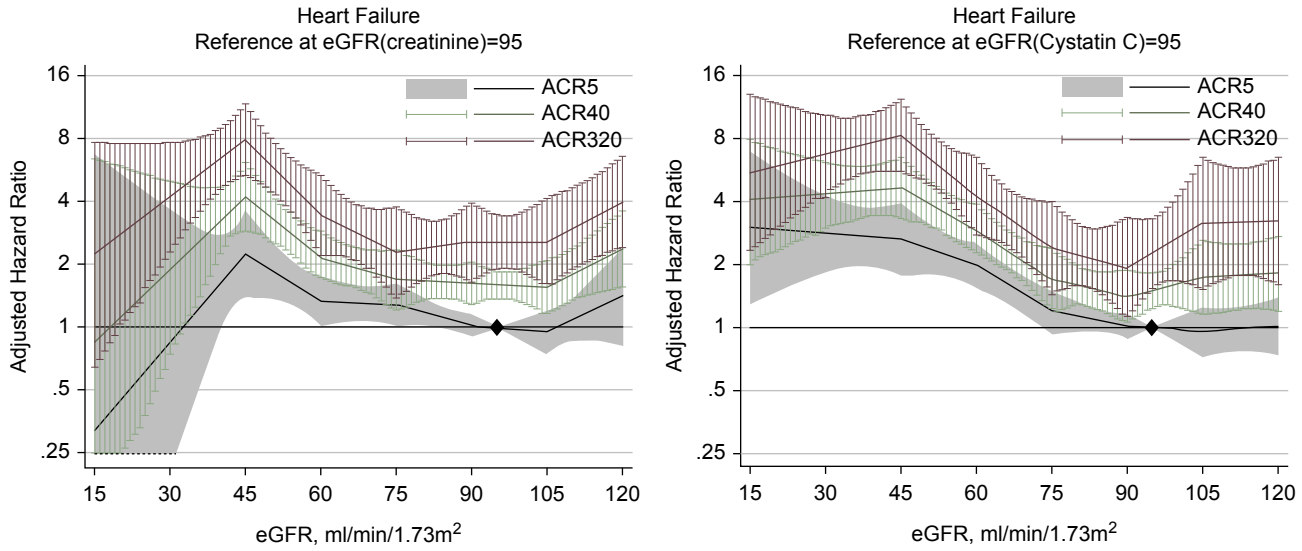

FIGURE 54.4 Hazard ratios with 95% confidence intervals of estimated glomerular filtration rate using creatinine-based or Cystatin C based estimates with heart failure in the Atherosclerosis Risk in Communities (ARIC) study. *ACR*, albumin:creatinine ratio; *eGFR*, estimated glomerular filtration rate. *Adapted from reference 18 with permission.*

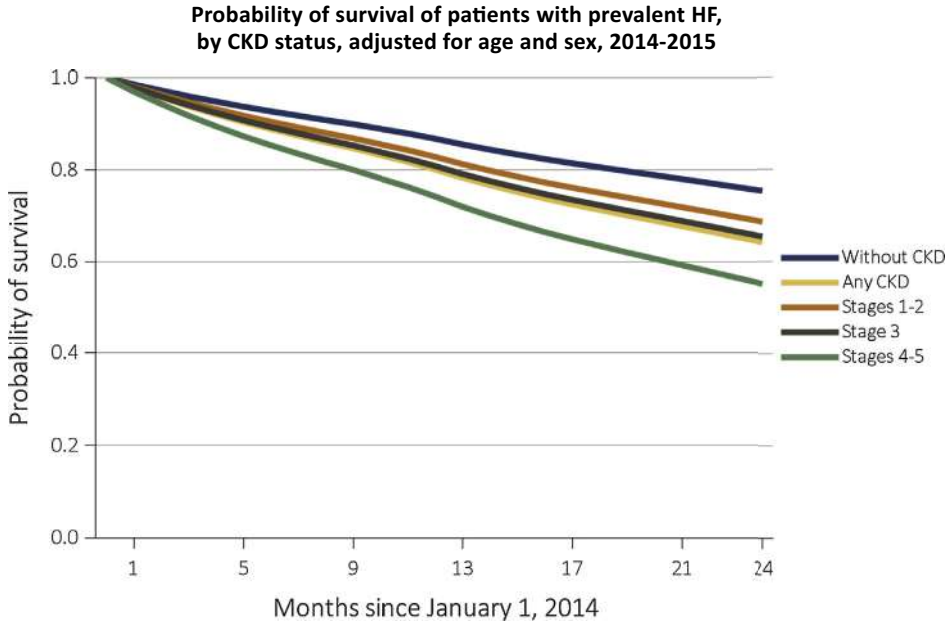

FIGURE 54.5 Probability of survival with prevalent heart failure based on stage of chronic kidney disease in elderly Medicare recipients. *CKD*, chronic kidney disease, *HF*, heart failure. *From USRDS, reference 9.*

the result of factors such as hypertension and cardiac valve calcification, which are extremely common in CKD and prevalent dialysis patients.[23,24] Phosphate retention, hyperparathyroidism, and related disorders falling under the umbrella term CKD mineral and bone disorder (CKD-MBD) lead to a progressive transformation of the vasculature and cardiac valves as they literally begin to ossify. Altered compliance of blood vessels resulting from chronic hypertension and potentially from CKD-MBD–related vascular calcification further contributes to pressure overload. Anemia and sodium retention, leading to excess extracellular fluid volume and hypertension, contribute to chronic volume overload and hypertrophy.[21] Volume overload may be further aggravated by the presence of an arteriovenous fistula or graft.[25]

With the ongoing exposure to pressure and volume overload, it is believed that increased cardiac workload

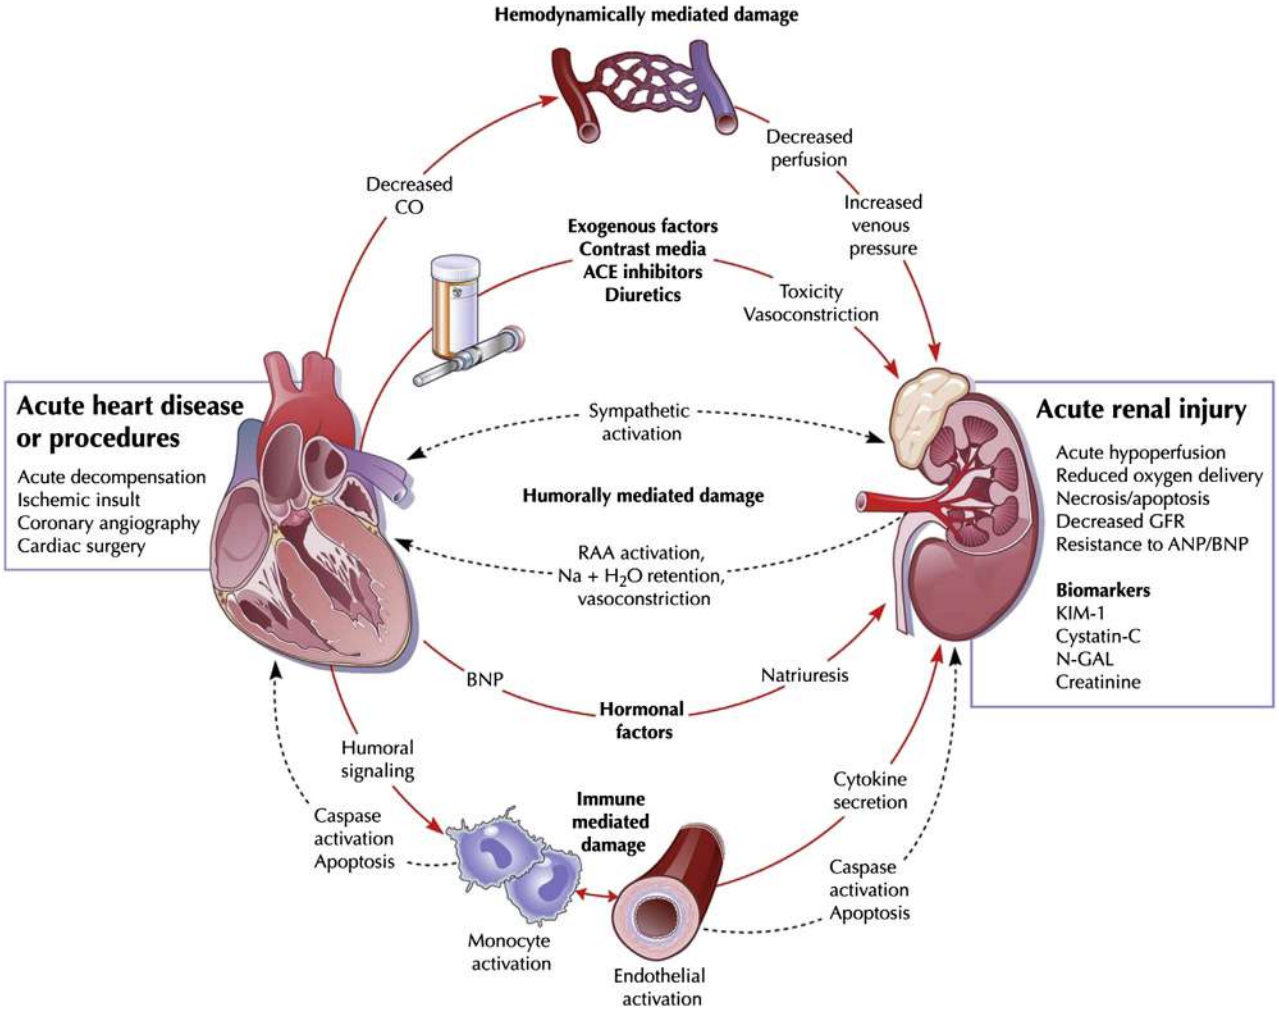

FIGURE 54.6 Pathophysiological interactions between heart and kidney in type 4 cardio-renal syndrome or "chronic reno-cardiac syndrome." *BMI*, body mass index; *CKD*, chronic kidney disease; *EPO*, erythropoietin; *LDL*, low-density lipoprotein. Figure illustration by Rob Flewell. *From reference 20 with permission.*

leads to compensatory ventricular hypertrophy. This has been shown in many other disease states to lead to the eventual outstripping of myocardial oxygen supply.[26] Myocyte death and cardiac fibrosis result, leading ultimately to chamber dilation and pump failure.[14,27] The failing heart, in turn, leads to activation of the renin–angiotensin–aldosterone system (RAAS), sympathetic nervous system, and other neurohormonal axes that themselves contribute both to worsening volume and pressure overload,[28] as well as playing a key role in progressive glomerulosclerosis and progressive kidney injury.[29,30] Finally, the recognition that some dialysis patients with severe cardiomyopathy improve following renal transplantation has led to speculation regarding some unidentified uremic myocardial depressant factor(s).[31,32]

PREVENTION AND TREATMENT OF HEART FAILURE IN CKD

The strategies of managing heart failure in CKD patients are limited by a paucity of relevant large-scale randomized controlled trials. Many pivotal trials of patients with established heart failure or myocardial infarction, with death or worsening heart failure as the primary outcome, purposefully excluded patients with significant CKD. Most studies of CKD patients typically employ composite cardiovascular endpoints as the primary outcome, where heart failure *per se* is a secondary outcome. Notwithstanding these limitations, management strategies include a selection of representative trials, both negative and positive, seeking to demonstrate the prevention of a new diagnosis of heart failure and

those treating existing heart failure. These trials are generally targeting factors described in the proposed pathogenesis of heart failure in CKD.

PREVENTION

As a general strategy to prevent incident heart failure, evidence from the SPRINT trial demonstrated that aggressive blood pressure control (targeting systolic BP to less than 120 mm Hg) could reduce new onset of heart failure in nondiabetic patients, even in the presence of CKD.[33] Similar findings in support of tight blood pressure control have been shown in patients regardless of the presence or absence of diabetes mellitus.[34]

In CKD patients, glycemic control is associated with the risk of incident heart failure.[35] Emerging evidence from the EMPA-REG OUTCOME study of around 7000 patients showed that the sodium-glucose cotransporter 2 (SGLT2) inhibitor empagliflozin reduced heart failure hospitalizations by approximately 35%.[36] This observation was also seen in patients with reduced eGFR and/or albuminuria.[37] These results were mirrored by the SGLT2 inhibitor canagliflozin in the CANVAS Program (CANVAS and CANVAS-R trials) of over 10,000 patients with type 2 diabetes mellitus.[38] It has been suggested that glycemic control was not the only factor responsible for reducing heart failure, as these drugs have diuretic effects as well as effects on the myocardium itself through cardiac Na+/H+ exchange, and changes in hematocrit had a greater association with outcome than measures of glycemic control.

The Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) Study was a double-blind, randomized, placebo-controlled study designed to evaluate the renoprotective effects of losartan in 1513 patients with type 2 diabetes and nephropathy, none of whom had heart failure at baseline.[39] Losartan resulted in a 16% reduction in the risk of the primary composite endpoint of doubling of S[Cr], ESRD, or death ($p = 0.02$). Of relevance to the prevention of heart failure in CKD patients, a significant reduction in the first hospitalization with heart failure was observed, occurring in 11.9% of the losartan group vs. 16.7% of the placebo group, a reduction of 32% ($p = 0.005$).

Similar to the RENAAL study, the Irbesartan Diabetic Nephropathy Trial (IDNT) was a double-blind, randomized, controlled study designed to evaluate the renoprotective effects of the angiotensin receptor blocker (ARB) irbesartan vs. amlodipine or placebo in 1715 patients with type 2 diabetes and nephropathy.[40] The patients in the irbesartan group had an unadjusted relative risk of reaching the primary composite endpoint of doubling of S[Cr], ESRD, or death that was 20% lower than that in the placebo group ($p = 0.02$) and 23% lower than that in the amlodipine group ($p = 0.006$). Baseline heart failure was not described, nonetheless the irbesartan group had a significantly lower incidence of congestive heart failure compared with placebo recipients (hazard ratio, 0.72 [CI, 0.52−1.00]; $p = 0.048$) or amlodipine recipients (hazard ratio, 0.65 [CI, 0.48−0.87]; $p = 0.004$).[41]

In more advanced CKD, the Fosinopril in Dialysis study was a randomized trial evaluating the safety and efficacy of angiotensin converting enzyme (ACE) inhibition with fosinopril on cardiovascular clinical outcomes in 397 hemodialysis patients with left ventricular hypertrophy.[42] Heart failure was included in the composite endpoint, which was not statistically significant between fosinopril and control groups, and heart failure outcomes alone were not reported.

TREATMENT

For CKD patients with established heart failure, the RAAS system has been an important target. For example, in the Valsartan in Heart Failure Trial (Val-HeFT), 5010 patients with class II, III, or IV heart failure were randomly assigned to receive the ARB valsartan or placebo in addition to optimal heart failure therapy, including ACE inhibition in 93% of patients.[43] Patients with S[Cr] >2.5 mg/dL were excluded from the trial, but nearly 60% of patients had an estimated GFR <60 mL/min, and 8% had dipstick positive proteinuria, allowing for a secondary analysis of the efficacy of valsartan in patients with CKD. Mortality and morbidity were highest in the patients with both reduced GFR and proteinuria, least in patients with normal GFR and no proteinuria, and intermediate in the remaining subgroups of patients. Although the addition of valsartan did not have an effect on overall mortality, the group with CKD who were randomized to valsartan did have a statistically lower rate of first morbid event (an outcome including death or heart failure hospitalization or intravenous vasoactive drug administration). An additional trial in 332 hemodialysis patients in which the ARB telmisartan was added to ACE inhibition in patients with left ventricular EF of ≤40% and followed for 3 years found a dramatic decrease in all-cause mortality and hospital admission for heart failure.[44] The former was decreased to 35.1% for the telmisartan group vs. 54.4% for control patients ($p < 0.001$). The latter was decreased to 33.9% for the telmisartan group compared with 55.1% for control patients ($p < 0.0001$).

In patients with both heart failure and CKD with eGFR 30−60 mL/min/1.73 m^2, mineralocorticoid receptor antagonists (MRAs) are generally as efficacious as they are in the absence of kidney disease.[45] Sadly, pivotal trials of MRAs in heart failure have excluded those with

more advanced CKD. The Randomized Aldactone Evaluation Study treated 1600 subjects with EF <35% using spironolactone or placebo but excluded patients with S[Cr] ≥ 2.5 mg/dL or S[K] > 5.0 mmol/L.[46] A reasonable number were included with eGFR <60 mL/min/1.73 m^2. They had similar positive outcomes in terms of mortality and heart failure hospitalization, coming at the expense of more hyperkalemia and worsening kidney function necessitating reduction or discontinuation.[47] Studies in advanced CKD are even more limited and include a large observational cohort from Taiwan indicating increased risk of death or hospitalization for heart failure among more than 1300 patients with eGFR <15 mL/min/1.73 m^2 receiving spironolactone.[48] At the time of this writing there is a randomized clinical trial of spironolactone in hemodialysis patients, which will hopefully answer questions regarding its safety and efficacy in dialysis patients with heart failure (ClinicalTrials.gov Identifier: NCT01848639).

Targeting the sympathetic nervous system in advanced CKD, a small study of 114 dialysis patients with dilated cardiomyopathy randomly compared carvedilol or placebo in addition to standard therapy. A first analysis was performed at one year and was a blinded trial. This was followed by an additional unblinded follow-up period of 12 months.[49] The primary endpoints included changes in left ventricular end-diastolic volume, end-systolic volume, EF, and clinical status 24 months after randomization. EF was 26% in both groups at baseline. Although the mean EF in the placebo group was essentially unchanged at 24% after 2 years, the carvedilol group had an early and sustained improvement to 37% ($p < 0.05$). Similar changes were seen in the other echocardiographic parameters. Heart failure symptoms were dramatically improved in the carvedilol group. At 2 years, 30 patients in the carvedilol group (51.7%) had died, compared with 41 (73.2%) in the placebo group ($p < 0.01$). There were significantly fewer all-cause cardiovascular deaths (29.3% vs. 67.9%, $p < 0.0001$) and heart failure hospitalizations (13.8% vs. 57.1%, $p < 0.0001$) among patients receiving carvedilol than among those receiving placebo.

Patients with less severe degrees of CKD have been included in several pivotal trials of beta-blockers in heart failure. For instance, the Metoprolol CR/XL Randomized Intervention Trial in Chronic HF randomized approximately 4000 symptomatic HFrEF patients to metoprolol or placebo, including approximately 500 patients with eGFR <45 mL/min/1.73 m^2. Metoprolol reduced mortality by nearly 60% for the CKD subgroup.[50] Similar results were seen in the Cardiac Insufficiency Bisoprolol Study II, which included patients with S[Cr] up to 300 μmol/L (3.4 mg/dL).[51]

A new class of agent targeting the RAAS system is the addition of a neprilysin inhibitor to an ARB, referred to as an Angiotensin Receptor and Neprilysin Inhibitor (ARNI). The first such agent LCZ696 combined sacubitril with valsartan. This agent is recommended as a replacement for an ACE inhibitor or ARB in HFrEF patients who remain symptomatic in spite of maximum optimized care. The study PARADIGM-HF (Prospective Comparison of ARNI with ACE Inhibitor to Determine Impact on Global Mortality and Morbidity in Heart Failure Trial) compared enalapril with LCZ696. It was stopped early due to a large benefit of LCZ696 in terms of overall mortality, cardiovascular mortality, hospitalizations, and HF symptoms.[52] Fewer participants randomized to LCZ696 developed worsening kidney function or high S[K]. However, the study excluded patients with eGFR <30 mL/min/1.73 m^2 at baseline or during the run-in, or any patient who developed a decrease in eGFR of >35% or high S[K] during the run-in. This limits the ability to recommend this class of drug for HF patients with CKD stage 4 or higher.

Observational data in CKD patients are also consistent with a beneficial effect of RAAS and sympathetic nervous system blockade. As shown in Figure 54.7 (from reference 53), the use of both beta-blockers and ACE inhibitors or ARBs is associated with better outcomes in elderly heart failure patients, including those with CKD. A frequently encountered problem arises when patients (particularly those with more advanced CKD) are intolerant of RAAS blockade because of significant (i.e. >30%) and persistent deterioration of kidney function or frequent hyperkalemia. In the Cooperative North Scandinavian Enalapril Survival Study, heart failure patients randomized to enalapril vs. placebo experienced a marked reduction in mortality and improvement in symptoms.[54] In a *post hoc* analysis of the data,[55] subjects in the enalapril group experienced a rise in S[Cr] to about 10−15% above baseline (usually within the first 2 weeks), consistent with the known hemodynamic effects of ACE inhibition on GFR, after which S[Cr] rose to a similar degree to the placebo group. S[Cr] doubled in significantly more patients receiving enalapril, though intercurrent illness or hypotension explained most of these occurrences. In most subjects S[Cr] returned to within 30% of baseline, including a number of patients who were able to continue on ACE inhibition at a lower dose.

Although the subgroup of truly ACE inhibitor and ARB intolerant heart failure patients has not been subjected to specific study, in clinical practice these remain a significant challenge. The fixed-dose combination of isosorbide dinitrate and hydralazine has been studied in populations that do not exclude those with CKD. One such study, the African-American Heart Failure Trial, demonstrated an early and sustained benefit of this combination when added to standard therapy in a study of over 1000 black patients with New York Heart

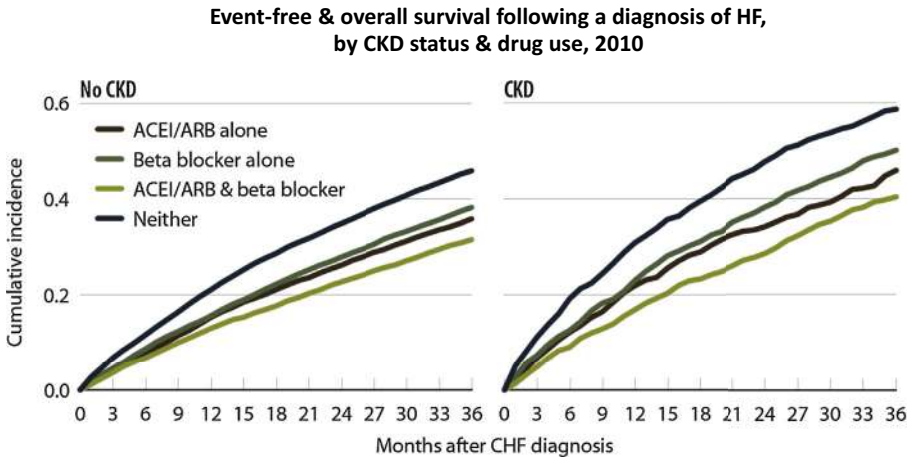

FIGURE 54.7 Survival following a diagnosis of congestive heart failure in Medicare recipients with and without a diagnosis of chronic kidney disease, accounting for use of beta blockers and renin–angiotensin blockade. *ACEI*, angiotensin converting enzyme inhibitor; *ARB*, angiotensin receptor blocker; *CHF*, congestive heart failure; *CKD*, chronic kidney disease. *From USRDS, reference 53.*

Association class III or IV heart failure.[56] The investigators found a 37% improvement in event-free survival ($p < 0.001$) and a 39% reduction in the risk for first hospitalization for heart failure ($p < 0.001$). The point estimates for risk reduction were similar in various subgroups, including patients with and without CKD, the former constituting approximately 17% of the study population. Although not as effective as the ACE inhibitor enalapril in terms of mortality and morbidity, the Vasodilator–Heart Failure Trials (V-HeFT I and II) did demonstrate that hydralazine and isosorbide dinitrate in combination confer a significant mortality benefit compared to placebo and caused less hyperkalemia and elevation of urea and S[Cr] than enalapril.[57,58] In practice, therefore, this seems a reasonable strategy to employ when RAAS blockade proves to be unsafe.

Given the link between CKD-MBD and heart outcomes in CKD patients, a number of studies have looked at agents targeting CKD-MBD. One such study, the DCOR (Dialysis Clinical Outcomes Revisited) trial, compared all-cause mortality and cause-specific mortality (cardiovascular mortality, infection, and other causes) in over 2100 hemodialysis patients treated with calcium-based phosphate binders vs. sevelamer,[59] 40% of whom were reported to have heart failure at baseline.[60] The primary outcome was not found to be different between groups, and heart failure outcomes were not described.

In the Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) trial, nearly 4000 patients receiving dialysis were randomized to receive cinacalcet or placebo.[61] The primary composite endpoint was reached in 48.1% of subjects randomized to cinacalcet and 49.2% receiving placebo for a relative hazard of 0.93 (95% CI, 0.85–1.02; $p = 0.11$). Although the primary outcome was not statistically significant, there was a modest reduction in first episode of heart failure in favor of cinacalcet, which was statistically significant with a relative hazard of 0.82 (95% CI, 0.68–0.99; $p = 0.03$).

Previous observational studies and prospective trials have suggested a potential role for 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) in congestive heart failure. Unlike many cardioprevention trials, the TNT (Treating to New Targets) study did not exclude patients on the basis of S[Cr] levels, allowing for *post hoc* analysis of this study of intensive lipid lowering with high dose atorvastatin in patients with CKD.[62] Over 3000 patients in this study, which enrolled approximately 10,000 patients with known coronary heart disease, had estimated GFR <60 mL/min. This subgroup had a mean age of 65.5 years, two-thirds were male, and 9% were current smokers and they were predominantly white (95.2%) with body mass index of 28.5 kg/m^2. Roughly 12% of these CKD patients had heart failure at baseline. After a median follow-up of 5 years, a first major cardiovascular event was experienced by 9.3% of those receiving atorvastatin 80 mg daily and 13.4% of those receiving atorvastatin 10 mg daily, a 32% relative reduction in risk with intensive lipid lowering (HR 0.68; 95% CI 0.55–0.84; $p < 0.0003$). Hospitalization for congestive heart failure was reduced by 46% in the intensive lipid lowering group (HR 0.54; 95% CI 0.38–0.77) compared with the less-intensive group, a treatment effect much more pronounced than that in the normal GFR group ($p = 0.011$ for heterogeneity). This trial cannot discern whether the effects on heart failure were due to cholesterol lowering *per se*, or some pleiotropic effect of the statin therapy.

As ventricular hypertrophy is believed to be an important step in the sequence of events leading

ultimately to chamber dilatation and heart failure, it is interesting to examine the approach taken to control of volume and uremia in the most advanced stages of CKD. The Frequent Hemodialysis Network (FHN) study[63] randomized 245 dialysis patients to three times weekly (conventional) or six times weekly (frequent) hemodialysis for 12 months. The coprimary composite outcome of the trial was (1) death or change in left ventricular mass (determined by cardiac magnetic resonance imaging), and (2) death or change in the physical health composite score of the RAND 36-item health survey. The frequent group experienced benefits in both outcomes, with a hazard ratio for death or increased left ventricular mass of 0.61 (95% CI, 0.46−0.82). This study was not powered to examine differences in death or major cardiovascular events, and episodes of new or worsening heart failure were not described, but the improvement in ventricular mass means this intervention most certainly holds promise for prevention of heart failure and merits further study. Although this study cannot be readily extrapolated back to the nondialysis CKD population, it does underscore the importance of volume and/or uremic factors in progression of ventricular hypertrophy.

Another study in this population, the IDEAL trial,[64] used a different approach to control uremic toxins and volume overload by studying early vs. late initiation of conventional dialysis. A substudy of IDEAL examined 182 subjects randomized on the basis of estimated GFR to early (GFR 10−14 mL/min/1.73 m^2) or late (GFR 5−7 mL/min/1.73 m^2) start of dialysis and followed with echocardiography at baseline and 12 months. Left ventricular mass index was elevated at baseline, but there was no significant change within or between groups at 12 months. In addition, at baseline there were echocardiographic features consistent with significant diastolic dysfunction; however, there were no differences between groups at 12 months and no changes were observed for left ventricular volumes, left ventricular EF, stroke volume, and other echocardiographic parameters. It is difficult, as with FHN, to extrapolate these data to the nondialysis CKD population, though the negative results of this intervention may suggest that waiting for dialysis-dependence to intervene to prevent progression of left ventricular mass may simply be too late.

As a number of observational studies have identified a relationship between anemia and left ventricular mass[21,65] in CKD patients, treatment of anemia has been an obvious target for treatment trials in this population. In a 24-month randomized trial of immediate vs. delayed treatment of anemia with erythropoietin in 172 CKD patients not on dialysis, Levin et al. found no statistically significant difference between groups for the primary outcome of mean change in left ventricular mass index, despite an early and sustained difference in mean hemoglobin concentration throughout the trial.[66] A meta-analysis[67] of a number of related studies, involving over 1700 CKD patients (both predialysis and dialysis), suggested that treatment of severe anemia with conventional hemoglobin targets for erythropoietin therapy (<12 g/dL) is associated with a reduction in left ventricular mass index, although these studies lacked randomly assigned, untreated controls. Studies of patients with more moderate anemia and target hemoglobin above 12 g/dL did not demonstrate a significant beneficial impact on left ventricular mass. These data, coupled with randomized controlled evidence where higher hemoglobin targets have been associated with worse outcomes, do not support the use of erythropoiesis-stimulating agents to prevent or treat heart failure in CKD.

SUMMARY

Congestive heart failure and CKD commonly coexist, and CKD patients with heart failure suffer a tremendous burden of morbidity and excess mortality. As a patient population that has previously been targeted for exclusion from clinical trials, recognition of the importance of cardio-renal syndromes has led to recent advances in our understanding of the management of heart failure in CKD. In some instances one of these disorders clearly predates and likely contributes to the development of the other. In other instances this relationship is not so clear cut and certainly could represent coexistence of disease processes with shared pathophysiology and risk factors. Nonetheless, given the important role of volume and pressure overload, along with neurohormonal activation, available clinical trial evidence supports interruption of the RAAS system as the most critical primary target for the prevention and treatment of heart failure. Additional evidence supports beta-blockade. Indirect evidence indicates a potential role for hydralazine and isosorbide dinitrate in select patients. The role of the intensity and frequency of dialysis, but not the timing of its initiation, are supported by data examining the surrogate outcome of left ventricular mass, and there is some limited evidence to indicate that CKD-MBD and lipid management may also influence the course of heart failure in CKD patients. Despite observational data and sound biologic rationale for anemia management with erythropoiesis-stimulating agents to treat or delay cardiovascular complications, this has not been borne out in clinical trials, which do indicate the potential for significant harm.

The authors agree with the recommendations found in the Kidney Disease: Improving Global Outcomes (KDIGO) 2012 Clinical Practice Guideline for the

Evaluation and Management of Chronic Kidney Disease,[68] which highlight the importance of risk factor modification to prevent CVD in the CKD population. Specifically, we recommend for all patients with CKD the following: smoking cessation; exercise; weight reduction to optimal targets; lipid modification; control of diabetes (HbA1C <7%); control of blood pressure to <140/90 mm Hg or <130/80 mm Hg in those with diabetes and/or albuminuria; aspirin for secondary prevention and correction of anemia to individualized targets. We certainly favor the use of angiotensin-converting enzyme inhibitors (ACEIs) or ARBs, particularly in those with albuminuria. It is expected that these measures will not only reduce risk of cardiovascular events and progression of CKD but also to a certain degree the risk of *de novo* heart failure.

For those who manifest signs and symptoms of congestive heart failure, KDIGO suggests that the level of care for heart failure should be the same for those without CKD.[68] We concur and would add that ACEIs or ARBs should be used regardless of stage of CKD, provided renal function does not demonstrate a persistent and significant decline (i.e. delta GFR >30%), and S[K] is carefully monitored and maintained consistently below 5.0 mmol/L. In either of these instances, dose reduction with careful monitoring or the combination of hydralazine and isosorbide dinitrate may be considered as alternatives. We recommend the use of beta-blockers having an indication in congestive heart failure, where tolerated. MRAs should be considered, recognizing that clinical trials excluded patients with moderate CKD (S[Cr] $\geq$ 2.5 mg/dL or 220 μmol/L) or hyperkalemia >5.0 mmol/L.[46] Limited data on the use of ARNI in more advanced CKD make it difficult to make a recommendation pending further study. We reserve the use of other classes of diuretics to manage symptoms of pulmonary edema and to aid in achievement of blood pressure goals. Lower limb edema, by itself, without other signs or symptoms of volume overload or threatened skin integrity does not necessarily mandate increasing diuretics, as edema is multifactorial and may not reflect central hypervolemia. Loop diuretics are the preferred class of diuretic simply based on efficacy and potency in the CKD population.

QUESTIONS AND ANSWERS

Question 1

A 52-year-old man presents for management of Stage G3bA3 CKD secondary to diabetic nephropathy. His eGFR is 34 mL/min/1.73 m^2. He has increasing shortness of breath, orthopnea, and swelling of his lower extremities.

What are the main features of the evolution of cardio-renal syndrome type 4 when CKD progresses?

A. Worsening left ventricular hypertrophy
B. Progressive cardiac remodeling
C. Decreased ejection fraction
D. Congestive heart failure
E. All of the above

Answer: E

Cardio-renal syndrome type 4 is defined as chronic abnormalities in renal function leading to cardiac disease. In a cohort of 190 CKD patients, who progressed over a period of approximately 2 years from moderate CKD to ESRD and underwent serial echocardiography, there was a decrease in mean ejection fraction from 53% to 50% ($p = 0.002$).[16] The proportion of participants with an ejection fraction $\leq$50% increased from 29% to 48% ($p < 0.001$). During this period the frequency of self-reported congestive heart failure nearly doubled. CKD, through a number of mechanisms, can lead to significant functional and structural changes to the heart, leading eventually to the clinical phenotype of congestive heart failure. Not only is heart failure more prevalent, but patients with CKD are also at higher mortality risk following the diagnosis of CVD, including heart failure.

Question 2

Which ONE of the following is NOT true regarding the association between CKD and heart disease?

A. CKD patients are at higher mortality risk following the diagnosis of CVD
B. CVD is responsible for 10% of deaths in CKD patients
C. CKD is a predictor of CVD independent of other cardiovascular risk factors
D. Decreased GFR is associated with hospitalization for events that include heart failure, coronary disease, stroke, and peripheral vascular disease

Answer: B

Answer B is not true and therefore is the correct answer for this question. CVD is responsible for approximately 50% of deaths in CKD patients, regardless of age.[14] Most of these events are ischemic or arrhythmic. **Answer A** is correct as CKD patients are at higher risk for mortailty following the diagnosis of CVD. **Answer C** is correct as observational studies have demonstrated that CKD predicts CVD independent of other risk factors. For example, a meta-analysis of nearly 1.4 million subjects found a progressive increase in all-cause mortality with declining GFR, and estimated relative odds of death increased in a stepwise manner to 1.9, 2.6, and 4.4 for GFR of 80, 60, and 40 mL/min, respectively, compared with a reference group with GFR 100 mL/min.[12]

Go et al. found not only an increase in all-cause mortality but also that hospitalization for events that included heart failure, coronary disease, stroke, and peripheral vascular disease increased with each diminishing category of GFR making **Answer D** correct.[13]

Question 3

A 62-year-old man with CKD secondary to diabetic nephropathy presented for management of congestive heart failure. His current S[Cr] is 3.8 mg/dL and eGFR is 16 mL/min/1.73 m^2.

Which ONE of the following has NOT resulted in improvement of cardiovascular outcomes in CKD patients?

A. ARB
B. Isordil
C. Beta blockers
D. Calcium-based phosphate binders

Answer: D

Answer D, calcium-based phosphate binders, has not been demonstrated to improve cardiovascular outcomes. Given the link between CKD-MBD and heart outcomes in CKD patients, the DCOR trial, compared all-cause mortality and cause-specific mortality (cardiovascular mortality, infection, and other causes) in over 2100 HD patients treated with calcium-based phosphate binders vs. sevelamer,[59] 40% of whom were reported to have heart failure at baseline.[60] The primary outcome was not found to be different between groups, and heart failure outcomes were not described. The other treatments, ARB, isordil, and beta blockers have been demonstrated in different trials to improve cardiovascular outcomes.[39–41,49,50,56]

Question 4

Which ONE of the following answers is a pathogenic factor in the development of cardio-renal syndrome type 4 in CKD patients?

A. Ischemia due to advanced vascular abnormalities
B. Sodium retention
C. Mineral and bone disorders (CKD-MBD)
D. All of the above

Answer: D

Answer D is correct as ischemia, anemia, and MBD can all contribute to the pathogenesis of cardio-renal syndrome type 4. CKD can contribute to heart failure through its role in exacerbating ischemic heart disease, or more directly through pressure and volume overload, which increase proportionately to the decline in renal function and contribute to ventricular hypertrophy.[21,22] Left ventricular hypertrophy is highly prevalent in patients with advanced CKD and dialysis-dependence.[27] Furthermore, the association between CKD and heart disease/heart failure may depend on atherosclerotic vascular disease and endothelial dysfunction. Cardiac valve calcification is extremely common in CKD due to phosphate retention, hyperparathyroidism, and related disorders falling under the umbrella term CKD mineral and bone disorder.[23,24] Sodium retention, leading to excess extracellular fluid volume and hypertension, contributes to chronic volume overload and hypertrophy. These factors and others contribute to myocyte death and cardiac fibrosis with heart dilation and pump failure.

Question 5

A 71-year-old woman with CKD Stage G4A3 secondary to diabetic nephropathy is admitted with congestive heart failure. Her estimated GFR is 20 mL/min/1.73 m^2.

Which ONE of the following is NOT true regarding management of her congestive heart failure?

A. ARBs can reduce the incidence of heart failure in diabetic CKD patients

B. ARBs improve cardiovascular outcomes in CKD patients with established heart failure

C. ARBs should not be used for CKD patients with congestive heart failure because of the risk of hyperkalemia

D. S[Cr] is likely to increase in CKD patients with heart failure started on an ACEI

Answer: C

Answer C is not true and is therefore the correct answer for this question. Patients may develop hyperkalemia making monitoring of S[K] an important component of management of these patients. However, in most patients the benefits of ARBs outweigh the risks. Both the RENAAL and IDNT studies demonstrated a decreased incidence of heart failure in diabetic CKD patients making **Answer A** true.[39,40] The Val-HeFT study targeted CKD patients with class II, III, or IV heart failure. Patients were randomly assigned to receive the ARB valsartan or placebo in addition to optimal heart failure therapy, including ACE inhibition in 93% of patients.[43] Although the addition of valsartan did not have an effect on overall mortality, the group with CKD who were randomized to valsartan had a statistically significant lower rate of first morbid event (an outcome including death or heart failure hospitalization or intravenous vasoactive drug administration) making **Answer B** true. The majority of patients treated with an ACEI (or ARB) will have a 10−15% increase in S[Cr] above baseline, usually within the first 2 weeks of starting treatment, consistent with the known hemodynamic effects of ACEIs on GFR, after which S[Cr] stabilizes, making **Answer D** true.[55] This small increase in S[Cr] is not an indication to stop treatment.

Cancer and Chronic Kidney Disease

Kenar D. Jhaveri[a], *Mitchell H. Rosner*[b]

[a]Division of Kidney Diseases and Hypertension, North Shore University Hospital and Long Island Jewish Medical Center, Zucker School of Medicine at Hofstra/Northwell, Great Neck, NY, United States; [b]Divison of Nephrology, University of Virginia, Charlottesville, VA, United States

Abstract

Nephrologists will encounter patients who develop kidney disease associated with malignancy or its treatment or will be faced with the challenges of treating patients with chronic kidney disease and cancer. To optimize clinical outcomes, knowledge regarding these issues is critically important. As the population age increases and as newer therapeutic options emerge, these issues will likely be more common and require the expertise of the nephrologist to optimize patient outcomes.

INTRODUCTION

The overall incidence of cancer is rising worldwide.[1] The relationship between cancer and chronic kidney disease (CKD) is complex. Cancer is associated with the development of numerous forms of CKD, and CKD affects cancer risk and outcomes. Although the overall incidence of CKD in cancer patients is unknown, it is known that elderly patients with cancer are at the highest risk for both *de novo* development of CKD related to the cancer, as well as having baseline CKD that may influence therapeutic decisions and outcomes associated with cancer treatment.[2]

Acute kidney injury (AKI) is common in cancer patients and can be associated with the subsequent development of CKD. The 1-year risk of AKI (defined as a >50% rise in serum creatinine concentration [S[Cr]]) in patients with cancer is 17.5%, with a 27% risk over 5 years based on a Danish population study.[3] In another study done at M.D. Anderson Cancer Center in the US, the rate of AKI was higher than the rate in most noncancer settings and was associated with poorer clinical outcomes.[4] A more recent study of patients admitted to an ICU with underlying cancer demonstrated that 59% of these patients developed AKI, mostly related to sepsis (80%), hypovolemia (40%), and urinary tract obstruction (17%).[5] This high rate of AKI is important, as many cancer patients are left with CKD following such AKI events, which ultimately affects long-term outcomes.[4]

Very few studies have evaluated the incidence and prevalence of CKD among cancer patients. One retrospective study evaluated the causes of CKD in patients who had a diagnosis of cancer in their childhood. Over 700 childhood cancer survivors were followed for changes in glomerular filtration rate (GFR).[6] The factors that were major predictors of diminished GFR later in life after experiencing treatment for childhood cancers were nephrectomy, abdominal radiation, and high-dose ifosfamide or cisplatin exposure. CKD following cancer can be a result of insults leading to ischemia, acute tubular necrosis (either due to nephrotoxins or in the setting of ischemia or sepsis), tumor infiltration of the renal parenchyma, and/or vascular, tubular, interstitial, or glomerular toxicities of chemotherapy agents. Toxicities from chemotherapy are likely the most common causes of CKD in cancer patients. In addition, because many of these patients are living longer, they are not exempt from developing CKD associated with common risk factors such as hypertension and diabetes mellitus.

CKD has a significant impact on cancer therapy and outcomes. The CANcer and DialYsis (CANDY) study, which retrospectively evaluated treatment patterns and clinical outcomes in patients undergoing chronic dialysis who subsequently developed cancer, showed that chemotherapy was omitted or prematurely stopped in many cases, or was often not adequately prescribed. Survival was poor in this cohort of patients.[7] This study highlights the challenges facing oncologists treating patients with cancer who are maintained on chronic dialysis. Unfortunately, no such study exists for CKD

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00055-3

patients not receiving dialysis. Although one French study demonstrated that few patients in their centers required dose adjustments for chemotherapy agents due to a prior diagnosis of CKD, another analysis of patients from Belgium noted that the prevalence of patients with cancer and estimated glomerular filtration rate (eGFR) <90 mL/min/1.73 m^2 was 64%.[7–9] These are important findings suggesting that GFR needs to be carefully assessed in patients with cancer.

Furthermore, for many chemotherapeutic and targeted therapy protocols, dose adjustments for suboptimal GFR are poorly defined and not evidence-based. A recent analysis demonstrated that 85% of recent trials of therapies for the five most common malignancies excluded patients with CKD.[10]

The risk of cancer in CKD patients is higher than in the general population, and CKD patients have a higher cancer-associated mortality rate.[11,12] Wong et al. analyzed a cohort of over 3000 patients over a mean of 10 years and found that men and patients with stage 3 or higher CKD had an increased risk of cancer.[11] The risk increased with GFRs starting at 55 mL/min/1.73 m^2. There was an increased risk of 29% for every 10 mL/min/1.73 m^2 decrement in eGFR.[11] The major cancers associated with CKD were of urinary origin and lung cancers. It is unclear why women had a lower risk. Weng et al. published the largest study to date analyzing cancer specific mortality in CKD.[13] In this study, CKD was significantly associated with liver cancer, kidney cancer, and urinary tract cancers. In kidney and urological cancers, increased mortality was associated with lower GFR.[13] Based on these data, there is increased risk of certain cancers with CKD. In addition, CKD appears to be a risk factor for poorer outcomes with cancer. Although not clear, an underlying proinflammatory state, altered host immunity, and poor nutritional status might be major contributors to this association. Furthermore, alterations in potentially curative therapeutic regimens may occur in the setting in CKD, which may limit efficacy.

LYMPHOMATOUS INFILTRATION OF THE KIDNEY AND CKD

A variety of cancers have been associated with infiltration of the kidney causing AKI, and much less commonly CKD. Lymphomas and leukemias have the highest risk of renal infiltration. Autopsy series have found the incidence of renal parenchymal infiltration to be 13%–40%.[14,15] However, most of these cases are not associated with changes in kidney function. Interestingly, glomerular diseases have been also noted in association with tumor infiltration of the kidney. The most common glomerular diseases in this setting have been membranoproliferative glomerulonephritis (MPGN) and MN.[16] Treatment of the underlying cancer is the most important part of management, and outcomes can be good with improvement in GFR.[17]

CHEMOTHERAPY AND TARGETED THERAPY INDUCED CKD

Many chemotherapeutic agents are associated with nephrotoxicity. Risk factors that can increase nephrotoxicity include patient age, preexisting CKD, exposure to other nephrotoxins (such as aminoglycoside antibiotics and iodinated contrast agents), and volume depletion. Most commonly, chemotherapy agents lead to electrolyte disorders or AKI, but there is significant risk of CKD from some agents. Table 55.1 lists some of the more common renal toxicities of chemotherapy agents.[18,19]

Cisplatin is a potent tubular toxin, associated with many tubulopathies.[20,21] These changes are mild and transient in most patients. Sustained elevations in S[Cr] are less common. In one study of 54 patients followed for more than 3 months, only one developed late onset azotemia.[22] Although long-term follow-up studies indicate that renal function either remains stable or improves over time, some patients may have a significant reduction in creatinine clearance despite normal S[Cr] levels.[23]

Alkylating agents such as ifosfamide, cyclophosphamide, and melphalan are used for many cancer treatments. Of these, ifosfamide is most often associated with nephrotoxicity.[24] Moderate to severe renal injury occurs when doses are above 100 g/m^2. In addition, ifosfamide may lead to long-term reductions in GFR. Farry et al. studied long-term follow-up of adult patients who received ifosfamide at a single center. There was a 15 mL/min decrease in GFR in the first year of treatment and then 22 mL/min in the next 4 years after treatment.[25]

Nitrosoureas have been noted to cause CKD. Semustine, carmustine, and lomustine are lipid-soluble alkylating agents used in treatment of brain tumors.[26,27] All three of these agents produce dose-related nephrotoxicity that can progress to CKD. In one study of over 150 patients treated with semustine and or carmustine, all patients who received more than 10 doses developed CKD.[27] Typically in these cases the urinary sediment is bland with not much proteinuria. In many patients, S[Cr] may not rise till months after treatment. Biopsy findings show extensive glomerular and interstitial fibrosis and tubular atrophy.[26]

Targeted therapies have recently evolved as promising agents for treatment of various cancers. Tyrosine kinase inhibitors and vascular endothelial growth factor

TABLE 55.1 Chemotherapy, Targeted Therapy and Immunotherapy Associated Kidney Dysfunction

Compartment of the Kidney	Toxicity	Chemotherapy Agent
Glomerular	Membranoproliferative glomerulonephritis	Gemcitabine, sirolimus
	Minimal change disease	Interferon alpha, beta and gamma, pamidronate, doxorubicin (adriamycin), daunorubicin (daunomycin), sirolimus, nivolumab
	Focal segmental glomerulosclerosis	sirolimus, temsirolimus, everolimus, doxorubicin (adriamycin), daunorubicin (daunomycin)
	Collapsing Glomerulopathy	Interferon alpha, beta and gamma, pamidronate, gefitinib, sirolimus, doxorubicin (adriamycin), daunorubicin (daunomycin), clofarabine
	Membranous nephropathy	Sirolimus
	Lupus-like nephritis	Ipilimumab
	IgA nephropathy	Sirolimus
Vascular	Thrombotic microangiopathy	Antiangiogenic agents (bevacizumab and tyrosine kinase inhibitors), gemcitabine, cisplatin, mitomycin and interferons, pembrolizumab, and nivolumab
Prerenal azotemia	Capillary leak syndrome	IL-2, denileukin diftitox, chimeric antigen receptor T-cell therapy
Tubular/interstitial	Acute tubular necrosis	Platinums, zoledronate, ifosfamide, mithramycin, pentostatin, imatinib, diaziquone, pemetrexed, clofarabine, arsenic trioxide
	Fanconi syndrome	Cisplatin, ifosfamide, azacitidine, diaziquone, imatinib, pemetrexed
	Salt Wasting	Cisplatin, azacitidine
	Magnesium wasting	Cisplatin, cetuximab, panitumumab
	Nephrogenic Diabetes Insipidus	Cisplatin, ifosfamide, pemetrexed
	Syndrome of inappropriate antidiuretic hormone	Cyclophosphamide, vincristine
	Acute interstitial nephritis	Sorafenib, sunitinib, (but can be any chemotherapy)
		Checkpoint inhibitors (ipilimumab, pembrolizumab, nivolumab)
	Crystal nephropathy	methotrexate

inhibitors are examples of such therapies. Tyrosine kinase inhibitors are classically associated with thrombotic microangiopathy (TMA). One case series reported that over time there is a chronic interstitial insult that leads to CKD in patients receiving these drugs.[28] Both sunitinib and sorafenib have been associated with acute interstitial damage and ultimately with chronic interstitial damage.[28] In addition, alectinib, a second-generation anaplastic lymphoma kinase tyrosine kinase inhibitor, has been reported to be rarely associated with progressive CKD.[29]

Many antiangiogenic agents and tyrosine kinase inhibitors lead to renal limited or systemic TMA[30] (Table 55.1). In addition, in one study examining sorafenib, among 54 patients initiating therapy, 93% had an increase in systemic blood pressure by day 6, and most experienced an increase in blood pressure by 24 hours of treatment initiation.[31] Hypertension improves when treatment is interrupted.[31] Hypertension if left untreated and severe may lead to the development of CKD. Renal limited TMA may go undiagnosed. It requires a high degree of clinical suspicion for confirmation by kidney biopsy. However, if diagnosed early, the syndrome can be reversible in some cases with cessation of the offending agent. Unfortunately, development of CKD is not unusual in patients with this syndrome.[32] In addition, all glomerular toxicities of chemotherapy agents can be potential causes of CKD if the insult is ongoing and long-term. Thus, for all agents with any potential nephrotoxicity, monitoring of GFR and urine studies should

be mandatory. Early diagnosis and rapid cessation of offending medications is critical to limit renal fibrosis and the eventual development of CKD.

Newer immunotherapies include checkpoints inhibitors such as anticytotoxic T-lymphocyte–associated protein 4 (CTLA-4) and anti-programmed death 1 (PD-1).[33] These agents have revolutionized the treatment of malignancies by engaging the patient's own immune system against the tumor, rather than targeting the cancer directly. Drugs of this class include ipilimumab, pembrolizumab, and nivolumab. These drugs have been associated with AKI that is generally immune-mediated and consistent with acute interstitial nephritis.[34] The onset of kidney injury seen with PD-1 inhibitors is usually late (3–10 months) compared to CTLA-4 antagonist–related renal injury, which happens earlier (2–3 months).[34] Glomerular diseases such as minimal change disease (MCD), MN, TMA, and lupus-like nephritis also have been rarely reported with these agents. PD-1, as opposed to CTLA-4 inhibitors, has been associated with kidney rejection in transplantation.[33] Steroids appear to be effective in treating the immune-related adverse effects noted with these agents.[33] Whether these drugs are associated with CKD is not yet clear, but vigilance in monitoring GFR over time is warranted.

PARANEOPLASTIC GLOMERULAR DISEASES AND CKD

Various kinds of cancers have been associated with glomerular diseases. The pathophysiology underlying this association in most cases is not clear. Both solid and hematological malignancies can produce abnormal tumor cell products that could lead to paraneoplastic glomerular disease. Table 55.2 summarizes the solid and hematologic malignancies that have been associated with glomerular diseases.

MN is the most commonly reported glomerular disease in patients with solid tumors.[35,36] The prevalence of malignancy in 240 patients with biopsy proved MN was around 10%.[37] Only half of these patients had cancer-related symptoms at the time of their biopsy. Most were diagnosed with cancer within a year of being diagnosed with MN.[37] The finding of nephrotic-range proteinuria in a patient with cancer or the development of proteinuria within a few months of diagnosis of cancer should raise strong suspicion of glomerular disease, especially MN.

Differentiating primary from secondary/cancer associated MN has been a great challenge for nephrologists and nephropathologists. Various studies have evaluated different parameters that could help make this distinction. These parameters could be clinical or historical clues, serological markers, or histopathological findings on the kidney biopsy.

Podocyte transmembrane glycoprotein M-type phospholipase A2 receptor (PLA2R) autoantibodies were first identified by Beck et al. in 2009.[38] It was postulated that these circulating antibodies were mainly found in patients with primary MN. Similarly, glomerular deposition of IgG4 on kidney biopsy is also a feature that has been predominantly described in patients with primary MN.[38] A study analyzed 10 patients with solid tumors and MN. Of these 10 patients, 3 had both elevated levels of anti–PLA2R antibodies and moderate glomerular IgG4 deposition on kidney biopsy. These findings suggest an underlying primary MN in these patients with solid tumors.[39] These three patients had persistence or relapse of proteinuria despite tumor resection, further supporting the notion that these were indeed patients with primary MN. Hoxha et al. showed enhanced staining of PLA2R in glomeruli of patients with primary MN compared with normal staining in tumor-associated MN.[40] Ohani et al. showed increased glomerular deposition of both IgG1 and IgG2 subtypes in patients with cancer-associated MN compared to those with primary MN.[41] Although the presence of circulating anti–PLA2R antibodies or enhanced glomerular PLA2R staining or the predominance of IgG4 in the glomeruli of patients with MN suggests primary MN even in the presence of cancer, caution is warranted in excluding malignancy solely on the basis of anti-PLA2R antibodies. A recent study by Radice and colleagues analyzed 252 consecutive MN patients and found that 7 patients with cancer were anti-PLA2R positive.[42] Thus, anti-PLA2R positivity in a patient with MN should not be considered sufficient to refrain from seeking a secondary cause, especially in patients with risk factors for neoplasia. The presence of increased inflammatory cells (more than 8 cells per glomeruli) was shown to be more suggestive of cancer-associated MN than primary MN.[37] Table 55.3 outlines features that help differentiate primary from secondary cancer-associated MN.

MCD has been associated with hematologic malignancies such as Hodgkin lymphoma, non-Hodgkin lymphoma, and other leukemias. Of all the lymphoid malignancies, MCD is classically associated with Hodgkin lymphoma, occurring in about 1% of Hodgkin's patients. MCD seems to be more frequent in Hodgkin lymphoma that exhibits a mixed cellularity and is of nodular sclerosing subtype. In one case series, the diagnosis of MCD preceded the diagnosis of lymphoma by several months; 71% of patients with Hodgkin lymphoma and MCD had systemic symptoms (i.e. fever, weight loss, and night sweats), and 90% had positive laboratory parameters suggesting an inflammatory syndrome (as

TABLE 55.2 Solid and Hematologic Malignancies Associated with Different Glomerular Diseases

Malignancy	Glomerular Diseases Reported
Lung cancer*	MN, MCD, MPGN, IgAN, FSGS, CGN, TMA
Colon cancer	MN, MCD, CGN
Stomach cancer	MN
Pancreas cancer	MN, MCD, IgAN

assessed by C-reactive protein level, sedimentation rate, and fibrinogen level).[43] Lymphoma-associated MCD is usually associated with a high frequency of steroid (50%) and cyclosporine resistance.[43] A poor response to the treatment of MCD should prompt an investigation for an underlying lymphoma. In this case series, the simultaneous diagnosis of Hodgkin lymphoma and MCD was associated with the remission of proteinuria in response to chemotherapy.[43] MCD-associated nephrotic syndrome usually relapses simultaneously with the hematologic malignancy and remains highly responsive to specific treatment for the malignancy. MCD can occur at the time of relapse even if it was initially absent, emphasizing the need to evaluate proteinuria during the follow-up of patients with Hodgkin lymphoma.

A case series of five patients described the glomerular histopathology of kidney biopsies in patients with lymphocytic leukemia and/or non-Hodgkin lymphoma.[38] Two cases of MPGN and one case each of MN, diffuse proliferative glomerular disease, and infiltrative disease were found.[44] They also reviewed 42 reported cases of glomerular diseases associated with chronic lymphocytic leukemia (CLL) from prior literature.[44] Of these 42 patients, 36 had nephrotic-range proteinuria, with the most common glomerular lesions being MPGN (35.7%) and MN (19%).

MPGN may be a subtle clue to a developing or undiagnosed lymphoplasmacytic malignancy. A study suggested an association between MPGN and monoclonal gammopathy of unclear significance (MGUS).[45] Twenty-eight patients with monoclonal gammopathy were analyzed and had bone marrow and kidney biopsies. Sixteen of them had normal bone marrow biopsies and were classified as MGUS. However, kidney biopsies from these patients showed granular immune deposits. There has been no proven relationship between the presence of monoclonal proteins and the development of MPGN. Although current observations suggest this possibility, more studies are needed to prove a causal association. This study also showed that monoclonal gammopathy in the presence of MPGN can be seen in various lymphoplasmacytic diseases, including low-grade B cell lymphoma, CLL, and multiple myeloma.[45]

There is also an association of increased cancer risk in patients with glomerulonephritis (GN). In a recent Danish study in 5594 patients with GN, 911 cancers were diagnosed.[46] Of these, 35% were prevalent at the time of kidney biopsy. Increased cancer rates were seen for minimal change disase, focal segmental glomerulosclerosis, mesangioproliferative glomeulonephritis, MN, membranoproliferative glomeulonephritis, ANCA-associated vasculitis, and lupus nephritis. Increased cancer rates were seen for lung, prostate, renal, non-Hodgkin lymphoma, myeloma, leukemia, and skin. The increased

TABLE 55.3 Differentiating Features between Primary and Solid Tumor-Associated Membranous Nephropathy (MN)

Membranous Nephropathy	Primary MN	Solid Tumor-Associated MN
Clinical Clues	Younger age, no history of smoking	Age over 65 years, smoking more than 20 pack-years
Serological	Presence of circulating anti-PLA2R autoantibodies	Absence of circulating anti-PLA2R autoantibodies
Histopathological/kidney biopsy findings	**1.** Predominance of glomerular IgG4 deposition	**1.** Predominance of glomerular IgG1/IgG2 deposition
	2. Enhanced glomerular PLA2R staining	**2.** Normal glomerular PLA2R staining
	3. Fewer than 8 inflammatory cells per glomeruli	**3.** Presence of more than 8 inflammatory cells per glomeruli

incidence was mainly limited to −1 to 1 year after biopsy, but skin cancer showed an increased risk over time. The diagnosis with the highest risk for cancer was membranoproliferative glomeulonephritis.

CKD ASSOCIATED WITH HEMATOPOETIC STEM CELL TRANSPLANTATION

CKD is now an increasingly important complication following hematopoetic stem cell transplantation (HSCT). Hingorani et al. found that CKD was identified in 23% of recipients surviving at least 3 months after HSCT.[47] AKI and graft vs. host disease (GVHD) were noted as risk factors for the development of CKD. Another study found that the average fall in GFR in patients that develop CKD is 24.5 mL/min/1.73 m^2 over 24 months.[48] Approximately 16.6% patients who underwent HSCT developed CKD.[48] Most of these patients were treated with nonmyeloablative protocols. The growth in nonmyeloablative protocols may actually increase the risk of CKD as older patients with more comorbidities become candidates for this procedure. Calcineurin inhibitors (CNIs), which are used for prophylaxis and treatment of GVHD, have been associated with the development of nephrotoxicity and may contribute to the development of CKD. Hypertension and TMA are two comorbidities linked to the development of CKD.[49–51]

Myeloablative allogeneic HSCT protocols can lead to low-grade TMA that over time leads to CKD. This has also been termed bone marrow transplant nephropathy or radiation nephropathy, which resembles the hemolytic-uremic syndrome or thrombocytopenic thrombotic purpura (TTP).[49] Diagnostic criteria for HSCT-related TMA include >4% schistocytes in blood smears, *de novo* prolonged or progressive thrombocytopenia, sudden or persistent increase in lactate dehydrogenase levels, decreased hemoglobin concentration, and decrease in serum haptoglobin concentration.[50] Clinically, nonnephrotic proteinuria, worsening hypertension, and renal dysfunction are adequate to diagnose TMA in most of these patients. Hypertension is usually the first sign of beginnings of renal limited TMA in many of these cases. Thrombocytopenia may be a major hindrance in performing kidney biopsies in these patients. Classically, risk factors associated with the development of TMA following HSCT include use of CNIs, allogeneic transplantation, total body irradiation use, older age, female gender, acute GVHD, and high-dose chemotherapy.[50] Acute GVHD grade 2–4, hepatic GVHD and venoocclusive disease, adenovirus infection, older age, female gender, and total body irradiation greater than 12 Gy are likely risk factors for the development of TMA.[52,53] In immune-depleted (T cell-depleted) patients where GVHD does not exist nor does the use of CNIs, TMA was likely to still occur, but only in the group that received total body irradiation.[54] Some have considered HSCT-associated TMA an "endothelial" variant of GVHD. HSCT-associated TMA is usually treated supportively, including control of hypertension and proteinuria. Due to the absence of randomized controlled trials, plasma exchange cannot be considered a standard of care for patients with HSCT-associated TMA.[55,56] Other agents such as rituximab and eculizumab have limited data on treatment of HSCT-associated TMA.

Glomerular disease can be a cause of CKD following HSCT. In HSCT patients with nephrotic-range proteinuria, renal biopsy findings may include MN, MCD, and focal and segmental glomerulosclerosis (FSGS).[57] However, MN accounts for a majority of the cases of HSCT-associated glomerular diseases, whereas MCD accounts for most of the remaining cases.[57] Host and donor marrow chimerism in addition to the presence of host lymphocytes surviving conditioning may be risk factors for MN after HSCT.[58] Brukamp et al. conducted a meta-analysis of 46 cases who had HSCT and glomerular disease.[57] Their study revealed a close temporal relationship between the development of nephrotic syndrome shortly after cessation of immunosuppression and the diagnosis of chronic GVHD. The majority (61%) of these patients had MN and 22% had MCD.[51] Other causes included FSGS, IgA nephropathy, and mesangial proliferative disease.

In patients who receive low-intensity HSCT, there is a higher chance of glomerular GVHD.[59,60] Nonmyeloablative HSCT was identified as a risk factor for nephrotic syndrome in a cohort study.[59] Of 163 patients with nonmyeloablative HSCT, 7 developed nephrotic syndrome compared to none of the 118 patients in the myeloablative HSCT cohort. The etiology and pathogenesis of nephrotic syndrome after allogeneic HSCT were elucidated by Luo et al.[59] They compared 257 patients with nephrotic syndrome after allogeneic HSCT with nonnephrotic syndrome patients. They concluded that there was association of occurrence of chronic GVHD in patients with nephrotic syndrome after allogeneic HSCT.

In contrast to the above mentioned studies, a retrospective analysis of 95 cases showed that chronic GVHD in HSCT patients with glomerular disease was not different than what is observed in the overall HSCT population.[60] Autologous HSCT recipients also develop glomerular diseases but do not experience GVHD.[61] It is possible that immune dysregulation caused by the induction agents might cause nephrotic syndrome in this population. With improving life expectancy, it is also possible that these glomerular diseases are *de novo* and unrelated to HSCT. T cell-depleted HSCT recipients are highly unlikely to develop glomerular diseases, and no such instances have been reported so far.

CHRONIC KIDNEY DISEASE ASSOCIATED WITH RENAL CELL CARCINOMA

In the US, it is estimated that there will be over 64,000 incident cases and 13,700 cancer-related deaths from renal cell carcinoma (RCC) per year.[62] Given the age and comorbid conditions in this patient population, it is not surprising that 25% of patients with RCC have CKD.[63] In fact, approximately 10% of tumor nephrectomy specimens demonstrate features of diabetic nephropathy, 2–9% may have FSGS and another 20% show hypertensive nephrosclerosis.[64] In the past, radical nephrectomy was considered the treatment of choice for isolated RCC or solitary renal masses (SRM). However, there is increasing awareness that radical nephrectomy is associated with a higher risk of CKD. Therefore, there has been a shift to partial nephrectomy as the treatment of choice for RCC.[65–67] Huang et al. reported the probability of being free from a GFR less than 60 mL/min/1.73 m^2 5 years after the procedure was 67% and 23% for partial and complete nephrectomy respectively, with no difference in oncologic outcome.[68] Furthermore, the lower risk of CKD following partial nephrectomy has translated to improved overall survival for patients with localized RCC.[66,67,69,70] In a pooled analysis of 41,010 patients, partial nephrectomy was associated with a 61% risk reduction in developing CKD and 19% risk reduction for all-cause mortality.[71] The American Urological Association released a position statement in 2009 that partial nephrectomy (nephron-sparing surgery) is preferred for T1 tumors (less than 7 cm in size) as the oncologic outcomes are equivalent to radical nephrectomy and the preservation of kidney function is beneficial for long-term outcomes.[72] Most recently, the American Society of Clinical Oncology (ASCO) published guidelines on the management of small renal masses (incidentally image-detected, contrast-enhancing renal tumors $\leq$4 cm in diameter) that further highlights the recommendation for "nephron-sparing surgeries" such as partial nephrectomy over radical surgical approaches.[73] This guideline recommends that radical nephrectomy should only be considered for patients with anatomically complex small renal masses for whom partial nephrectomy might result in unacceptable morbidity.

A recent study also highlights that "surgically induced CKD" such as that occurring after nephrectomy is more stable than CKD due to medical causes such as diabetes.[74] This is especially true if the postoperative GFR is >45 mL/min/1.73 m^2. However, all patients undergoing either partial or radical nephrectomy should have close nephrology follow-up with close attention to treatment of risk factors for CKD progression.

KIDNEY DISEASE ASSOCIATED WITH PLASMA CELL DYSCRASIAS AND PARAPROTEINS

Plasma cell disorders encompass a spectrum of diseases that include multiple myeloma, immunoglobulin (Ig)-mediated amyloidosis, plasmacytomas, and the premalignant condition of MGUS. Kidney involvement in these disorders is common and abnormal GFR is seen in up to half of myeloma patients at the time of presentation.[75] Abnormal kidney function in patients with multiple myeloma significantly contributes to excessive mortality and can limit clinical outcomes associated with both systemic therapies and stem cell transplantation (SCT).[76]

Kidney injury associated with plasma cell cancers can be divided into Ig-dependent and Ig-independent mechanisms, although in any particular patient, several mechanisms may be operative.[77] Virtually all nephropathological syndromes have been observed with Ig-dependent kidney involvement (Table 55.4). However, three distinct syndromes account for the vast majority of Ig-mediated kidney disease: (1) cast nephropathy, in which proteinaceous deposits consisting of filtered monoclonal Igs in combination with other urinary

TABLE 55.4 Kidney Involvement with Plasma Cell Dyscrasias

Immunoglobulin Dependent	Immunoglobulin Independent
Cast nephropathy	Hypercalcemia
Monoclonal immunoglobulin deposition disease	Tumor lysis syndrome
AL amyloidosis	Medication-related toxicity: bisphosphonates, other drugs
Membranoproliferative, diffuse proliferative, crescentic and cryoglobulinemic glomerulonephritis	Renal invasion by plasma cells
Minimal change disease	Pyelonephritis
Membranous glomerulonephritis	
Immunotactoid and fibrillary glomerulonephritis	
IgA nephropathy	
Tubulointerstitial nephritis	
Thrombotic microangiopathy	

proteins (such as Tamm–Horsfall protein) obstruct the renal tubules as well as elicit an accompanying tubulointerstitial nephritis that typically results in AKI; (2) monoclonal Ig deposition disease (MIDD), characterized by the deposition of monoclonal proteins in the glomerulus and tubular basement membranes leading to local tissue injury; and (3) AL amyloidosis, where monoclonal light chains with specific physiochemical properties form β-pleated sheet structures that deposit in the glomeruli and lead to local tissue injury. Ig-independent mechanisms of kidney injury include volume depletion, sepsis, pyelonephritis, hypercalcemia, uric acid nephropathy, tumor lysis syndrome, rhabdomyolysis, direct parenchymal invasion by plasma cells, and drug-induced causes (including nonsteroidal anti-inflammatory agents, bisphosphonates, and renin–angiotensin system inhibitors).[77] The Ig-dependent processes typically are associated with more chronic presentations as well as with predominant glomerular pathologies. An exception is cast nephropathy that usually presents as AKI.

Given the wide spectrum of kidney disease associated with plasma cell disorders, kidney biopsy is recommended when any of these etiologies is suspected. Suspicion should be based on clinical findings such as fatigue, weight loss, bone pain, and orthostatic hypotension or the presence of autonomic neuropathy coupled with laboratory abnormalities such as anemia, hypercalcemia, proteinuria, Fanconi syndrome, and a low anion gap (due the presence of an excess of cationic light chain proteins). Urine dipstick analyses typically do not detect light chains, but tests of total urine protein are abnormal. Thus, a negative urine dipstick test for albumin and the simultaneous detection of significant urine total protein is highly suggestive of light chain proteinuria and requires further testing. Both MIDD and AL amyloidosis typically present with nephrotic-range proteinuria and albuminuria indicative of global glomerular damage.

Detection of Monoclonal Ig

Previously, the detection of monoclonal Ig proteins was with protein electrophoresis and immunofixation, which had significant limitations both in their diagnostic and prognostic abilities.[78] Newer free light chain (FLC) assays are much more sensitive in detecting kappa and lambda light chains in the serum and are complementary to the traditional detection methods.[79] Although elevations in FLCs can be seen in numerous inflammatory conditions, abnormalities in the kappa:lambda ratio indirectly suggest clonal expansion specifically seen with plasma cell disorders.[79] Furthermore, in newly diagnosed myeloma patients, high serum FLC levels are associated with an increased risk of kidney injury.[80] However, it is critically important to analyze the value of FLC ratios in the context of GFR. Because impaired GFR will lead to decreased clearance of FLCs, the normal values of FLC and their ratios are changed in patients with CKD. Therefore caution is warranted in interpreting these values when the GFR is abnormal.[81]

Although accumulation of FLCs has been observed in patients with CKD, the question arises regarding whether these polyclonal increases in kappa and lambda light chains may influence progression of CKD. Thus far, data in this area have not been conclusive.[82]

Monoclonal Ig Deposition Disease

Multiple myeloma is the most common underlying disease associated with MIDD (40–50% of cases). Biopsy proven MIDD can precede the clinical detection of a paraprotein in up to 15–30% of cases.[83] MIDD is typically

associated with kappa light chains, which may have atypical glycosylation or amino acid substitutions that promote misfolding and precipitation.[84] Although the majority of cases of MIDD are due to deposition of light chains, heavy chain and light and heavy chain deposition can also be found.[83] On light microscopy, MIDD demonstrates thickening of the tubular and glomerular basement membrane, as well as the presence of glomerular nodules very similar in appearance to the classic Kimmelstiel-Wilson lesions of diabetic nephropathy. Most patients with MIDD present with isolated renal involvement, although cardiac and liver disease occasionally can be seen as well. Patients are typically younger than those with multiple myeloma or amyloidosis, and males are more often affected than females. Presentation is typically with decreased GFR, hypertension, and nephrotic-range proteinuria with a rapidly progressive course in the absence of chemotherapy. Chemotherapy stabilized or improved renal function in two-thirds of patients with MIDD who presented with S[Cr] of <5.0 mg/dL, emphasizing the importance of early detection and therapy.[83] The prognostic significance of kidney involvement is highlighted by the fact that the initial S[Cr] is the strongest predictor of renal and patient survival in MIDD.[83]

AL Amyloidosis

AL amyloidosis results from extracellular deposition of fibril-forming monoclonal immunoglobulin light chains (most commonly of the lambda isotype), which are usually secreted by a small plasma cell clone.[85] Most patients have evidence of isolated monoclonal gammopathy or smoldering myeloma. The occurrence of AL amyloidosis in patients with symptomatic multiple myeloma is unusual. AL amyloidosis affects men slightly more often than women. The average age of diagnosed patients is 65 years and around 10% of patients are less than 50 years old.[86] The key event in the development of AL amyloidosis is the change in the secondary or tertiary structure of an abnormal monoclonal light chain, which results in a conformation that leads to assembly into monomers that stack together to form amyloid fibrils.

Clinical presentations can be varied because of the wide number of tissues or organs that may be affected. Kidney involvement is the most frequent, found in two-thirds of patients at the time of diagnosis. The characteristic presentation is with heavy proteinuria (composed mainly of albumin, with detectable urine monoclonal Ig light chains in most cases), with nephrotic syndrome and decreased GFR in 20–45% of cases.[87] As opposed to MIDD, hypertension and hematuria are usually absent.[88] Although it has been stated that increased kidney size is characteristic of AL amyloid nephropathy, this is not a constant feature.[89] The diagnosis of renal amyloidosis relies on the pathological demonstration of renal amyloid and/or, when a kidney biopsy is not available, on histological evidence from another tissue with proteinuria ≥0.5 g/day predominantly composed of albumin.[90] Cardiac involvement, which is present at diagnosis in more than 50% of patients, leads to restrictive cardiomyopathy.

The diagnosis of amyloid is based on the finding, by light microscopic examination, of amorphous extracellular Congo red positive deposits, which display characteristic dichroism and apple green birefringence under polarized light. Whenever possible, noninvasive biopsies of abdominal fat and minor salivary glands should be performed initially.[91] If these tissue biopsies fail to demonstrate amyloid deposition, or are insufficient for amyloid typing, biopsy of a clinically affected organ should be considered. When a kidney biopsy is performed in patients with renal involvement, it allows identification of Ig light chain amyloid deposits in more than 80% of cases.[87] Deposits predominate in the mesangium and along the glomerular basement membranes. Interstitial and vascular deposits are also frequently observed. Electron microscopy may be useful to confirm the presence of amyloid deposits, which typically display the ultrastructural appearance of randomly arranged fibrils, 7–10 nm in external diameter.[87]

Treatment of systemic AL amyloidosis relies mainly on chemotherapy aimed at suppressing the underlying plasma cell clone secreting amyloid-forming Ig light chains. The presence of significant cardiac involvement is the greatest predictor of poor long-term outcomes.[92]

Monoclonal Gammopathy of Unclear Significance and CKD

Both CKD and MGUS are common independent findings in patients over 50 years. There does not seem to be an association between the presence of FLCs and the risk of developing ESRD in these patients.[93] However, persistent or rising levels of monoclonal Ig combined with unexplained or worsening CKD may warrant a renal biopsy to document Ig deposition in the kidney. Such a syndrome has been termed monoclonal gammopathy of renal significance.[94] Both AKI and progressive CKD are reported prodromes for the development of multiple myeloma.[94] However, routine screening of the CKD population for multiple myeloma is of limited value and the decision to perform specific diagnostic testing for light chains should be guided by the presence of additional features consistent with myeloma.[95]

Treatment Issues in the Patient with CKD

Given the risk of rapid progression of monoclonal Ig-induced kidney injury, rapidly acting chemotherapeutic

agents need to be instituted as quickly as a diagnosis is established. The greatest likelihood of preserving kidney function is with early, effective therapy.

A cornerstone of therapy is the proteasome inhibitor bortezomib, which along with dexamethasone, is highly effective in treating plasma cell disorders when kidney injury is present.[96] A novel feature of bortezomib is that it inhibits the NF-κB and MAP kinase pathways, potent anti-inflammatory properties that may have beneficial effects in mitigating renal injury.[97] When bortezomib is combined in various regimens with dexamethasone, melphalan, doxorubicin, or thalidomide, 40–50% of patients who respond to therapy have significant improvement in kidney function within a few weeks.[98–100] Bortezomib does not require dosing adjustments for decreased GFR.

Another chemotherapeutic agent of benefit is thalidomide and its newer derivative lenalidomide, which are usually combined with dexamethasone. Thalidomide does not require dose adjustment with renal dysfunction, but lenalidomide does require reduction in dose. Myelosuppression is more common in patients with CKD treated with thalidomide or lenalidomide.[101] Thalidomide, lenalidomide, and dexamethasone are associated with a higher risk of thrombotic events, which can be exacerbated by nephrotic syndrome and/or erythropoietin use and may complicate the placement of arteriovenous access if needed for dialysis.[89]

Plasmapheresis remains a controversial therapy for monoclonal Ig-associated kidney diseases. An option to increase the removal of nephrotoxic FLCs is the addition of plasmapheresis or hemodialysis with a "high-cutoff" membrane, which allows for the removal of larger molecular weight proteins (up to 50 kDa). The goal is to rapidly decrease FLC levels. One study demonstrated that a 60% reduction in FLC levels by day 21 after diagnosis is associated with kidney recovery in 80% of cases.[102] Initial studies of the treatment of light chain nephropathy with plasmapheresis remains controversial and are not applicable to modern day bortezomib-based therapy.[103] Two recent clinical trials, the Studies in Patients with Multiple Myeloma and Renal Failure Due to Myeloma Cast Nephropathy (MYRE) and the European Trial of Free Light Chain Removal by Extended Hemodialysis in Cast Nephropathy (EuLITE) have reported using extracorporeal therapy in addition to bortezomib-based therapy in patients presenting with newly diagnosed myeloma and a need for acute dialysis.[104,105] The MYRE study randomized 98 patients to either standard high-flux hemodialysis (HF-HD) or to high-cutoff HD (HCO-HD). There was no difference in the primary endpoint of dialysis independence at 3 months between the HF-HD and HCO-HD groups (33% vs. 43%, respectively; $p = 0.31$). However, at 6 months, more patients in the HCO-HD arm than the control group were independent of dialysis (60% vs. 38%, respectively; $p = 0.03$). The difference at 6 months was tempered by concern that the renal response to bortezomib in the HF-HD group was less than had been seen in other studies, suggesting that this population may have been atypical.[104,105] The EuLITE study randomized 90 patients in a similar manner to the MYRE study to either HF-HD or HCO-HD in addition to bortezomib-based chemotherapy. However, the dialysis regimens in the EuLITE study were significantly different than the MYRE study, making comparisons difficult. However, at 3 months there was no difference in kidney recovery between the HF-HD and HCO-HD groups (55.8% vs. 51.6%, respectively; $p = NS$). Given that both studies were small, with equivocal results, the routine use of HCO-HD cannot be routinely recommended.

HSCT is an option for patients with myeloma and renal failure but requires dose-adjustment in conditioning regimens with an increased risk for toxicity.[106] There are small numbers of patients with myeloma and ESRD that have undergone combined kidney and allogeneic HSCT from an HLA-identical sibling without the requirement for immunosuppression.[107]

Most centers require that patients with myeloma achieve and maintain a durable remission for at least 3–5 years before being considered for transplantation.[108] Kidney transplantation is possible in highly selected patients with MIDD or AL amyloidosis once they have achieved hematologic remission, usually after HSCT.[109] For those patients with MGUS and ESRD, data on kidney transplantation are limited, but there is concern that the progression to myeloma may be accelerated by immunosuppression.[110] Thus, Ig levels should be monitored closely and should be stable before transplantation.

MANAGEMENT OF ANEMIA IN THE PATIENT WITH CKD AND CANCER

Erythropoiesis-stimulating agents (ESAs) have been extensively used to reduce transfusion requirements and improve quality of life (QOL) in both cancer and CKD patients.[111,112] However, the likelihood of response and duration of treatment differs in the two settings. In renal anemia, ESAs act as hormone-replacement therapy substituting for the loss of production of endogenous erythropoietin and are thus part of chronic therapy. In the cancer patient, although endogenous erythropoietin production may be suppressed by the tumor and particularly by the release of inflammatory mediators, anemia is usually a side effect of chemotherapy. Thus, ESAs are administered not as maintenance therapy but as an

aspect of acute patient support. Response to ESAs is slower and less certain in cancer patients than in those with CKD.[113] In both settings, early studies showed that reversal of severe anemia was accompanied by substantial improvement in QOL.[111,112] However, again in both settings, subsequent studies indicated that efforts to *normalize* hemoglobin might worsen outcomes, including survival.[114–118] This concern was reinforced by the suggestion that malignant cells had erythropoietin receptors and that administration of ESAs might therefore accelerate tumor growth. Moreover, cancer patients treated with ESAs are more susceptible to venous thrombosis.[119] The ASCO and the American Society of Hematology synthesized available data in its most recent practice guidelines, which are abstracted in Table 55.5.[120] When approaching the patient with CKD, the clinician should determine if the use of ESAs is due to underlying CKD or associated with chemotherapy-induced myelosuppression. In either case, an individualized approach that minimizes the risks of ESAs and targets a hemoglobin level that minimizes the need for transfusion should be instituted. Those patients with CKD and associated myelosuppression may not respond to ESA therapy. Careful monitoring with a time-limited trial is recommended. Those patients with chemotherapy-induced anemia may only require ESA support for a short period of time. However, those patients with significant CKD may require continued ESA support.

TABLE 55.5 Recommendations for erythropoiesis-stimulating agent (ESA) Use for Patients with Cancer

1. The use of epoetin or darbepoetin is recommended as a treatment option for patients with chemotherapy-associated anemia and an Hb concentration that has decreased to less than 10 g/dL to decrease transfusions. RBC transfusion is also an option, depending on the severity of the anemia or clinical circumstances. Patients should be counseled on the specific risks and potential benefits of ESA use.
2. An optimal level to initiate ESA therapy in patients with anemia and Hb between 10 and 12 g/dL cannot be definitively determined from the available evidence. Under these circumstances, whether or not to initiate ESA treatment should be determined by clinical judgment, consideration of the risks and benefits of ESAs, and patient preference
3. Clinicians should carefully weigh the risks of thromboembolism in patients for whom epoetin or darbepoetin is prescribed
4. It is recommended that starting and modifying doses of ESA follow FDA guidelines
5. Continuing epoetin or darbepoetin treatment beyond 6–8 weeks in the absence of response (e.g. a 1–2 g/dL increase in Hb or no diminution of transfusion requirements) does not seem to be beneficial
6. Hb can be increased to the lowest concentration needed to avoid transfusions, which may vary by patient and condition. An optimal target Hb concentration cannot be definitively determined from the available literature. Modification to reduce the ESA dose is appropriate when Hb reaches a level sufficient to avoid transfusion or the increase exceeds 1 g/dL in any 2-week period to avoid excessive ESA exposure

CHEMOTHERAPY AND TARGETED THERAPY DOSING IN CKD

The kidneys are one of the major routes of elimination for most chemotherapy agents. Hence dose adjustments are required when most chemotherapy agents are administered to patients with CKD. It is often challenging, as these agents also have a very narrow therapeutic index. Many chemotherapy and targeted therapy trials have excluded patients with severe CKD. As a result, the patient with CKD may receive either too little or too much chemotherapy. Dosing guidelines often do not have a significant evidence basis for chemotherapy use in CKD patients. In addition, the method of calculating dose adjustments in patients with CKD, extrapolating from pharmacokinetic data, may not always conform with clinical practice. CKD status and the uremic milieu can lead to altered hepatic metabolism of drugs.[121] Despite these issues, CKD patients receiving chemotherapy or targeted therapies constitute a large group of patients that need proper dosing of agents. A list of common chemotherapy and targeted therapies agents requiring dose adjustments is presented in Table 55.6.[122–124]

SUMMARY: ONCONEPHROLOGY, A NEW FOCUS IN NEPHROLOGY

All nephrologists will encounter kidney disease in patients with cancer. The kidney disease may be preexisting and may affect dosing of chemotherapy, or the kidney disease may be a manifestation of the malignancy or its therapy. In each case, the nephrologist requires an understanding of the kidney diseases associated with malignancy. The nephrologist should also be a member of the team caring for patients with CKD and cancer, offering input into medication dosing and monitoring of GFR and electrolytes. Some have termed this intersection of kidney disease and cancer, onconephrology (encompassing both hematology and oncology related kidney diseases). The goal is that onconephrologists will help cancer care teams prevent kidney problems or resolve them as they arise and improve patient outcomes.

TABLE 55.6 Chemotherapy Dose Adjustments in Chronic Kidney Disease Patients

Chemotherapy Agents	Dose Adjustment Required for eGFR 10–50 mL/min (%)	Dose Adjustment Required when eGFR <10 mL/min (%)	Evidence Level
Capecitabine	75	50–75	B
Cisplatin	75	50, avoid if possible	A
Carboplatin	50 (AUC based)	50	D
Chlorambucil	75	50	B
Ifosfamide	100	75	B
Cyclophosphamide	100	75	D
Cytarabine	50	10	D
Dacarbazine	75 for eGFR 60–45	70	D
Doxorubicin	100	100	D
Daunorubicin	100	100	D
Epirubicin	100	100	D
Etoposide	75	50	B
Carmustine	75 for eGFR 30–60	Avoid if eGFR<30	D
Lomustine	70 for eGFR 30–60	Avoid if eGFR<30	B
Semustine	70 for eGFR 30–60	Avoid if eGFR<30	B
Streptozocin	75	50	D
Mitomycin C	100	75	B
Mithramycin	75	50	B
Azacitidine	100	100	B
Gemcitabine	100	100	B
Cytarabine	100	100	D
Methotrexate	50	Avoid	A
Pentostatin	60 for eGFR 30–60	Avoid when eGFR <30	B
Fludarabine	75	50	D
Cladribine	75	50	D
5-Fluorouracil	100	100	B
Melphalan	75	50	B
Oxaliplatin	100	50	A
Paclitaxel	100	100	A
Pemetrexed	100 if GFR 45–79 with oral folic acid and Vit B12	Avoid with eGFR <45	B
Temozolomide	100	100	B
Topotecan	75	50	A
Vincristine	100	100	B
Vinblastine	100	100	B
Sunitinib	100	100	B
Sorafenib	50	50	D
Erlotinib	100	100	B
Gefitinib	100	100	B
Imatinib	100	50	A

AUC, area under the curve; *eGFR*, estimated glomerular filtration rate; *GFR*, glomerular filtration rate. Strength of evidence: A, human trials; B, human case studies; C, *in vitro* data; D, Clinical opinion.

QUESTIONS AND ANSWERS

Question 1

A 56-year-old man with renal cell cancer receives chemotherapy with sunitinib. His baseline S[Cr] is 0.9 mg/dL. After 2 months of treatment, the oncologist notices that the S[Cr] is rising and currently is 2.0 mg/dL. The patient complains of lower extremity swelling. He has no known history of hypertension. He has normal vital signs except for slight new hypertension 145/90 mm Hg. His cardiac, lung, and abdomen exam is benign, but he has 1+ lower extremity edema bilaterally. His laboratory data are presented below:

Na 145 mEq/L, K 4.3 mEq/L, Cl 110 mEq/L, CO_2 19 mEq/L, BUN 30 mg/dL, S[Cr] 2.0 mg/dL, Albumin 2 g/dL.
Urinalysis with 2+ protein, no blood or cells
FeNa is 2%
CBC with WBC 14,000/mm^3, Hemoglobin 10 g/dL, Platelets 100/mm^3. Normal coagulation profile, haptoglobin is <10 mg/dL and LDH is 400 IU/L

Which **one** of the following is true regarding his condition:

A. Repeated exposure to sunitinib will lead chronic tubular damage
B. Repeated exposure to sunitinib will lead to a chronic thrombotic microangiopathy
C. Repeated exposure to sunitinib will lead to membranous nephropathy
D. Repeated exposure to sunitinib will less likely cause CKD

Answer: B

Renal TMA is a complication of all tyrosine kinase inhibitors such as sunitinib and sorafenib.[125] The classic syndrome includes hypertension, proteinuria, microangiopathic hemolytic anemia, and subacute decrease in GFR. Complement levels are usually normal and haptoglobin is usually low. Tubular toxicity is not a common finding with this drug class. Other findings such as acute and chronic interstitial nephritis with this agent have been reported.[126] Chronic tubular damage has not been consistently reported with this agent.

Question 2

A 45-year-old man treated with allogeneic HSCT for ALL develops nephrotic-range proteinuria. The serum albumin concentration is 2 g/dL. The patient has no prior history of renal disease. A kidney biopsy reveals membranous nephropathy. Which ONE of the following is the MOST likely cause of associated MN in patients with nephrotic syndrome after HSCT?

A. Drug-induced injury
B. Graft vs. host disease
C. Antipodocyte antibodies
D. Antiphospholipase receptor A2 antibodies
E. Renal vein thrombosis

Answer: B

Glomerular disease can be a cause of CKD following HSCT. Other causes include AKI, CNI, and TMA. In HSCT patients with nephrotic-range proteinuria, the renal biopsy findings may include MN, MCD, and FSGS. However, MN accounts for a majority of the cases of HSCT-associated glomerular diseases, whereas MCD accounts for most of the remaining cases.[57] Brukamp et al.[57] conducted a meta-analysis based on 46 patients who had HSCT and glomerular disease. Their study revealed a close temporal relationship between the development of nephrotic syndrome shortly after cessation of immunosuppression and the diagnosis of chronic GVHD. Within 9 months after discontinuation of immunosuppressive agents, most patients developed nephrotic syndrome. In a few cases, the temporal relationship was also concomitant with development of chronic GVHD. Because the MN here is secondary, the Anti-PLAR2 antibodies would be negative. Drug-induced causes such as CNI use usually lead to nonnephrotic-range proteinuria from TMA. Renal vein thrombosis is a result of nephrotic syndrome and not a cause of nephrotic syndrome in most cases.

Question 3

A 68-year-old man develops nephrotic-range proteinuria. A kidney biopsy confirms stage 2 membranous nephropathy. His prior history is relevant for hypertension for 5 years and 30 pack-years of tobacco use. He has no weight loss, no cough, or shortness of breath. Which of the following clinical and biopsy findings help distinguish secondary membranous from cancer from primary membranous?

A. Age over 65 and history of smoking are clinical risk factors for secondary membranous nephropathy
B. Absence of circulating anti-PLA2R autoantibodies in serum favors primary membranous nephropathy
C. Presence of IgG4 deposition in the glomeruli favors secondary membranous nephropathy
D. Presence of more than 8 inflammatory cells per glomeruli favors primary membranous nephropathy
E. All of the above

Answer: A

Delineating primary from secondary/cancer associated MN has been a great challenge for nephrologists and nephropathologists. Various studies have elucidated different parameters that help in making this

differentiation.[38–41,127] These parameters could be clinical or historical clues, serological markers, or histopathological findings on the kidney biopsy. Table 55.3 in the chapter summarizes these parameters. Based on that summary in Table 55.3, Choice A is correct.

Question 4

A 70-year-old patient is evaluated for new-onset hematuria. Diagnostic work-up reveals a 5-cm localized mass in the left kidney with imaging patterns consistent with RCC. Further evaluation shows no evidence of metastatic spread or local lymph node involvement. Laboratory work-up reveals an estimated glomerular filtration rate of 46 mL/min/1.73 m^2.

Which of the following would be the best course of therapy?

A. Chemotherapy with a tyrosine kinase–based medication
B. Surveillance with yearly imaging
C. Radical nephrectomy
D. Partial nephrectomy
E. Percutaneous needle biopsy

Answer: D

In the past, radical nephrectomy was considered the treatment of choice for isolated RCC or SRM. However, there is increasing awareness that radical nephrectomy is associated with a higher risk for CKD and its resultant morbidity and mortality. Thus, there has been a shift to partial nephrectomy as the treatment of choice for patients with RCC. This is especially critical in patients with baseline CKD where complete nephrectomy has a risk of leading to ESRD. Tyrosine kinase inhibitors and other chemotherapeutic regimens are reserved for more advanced disease as is radical nephrectomy. Surveillance would risk spread of the cancer over time. Needle biopsy is seldom required as imaging is sufficiently sensitive and specific to make an accurate diagnosis.[65–67]

Question 5

A 65-year-old man presents with the chief complaint of progressive weakness over the past several months. One year ago, he was known to have normal kidney function. He is normotensive and his physical examination is unremarkable. Laboratory studies reveal the following: sodium 135 mmol/L, chloride 105 mmol/L, potassium 3.0 mmol/L, bicarbonate 18 mEq/L, S[Cr] 1.8 mg/dL, urea nitrogen 22 mg/dL, glucose 110 mg/dL, hematocrit 25%, white blood cell count 5600/mm^3, platelets 340,000/mm^3.

Urinalysis shows trace protein, 1+ glucose, normal sediment. 24-h urine protein excretion is 4.8 g. A bone marrow aspirate reveals the diagnosis of multiple myeloma.

Which one of the following is characteristic of the renal abnormality seen in this patient?

A. Evidence of nephrocalcinosis on renal imaging
B. The serum bicarbonate concentration will increase after the administration of oral bicarbonate at 80 mEq/day but then decrease to 18 mmol/L after the therapy is discontinued
C. Bicarbonate therapy will cause serum potassium concentration to decline slightly as a result of a shift into cells
D. The urine pH will be persistently alkaline
E. The urine anion gap will be negative

Answer: B

This patient has multiple myeloma. The finding of AKI, anemia, and trace protein on dipstick, but nephrotic-range protein on laboratory quantification is indicative of this diagnosis. In some patients, light chains, which are freely filtered by the glomerulus, may lead to proximal tubular toxicity (here noted by the presence of glucosuria with a normal serum glucose). Thus, a type II renal tubular acidosis (RTA) may be present, which is typified by a transient increase in serum bicarbonate levels with base therapy, but a rapid return to lower levels once therapy is stopped (indicative of a new set-point for bicarbonate resorption in the tubule). The ability to acidify the urine is maintained, and thus, in the steady state, urine pH may be acidic. The urine anion gap can be variable. Nephrocalcinosis is typical of distal RTA.[128]

Question 6

A 65-year-old patient with stage 4 CKD secondary to diabetes mellitus is diagnosed with locally advanced lung cancer. He has been receiving darbopoietin 100 mcg monthly for anemia. His most recent hemoglobin is 9.9 g/dL, which has been stable for the past 3 months.

With his recent diagnosis of cancer, which of the following changes to his darbopoietin dosing should be made?

A. Darbopoietin dosing should be increased to bring the hemoglobin level to 11 g/dL
B. Darbopoietin dosing should be limited to achieve the lowest possible hemoglobin level to avoid the need for transfusions
C. Darbopoietin dosing should be held until the hemoglobin level is less than 7 g/dL
D. Darbopoietin should not be administered until his malignancy is under control

E. Erythropoietin is the preferred erythropoiesis-stimulating agent in patients with cancer

Answer: B

The most recent guidelines from the American Society of Hematology support limiting erythopoietin dosing to the minimum needed to avoid transfusions. There are no clear, evidence-based hemoglobin targets and thus Answers A and C are incorrect. There is no guidance that suggests avoiding erythropoietin completely in patients with cancer is appropriate. Therefore Answer D is incorrect. Furthermore, there is no evidence favoring one form of erythropoiesis-stimulating agent in the treatment of anemia in a patient with ESRD and malignancy. Therefore Answer E is incorrect.[120]

CHAPTER

The Interdisciplinary Clinic for Chronic Kidney Disease

Roberto Pisoni[a], *Carolyn A. Bauer*[b], *Jerry Yee*[c], *Ruth C. Campbell*[a]

[a]Medical University of South Carolina, Division of Nephrology, Charleston, SC, United States; [b]Division of Nephrology, Bronx, NY, United States; [c]Henry Ford Hospital, Division of Nephrology and Hypertension, Detroit, MI, United States

Abstract

The chronic kidney disease (CKD) clinic has emerged as an interdisciplinary care (IDC) model that encompasses patient education, medical management of CKD complications and CKD risk factors, and quality improvement. The CKD clinic team may include physicians, advanced practice providers, nurses, dieticians, pharmacists, and social workers. Team structure and clinic goals should be tailored to local practice needs. Common goals include CKD education, renal replacement therapy (RRT) planning, and treatment of complications of CKD based on national/international guidelines. Data suggest that CKD clinics slow CKD progression, improve CKD and RRT education, and lead to greater rates of home dialysis and permanent access placement. Financing of CKD clinics remains problematic as many insurers do not pay for IDC services. The long-term viability of the CKD clinic model may ultimately depend on demonstrating effectiveness and a reduction in overall patient care costs.

BACKGROUND

Chronic kidney disease (CKD) is a global health problem.[1] Approximately 15% of the US and Canadian populations have CKD.[2,3] The prevalence of CKD has been rising due to increased prevalence of hypertension, obesity, and diabetes mellitus.[4] This is mainly driven by the elderly with significant comorbidities.[5] Individuals with CKD have high morbidity and mortality and increased health care utilization.[6] High poverty rates and low health literacy contribute to the poor outcomes of the CKD population.[7–10] As a result, CKD presents an increasing substantial burden to health services. In 2013, the cost of end-stage renal disease (ESRD) care was $32.8 billion, accounting for more than 7% of US Medicare spending, and was estimated to be over $1 trillion worldwide.[11,12]

The care of individuals with CKD is complex and requires many interactions by nephrologists with patients, their family, other providers, and inpatient services. This occurs despite an increasing physician workload, the pressure to improve outcomes and limit costs, and a shrinking workforce with fewer US nephrology fellowship applicants.[13] These issues have led to a critical evaluation of how CKD care is delivered and what outcomes should be targeted in health care systems. Which individuals would benefit most from intensive management from an interdisciplinary care (IDC) clinic? What should be the CKD goals of care? Slowing CKD progression, decreasing cardiovascular morbidity and mortality, improving perception of quality of life, management of CKD complications, preparation for ESRD care, or all of these? How will this care be delivered in the most cost-effective way and by whom? The IDC clinic has emerged as an alternative to the traditional model of care for individuals with CKD as a way to address many of these pressing issues. In particular, such a clinic may address patient education, quality improvement, management of CKD risk factors and complications, and timely patient preparation for renal replacement therapy (RRT).

DEFINITION OF THE CKD IDC CLINIC

There is no single definition of IDC for CKD. IDC requires that health care providers of different disciplines, including physicians, advanced practice providers

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00056-5

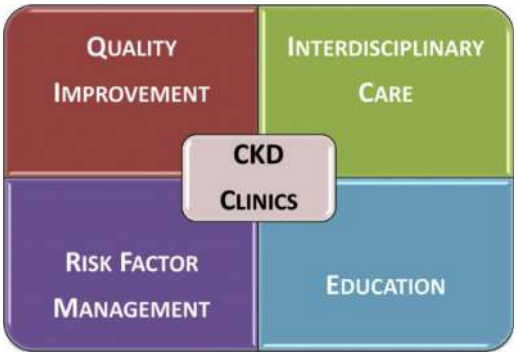

FIGURE 56.1 Interdisciplinary chronic kidney disease clinical aspects of care. Quality improvement, interdisciplinary care, risk factor management, and education of CKD patients require balanced integration.

(APPs: nurse practitioners or physician assistants), nurse specialists, pharmacists, dieticians, and social workers work collaboratively, cohesively, and synergistically and communicate together as a team to provide care for patients. The Kidney Disease: Improving Global Outcomes (KDIGO) 2012 guidelines specify that interdisciplinary nephrology care should encompass dietary counseling, education regarding different RRT modalities, transplantation options, vascular access surgery, and ethical, psychological, and social care (Figure 56.1).[14] This approach to CKD care often entails collaboration of health care providers to implement evidence-based, guideline-driven protocols in CKD care within the confines of the patient's (or the patient's health care proxy's) expressed wishes. Financial restraints of the provider(s) and/or patient(s) may limit the ability to offer all of these services to patients. Additionally, not all insurance providers will provide reimbursement for some or all of the disciplines included in IDC-based CKD care in the US. Thus, nephrology practices should identify which aspects of patient care (such as education regarding management of ESRD) or clinical outcomes (such as arteriovenous fistula [AVF] placement) are needed urgently by their patient population and use the available components of IDC to construct an intervention. To do this, the IDC CKD team needs to monitor changes in outcomes for quality improvement processes to maximize patients' benefits.

Based on local needs and resources, IDC clinics often have different staffing models and configurations. Many include APPs who do a large part of the patient education and coordination and follow protocols to achieve guideline benchmarks with the collaboration of a nephrologist. Of APPs associated with nephrology practices in the US, 83% report working in CKD or anemia management clinics.[15] IDC CKD clinic teams may include members similar to the make-up of dialysis units, with dieticians, nurses, and social workers to provide resources and patient support. When patients are deemed likely to progress to ESRD, coordination with transplant surgeons, vascular surgeons, and interventional radiologists is important to ensure timely access placement and a smooth transition to dialytic management of ESRD. Given the increasingly elderly CKD population, geriatricians and palliative care physicians can aid with prognostication, advanced care planning, and symptom management.

Although there is always a focus on patient education and management of comorbidities and complications, how an IDC clinic may achieve these goals may differ. The degree of renal dysfunction required to participate in an IDC clinic may vary. Some IDC clinics standardize the number of visits that a patient will receive from each provider based on CKD stage, others base interventions on individual risk factors and patient preferences. A common IDC CKD clinic structure has the nephrology practice provide interdisciplinary services. Some IDC clinics alternate patients between IDC visits and general nephrology visits. Other IDC clinics may incorporate a nephrology evaluation as part of their services and take referrals directly from primary care physicians (PCPs) instead of accepting patients only from a participating nephrologist.[16] This illustrates the importance of clearly defining the role of the IDC team in relation to both nephrology and primary care.

Different types of nephrology practices and multiple health care delivery models lead to vast differences in IDC in CKD. In the US, these centers range from private practices that include an APP to large integrated managed care consortiums, such as Kaiser Permanente, and to governmental health care agencies, like the Veterans Affairs (VA) System. Although IDC clinics for CKD are prevalent in Canada and Taiwan, the number of patients who receive IDC for CKD in the US is difficult to measure. The US Renal Data System (USRDS) states that of approximately 120,000 patients who progressed to ESRD in 2015, only 8% had dietary care.[2] In addition to IDC clinics started by nephrologists and hospital systems, dialysis providers and start-up companies are contracting with health systems, health plans, nephrologists, and governmental agencies to help manage pre-ESRD patients. These companies employ proprietary risk stratification algorithms, management protocols, technology platforms,

and telephone management to decrease hospitalization and defray health care costs. The VA has started using telehealth to expand their CKD outreach.[17]

TARGET POPULATION OF THE CKD IDC CLINIC

Individuals at the highest risk of progression to ESRD and those who have CKD complications that need specialized management (e.g. anemia, mineral and bone disease, metabolic acidosis, hyperkalemia) are logical populations to target for IDC. The 2012 KDIGO CKD guidelines suggest that patients with progressive CKD be treated in an IDC setting, but no glomerular filtration rate (GFR) cutoff is specified.[14] An accurate identification of this population is necessary. Models are available to estimate the risk of progression to ESRD.[18] An internationally validated risk prediction model of ESRD, called Kidney Failure Risk Equation (KFRE), is available as a web-based calculator and smartphone app.[19–21] Its four-variable version incorporates an individual's age, sex, estimated GFR (eGFR), and urine albumin:creatinine ratio (UACR), whereas the eight-variable equation additionally incorporates serum calcium (S[Ca]), phosphorus, bicarbonate, and albumin (S[Alb]) levels and is incrementally more accurate than the four-variable version. In Ontario, Canada, KFRE is used in the clinical setting to triage nephrology referrals and determine the need of IDC and the time for AVF creation.[22,23] The rate of GFR change over time, the degree of proteinuria, and advanced age are key predictors of fast progression of CKD and may help identify the potential target population for IDC. The 2012 KDIGO guidelines define rapid CKD progression as loss of eGFR >5 mL/min/1.73 m^2 per year.[14] Of more than 36,000 adults with eGFR 30–59 mL/min/1.73 m^2 within a large integrated health care delivery system in northern California, 23% of individuals with diabetes and 15% of those without were recently identified as fast CKD progressors over a 2-year period.[24] Within this population, proteinuria, age >80 years, elevated systolic blood pressure, and heart failure were independent predictors of fast CKD progression regardless of the presence of diabetes. Individuals with these risk factors may warrant more aggressive modification of risk factors and education for RRT. The 2012 KDIGO guidelines recommend referral for access planning when the anticipated risk of starting RRT is >10% within 1 year.[14]

Proteinuria is the strongest modifiable predictor of progression to ESRD in both diabetic and nondiabetic CKD patients.[24,25] Proteinuria is also an independent predictor of cardiovascular disease (CVD) and death.[26–29] Both the relative reduction in proteinuria and the level of achieved proteinuria after initiation of renoprotective treatment are predictors of the subsequent rate of GFR decline over time.[30–32] The degree/category of albuminuria is now included in the KDIGO classification of CKD. The 2012 KDIGO guidelines recommend individuals with UACR >300 mg/g or protein:creatinine ratio >500 mg/g be referred to a nephrologist.[14] A standardized, multimodal intervention targeting urinary protein excretion has been shown to be effective to slow CKD progression in subjects with nondiabetic CKD at high risk of progression to ESRD.[33]

Although elderly patients with CKD are more likely to die than progress to ESRD, they represent the fastest growing group to develop ESRD in several countries. Approximately 25% of incident ESRD individuals were over 75 years of age in 2010.[34] Elderly individuals benefit from starting dialysis with a permanent access.[35] However, there is small survival benefit, and quality of life may actually decrease from starting dialysis in individuals older than age 80 years and with a high burden of comorbidities and/or living in a nursing facility.[36,37] Thus, a thoughtful discussion of RRT modalities, including the option of supportive, nondialytic care, is extremely important. Screening for sensory deficits (e.g. vision, hearing, and reaction), anxiety, depression, and cognitive impairment and involving individuals' family/caregivers is important in this population as these conditions may affect individuals' ability to communicate effectively, retain the information provided, and adhere to treatment recommendations. Individuals with advanced CKD are at high risk of progression to ESRD and have higher rates of CKD complications such as anemia, bone and mineral disease, and CVD that need specialized management. Treating these complications is associated with decreased morbidity and improved quality of life.[14]

GOALS OF THE CKD IDC CLINIC

The ultimate goals of a CKD IDC clinic are to improve morbidity and mortality of patients with kidney disease. The IDC team has the challenging task of using evidence-based guidelines and information from recent studies to decrease the high risk of cardiovascular events and death in the CKD population, decrease the rate of progression to ESRD, treat known complications of CKD, and prepare patients at the highest risk of ESRD for dialysis and when possible renal transplantation (Table 56.1). All of these interventions must be done with the patient's, and often families', understanding and must be consistent with the patient's wishes and values. To accomplish these goals effectively, members of the IDC team must focus on patient education and

TABLE 56.1 Principal Goals of an Interdisciplinary Care Chronic Kidney Disease Clinic

Goal	Comment
Coordination of CKD care	Collaborative engagement/partnership with primary care physicians and specialists
Determination of CKD progression risk and rate	Estimation of GFR decline; proteinuria determination(s)
Mitigation of CKD complications and cardiovascular risk	Blood pressure; mineral and bone disorders; metabolic acidosis; anemia; lipids
CKD education	Multiple component/personnel utilization; MIPPA
Transition to RRT for ESRD	Discussion for prognosis; RRT modality/option planning; transplant and vascular access evaluations

Abbreviations: *CKD*, chronic kidney disease; *ESRD*, end-stage renal disease; *GFR*, glomerular filtration rate; *MIPPA*, Medicare Improvement of Patients and Providers Act; *RRT*, renal replacement therapy.

protocol-driven care based on national and international guidelines, such as the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI) and the KDIGO guidelines.[14,38] Treatment protocols should also include findings of large randomized controlled trials (RCTs) that have not yet been integrated into published guidelines to provide the best practices for this high-risk population. To slow progression of kidney disease and improve cardiovascular factors, control of underlying causes of CKD such as diabetes and hypertension needs to be addressed. Complications of CKD including metabolic bone derangements, anemia, electrolyte disturbances, and fluid imbalance must be diagnosed and treated. Given the immunosuppressive nature of advancing CKD and the possible need for kidney transplantation, vaccines to prevent influenza viruses, streptococcal pneumonia (including both the pneumococcal polysaccharide and the 13-valent conjugate pneumococcal vaccinations), herpes zoster, and hepatitis B should be administered in the recommended settings.[39–42]

Patient Education

Despite the awareness of the importance of patient education in improving health outcomes in CKD, almost 80% of newly initiated dialysis patients started hemodialysis (HD) using a catheter.[34,43–47] CKD IDC allows multiple disciplines to facilitate and optimize patient education and has been shown to lead to increased selection of home dialysis modalities, improved permanent access placement, and decreased mortality.[43,45,46] Educational interventions offered for only one day have significant benefits.[43,48] In 2010, under the Medicare Improvement of Patients and Providers Act (MIPPA), Medicare started to reimburse for CKD education provided by a physician, APP, or clinical nurse specialist for Medicare recipients with CKD stage 4 or 5. Up to six sessions of education are reimbursed and can be delivered either as a class or on an individual basis in the outpatient setting.[49] The classes must cover management of comorbidities, prevention of uremic complications, and options for RRT (including HD, peritoneal dialysis [PD], home therapies, access options, and transplantation). A recent survey of US nephrology practices found that 60% offered a CKD education class and that an APP delivered 87% of the classes.[50] The educational materials for these classes were either developed locally, originated from the NKF CKD education series "Your Treatment, Your Choice," or represented a hybrid of local and NKF materials.

An important consideration in CKD education programs is the impact of health literacy. Low health literacy, or how well a patient understands and assimilates information to make decisions regarding his or her health, is common among CKD patients and is associated with increased mortality on dialysis and with lower referral rates for transplantation.[10,51,52] Cognitive impairment is also common in individuals with CKD. A recent study found that 19% of patients with eGFR <20 mL/min/1.73 m^2 had cognitive impairment, which was associated with an increased rate of using a dialysis catheter for dialysis initiation and a lower rate of PD as a first modality.[53] These data support the need to assess patients' understanding of the education that they have been given. An advantage of the NKF "Your Treatment, Your Choice" program is that it provides outcome assessment tools to help determine whether class participants found the information understandable and helpful. IDC may allow for more time and resources to identify barriers to learning.

Cardiovascular Risk Management

Patients with CKD have an extremely high burden of CVD. In addition to delaying and preparing for ESRD, the goal of CKD IDC is to improve patients' cardiovascular health and decrease the incidence of heart attacks, strokes, and congestive heart failure (CHF). The higher risk of death compared with the progression to ESRD becomes even more pronounced in the expanding elderly stage 3 and 4 CKD population, mostly due to CVD.[2,6,54] Traditional risk factors for CVD such as increasing age, hypertension, diabetes, and hyperlipidemia are highly prevalent in the CKD population. In addition, other

nontraditional risk factors for CVD have been identified in patients with CKD, including anemia, fluid overload, vascular calcifications, inflammation, malnutrition, and increased oxidative stress.[55–58] Albuminuria, even when not associated with diabetes, is associated with higher incidence of cardiovascular events.[59,60] Patients frequently have CHF and CKD that need to be comanaged. Treatment with diuretics and angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) are mainstays of therapy in both conditions. Having CHF and CKD increases a patient's mortality risk and may require earlier dialysis initiation.[61,62] CKD IDC should focus on interventions that modify CVD risk factors. Guideline-driven care for CKD can improve cardiovascular risk, and CKD IDC has been shown to improve mortality both before and after starting dialysis.[44,63–66]

Interventions to decrease cardiovascular events in CKD have had varied results. Smoking is associated with CVD, and observational data suggest that smoking may influence the progression of renal disease. Therefore, smoking cessation should be addressed with each patient.[67,68] Conversely, it is unclear if aspirin therapy confers cardiovascular protection in this high-risk population. A *post hoc* analysis of the large RCT, the Hypertension Optimal Treatment (HOT) study, demonstrated that aspirin decreased mortality and major cardiac events in patients with diastolic hypertension and eGFR <45 mL/min/1.73 m^2.[69] However, a recent meta-analysis including HOT and two other randomized trials did not show any benefit of aspirin in the primary prevention of CVD in the CKD population, and its use was associated with increased bleeding risk.[70] In addition, a meta-analysis evaluating the use of aspirin for secondary prevention in CKD patients with acute coronary syndromes undergoing revascularization procedures revealed only a nonsignificant improvement in cardiovascular outcomes, but an increased bleeding risk.[71] Despite the recommendation of aspirin therapy by the KDIGO 2012 guidelines, more data are likely required to determine the role of aspirin in this population.[14]

Lifestyle modification and lipid lowering can also benefit patients with CKD. Aggressive lipid lowering therapy in pre-ESRD CKD patients has been shown to improve cardiovascular outcomes in RCTs.[72,73] International treatment guidelines now recommend that all pre-ESRD CKD patients over 50 years old be started on a statin, as well as those patients younger than age 50 who are at high risk for coronary artery disease or stroke.[74] In addition to medications, CKD patients should be educated about healthy lifestyle modifications. Dieticians and other members of the IDC team encourage adherence with individualized diets, weight loss when necessary, and appropriate exercise programs.

Hypertension Control

Control of hypertension by CKD IDCs is essential given that it both slows progression of renal disease and decreases the incidence of cardiovascular events.[75–79] New guidelines, including the 2017 American College of Cardiology/American Heart Association and the 2018 European Society of Cardiology/European Society of Hypertension, have altered the blood pressure target to initiate and treat hypertension based on cardiovascular risk.[80,81] These guidelines suggest targets of <130/80 mm Hg in high-risk individuals, which include CKD patients, based on newer studies especially the large randomized Systolic Blood Pressure Intervention Trial (SPRINT). SPRINT excluded patients with diabetes, but 28% of more than 9000 participants had CKD with eGFRs of 20–59 mL/min/1.73 m^2.[82] These newer guidelines are more consistent with the 2012 KDIGO blood pressure guidelines for patients with CKD, which recommended a blood pressure target <130/80 mm Hg for those patients with albuminuria based on renal outcome trials.[83–85] Points of controversy in the guidelines include BP targets in the elderly, those without albuminuria, and those with wide pulse pressures.

Controlling BP in CKD patients takes many visits and interventions, including low salt diet, home BP monitoring, and adherence to medication. A patient-focused, interdisciplinary team providing patient education is recommended to improve hypertension control. CKD IDCs have been shown to improve hypertension control.[86] Management of BP in CKD is particularly difficult because hypertension often worsens as CKD progresses, requires multiple drug combinations, and may be complicated by fluid overload, acute kidney injury, and hyperkalemia. ACEIs or ARBs are used as first-line medications in CKD and are most beneficial in the setting of proteinuria, which is a risk factor both for the development of CVD and advancing CKD.[14] Second-line medications include calcium channel blockers or diuretics followed by beta blockade.[14]

Management of CKD Complications

The CKD IDC team must address complications that arise as CKD progresses. Complications include anemia, metabolic derangements, and metabolic bone disease. Individual dietary counseling is an important part of CKD IDC to decrease complications and engage the patients. Nutritional counseling is paramount as CKD patients are often asked to follow multiple diets including low sugar, low protein, low salt, low potassium, low phosphorus, and fluid restriction, while avoiding malnutrition. CKD clinics educate patients to avoid nephrotoxins, particularly nonsteroidal

antiinflammatory drugs, and ensure that all medications are appropriately dosed based on a patient's eGFR.

Anemia of CKD

As CKD advances, many patients develop anemia of CKD due to ineffective iron use, inflammation, and decreased production of erythropoietin.[87] Previously, CKD clinics were often centered on administration of erythropoiesis-stimulating agents (ESAs) for treatment of anemia. However, the use and insurance coverage of these drugs have greatly decreased because the Trial to Reduce Cardiovascular Events with Aranesp Therapy, the Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta trial, and the Correction of Hemoglobin and Outcomes in Renal Insufficiency trial did not demonstrate benefits of hemoglobin normalization and demonstrated potential harm.[88–90] The Food and Drug Administration (FDA) issued a "black box" warning concerning thrombosis and cancer growth associated with these drugs and required that providers distribute a medication guide (risk evaluation and mitigation strategies) to every patient receiving a new prescription.[91] Presently, treatment of anemia with ESAs should be individualized to limit blood transfusions. When CKD programs initiate ESAs, they need to carefully monitor patients monthly to ensure their hemoglobin levels do not rise too rapidly or exceed 11 g/dL. All anemic patients must be screened for iron deficiency, which should be treated with intravenous or oral iron compounds. Supplementing iron may also decrease the amount of ESA necessary.[92] In addition, appropriate evaluations for occult blood loss must be performed before ESA administration.

Metabolic Bone Disease

CKD is often complicated by metabolic bone disease. CKD patients may have deranged circulating calcium levels, elevated circulating phosphate and intact parathyroid hormone levels, and vitamin D deficiency. The KDIGO working group recently published updated mineral and bone disorder guidelines in 2017, which stated that activated vitamin D analogs, such as calcitriol, are no longer routinely recommended to treat hyperparathyroidism but may be considered in severe and progressive cases.[93] Activated vitamin D therapy was associated with hypercalcemia and did not improve cardiovascular outcomes.[94,95] Dieticians and clinicians should encourage low phosphorus diets, adequate 25-hydroxyvitamin D repletion, and avoidance of high doses of calcium-based phosphate binders.

Hyperkalemia and Acidosis

Hyperkalemia and acidosis are complications of CKD that need to be evaluated and treated. Improving acidosis has been shown to decrease progression to ESRD, mitigate bone buffering, and improve nutritional status and lean body mass.[96–98] Hyperkalemia may occur as CKD progresses, which requires dietary management and can hasten the need for RRT. In addition, hyperkalemia limits the use of ACEIs or ARBs. Potassium-binding resins (patiromer and sodium zirconium cyclosilicate) were recently approved by the US FDA and can be used in the setting of chronic ACEI and ARB use.[99–101]

Management of Underlying Disorders

CKD clinic staff must coordinate with primary care providers to ensure that the underlying causes of CKD, such as diabetes and hypertension, are addressed. Diabetes, which is a risk factor for both CVD and CKD, must be controlled by diet and usually by medications. Coordination with the IDC team including the dietician, PCP, and nephrologist is important to control diabetes and prevent hypoglycemia. Comanagement with PCPs and cardiology is also necessary when treating both CKD and CHF, as many therapies impact both disorders. Effective communication with PCPs and other involved physicians is essential to ensure that all providers recognize their specific responsibilities when treating these diseases.

Slowing CKD Progression

The IDC team should address interventions to slow the decline of kidney function. Unfortunately, few interventions delay progression to ESRD. Control of hypertension, especially with ACEIs or ARBs in diabetic and nondiabetic patients with proteinuria, retards progression of CKD and decreases the incidence of cardiovascular events.[75,76,78,79,102–104]

Dietary sodium restriction and diuretic therapy can further increase the efficacy of hypertension and proteinuria reduction by ACEIs or ARBs.[105,106] Other interventions that may slow progression of kidney disease include treatment of metabolic acidosis, avoiding nephrotoxins (e.g. nonsteroidal antiinflammatory drugs and exposure to contrast agents) and volume depletion, quitting smoking, and effective education.[96,107,108] Dieticians and pharmacists in an IDC clinic may work in concert with nephrologists to ensure patient adherence to diet and medications and to determine medications that should be discontinued or whose dose/frequency should be adjusted according to the level of kidney function. A randomized study of individuals with advanced CKD showed that a single educational session with the provision of a printed summary booklet and supportive telephone calls delayed initiation of RRT by approximately 3 months.[43]

Transitioning from CKD to ESRD

IDC should safely and effectively transition individuals with advanced CKD to ESRD with the goal to lower the high morbidity and mortality associated with starting dialysis.[34,109] Ultimately, this should result in reduced costs. The pathways for transitions from CKD to RRT should be well defined, along with the role of the various IDC team members involved. The IDC team should provide patient-centered action plans for initiating dialysis, coordinate listing for kidney transplantation, and define goals of care for individuals who may not desire or benefit from these modalities. Education, in individual and/or group sessions, regarding RRTs is fundamental to this process. Patients and their relatives need to understand the different RRT options (PD, in-center or home HD, and transplantation) to facilitate informed decision-making that best accommodates their desires and circumstances. A discussion of each patient's prognosis and the risks and benefits of each RRT modality should be provided to each individual. The modality of RRT should be established at least 6 months to 1 year before the development of ESRD to allow for timely AVF placement in appropriate patients and to perform the work-up required before transplantation. Individuals who are independent, enjoy travel, are working, and have adequate supply space may opt for PD or home HD. Preparation for dialysis should occur simultaneously with evaluation for transplantation. Individuals must prepare for RRT before the onset of uremia. Patients should be educated to avoid venipuncture, intravenous lines, and BP measurements in the nondominant arm to protect the veins for the potential creation of an AVF and after this is created.

Hemodialysis

Data from the Dialysis Outcomes and Practice Patterns Study show consistent higher mortality rate in the first 120 days after starting HD. However, this mortality rate is significantly higher in the US compared with other countries.[34,109] Risk factors associated with early mortality in HD are older age, hypoalbuminemia, heart failure, use of HD catheter, and lack of predialysis care.[110,111] Individuals beginning HD using a catheter have significantly increased mortality and morbidity compared with those who begin HD using an AVF.[112,113] Pre-ESRD nephrology care and presence of permanent AV access provided most of the 1-year survival advantage shown in patients who started dialysis while receiving care through the Military Health System (MHS) compared with those who initiated dialysis outside the MHS.[114] Pre-ESRD nephrology care for more than 12 months had a comparable survival impact to that of a functioning AVF in this population. Current guidelines recommend consideration of AVF creation when the risk of ESRD is estimated to be greater than 10% within 1 year.[14] Collaborative partnership with a surgeon with high-expertise in AVF and AV graft construction ensures consistent establishment of well-functioning permanent HD accesses in suitable candidates. IDC teams should aim to facilitate the initiation of dialysis in the outpatient setting in appropriate individuals, therefore limiting the need of hospitalization and related high costs. IDC dieticians should work with individuals to prevent, diagnose, and treat malnutrition. Individuals with CHF should be closely monitored and treated for volume overload.

Peritoneal Dialysis

Individuals interested in PD should meet with a PD nurse to receive further education before deciding which RRT modality to pursue. The IDC team should determine whether the patient's living environment has adequate space to perform the mandatory sterile procedures and store supplies. Individuals should also be closely monitored for symptoms, signs, and laboratory studies suggestive of uremia to coordinate the timing of PD catheter placement with an experienced surgeon. Individuals should then be smoothly transitioned into a PD unit to initiate PD training following catheter insertion. Family members should be encouraged to learn about PD and assist the patient.

Kidney Transplantation

Transplantation offers the best survival advantage among the RRT modalities. Transplantation before starting dialysis is associated with improved mortality and allograft survival.[115–117] The IDC team should educate individuals and their families about transplantation, ensure timely referrals for transplant evaluation, and facilitate discussions about living kidney donations between individuals and their families. Individuals should be wait-listed when eGFR <20 mL/min/1.73 m^2 to accrue time on the deceased-donor waiting list before starting dialysis and potentially decrease the duration of dialytic care.

Advanced Care Planning

ESRD in the elderly is associated with a high risk of mortality and decreased functional status and therefore warrants advanced care planning. In the US, 20% of patients who died in the initial 120 days after starting dialysis had discontinued treatment.[109] Predictive tools available to risk stratify a patient's outcomes can aid a clinician's understanding of an individual's prognosis. Clarifying patients' wishes before ESRD may decrease aggressive and costly measures that patients may not want at the end of their lives. If progression to ESRD is likely, the risks and benefits of dialysis and transplantation should be provided to patients to ensure informed

decision-making. In addition, patients should clarify circumstances under which they would want to withdraw from dialysis. Allowing a patient to make these decisions before the onset of an emergency setting benefits the patients' families who will understand their loved ones' wishes before they reach kidney failure. For patients who decide on medical management at stage 5 CKD—the "no dialysis" option—IDC programs should continue to provide services that facilitate the patients' overall wellness and comfort.

CLINICAL OUTCOMES OF THE CKD IDC CLINIC

The prevailing literature suggests that IDC slows CKD progression, decreases hospitalizations, improves mortality rates during transition from CKD to ESRD, and improves AVF placement before initiation of RRT. Snyder and Collins found that a higher number of preventive measures including monitoring of lipids, glucose, and mineral and bone parameters as well as influenza vaccination were associated with a significantly decreased risk of atherosclerotic heart disease in a Medicare CKD cohort.[63] Hemmelgarn et al. showed a 50% decreased mortality risk in a predialysis cohort with IDC compared with a propensity-matched control group that had standard nephrology care.[64] Decreased mortality was also shown in a cohort of patients who had access to IDC in Taiwan.[118] Exposure to IDC decreased mortality rates after dialysis initiation in two other cohort studies.[44,65] Data from Fresenius Medical Care North America, a large dialysis organization, showed that individuals who underwent a predialysis educational program were significantly more likely to choose PD as their RRT, begin HD with an AVF or AV graft, and were less likely to die within the first 90 days following onset of dialysis.[119]

The Multifactorial Approach and Superior Treatment Efficacy in Renal Patients with the Aid of Nurse Practitioners (MASTERPLAN) study, a randomized trial of 788 Dutch patients with CKD stages 3 and 4, showed that the implementation of CKD guidelines by nurse practitioners added to standard nephrology care, after an extended median follow-up of almost 6 years, slowed eGFR decline by 0.45 mL/min/1.73 m^2 per year, and decreased the incidence of the composite endpoint (death, ESRD, and a 50% increase in S[Cr]) by 20% compared with standard nephrology care.[120] The previously published MASTERPLAN trial with median follow-up of 5 years did not show a significant difference in CVD outcomes, but showed that APP supported care significantly decreased CVD risk factors (hypertension, low-density lipoprotein cholesterol, anemia, and proteinuria).[86] The latter trial had several limitations including contamination bias, fewer than expected events likely related to the inclusion of a relatively young and "healthy" CKD population, and being underpowered to demonstrate a significant difference in CVD outcome.

Other trials have shown that CKD education and IDC can slow the progression of CKD to ESRD. A randomized trial demonstrated that a single 90-minute education session along with follow-up phone calls significantly delayed dialysis initiation by approximately 3 months in individuals expected to start dialysis within 6–18 months.[43] English patients with eGFRs <30 mL/min/1.73 m^2 who had access to a nurse, patient education, medication management, and nutrition counseling had a slower eGFR decline over time with the greatest benefit in those patients with rapidly progressive CKD.[121]

Data are conflicting regarding the efficacy of IDC in early CKD and nonprogressive CKD patients. Slower CKD progression was detected in subjects enrolled in IDC compared with historical controls in a large health maintenance organization population.[122] A Canadian RCT found no difference in GFR decline and control of most CKD risk factors by adding a nurse-coordinated model in subjects with slowly progressive CKD.[123] However, nurse-coordinated care was associated with fewer visits to specialists and hospitalization days.

Cohort studies performed in California, Taiwan, and Canada showed that patients exposed to IDC had significantly more AVFs placed and decreased hospitalizations.[48,124,125] A single-center study showed that guideline-driven care by APPs was associated with improved functioning, permanent vascular accesses, and decreased hospitalizations 12 months after dialysis initiation.[126]

ECONOMICS OF CKD IDC CLINICS

CKD IDC have different components and funding sources. IDC is funded by the National Health Service in certain countries such as Canada and Taiwan, whereas many fee-for-service insurance providers only reimburse for physicians or APP visits in the US. This may cause IDC clinics not to be available in many locations. Dieticians are reimbursed by Medicare for stage 4 CKD patients but may not be covered by other US insurance companies. The MIPPA benefits include six education classes, if taught by a physician, an APP, or clinical nurse specialist. A social worker can bill insurance companies only if providing counseling for a DSM-V mental disorder diagnosis. Nursing staff can charge for administration of injectable medications and vaccines. Pharmacist services are not reimbursable in

the US. In addition, enhanced administrative personnel efforts required to coordinate all the providers and educational services are not reimbursable.

Grants, awards, donations, or alternative sources of funding have often been required, which has initially limited CKD IDC clinics to large academic institutions in the US. Data revealing cost savings with implementation of CKD IDC clinics have generated interest by health care organizations that assume responsibility for the quality, cost-effectiveness, and general health care in creating CKD IDC clinics or partnering with other businesses that offer CKD IDC. As mentioned previously, dialysis providers and related companies have developed interdisciplinary models that employ telephone calls and leverage technology to provide care. After such companies enroll a CKD patient, patient profiles may be input into their ESRD facilities as patients progress toward kidney failure. Increased outpatient dialysis starts and greater AVF and PD selection rates can help persuade funders that CKD clinics are cost-effective and sustainable.

In 2007, the average inpatient cost for the first month of dialysis in the US was $9846 per Medicare member and $22,841 per employer group health plan member.[127] This cost could be greatly reduced by increasing outpatient dialysis starts. Increased AVF rates will also lower the expense associated with ESRD. AVFs were associated with approximately $3000 lower vascular access-related expenses compared with HD catheters.[128] IDC may increase the rate of PD as the initial modality for ESRD, which is also cost-effective; according to the USRDS, the total yearly expenditure per patient in 2015 for HD was $89,000 compared with $75,000 for PD.[2] Improved advanced care planning may also defray costs. Discussing patients' wishes and values before ESRD may decrease the number of patients who start dialysis and withdraw within the first 120 days.

Studies have assessed the cost-effectiveness of CKD IDC clinics. IDC clinics show greater pre-ESRD costs compared with conventional nephrology care and likely decrease mortality which would also drive up health care costs. Despite the increased costs of an IDC team, a study in Taiwan reported saving $1200 in patients beginning dialysis.[125] After Taiwan started a nationwide multidisciplinary pay-for-performance initiative in 2006, enrollees were compared with a cohort of patients not enrolled, finding that pre-ESRD patients who attended IDC had lower hospitalization costs but higher outpatient costs.[129] However, once these patients progressed to dialysis, the outpatient, hospitalization, and dialysis costs were less than those of patients who did not receive IDC care.[130] A theoretical model evaluating the cost-effectiveness of US Medicare reimbursement for multidisciplinary care revealed a 0.23 quality of life year (QALY) gain over usual care, with a cost of $51,285 per QALY gained. Although the multidisciplinary care was more costly than standard care, it resulted in a reasonable cost per QALY gained compared with ESRD.[131]

Because financial restraints limit the ability to offer all possible services to all CKD patients, IDC clinics must prioritize the interventions with the best outcomes. Not all patients may benefit to the same degree from IDC. Choosing the patient population most likely to benefit would decrease costs. Progression of CKD may be a slow, unpredictable process, and several years may be needed to demonstrate a financial benefit, particularly if a patient changes health care systems or insurance providers. The additional time spent seeing different providers in IDC and the costs incurred by patients during travel could adversely impact patient engagement. Overcoming some of these barriers may necessitate intensive case management and is potentially costly.

PATIENT SATISFACTION WITH CKD IDC CLINICS

There is lack of data examining patient satisfaction with IDC clinics for CKD. A recent cross-sectional study from Australia, involving adult subjects with CKD, not on dialysis, who attended nurse-led CKD clinics, showed high satisfaction with the quality of care provided in the majority of those who responded to a survey questionnaire.[132] Limited waiting time about access to services, adequate coordination of care, in-depth specialty knowledge, and listening to and understanding individual patient needs were factors contributing to patient satisfaction.

CONCLUSIONS

The CKD clinic has emerged as an IDC model that encompasses patient education, medical management of CKD complications and risk factors, RRT planning, and quality improvement. The CKD IDC clinic team may include physicians, APPs, nurses, dieticians, pharmacists, and social workers. CKD IDC clinics are associated with greater patient preparedness and improved health outcomes during the transition from CKD to ESRD, especially among individuals at increased risk for CKD progression. Different models for IDC in CKD exist. Team structure and clinic goals should be tailored to local practice needs and resources. Funding for IDC services may be challenging as many insurers do not pay for these services despite the potential cost savings

of such clinics. Although CKD IDC appears promising, studies with longer follow-up and higher-risk patients are required to better understand the quality and utility of IDC teams in the management of patients with CKD.

QUESTIONS AND ANSWERS

Question 1

A 48-year-old man with a medical history of obesity, hypertension, diabetes, and hyperlipidemia presents to an IDC CKD clinic. He is a current smoker and drinks four glasses of wine per day. His laboratory results are significant for an eGFR 29 mL/min/1.73 m^2, urinary protein-to-creatinine 2 g/g, an LDL-C 130 mL/dL, and hemoglobin 9.1 mg/dL.

Which one of the following agents may increase cardiovascular risk in this patient?

A. Angiotensin-converting enzyme inhibitor
B. Aspirin
C. ESA
D. 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitor

Answer: C

Aspirin, 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitors, smoking cessation, and blood pressure control may reduce cardiovascular risk in CKD patients. ESAs have been associated with a small increase in the risk of stroke.[69,73,90,133]

Question 2

A 78-year-old man with a history of hypertension, diabetes, and hyperlipidemia presents to an IDC CKD clinic for evaluation. His laboratory results are significant for an eGFR of 16 mL/min/1.73 m^2, UACR 30 mg/g, S[Ca] 8.9 mg/dL, S[Alb] 4.5 g/dL, serum phosphorus 4.6 mg/dL, and venous total carbon dioxide 20 mmol/L.

Which one of the following statements regarding this patient's CKD care is correct?

A. Education for this patient could delay the start of dialysis
B. The patient's nephrologist should have referred him to an IDC CKD clinic when his eGFR was greater than 30 mL/min/1.73 m^2
C. An IDC CKD clinic is required to have a social worker and pharmacist on staff
D. The patient no longer needs to see his primary physician now that he has enrolled in the CKD clinic.

Answer: A

Patient education has been shown to delay the start of dialysis by approximately 3 months.

A randomized study in advanced CKD found a 3-month delay to the start of dialysis in patients who received a single education intervention with nurse follow-up. There is conflicting evidence regarding the efficacy of CKD clinics in early CKD. In a large health maintenance organization cohort, IDC care was found to retard CKD progression. However, in a randomized trial of Canadian patients with slowly progressive early CKD, the CKD program did not improve outcomes. IDC clinics have different staffing models. Economic constraints often limit the ability of an IDC program to hire ancillary providers who cannot bill in a fee-for-service model. The IDC does not replace the need for primary care. The IDC teams needs to coordinate care with the primary care provider to ensure understanding of each provider's role.[123,134,135]

Question 3

A 64-year-old woman presents to an IDC CKD clinic with an eGFR of 20 mL/min/1.73 m^2 and a hemoglobin of 9.1 g/dL.

Which one of the following statements regarding the use of ESAs in CKD is correct?

A. ESAs should be used to delay the progression of CKD
B. ESAs should be used to normalize the patient's hemoglobin
C. ESAs should be used to prevent stroke
D. ESAs should be used to avoid blood transfusions

Answer: D

The FDA recommends that ESAs be used in CKD to avoid blood transfusions to mitigate risk for allosensitization of potential kidney allograft recipients. Normalization of hemoglobin did not improve outcomes and was associated in some studies with increased risk. ESAs did not retard the progression of CKD.[88,90,136]

Question 4

A 71-year-old woman with CKD due to diabetic nephropathy presents to her nephrologist for a routine visit. Her laboratory testing reveals an eGFR 32 mL/min/1.73 m^2 (Chronic Kidney Disease Epidemiology Collaboration [CKD-EPI] formula), UACR 40 mg/g, S[Ca] 9 mg/dL, S[Alb] 4 g/dL, serum phosphorus 4.5 mg/dL, and serum bicarbonate concentration 21 mmol/L. Her eGFR has been stable from her last visit 6 months ago.

Which one of the following statements describing her 2-year risk of progression to ESRD is correct?

A. 3%
B. 5%
C. 7%
D. 21%

Answer: A

Using the ESRD calculator developed by Tangri et al., the estimated risk of progression to ESRD requiring dialysis or transplantation is 3%. The equation is also available as a smartphone app.[19,20]

Question 5

A 49-year-old man with type 2 diabetes presents to his nephrologist for routine follow-up. He had a renal biopsy 2 years ago for nephrotic range proteinuria that showed focal segmental glomerulosclerosis. His laboratory results show an eGFR of 35 mL/min/1.73 m^2 by the CKD-EPI equation, UACR 2800 mg/g, S[Ca] 8.7 mg/dL, S[Alb] 2.8 g/dL, serum phosphorus 4.0 mg/dL, and serum bicarbonate 22 mmol/L. His eGFR 1 year ago was 41 mL/min/1.73 m^2 and 55 mL/min/1.73 m^2 at the time of the biopsy.

Using the 2012 KDIGO guidelines, which one of the following statements best describes the rate of loss of GFR?

A. Slow progression
B. Nonprogression
C. Rapid progression
D. Regressive progression

Answer: C

Rapid progression, per 2012 KDIGO guidelines, is defined as a sustained decline in eGFR of >5 mL/min/1.73 m^2 per year. The ability to identify patients with rapid progression allows for earlier referral to CKD and RRT education, rather than simply identifying CKD stage.[14]

Question 6

A nephrology practice would like to start an Interdisciplinary Chronic Kidney Disease Clinic that focuses on education and has decided to use NKF materials: "Your Treatment, Your Choice." The practice is involved in the process of writing a business plan to support the personnel who will be involved in the education.

Which one of the following statements regarding the MIPPA benefit for CKD education is correct?

A. Patients with eGFRs >30 mL/min/1.73 m^2 are eligible for the CKD education benefit
B. Patients with an albumin:creatinine ratio >2000 mg/g are eligible for the CKD education benefit
C. Eligible patients may receive up to 10 sessions of CKD education
D. CKD education must be delivered by a physician, APP (nurse practitioner/physician assistant), or clinical nurse specialist

Answer: D

The MIPPA establishes Medicare coverage for six educational sessions for Medicare beneficiaries with stage 4 CKD (precursor to kidney failure, defined as an eGFR of 15–29 mL/min/1.73 m^2). Educational sessions must cover management of CKD (management of comorbid conditions, reducing progression to ESRD and prevention of complications) and RRT options. Both individual and group sessions are eligible for coverage. Each session should be 1 hour, with at least 31 documented minutes of time for billing purposes. The educational sessions must be delivered by a physician, APP (nurse practitioner/physician assistant), or clinical nurse specialist.[49]

CHAPTER

57

Slowing Progression of Chronic Kidney Disease

Paul Drawz[a], *Thomas H. Hostetter*[b], *Mark E. Rosenberg*[a]

[a]Division of Renal Diseases and Hypertension, University of Minnesota Medical School, Minneapolis, MN, United States; [b]Department of Medicine, University of North Carolina, Chapel Hill, NC, United States

Abstract

Early identification of chronic kidney disease (CKD) provides an opportunity to implement therapies to improve kidney function and slow progression. This chapter will first review the epidemiology of progression to define the normal and CKD-related rate of decline in kidney function and discuss the competing risks between death and development of end-stage renal disease. Common pathophysiologic mechanisms underlie the progression of most kidney diseases, including glomerular capillary hypertension, renal fibrosis induced by renal inflammation, podocyte loss, proteinuria, and activation of systems such as the renin–angiotensin–aldosterone system and intrarenal activation of developmental and injury pathways. These pathophysiologic factors present potential targets for therapy. The importance of controlling blood pressure will be discussed along with the target blood pressure in CKD patients. Therapy directed at inhibiting the renin–angiotensin–aldosterone system remains the mainstay of treatment with single agent inhibition of this system being as good as dual blockade with fewer adverse effects. Other therapies include glycemic control, correction of metabolic acidosis, and dietary protein restriction. Emerging therapies targeting endothelin, uric acid, kidney fibrosis, oxidant stress, and kidney augmentation hold promise for the future.

INTRODUCTION

The increasing incidence and prevalence of chronic kidney disease (CKD) places significant health burdens on patients and costs on our already stressed healthcare system. Screening programs and the reporting of estimated glomerular filtration rate (eGFR) are leading to earlier identification of CKD, allowing a focus on what can be done to slow progression of CKD once it is identified. Progression of kidney disease is defined as a loss of GFR over time and includes the need to initiate renal replacement therapy (RRT). Common mechanisms underlie progression of kidney disease and form the basis for therapeutic interventions. Established and emerging therapies should be rational, based on solid evidence and easily and inexpensively applied widely to diverse populations.

EPIDEMIOLOGIC ISSUES

Rates of Progression

Once the diagnosis of CKD is established, it is important to monitor GFR and magnitude of proteinuria to assess evidence of progression. The frequency of measurement of these parameters will depend on the severity and course of CKD, following the general principle that more frequent monitoring is needed as kidney disease progresses. Progression of CKD is variable depending on the population being studied, the underlying disease, the adequacy of therapy, the presence of risk factors, and other unknown factors. To provide perspective on CKD progression it is important to note the decline in kidney function in various populations. The Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guideline for the evaluation and management of CKD reviewed the available longitudinal population studies and showed a decline in kidney function of 0.3–1.0 mL/min/1.73 m^2/year in those without proteinuria or comorbidity.[1] Rates were two to three times higher in those with proteinuria and/or significant comorbidity.

In patients with established CKD, more rapid rates of progression were present. For example, in the Modification of Diet in Renal Disease (MDRD) study the rate of progression ranged from 2.3 to 4.5 mL/min/year.[2] In a study of 4231 patients with a GFR less than 60 mL/min/1.73 m^2, the mean decline in GFR was 2.65 mL/min/1.73 m^2/year.[3] Based on these data, KDIGO defines rapid progression as a sustained decline in eGFR of more than 5 mL/min/1.73 m^2/year. This population of

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00057-7

rapid progressors should be the target of more aggressive intervention, as they are at higher risk for the development of end-stage renal disease (ESRD) and cardiovascular complications.

Predicting Risk of Progression

An important tool to aid clinicians in their approach to progression is risk prediction formulas that estimate the likelihood of developing ESRD. Tangri and colleagues, in a cohort of patients with stage 3–5 CKD, developed a four-variable risk equation.[4–7] The formula is based on age, sex, eGFR, and albumin:creatinine ratio. It is available online (https://qxmd.com/calculate/calculator_308/kidney-failure-risk-equation-4-variable). This formula was able to predict ESRD at 2 and 5 years and can be used by clinicians to target therapies to those at highest risk for progression.

Competing Risk of Cardiovascular Disease

Not all patients with CKD progress to ESRD. More patients will die before they reach ESRD, predominantly of CVD. These competing risks between ESRD and CVD depend on the population of patients studied, with the general finding that older patients with milder CKD are more likely to die of CVD, whereas younger patients with more severe CKD are more likely to progress to ESRD.[8–11] Emphasis should be placed on both reducing cardiovascular risk and slowing progression of CKD.

PATHOPHYSIOLOGIC MECHANISMS OF PROGRESSION

Common mechanisms underlie the progression of most kidney diseases. These mechanisms initially involve adaptive changes to loss of nephrons that eventually have maladaptive consequences. Clinical manifestations of progression common to most renal diseases are decreased GFR, hypertension, and proteinuria. Common pathologic findings are glomerulosclerosis, tubulointerstitial fibrosis, inflammation, tubular atrophy, and capillary loss. These common mechanisms provide important targets for therapeutic intervention. A number of excellent reviews on pathophysiology of CKD are available.[12–14]

Glomerular Hyperfiltration

The best described common mechanism of progression, and the one that changed the paradigmatic way we approach CKD, is that of glomerular hyperfiltration.[15–18] Reductions in nephron number cause increased filtration rate in residual nephrons—the greater the degree of nephron loss, the greater the compensatory increase in the function of the residual units. After these seemingly adaptive increases in function, pathologic changes appear, resulting in the development of glomerular sclerosis. Not only does graded reduction in renal mass lead to graded increases in injury of the residual nephrons, but renal ablation also hastens injury in other experimental renal diseases. For example, diabetic animals have greater degrees of glomerular sclerosis if they undergo unilateral nephrectomy.[19] In addition, concurrent dietary manipulations that modify renal hemodynamics also alter the degree to which any given level of reduction of renal mass provokes subsequent glomerulosclerosis. In particular, dietary protein restriction lessens renal injury with reductions in renal mass in experimental models. Because higher dietary protein elevates whole-kidney glomerular and single-nephron filtration rate, its combination with compensatory hyperfiltration exaggerates and its restriction lessens disease.[20]

There appears to be a critical amount of renal mass that has to be lost before hyperfiltration leads to adverse consequences. Unilateral nephrectomy, such as occurs in kidney donors, is not usually enough to lead to significant progressive kidney disease.[21] On the other hand, some have suggested that loss of renal mass, perhaps at susceptible periods of development or in susceptible individuals, may be associated with subsequent injury. For example, unilateral renal agenesis is a relatively rare congenital condition, but it has been associated with proteinuria and sclerosis of the single kidney as patients age.[22] Conceivably in this circumstance, the solitary kidney has subtle developmental defects that render it susceptible to injury. Likewise, progressive damage to the remaining kidney after removal of a contralateral diseased kidney may reflect unrecognized bilateral diseases.[23] However, with greater loss of renal mass, injury may be seen in humans. One study of subtotal nephrectomy for aggressive renal cancer suggested sclerotic injury develops in the spared but hypertrophied glomeruli.[24] Perhaps as in animal studies, some variations occur among different groups of people and susceptibility to loss of renal mass may be more pronounced in some individuals.

If increased single-nephron filtration causes subsequent injury, the question arises regarding what determinant of filtration is responsible for the damage. Filtration is governed by the imbalance of hydrostatic and oncotic pressures across the glomerular capillary wall. The increase in glomerular capillary pressure seems to be preeminent among the determinants of increased single-nephron filtration after renal mass reduction in aggravating progressive sclerotic changes.[15] In most disease models, the capillary

hypertension can be attributed to decreases in afferent vascular resistance within the kidney. In most cases this is accompanied by arterial hypertension, with resultant excess transmission of the arterial pressure to the glomerulus. The efferent vascular resistance often is maintained at a level close to normal. One can envision this latter phenomenon as also contributing to the maintenance of glomerular pressure because postglomerular resistance fails to decrease in parallel with the preglomerular resistance.

The remarkable efficacy of drugs that reduce angiotensin II (AII) levels or action in models with glomerular hypertension and in clinical studies support this view based on the following considerations. This response to angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) suggests that AII may in some fashion maintain increased glomerular pressures. As one of its prime actions, AII preferentially constricts the efferent arteriole. On this basis, AII often has been invoked as maintaining efferent tone in the face of afferent vasodilation, the latter mediated by less well-defined vasodilators. Prostaglandin species and nitric oxide may disproportionately play roles in this portion of the renal circulation. Glomerular hypertension results and is especially severe if arterial hypertension conspires with these intrarenal adjustments.

The potential for glomerular capillary pressures to induce progressive sclerotic injury seems clear. This link raises the question of how increased glomerular pressure is translated into cellular pathology. Following renal mass reduction, renal hypertrophy occurs including enlargement of glomeruli. Increased glomerular tension, as predicted by the Laplace law, may represent a final common pathway by which compensatory growth and/or glomerular hypertension result in glomerular injury.[25] Greater wall tension on glomerular capillaries would occur in larger glomeruli leading to more injury.[25] Elevated glomerular pressure may also lead to podocyte damage and increased protein leakage across the glomerular basement membrane, an initiating factor in the development of glomerular sclerosis.[26] Mechanical stress, as could occur with glomerular hypertension, can also lead to adverse effects on glomerular endothelial and mesangial cells.[27–29]

Measurement of SNGFR in Humans and Its Implications

Denic and colleagues reported estimates of single nephron glomerular filtration rate (SNGFR) in humans.[30] The subjects were living kidney donors, and SNGFR was calculated by dividing total GFR (iothalamate clearance) by nephron number derived by CT scan and kidney biopsy. The resulting value of 80 nL/min was higher but consistent with animal measurements derived from direct sampling of glomerular ultrafiltrate.[15] As discussed above, glomerular hyperfiltration occurs in models of diabetes and following reduction of renal mass. The increased glomerular pressures and flows that drive hyperfiltration play a role in progression of kidney diseases. In the Denic study, an elevated SNGFR was associated with risk factors for progression including obesity, a family history of ESRD, and more glomerulosclerosis, suggesting compensation in remaining nephrons to maintain total GFR. Measurement of SNGFR provides a unique window into the inner workings of the kidney and in many ways confirms the experimental models of kidney disease progression. Although far from a routine clinical test, the level of SNGFR may be an important determinant of renal reserve, dictating the aggressiveness of therapy to slow progression of kidney diseases.

In a follow-up study these investigators demonstrated the number of nonsclerotic glomeruli decreased with aging and to a greater extent than the decrease seen in cortical volume (Figure 57.1).[31] This age-related loss of nephrons was associated with older age, shorter height, family history of ESRD, higher serum uric acid levels, and lower measured GFR and was not always reflected by the degree of glomerulosclerosis seen on kidney biopsy, suggesting resorption of sclerotic glomeruli.

Renal Fibrosis

The extent of tubulointerstitial disease is a major risk factor and predictor of progression in all forms of kidney disease.[32,33] Progression of CKD is better correlated with the degree of interstitial fibrosis than with glomerular damage.[34] However, controversy exists regarding whether the driver for progression associated with tubulointerstitial fibrosis is the interstitial fibrotic process that subsequently destroys healthy nephrons, or whether fibrosis occurs as a consequence of tubular injury as part of healing.[35] Explanations for how a glomerular disease can lead to scarring in the interstitium have been elegantly reviewed.[32,36] Inflammation plays an important role in leading to tubulointerstitial fibrosis mediated by a variety of cytokines, chemokines, and growth factors, including monocyte chemoattractant protein-1, nuclear factor κB (NF-κB), transforming growth factor β (TGF-β), platelet-derived growth factor (PDGF), interleukin-10 (IL-10), and others.[37]

Loss of Podocytes

Loss of podocytes is commonly seen in progressive kidney disease, and plays a role in accelerating progression.[38] Damage to podocytes leads to disruption of the glomerular filtration barrier and to loss of separation between the glomerular tuft and Bowman's capsule.[22] The

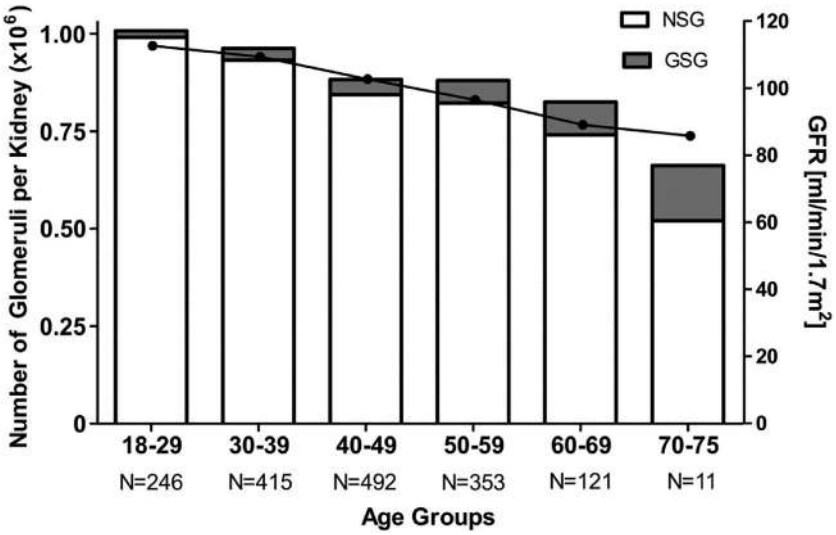

FIGURE 57.1 Nephron number (left axis) and glomerular filtration rate (GFR) (right axis) in different age groups of kidney donors demonstrating a decrease in both measurements with aging. *GSG*, globally sclerotic glomeruli; *NSG*, nonsclerotic glomeruli. *Reproduced from Reference 31 with permission from American Society of Nephrology.*

consequence is focal glomerulosclerosis, or if inflammation is involved, a proliferative crescenteric process that can lead to obliteration of glomeruli or obstruction of the glomerular tubular junction and loss of filtration. An important role for podocyte injury as a pathogenic factor is supported by experimental models of podocyte-specific injury and the identification of podocyte-specific genes as a cause for genetic forms of focal segmental glomerulosclerosis (FSGS).[14,39] Parietal epithelial cells lining Bowman's space have been recognized as playing a role in progression of kidney disease and as a potential therapeutic target.

The Notch signaling pathway plays a critical role in kidney development, after which its activity is decreased.[40] Reactivation of Notch signaling in glomerular cells occurs in such disorders as FSGS, diabetic nephropathy, HIV-associated nephropathy (HIVAN) and lupus nephritis, where it may play a pathogenic role in progression of kidney disease. Supporting evidence for such a role comes from experimental models demonstrating sustained activation of Notch signaling in podocytes results in podocyte dedifferentiation, detachment, and apoptosis, leading to albuminuria, glomerulosclerosis and death secondary to renal failure.[41,42] Inhibition of Notch signaling improves the course of experimental diabetic nephropathy, suggesting Notch signaling is a potential therapeutic target in human disease.[43,44]

Renin–Angiotensin–Aldosterone System

The renin–angiotensin–aldosterone system (RAAS) plays an important pathophysiologic role in the progression of CKD.[26,45–47] Mechanisms for these adverse effects include glomerular hypertension secondary to preferential maintenance of efferent arteriolar tone, promotion of glomerulosclerosis and systemic and glomerular hypertension. AII can also have direct effects of increasing mesangial cell proliferation and matrix expansion. Profibrotic actions mediated by AII include increases in fibrotic growth factors such as basic-fibroblast growth factor, TGF-β, PDGF, and plasminogen activator inhibitor-1.[48–52] Activation of the transcription factor NF-κB, enhanced expression of cell adhesion molecules, stimulation of proinflammatory cytokines, monocyte activation, and generation of reactive oxygen species are other ways in which AII can contribute to renal damage.[10,26,28,29,52–55] Aldosterone, in addition to AII, may contribute to damage both by raising vascular pressures and by activating profibrotic pathways.[56–58]

Proteinuria

Proteinuria is a risk factor for the development of ESRD in the general population and a powerful predictor of renal outcomes in CKD patients.[59–61] Reduction of proteinuria in clinical trials is associated with improved renal outcomes.[62–64] The fact that proteinuria is a prognostic factor in most kidney diseases has given rise to the hypothesis that proteinuria may be a direct pathogenic factor involved in transferring glomerular injury to the tubulointerstitium.[62] Potential mechanisms include damage by toxic molecules in proteinuric tubular fluid, excessive reabsorption, and degradation of proteins by tubular cells leading to spillage of lysosomal enzymes into the cytoplasm with intracellular toxic effects on tubular cells, and production of profibrotic and proinflammatory molecules produced by tubular cells as a consequence of the proteinuria.

There is no uniform consensus regarding the "proteinuria hypothesis," because not all studies have found deleterious effects of filtered proteins on tubular cells.[28] Furthermore, tubulointerstitial damage is not a feature of minimal change disease, in which heavy proteinuria is found.[26] A counterargument is that the selectivity of the proteinuria is also an important factor, and that when the proteinuria is highly selective as in minimal change disease, there is less damage to tubules and interstitium.

THERAPY TO SLOW PROGRESSION OF CKD

The diagnosis of CKD and assessment of the tempo of progression set the stage for implementing therapies directed at slowing progression and preventing the development of ESRD. Established therapies exist to slow progression of CKD and emerging therapies are being tested for effectiveness in CKD patients (Table 57.1).

Blood Pressure Control

CKD and hypertension are interrelated. CKD is associated with a number of physiologic alterations that lead to elevated blood pressure including sodium retention, increased sympathetic tone, and endothelial dysfunction. The majority of patients with CKD have hypertension, and its prevalence is over 90% among patients with moderate to severe CKD.[65] On the other hand, hypertension may be a cause of and accelerate progression of CKD.[66,67] Given this tight relationship between CKD and hypertension, and early prepost studies that demonstrated a potential slowing of progression of CKD associated with administration of antihypertensive medications, it has long been presumed that blood pressure control is critical to slowing the progression of CKD.[68] In fact, the KDIGO Clinical Practice Guideline for the Management of Blood Pressure in Chronic Kidney Disease claimed that "lowering blood pressure in CKD patients reduces the rate of CKD progression."[69] Unfortunately, although observational studies demonstrate that lower-achieved blood pressures are associated with slower decline in renal function, the assumption that lower blood pressure targets slow progression of CKD is not supported by evidence from multiple randomized controlled trials (RCTs).

TABLE 57.1 Interventions to Slow Progression of Chronic Kidney Disease (CKD)

ESTABLISHED THERAPIES
Hypertension control
Renin–angiotensin–aldosterone system blockade
Dietary protein restriction
Correction of metabolic acidosis
Glycemic control
Comprehensive CKD clinics
EMERGING THERAPIES
Endothelin antagonists—avosentan, atrasentan
Anti-inflammatory agents—bardoxolone, pentoxifylline
Antifibrotic agents—pirfenidone, TGF-β antibodies
Specific glucose-lowering agents (SGLT2 inhibitors, GLP-1 analogues)
Cellular therapies

Blood Pressure Target to Slow Progression of CKD

A number of studies have evaluated the effect of standard vs. intense blood pressure targets on progression of CKD. All failed to demonstrate slowing of progression of CKD with the more intense blood pressure targets (Table 57.2). Among the 840 participants in the MDRD study, there was no difference in decline in GFR over 2.2 years of follow-up between the usual blood pressure target (mean arterial pressure [MAP] 107 mm Hg [approximately 140/90 mm Hg]) and the low blood pressure target (MAP target 92 mm Hg [approximately 125/75 mm Hg]) groups.[2] In the African American Study of Kidney Disease and Hypertension (AASK) trial, 1094 African Americans with CKD but without diabetes were randomized to a usual blood pressure target (MAP 102–107 mm Hg) and a low blood pressure target (MAP 92 mm Hg).[73] As in MDRD, there was no difference in GFR decline between groups and the occurrence of a 50% decline in GFR, ESRD, death, or a composite of the three was similar in both groups. Similar lack of reduction in CKD progression was observed in three smaller trials comparing standard and low blood pressure targets (REIN-2, Lewis et al., and Toto et al.) (Table 57.2).[70–72] Although the primary results of these trials do not indicate a benefit of lowering blood pressure, secondary analyses have revealed potential benefits in certain subgroups, such as in participants with proteinuria.

In secondary analyses of the MDRD study, there was a benefit of the low blood pressure target in the minority of participants with significant proteinuria (>3 g/day) (Figure 57.2).[2] Additionally, in long-term passive follow-up, the low blood pressure target was associated with a reduction in the development of ESRD in the entire cohort.[76] Similarly, in the long-term follow-up of the AASK cohort, the intense blood pressure target was associated with a reduction in a composite outcome of doubling of serum creatinine concentration (S[Cr]), ESRD, or death among the minority (33%) of

TABLE 57.2 Outcomes of Trials Evaluating the Effect of a Low Blood Pressure Target on Progression of Renal Disease

Study/Patients	N	Low BP Target (mm Hg)	Standard BP Target (mm Hg)	Outcome	Secondary Analyses
Nondiabetic, hypertensive, CKD[70]	77	DBP 65–80	DBP 85–95	GFR slope (mL/min/1.73 m^2/yr) −0.31 vs −0.050 p > 0.25	NR
Type 1 diabetic nephropathy[71]	129	MAP 92	MAP 100–107	Change in iGFR (mL/min/1.73 m^2) 62–54 vs 64–58 p = 0.62	Median proteinuria 535 vs. 1723 mg/24 h p = 0.02
REIN-2 non-DM proteinuria[72]	335	DBP <90	<130/80	ESRD HR 1.00 (95% CI 0.61–1.64) p = 0.99	No difference in urinary protein excretion
MDRD (Study 1) GFR[2] 25–55 mL/min/1.73 m^2	585	MAP <92	MAP 107	GFR slope (mL/min/3 yrs) 10.7 vs. 12.3 p = 0.18	**1.** Benefit of low BP target in patients with significant proteinuria **2.** Decreased risk of kidney failure in low BP target arm in long-term follow-up HR 0.68 (95% CI 0.57–0.82)
MDRD (Study 2) GFR[2] 13–24 mL/min/1.73 m^2	255	MAP <92	MAP 107	GFR slope (mL/min/yr) 3.7 vs. 4.2 p = 0.28	
AASK—nondiabetic AA with CKD[73]	1094	MAP <92	MAP 102–107	GFR slope (mL/min/1.73 m^2/yr) −2.21 vs. −1.95 p = 0.24	Long-term follow-up **1.** No difference in doubling of S [Cr], ESRD, or death overall **2.** Decreased risk of composite among patients with a UPCR>0.22 (HR 0.73)
SPRINT—nondiabetic with CKD[74]	2646	SBP <120	SBP <140	Decrease in eGFR of ≥50% or ESRD HR 0.90 (95% CI 0.44–1.83)

The *open circles* are the low blood pressure target arm (mean arterial pressure [MAP] 92 mm Hg) and the *closed circles* are the usual blood pressure target arm (MAP 107 mm Hg). *Reproduced from Reference 2 with permission from Massachusetts Medical Society, © 1994.*

participants with proteinuria (urine protein:creatinine ratio [UPCR] >0.22 g/g). In combined analyses of individual-level data from both MDRD and AASK that included posttrial follow-up, intense blood pressure lowering was associated with reduced risk for ESRD (HR 0.88, 95% CI 0.78−1.00) and all-cause mortality (HR 0.87, 95% CI 0.76−0.99).[77] The results of these secondary analyses have led some experts to recommend lower blood pressure targets in CKD patients with proteinuria.

The more recent results from the Systolic Blood Pressure Intervention Trial (SPRINT) are consistent with prior studies. SPRINT randomized 9361 participants, of whom 2646 had CKD at baseline, to an intense blood pressure target (systolic BP <120 mm Hg) or a standard blood pressure target (<140 mm Hg). After a median follow-up of 3.3 years, the study was terminated early due to a significant reduction in the primary cardiovascular composite outcome in the intensive treatment group.[78] There was no significant effect modification by baseline CKD status. Among those with CKD, the intensive treatment was associated with a reduction in the primary cardiovascular outcome and all-cause mortality. The prespecified kidney outcome was a composite of ≥50% decrease in eGFR from baseline or ESRD. Although the number of events was low, there was no difference in the kidney outcome between the intensive and standard groups (HR 0.90, 95% CI 0.44−1.83) (Figure 57.3).[74] These results have been incorporated in the recent clinical practice guideline from the American Heart Association/American College of Cardiology that recommends a blood pressure target of ≤130/80 mm Hg.[79] Although the appropriate blood pressure goal to reduce progression of CKD is unknown, a target blood pressure of ≤130/80 mm Hg is reasonable given the benefits with regard to CVD risk reduction.

Other Methods of Measuring Blood Pressure

The previous discussion of BP targets as they relate to slowing progression of CKD is predicated on measurement of BP in the clinic. Methods for measuring BP outside the clinic have been available for over 30 years.[80] Measurement of BP outside the clinic may provide a more accurate and independent assessment of the risk of CVD and mortality associated with hypertension.[75] Patients with elevated BP outside the clinic, with either normal clinic BP (masked hypertension) or elevated clinic BP (sustained hypertension), are at increased risk for adverse clinical events, regardless of their clinic BP.[81] In patients with CKD, blood pressures measured at home and with ambulatory blood pressure monitoring (ABPM) are stronger and independent predictors of ESRD.[71,72] An advantage of ABPM is the ability to measure BP throughout the day and night. Nighttime BP and the relative decline in BP from day to night, otherwise known as dipping status, are independent predictors of cardiovascular events and all-cause mortality.[82]

Despite the potentially stronger relationship between home and ambulatory blood pressure and adverse outcomes, further research is needed to determine whether modifying antihypertensive treatment based on home and ambulatory blood pressure reduces adverse clinical events.

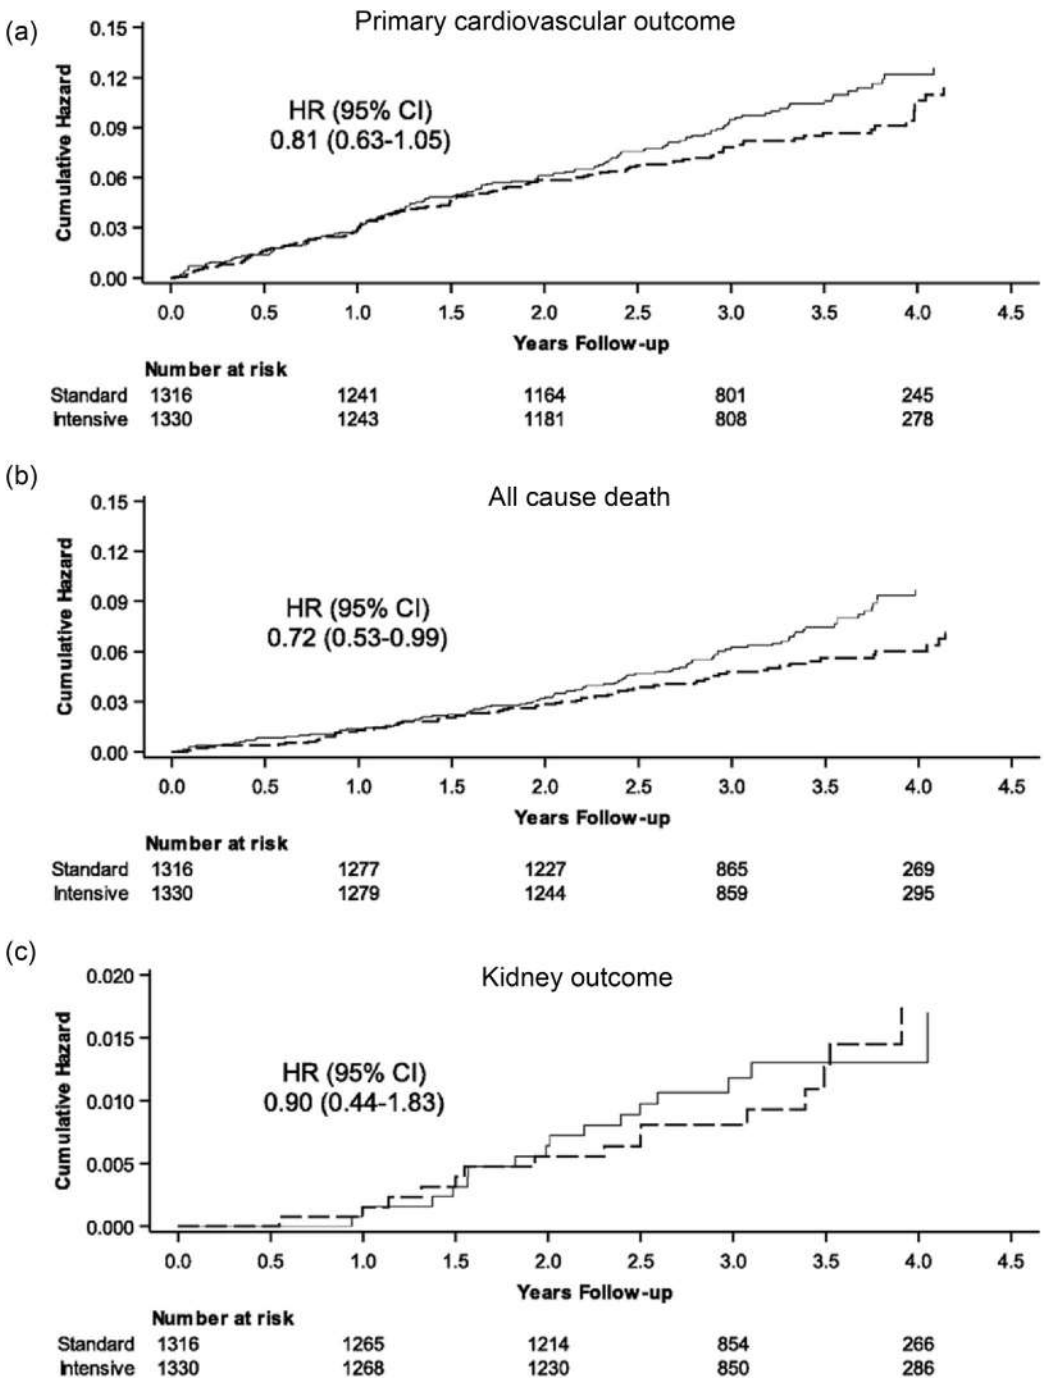

FIGURE 57.3 Outcomes in Systolic Blood Pressure Intervention Trial participants with CKD. Dashed lines are the intensive group (SBP<120 mm Hg) and solid lines are the standard group (SBP <140 mm Hg). (a) Primary cardiovascular outcome (composite of myocardial infarction, acute coronary syndrome, stroke, acute decompensated heart failure, and death from cardiovascular cause). (b) All cause death outcome. (c) Kidney outcome (composite of a ≥50% decrease in estimated glomerular filtration rate (eGFR) from baseline or the development of end-stage renal disease. Significant differences favoring the intensive group are demonstrated in panels a and b, but no difference was seen in the renal outcome shown in panel c. *Reproduced from Reference 74 with permission from American Society of Nephrology.*

Finally, it is now feasible to measure central aortic blood pressure in the clinic.[83] Newer devices allow measurement of 24-hr ambulatory central blood pressure.[84] Whether central blood pressure is a better predictor of progression of renal disease than peripheral blood pressure is unknown, but central blood pressure may be important in patients with CKD, given the relationship between renal function and aortic stiffness.[85] There are no randomized trials to guide clinicians regarding the use of clinic BP targets as opposed to ambulatory/

newer BP targets in patients with CKD. Despite this, the new AHA/ACC guidelines and the US Preventive Services Task Force recommend obtaining BP measurements outside the clinic in the diagnosis of hypertension, and to guide therapy for those on antihypertensive medications.[86–88] Further research is needed to define the clinical utility of blood pressures measured outside the clinic.

Inhibition of the Renin–Angiotensin–Aldosterone System

RAAS inhibition remains the major strategy for slowing progression of CKD. The system can be inhibited at multiple steps, with a number of different drugs that include ACEIs, ARBs, renin inhibitors, and aldosterone antagonists. Animal studies, initially in the remnant kidney model, demonstrated a beneficial effect of ACEIs on limiting kidney injury.[89] Subsequent animal studies demonstrated a preferential effect of ACEIs over other antihypertensives that achieved similar reductions in systemic blood pressure in arresting progressive kidney disease.[90,91] The beneficial effects are related in part to efferent arteriolar vasodilation and subsequent decrease in glomerular hypertension, effects mediated by inhibiting the preferential role of AII on this vessel, but also through ACEI increasing bradykinin levels.[92] These and other studies laid the foundation for the first clinical studies demonstrating ACEI can slow the progression of diabetic kidney disease in humans.

Evidence has mounted over the years that RAAS inhibition has preferential effects on reducing proteinuria and slowing progression of CKD compared to other agents. The magnitude of these beneficial effects of RAAS blockade is estimated to be about a 20% risk reduction. A beneficial effect has been demonstrated in both diabetic and nondiabetic kidney disease, in early and late-stage CKD, and with ACEIs and ARBs.[93–99] In diabetics, most studies have demonstrated RAAS blockade slows progression from normoalbuminuria to microalbuminuria, from microalbuminuria to overt diabetic nephropathy, as well as the progression of established diabetic nephropathy.[94,96,100–102] However, in a trial in normotensive, normoalbuminuric type 1 diabetic patients, with normal GFR, early treatment with ARBs or ACEIs did not slow nephropathy progression, assessed as either the fraction of glomerular volume occupied by mesangium or the incidence of microalbuminuria.[103]

Inhibition of renin is another means of interrupting the RAAS. Addition of a renin inhibitor to an ARB reduced proteinuria in patients with diabetic nephropathy.[104–106] However, add-on therapy with a renin inhibitor was associated with adverse effects.

Dual Blockade of the RAAS

On the basis of preclinical studies, and the reasoning that single agents directed at inhibiting the RAAS do not completely block the system, studies combining drugs to inhibit the RAAS pathway at more than one site have been performed. The most common combination has been an ACEI plus an ARB. Initial animal and clinical studies demonstrated a beneficial effect of dual therapy on the surrogate endpoint of proteinuria. Also, meta-analysis demonstrated a greater reduction in proteinuria with combination therapy but did not examine GFR endpoints.[107] The field was misled by the COOPERATE study that demonstrated a dramatic beneficial effect of dual blockade on long-term renal outcomes, but the study was subsequently retracted due to inconsistencies in the data.[108] Enthusiasm for dual therapy was subsequently reduced by the Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial.[109] In this study 25,620 subjects with established atherosclerotic vascular disease or diabetes with end-organ damage were randomized to receive the ACEI ramapril, ARB telmisartan, or both drugs. Combination therapy was associated with a higher occurrence of the composite primary renal outcome of dialysis, doubling of S[Cr] and death. Interestingly there was dissociation between a greater reduction in proteinuria with combination therapy but worse renal outcomes.

The ALTITUDE trial studied the effects of adding the renin inhibitor aliskiren to ACEI or ARB therapy.[106] This study was terminated early secondary to adverse outcomes including hyperkalemia, hypotension, and stroke. The Veterans Administration multicenter trial in type 2 diabetic patients with nephropathy, examining the effects of combining losartan and lisinopril compared with losartan alone (NEPHRON-D), was stopped because of a higher incidence of acute kidney injury (AKI) and hyperkalemia in the combination group.[110]

In a systematic review and meta-analysis of dual blockade compared with monotherapy, RCTs stratified for patients with and without heart failure were analyzed.[111] This analysis was not directed at patients with CKD. Dual blockade did not improve all cause or cardiovascular mortality but was associated with a reduction in hospitalizations for heart failure compared to monotherapy. However, dual therapy was associated with a higher incidence of hypotension, hyperkalemia, acute renal failure, and withdrawal of treatment because of adverse events. A meta-analysis examining the safety of combined vs. single RAAS blockade in CKD patients demonstrated a greater reduction in proteinuria and GFR, without any benefit on the outcomes of doubling of S[Cr], hospitalization, or

mortality.[112] Similar to other studies, combination therapy was associated with a higher risk of hyperkalemia and hypotension. Based on these studies, dual blockade of RAAS is not recommended.

Despite these studies, the issue of dual blockade remains an active one. An ongoing trial, Preventing ESRD in Overt Nephropathy of Type 2 Diabetes (VALID), is comparing the effects of dual inhibition of the renin–angiotensin system on ESRD and cardiovascular events in type 2 diabetic patients with overt nephropathy (S[Cr] between 1.8 and 3.2 mg/dL and spot morning urine albumin:creatinine ratio (UACR) >1000 mg/g [ClinicalTrials.gov: NCT00494715]). Patients will be treated for 3 years to comparable BP levels with the ACEI benazepril, the ARB valsartan, or combination therapy using halved dosages of the ACEI and ARB together.[113]

Aldosterone Antagonism

Aldosterone antagonists have beneficial effects in many different animal models of kidney disease, whether used alone or when combined with other RAAS inhibitors.[114,115] In human disease, both nonselective antagonists such as spironolactone, and selective antagonists such as eplerenone, have been studied. Most studies have only examined the surrogate endpoint of proteinuria and have demonstrated that aldosterone antagonists reduce proteinuria compared to ACEIs or ARBs alone.[116] These studies were small, with short-term follow-up, and have not addressed the effects of aldosterone antagonism on progression of CKD. Some studies have examined the effects of aldosterone antagonists on GFR but have not shown a change in end of study GFR. A beneficial effect on reducing blood pressure has been demonstrated in many studies. Adverse effects of aldosterone antagonism, including gynecomastia and especially hyperkalemia, limit the attractiveness of this approach. These risks coupled with the lack of conclusive evidence for efficacy argue against using aldosterone blockade to slow progression of CKD at this time.

Trials are ongoing examining the effects of finerenone, a nonsteroidal mineralcorticoid receptor antagonist that is more selective than spironolactone and has greater receptor affinity than eplerenone. The Mineralcorticoid Receptor Antagonist Tolerability Study-Diabetic Nephropathy resulted in a dose-dependent reduction of proteinuria after 90 days of treatment with finerenone in diabetic patients with albuminuria (mostly on an ACEI or ARB).[117] Hyperkalemia developed in 1.8% of patients compared to none in the placebo group.

Other Therapeutic Considerations

Dietary Protein Restriction

In most experimental renal diseases, increased protein intake is associated with progressive decline in GFR, increases in proteinuria, and worse glomerulosclerosis.[20,118] Unfortunately, the concept of restricting protein intake to slow progression of CKD has not easily translated to the clinic.[119,120] In the MDRD study, the largest RCT, no reduction in progression of CKD was observed with dietary protein restriction.[2] However, a Cochrane review of 10 randomized trials including 2000 nondiabetic participants found that low-protein diets reduced the incidence of a composite of death or ESRD.[121] Additionally, there appeared to be a dose–response effect of dietary protein restriction in CKD patients.[121] A significant benefit was observed when a very low–protein diet (0.3–0.6 g/kg/day) was compared to a higher-protein diet (RR 0.63, 95% CI 0.48–0.83). There was only marginal benefit when a low-protein diet (0.6 g/kg/day) was compared to a higher-protein diet (RR 0.76, 95% CI 0.54–1.05). No analysis was performed evaluating the impact of low-protein diet on development of ESRD. Despite the findings from this review, the negative results from MDRD and the difficulty in counseling patients to follow low-protein diets has led to the infrequent prescription of low-protein diets for patients with CKD. Avoidance of high-protein diet is recommended for all patients with CKD in the absence of malnutrition. With the appropriate monitoring and nutritionist support, it is reasonable to counsel patients with CKD to target a protein intake of 0.6 g/kg/day.

Bicarbonate Supplementation

Moderate and severe CKD is associated with metabolic acidosis *via* multiple mechanisms, including decreased ammoniagenesis, reduced excretion of protons, and hyperkalemia. Low S[HCO_3] is associated with increased risk for progression of CKD and even loss of kidney function in the general population.[122,123] Two RCTs have evaluated whether treating metabolic acidosis reduces progression of CKD. One hundred and thirty-four patients with a creatinine clearance of 15–30 mL/min/1.73 m^2 and a S[HCO_3] < 20 and >16 mmol/L were randomized to $NaHCO_3$ 600 mg three times a day vs. placebo. After 2 years, treatment with $NaHCO_3$ slowed decline in creatinine clearance and was associated with a decrease in the rate of developing ESRD (6.5% vs. 33%, $p < 0.001$).[124] A second study of 120 patients with hypertensive CKD with a GFR between 60 and 90 mL/min/1.73 m^2 and a UACR between 200 and 2000 mg/g randomized participants to $NaHCO_3$, NaCl (both 0.5 mEq/kg/day), and placebo

and followed them for 5 years. Treatment with $NaHCO_3$ slowed decline in GFR compared to NaCl and placebo, and also was associated with decreased UACR during follow-up.[125] The beneficial effect of bicarbonate supplementation on progression of CKD may be mediated through decreases in activation of complement by ammonia and by endothelin and aldosterone, and may also extend to improvement in physical functioning.[126,127]

To address the sodium load associated with alkali therapy, the effect of TRC101, a sodium-free acid binder, was examined in 135 CKD patients with a mean eGFR of 35 mL/min/1.73 m^2. Therapy was demonstrated to increase serum bicarbonate levels safely.[128]

In summary, bicarbonate supplementation is recommended to slow progression of CKD in patients with low bicarbonate levels, but the benefits of bicarbonate supplementation may extend to those with bicarbonate levels in the normal range. Further study is needed to determine the degree of effectiveness of bicarbonate supplementation.

Allopurinol

Uric acid levels are elevated in patients with renal dysfunction, and hyperuricemia is associated with endothelial dysfunction, activation of the RAAS, and hypertension.[129] A number of small, short-term clinical trials have suggested that lowering uric acid benefits patients with CKD. In one such study, 113 patients with eGFR <60 mL/min/1.73 m^2 were randomized to allopurinol 100 mg/day vs. usual therapy. After 24 months, those in the allopurinol group had a significant reduction in S[UA], an increase in eGFR, and a reduction in risk for cardiovascular events compared to the usual care group.[130] In long-term observational follow-up, treatment with allopurinol was again associated with reduced risk for a composite of starting dialysis, doubling of S[Cr], or ≥50% decline in eGFR (HR 0.32, 95% CI 0.15–0.69).[131] Allopurinol has been associated with reduction in risk for progression of CKD and, in a study of type 2 diabetic patients with urine protein excretion >500 mg/day, significant reduction of proteinuria.[132] A meta-analysis of 11 studies including 753 participants found that urate-lowering therapy was associated with slowing of progression of CKD.[133] Follow-up was 12 months or less in all but one of the studies included in the meta-analysis. The benefits of allopurinol may extend beyond its reduction in uric acid levels, through other properties including antiinflammatory and antioxidant effects, and reduction in reactive oxygen species.[134] In a study of febuxostat, a nonpurine-selective inhibitor of xanthine oxidase, in 443 patients with stage 3 CKD and asymptomatic hyperuricemia treated for 108 weeks, the decline in eGFR was not different compared to a placebo-treated group.[135] Until results are available from larger, long-term RCTs, lowering uric acid to reduce progression of CKD cannot be recommended, especially considering the relatively high incidence of serious allergic reactions with allopurinol.

Glycemic Control

Intensive Glucose Control

Diabetes mellitus is a major cause of CKD and ESRD. Elevated blood glucose and hemoglobin A1c are associated with progression of CKD. In patients with both type 1 and type 2 diabetes, intensive blood glucose control reduced the incidence of abnormal albuminuria and its progressive increase.[136–141] Intense therapy likely reduces progression of CKD in patients with type 1 diabetes as demonstrated in long-term follow-up of the Diabetes Control and Complications Trial (DCCT).[142] However, the results of intensive glucose control on the decline in GFR, or development of ESRD, have been mixed.[138,141,143] A meta-analysis of seven trials including 28,065 participants with type 2 diabetes revealed that while intensive glucose control reduced albuminuria, there was no improvement in the rate of doubling of S[Cr] or development of ESRD.[144] Most of the studies mentioned above excluded participants with elevated S[Cr] at baseline. In the Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation trial (ADVANCE) study, intensive glucose control in type 2 diabetics reduced the occurrence of new or worsening nephropathy and ESRD with the caveat that there were a small number of ESRD events.[140] In a 6-year posttrial follow-up of ADVANCE, ADVANCE Observational (Advance-ON), the reduction in ESRD persisted.[145,146] Of importance, there was no increased risk of cardiovascular events or death. Based on these data, it is reasonable to target a hemoglobin A1c of approximately 7% in patients with CKD and diabetes.

Specific Glucose-Lowering Drugs

An emerging area is the investigation of whether some glucose-lowering drugs have beneficial effects on diabetic nephropathy and cardiovascular outcomes above and beyond their effects on glucose control. This area will be reviewed below.

Sodium-Glucose Cotransporter 2 (SGLT2) Inhibitors

These drugs inhibit sodium and glucose transport in the S1 segment of the proximal tubule and consequently increase glucose and sodium excretion. In addition to effects on glycemic control, SGLT2 inhibitors lower BP, weight, and albuminuria and are associated with a decline in GFR.[147] In the first of these studies, Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPA-REG OUTCOME

trial), the effect of empagliflozin was examined in 7020 adults with type 2 diabetes mellitus and established CVD with an eGFR of at least 30 mL/min/1.73 m^2.[148] Empagliflozin treatment over a median follow-up of 3.1 years reduced the risk of cardiovascular events, defined as a composite of first occurrence of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke. The risk of the prespecified renal outcome of incident or worsening nephropathy (progression to macroalbuminuria, doubling of S[Cr] accompanied by an eGFR $\leq$45 mL/min/1.73 m^2, initiation of RRT, or death from renal disease) and incident albuminuria was also reduced by empagliflozin (Figure 57.4).[150] Interestingly, treatment with empagliflozin was associated with a decrease in eGFR that was reversible after stopping the study drug.

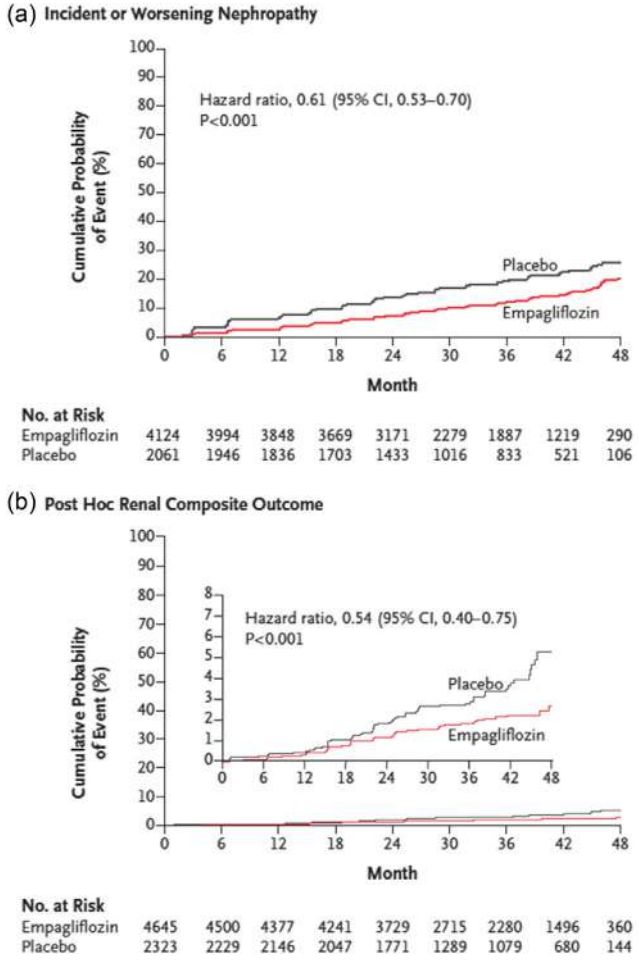

FIGURE 57.4 Empagliflozin and progression of kidney disease in type 2 diabetes. Kaplan–Meier analysis of (a). incident or worsening nephropathy (defined as progression to macroalbuminuria, a doubling of S[Cr] accompanied by an eGFR $\leq$45 mL/min/1.73 m^2, initiation of renal replacement therapy, or death from renal disease). (b) *Post hoc* renal composite outcome in which progression to macroalbuminuria was excluded from the composite renal outcome. The inset in panel b expands the y axis. *Reproduced from Reference 149 with permission from Massachusetts Medical Society, © 1994.*

In the CANVAS Program, the SGLT2 inhibitor canagliflozin was studied in 10,142 type 2 diabetic subjects at high risk for CVD. Canagliflozin decreased the primary cardiovascular endpoint of death from cardiovascular cause, nonfatal myocardial infarction, or nonfatal stroke.[151] The renal outcomes were not statistically significant based on the "prespecified hypothesis testing sequence," with a possible benefit in progression of albuminuria and the composite of sustained 40% reduction in eGFR, the need for RRT, or death from renal causes. There was an unexplained increased risk for amputation in the canagliflozin group.

The use of SGLT2 inhibitors is not recommended when the eGFR is <30 mL/min/1.73 m^2. To assess the safety and efficacy of SGLT2 inhibitors in patients with more severe CKD, the results of 11 phase 3 randomized placebo-controlled trials in type 2 diabetic patients treated for an average of 102 weeks with dapagliflozin, another SGLT2 inhibitor, were analyzed. These patients had stages 3b and 4 CKD (eGFR of 15–45 mL/min/1.73 m^2).[152] In this analysis dapagliflozin did not improve glycemic control but decreased albuminuria, BP, and body weight. Interestingly, serum phosphate concentration levels increased, but there were no other serious adverse effects.

These results demonstrating renal protective effects of SGLT2 inhibitors are promising, but before they are widely used as renal protective agents studies are needed examining long-term kidney outcomes. In this regard the Canagliflozin and Renal Endpoints in Diabetes with Established Nephropathy Clinical Evaluation trial (CREDENCE; ClinicalTrials.gov number NCT02065791) provides important information about renal outcomes.[147] This was a trial in 4400 patients with type 2 diabetes and UACR >300 to $\leq$5000 mg/g and eGFR $\geq$30 to <90 mL/min/1.73 m^2 adding canagliflozin to standard care consisting of maximum labeled or tolerated dose of ACEI or ARB. The primary endpoint was a composite of time to dialysis or kidney transplantation, doubling of S[Cr], and renal or CV death. The relative risk of the primary outcome was 30% lower in the canaglifozin group than in the placebo group. The canaglifozin group also had a lower risk of cardiovascular death, myocardial infarction, or stroke. There were no differences in the rates of amputation or fracture. This exciting study provides strong data for a renal protective effect of canaglifozin.

The potential mechanism of the beneficial effects of SGLT2 inhibitors may be through decreasing hyperfiltration. By reducing proximal reabsorption of sodium, distal sodium delivery is increased, activating tubular glomerular feedback leading to afferent arteriolar vasoconstriction and a reduction in hyperfiltration. This is a

class effect and is reversible after stopping the drug. If true then these drugs may also be effective in nondiabetic kidney disease, a hypothesis that is being tested in the Study to Evaluate the Effect of Dapagliflozin on Renal Outcomes and Cardiovascular Mortality in Patients With CKD (DAPA CKD) in which half the patients are diabetic and half are nondiabetic. The primary outcome is a composite of ≥50% sustained decline in eGFR, ESRD, or CV or kidney death (ClinicalTrials.gov NCT03036150).[147]

Dipeptidyl Peptidase Inhibitor Linagliptin

Linagliptin inhibits the breakdown of incretin hormones, which leads to increased glucose-dependent insulin secretion, inhibition of glucagon secretion, and improved glucose control. Pooled data from 13 phase 2 or 3 trials of the dipeptidyl peptidase inhibitor (DPP-4) linagliptin in type 2 diabetics showed intervention reduced the risk of kidney disease events by 16% compared to placebo.[153] The ongoing Cardiovascular safety and Renal Microvascular outcomE study with LINAgliptin in type 2 diabetics at high cardiovascular risk (CARMELINA) study is a randomized, double-blind, placebo-controlled trial with a cardiovascular primary outcome and a renal secondary outcome (ClinicalTrials.gov Identifier: NCT01897532).

Glucagon-like Peptide-1 Analogues

Another class of glucose-lowering medications is the human glucagon-like peptide-1 (GLP-1) analogues that act by stimulating insulin release. Cardiovascular and renal protective effects have been demonstrated with these agents. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial in type 2 diabetic patients with high cardiovascular risk demonstrated improved cardiovascular outcomes and lower mortality in patients treated with liraglutide.[154] The effects of liraglutide on renal outcomes were a prespecified secondary outcome comprised of new onset of persistent macroalbuminuria, persistent doubling of S[Cr], the need for RRT, or death due to renal cause.[155] Over a median follow-up of 3.84 years, liraglutide decreased the composite renal outcome, with the result driven primarily by a decrease in new onset of persistent macroalbuminuria. The beneficial effect was not related to glucose control, BP reduction, or a reduction in body weight, but it is likely multifactorial, acting through antiinflammatory and antioxidant mechanisms.[156–158]

In the Trial to Evaluate Cardiovascular and Other Long-Term Outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN 6), treatment once weekly with the GLP-1 receptor analogue semaglutide reduced the incidence of the primary cardiovascular outcome of cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke in 3297 patients with type 2 diabetes.[159] The prespecified secondary renal outcome of rates of new or worsening nephropathy was lower with semaglutide compared to placebo.

Emerging Therapies

Endothelin Antagonists

Endothelins are vasoconstricting peptides. Endothelin-1 (ET-1) is the major isoform in the human kidney. ET-1 has a number of potentially adverse effects on the kidney in animal models, including vasoconstriction, glomerular hypertension, proteinuria, and interstitial fibrosis. Preclinical studies have demonstrated that ET-1 antagonism reduces proteinuria and improves GFR.[160,161] However, a multicenter randomized trial of the endothelin antagonist avosentan compared with placebo was terminated after 4 months due to excess cardiovascular events in the avosentan group.[162] There was less proteinuria with avosentan but no difference in time to doubling of S[Cr], ESRD, or death. Atrasentan is another endothelin antagonist that is more selective for the endothelin A receptor. Patients with type 2 diabetes on maximal doses of ACEI or ARB, eGFR 30–75 mL/min/1.73 m^2, and UACR 300–3500 mg/g were randomly assigned to placebo or to 0.75 or 1.25 mg of atrasentan for 12 weeks.[163]

Atrasentan significantly reduced albuminuria, although there was a large variability between patients. Edema as a side effect was most common with the highest 1.25 mg dose.

These results led to a Phase 3 trial examining the effects of atrasentan on renal outcomes in diabetic patients is the Study Of diabetic Nephropathy with AtRasentan (SONAR); NCT01858532).[164] This double-blind, placebo–controlled trial in patients with stage 2–4 CKD and macroalbuminuria used an enrichment design randomizing patients with a ≥30% decrease in urinary albumin excretion at 6 weeks with no substantial fluid retention during the enrichment period. The primary endpoint was a composite of sustained doubling of S[Cr] or ESRD. 2648 patients were randomly assigned to atrasentan 0.75 mg orally per day or placebo with median follow-up of 2.2 years. Atrasentan significantly reduced the risk of renal events with no differences seen in hospital admission for heart failure or death.

Antiinflammatory Agents

Inflammation and oxidant stress can accelerate the progression of CKD. Bardoxolone methyl is a synthetic oleanane triterpenoid that activates NRF2, a transcription factor that controls expression of antioxidant, antiinflammatory, and cytoprotective genes.[165] In a phase 2 RCT

involving 227 adults with type 2 diabetes and moderate to severe CKD, bardoxolone improved eGFR at 24 and 52 weeks, but albuminuria was increased with higher doses of bardoxolone (BEAM Study).[166] A phase 3 trial evaluating the effect of bardoxolone on clinical endpoints in 2185 patients with type 2 diabetes and an eGFR between 15 and 30 mL/min/1.73 m^2 was stopped due to excess cardiovascular events, mainly heart failure, in the bardoxolone arm (BEACON Study).[167] In a *post hoc* analysis of this study, a bardoxolone-associated increase in eGFR was sustainable for 1 year and was associated with improved renal outcomes.[168]

This class of inflammatory modulating drugs presents an intriguing therapeutic option that is being tested in the CARDINAL Program, a phase 2/3 trial designed to assess the safety, tolerability, and efficacy of bardoxolone in Alport syndrome.[169,170]

Pentoxifylline is a nonspecific phosphodiesterase inhibitor originally approved for the treatment of peripheral vascular disease. It also has antiinflammatory and antifibrotic properties.[171] There have been several meta-analyses demonstrating mixed results of pentoxifylline on proteinuria.[172–175] In a randomized open-label trial in patients with type 2 diabetes mellitus and stage 3–4 CKD, treatment with pentoxifylline for 2 years in addition to RAAS inhibitors reduced the rate of decline in eGFR and lowered albuminuria compared to a control group.[176] More definitive long-term trials looking at hard renal endpoints are needed before pentoxifylline can be considered standard therapy for preventing progression of diabetic kidney disease.

Antifibrotic Therapies

Pirfenidone is a synthetic molecule that has been demonstrated to have antifibrotic properties in both cell culture and mouse models of diabetic kidney disease.[177] Trials in humans have been promising as well. In an open-label trial involving 18 patients with FSGS treated with pirfenidone for a median of 13 months, treatment was associated with a 25% improvement in the slope of change in GFR.[178] In a RCT including 52 participants with diabetic nephropathy, eGFR increased in participants assigned to pirfenidone 1200 mg/day, whereas a decline in GFR was noted in participants assigned to placebo ($p = 0.026$ vs. pirfenidone at 1200 mg/day).[179] The dropout rate was high in a third arm of the trial in which participants were assigned to pirfenidone 2400 mg/day.

Sulodexide, another antifibrotic agent, showed promise in early studies, but larger, more recent trials have failed to demonstrate a beneficial effect in patients with diabetic nephropathy.[180–183] Larger RCTs are needed to evaluate whether pirfenidone will be beneficial in slowing the progression of CKD.

Cellular Therapy and Kidney Augmentation

A number of factors are driving the use of cellular therapy and kidney augmentation to treat CKD. These include the availability of and initial success in using mesenchymal stem cells (MSCs) in nonrenal conditions and in treating AKI and kidney transplant patients.[184,185] Also, the growing gap between patients on the kidney transplant wait list and the availability of kidneys has generated interest in alternative approaches to renal replacement. A beneficial effect of MSC infusion has been demonstrated in animal models of kidney disease such as glomerulonephritis, Alport syndrome, FSGS, lupus nephritis, diabetic nephropathy, and the remnant kidney model.[186] In the glomerulonephritis model, maldifferentiation of intraglomerular MSCs into adipocytes occurred and was accompanied by glomerular sclerosis.[187] MSCs have been infused into patients with CKD, although the data from such studies are difficult to interpret. Umbilical cord-derived MSCs have been used for patients with lupus nephritis but had no additional effect compared to standard therapy.[188]

Implantable bioartificial kidney devices have been envisioned in which renal tubular cells are part of the device and are linked to a glomerular membrane.[189,190] The goal of these approaches is to restore the metabolic, immune, and transport functions of the kidney. Kidney cells are also critical components of a bioengineered kidney designed by injecting endothelial and neonatal kidney cells into a decellularized kidney scaffold.[191] Such a device has demonstrated *in vitro* and *in vivo* function. A kidney-on-a-chip model has been developed to allow kidney cells to be cultured in three-dimensional channels using a microfluidic device.[192] This model has been used to examine nephrotoxicity, kidney stones, kidney fibrosis, and disease modeling and may help facilitate the development of whole organs to be used for renal replacement. Work continues in this rapidly developing area with enormous potential for the treatment of CKD but also with many barriers to success.[193]

CONCLUSION

Slowing progression of kidney disease is a critical goal for CKD patients. Given the limited evidence for slowing progression of CKD with intensive BP control (systolic BP <120 mm Hg) vs. standard control (SBP <140 mm Hg), current recommendations to target BP <130/80 mm Hg are based on beneficial reductions in cardiovascular events and all-cause mortality. RAAS blockade can slow progression of CKD and is the most widely studied and used treatment. Single agent inhibition of the RAAS should be used, as dual blockade is not

more efficacious and is associated with a higher incidence of adverse events. A few other interventions may also slow progression of CKD, including glucose control with a specific beneficial effect of SGLT2 inhibitors and GLP-1 analogues. Bicarbonate supplementation should be considered in the treatment of patients with CKD, as there may be beneficial effects on outcomes. Low-protein diets may be effective in nondiabetic kidney disease. Lowering uric acid may reduce progression, although the evidence is not robust. Future therapies directed at endothelin, fibrosis, oxidant stress, and inflammation are being studied with the hope that our therapeutic armamentarium will increase in the future.

QUESTIONS AND ANSWERS

Question 1

A 55-year-old man is referred to the nephrology clinic for management of CKD. He has a history of hypertension, gout, and an 8-year history of type 2 diabetes complicated by retinopathy. He is currently taking amlodipine 10 mg daily, hydrochlorothiazide 25 mg daily, and glipizide 5 mg daily. His review of systems is completely negative. On examination, his blood pressure is 150/85 mm Hg, which is similar to recent values at his primary care provider's office. S[Cr] is 2 mg/dL (eGFR 36 mL/min/1.73 m^2), HCO3 is 22 mmol/L, Vitamin D 20 nmol/L, UACR is 85 mg/g, and HbA1c is 8.5%.

Which ONE of the following is most likely to slow progression of his CKD?

A. Cholesterol lowering with simvastatin 40 mg daily
B. ACE inhibition with lisinopril 40 mg daily
C. Correction of acidosis with sodium bicarbonate 650 mg TID
D. Dietary protein restriction
E. Vitamin D supplementation

Answer: B

RAAS blockade (Choice B) reduces progression of proteinuria in diabetic nephropathy and slows progression of CKD. Although treatment with a statin (Choice A) may reduce the incidence of CVD in patients with CKD, the SHARP study failed to demonstrate a benefit of cholesterol lowering with regard to progression of CKD.[194] Treatment with sodium bicarbonate (Choice C) has slowed progression of CKD in two small studies, but larger studies are needed to confirm these beneficial effects.[124,125] In the largest study to date, MDRD, dietary protein restriction did not affect rate of decline in renal function (Choice D).[2] There have been no studies demonstrating that vitamin D supplementation (Choice E) slows progression of CKD.

Question 2

A 60-year-old woman is referred to the nephrology clinic for management of hypertension and CKD. She has a 15-year history of hypertension and S[Cr] is 2.1 mg/dL (eGFR 25 mL/min/1.73 m^2). She is taking lisinopril 40 mg daily and hydrochlorothiazide 25 mg daily. Her review of systems is completely negative. On examination, her blood pressure is 155/78 mm Hg, which is similar to recent values at her primary care provider's office. Her UACR is 200 mg/g.

Which ONE of the following is correct regarding treatment of her hypertension?

A. The most appropriate BP target for her is <140/90 mm Hg, which will reduce her risk of CVD
B. The most appropriate BP target for her is <140/90 mm Hg, which will reduce her risk of CVD and slow progression of her CKD
C. The most appropriate BP target for her is <130/80 mm Hg, which will reduce her risk of CVD
D. The most appropriate BP target for her is <130/80 mm Hg, which will reduce her risk of CVD and slow progression of her CKD
E. The most appropriate BP target for her is <125/75 mm Hg, which will reduce her risk of CVD and slow progression of her CKD

Answer: C

Targeting a BP of 130/80 mm Hg will reduce her risk of CVD (Choice C). Although the most appropriate target is not clear, the most recent guidelines from the American Heart Association/American College of Cardiology recommend a blood pressure target of ≤130/80 mm Hg for CKD patients.[88] A number of clinical trials, including MDRD, AASK, and SPRINT, have failed to demonstrate a benefit of lower BP targets with regard to slowing progression of CKD, especially among patients with lower levels of proteinuria (Choices B, D, and E).[2,73,74]

Question 3

A 45-year-old man is seen in follow-up in the nephrology clinic for management of CKD. He has stage 3 CKD with an eGFR of 40 mL/min/1.73 m^2 secondary to FSGS. He also has a past medical history significant for hypertension and dyslipidemia. He is doing well and takes lisinopril 40 mg daily, chlorthalidone 25 mg daily, and simvastatin 40 mg daily. On examination, his blood pressure is 128/78 mm Hg. Cardiac examination reveals a regular rate and rhythm with no S3 or S4, lungs are clear to auscultation, and extremities are without edema. His UPCR is 350 mg/g, which has been stable for the past 2 years. After attending a recent research conference, you consider treatment with pentoxifylline, a novel new agent with potential to slow progression of CKD.

Which of the following is the mechanism of action of pentoxifylline?

A. It is an ET-1 antagonist that reduces proteinuria and improves GFR
B. It is a selective inhibitor of protein kinase C-β
C. It reduces uric acid by inhibiting the enzyme xanthine oxidase
D. It has antiinflammatory and antifibrotic properties
E. It inhibits the renin−angiotensin aldosterone system

Answer: D

Pentoxifylline has both antiinflammatory and antifibrotic properties (Choice D) and, in small pilot studies, has reduced proteinuria and slowed progression of CKD. A larger randomized trial to evaluate the role of pentoxifylline in the care of patients with CKD is underway. Examples of ET-1 antagonists include avosentan and atrasentan (Choice A). Selective inhibitors of protein kinase C-β (Choice B), such as ruboxistaurin, have been shown to reduce albuminuria and stabilize eGFR in patients with diabetic nephropathy. Allopurinol reduces uric acid by inhibiting the enzyme xanthine oxidase (Choice C) and may lower blood pressure and slow progression of CKD but larger RCTs are needed to evaluate its use in CKD patients.

Question 4

A 57-yr-old woman has progressive decrease in GFR from biopsy proven focal and segmental glomerular sclerosis. Her current S[Cr] is 3.7 mg/dL and eGFR using the abbreviated MDRD equation is 16 mL/min/1.73 m^2. A UPCR is 4560 mg/g. Other medical problems include hypertension, currently treated with furosemide 40 mg orally twice daily and lisinopril 40 mg once daily. Her BP is 140/85 mm Hg.

Which ONE of the following statements is correct?

A. She should be referred for mesenchymal stem cell (MSC) infusion therapy to reduce her risks for progression to ESRD
B. The renin inhibitor aliskiren should be added to her antihypertensive regimen to reduce the risks of progression to ESRD
C. Vitamin D should be added because of its benefits in slowing progression of CKD
D. Addition of a dihydropyridine calcium channel blocker should be avoided because of the risk of accelerating the progression of her renal disease
E. Management in a multidisciplinary CKD clinic is associated with better adherence to CKD guidelines and improved outcomes once patients initiate dialysis

Answer: E

This patient has Stage 4 CKD secondary to focal and segmental glomerular sclerosis. Significant proteinuria is present and the blood pressure is poorly controlled. There is evidence supporting Answer E, that the way we deliver care to CKD patients can affect health outcomes. Specifically multidisciplinary CKD clinics are associated with better adherence to CKD guidelines, a higher incidence of fistula use at initiation of dialysis, more outpatient dialysis starts (vs. emergency inpatient starts), and improved outcomes once patients initiate dialysis.[1] MSC infusion has been used following kidney transplantation with mixed results and is being studied in the setting of AKI.[184,186] There is no evidence that such MSC therapy alters the course of CKD; therefore, Answer A is incorrect. There is no evidence that vitamin D alters the progression of CKD making Answer C incorrect. The ALTITUDE trial studied the effects of adding the renin inhibitor aliskiren to ACEI or ARB therapy.[106] This study was terminated early secondary to adverse outcomes including hyperkalemia, hypotension, and stroke in the dual therapy arm. Calcium channel blockers should not be the drugs of first choice in the setting of CKD. However when used in combination with an ACEI or ARB, dihydropyridine calcium channel blockers can effectively lower blood pressure and do not limit the antiproteinuric effects of the ACEI or ARB. There is no evidence that calcium channel blockers accelerate the progression of CKD, making Answer D incorrect.

Question 5

A 54-yr-old man presented with edema and hypertension (BP 150/100 mm Hg). He was found to have S[Cr] 2.8 mg/dL and a urinary protein excretion of 6 g/24 h. A renal biopsy showed membranous glomerulonephritis. He was started on the ACE inhibitor lisinopril, 20 mg/day, and a loop diuretic. One week later his BP was 125/75 mm Hg, his urinary protein excretion decreased to 3 g/24 h, but S[Cr] had increased to 3.2 mg/dL.

Which ONE of the following statements regarding his management would be MOST appropriate?

A. Replace the ACE inhibitor with a beta blocker and evaluate for renal artery stenosis
B. Discontinue the loop diuretic
C. Continue the current antihypertensive regimen and recheck S[Cr] in 1 week
D. Replace the ACE inhibitor with an AII receptor blocker
E. Add steroids and cyclophosphamide to his current drug regimen to treat his glomerular disease

Answer: C

In this patient with CKD secondary to membranous glomerulonephritis treatment with an ACE inhibitor brought his blood pressure into the target range and significantly reduced proteinuria, but was associated with an increase in S[Cr] from 2.8 to 3.2. This increase in S[Cr] is expected, due to the effects of the ACE inhibitor on dilating the efferent arteriole.[18] A decline in GFR has been observed in most clinical studies of ACE inhibitor or ARB treatment. As long as this decrease is less than 30% then treatment can be continued. Therefore, the best response is to continue the current antihypertensive drugs and recheck S[Cr] in one week. There is no evidence that using an ARB instead of an ACE

inhibitor would be more beneficial. Substituting the ACE inhibitor for other treatment would mean a loss of the potential renal protective effects of the ACE inhibitor. The 13% increase in S[Cr] is not enough to launch an evaluation for renal artery stenosis. There are no data demonstrating that discontinuing the loop diuretic or adding cytotoxic therapy would beneficial.

Question 6

A 63-yr-old man has CKD from IgA nephropathy. Two years ago he was hypertensive, S[Cr] was 2.1 mg/dL, estimated GFR by the MDRD equation was 34 mL/min/1.73 m^2, and UPCR was 2000 mg/g. Treatment was started with an ACEI. Over the past two years S[Cr] has increased to 3.4 mg/dL, estimated GFR has decreased to 20 mL/min/1.73 m^2, and UPCR is 2600 mg/g despite maximal dosing of his ACE inhibitor. His current BP is 125/80 mm Hg.

Which ONE of the following changes in his management would be BEST?

A. Switch to a different ACE inhibitor because the current one is ineffective
B. Discontinue the ACE inhibitor and start a dihydropyridine calcium channel blocker
C. Add an ARB to his current medications
D. Intensify BP control by starting a beta blocker
E. Continue current treatment and begin to prepare the patient for renal replacement therapy

Answer: E

This patient with CKD secondary to IgA nephropathy has had progression of his renal failure with estimated GFR decreasing from 34 to 20 mL/min/1.73 m^2 despite maximal dosing of his ACE inhibitor and optimal control of blood pressure. There is no evidence that switching to a different ACE inhibitor will be more effective so Answer A is incorrect. The cornerstone of therapy for this patient is inhibition of AII; therefore, stopping the ACE inhibitor and starting a calcium channel blocker is not indicated, making Answer B incorrect. Addition of an ARB to his current medications has not been demonstrated to improve renal outcomes and is associated with more adverse effects.[107,109] Therefore, dual therapy with ACEI and ARB is not recommended and Answer C is incorrect. There is no evidence that further lowering his blood pressure below 125/80 mm Hg will be beneficial, making Answer D incorrect. The correct course of action is to continue his current therapy and begin the process of preparing the patient for renal replacement therapy. This should involve education about options, assessment of his candidacy and potential donors for transplantation, and planning vascular access if there are no donors or he is not a candidate for transplantation. Therefore, Answer E is correct.

Approach to the Patient with Non-nephrotic Proteinuria

Renu Regunathan-Shenk, Ehsan Nobakht, Scott D. Cohen

Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States

Abstract

This chapter reviews the approach to the patient with non-nephrotic proteinuria. The definition and prevalence of proteinuria are considered. Proteinuria is important because it has implications for progression of chronic kidney disease (CKD) and increased cardiovascular risk. The type of proteinuria may provide important diagnostic clues to the etiology of CKD. Evaluation includes review of the urine sediment, serological evaluation, and renal biopsy if appropriate. Lifestyle modification and antagonism of the renin–angiotensin–aldosterone system form the cornerstone of conservative management for all patients with proteinuric kidney disease. Immunosuppressive therapy may be indicated, depending on the etiology of the patient's renal disease. Additional specific therapies to reduce proteinuria and slow progression of CKD are eagerly awaited.

INTRODUCTION

Proteinuria has been a classic sign of kidney disease since the premodern era. Hippocrates (460–370 BCE) first described the relationship between "foamy urine" and renal disease. Avicenna (Ibn Sina) (980–1037), the Persian physician, also addressed this relationship.[1,2] In 1832, Dr. Richard Bright explained the association of proteinuria and kidney disease.[3] Today, proteinuria is defined as excretion of more than 150 mg of proteinuria within 24 hours. There are different types of protein which may be excreted in the urine of healthy individuals, including albumin, immunoglobulins, and Tamm–Horsfall mucoprotein, which is the most abundant urinary protein in individuals with normal renal function.[4] Albuminuria is the hallmark of glomerular damage and a consequence of impaired glomerular filtration function. A graded association between albuminuria and adverse outcomes regardless of cause of kidney disease and glomerular filtration rate (GFR) categories has been established.[5]

DEFINITION OF PROTEINURIA

There are different types of proteinuria which may indicate the site of damage along the nephron.[6] Albuminuria is a marker of injury to the glomerular filtration barrier, while urinary excretion of predominantly low molecular weight proteins (such as beta-2 microglobulin and alpha-1 macroglobulin) may be viewed as potential evidence of tubular damage or overflow proteinuria, but low molecular weight proteinuria can also be seen in glomerular disease.[7,8] Proteinuria greater than 3.5 g/day or nephrotic range proteinuria with or without nephrotic syndrome suggests underlying glomerulopathy, such as focal segmental glomerulosclerosis (FSGS), membranous nephropathy, minimal change disease, diabetic nephropathy, or amyloidosis.

Non-nephrotic proteinuria has a distinct differential diagnosis. Non-nephrotic proteinuria may be associated with glomerular diseases, however, the differential diagnosis expands to include each renal compartment, including diseases of the renal vasculature and tubulointerstitium.

Proteinuria is classically categorized into glomerular, tubular, and overflow etiologies.[9] The structure of the glomerular basement membrane (GBM) allows the passage of small amounts of protein each day through diffusion and convection. This protein is then largely reabsorbed in the proximal convoluted tubule.[10] Tamm–Horsfall protein is secreted into the tubule in the thick ascending limb of Henle's loop.[11]

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00058-9

The glomerular filtration barrier consists of three layers.[12] The first layer is the endothelial fenestrae, which are in direct contact with the blood.[12] The fenestrations are pores that measure less than 100 nm in diameter and are coated with a negatively charged glycocalyx which serves as both a size and charge barrier to passage of negatively charged molecules greater than 100 nm, including albumin.[12] The second layer is the GBM, made up of type IV collagen and laminin, along with negatively charged proteoglycans, including heparin sulfates.[12] The third or outermost layer is composed of the visceral epithelial cells or podocytes, with their interdigitating foot processes, linked by slit diaphragms which create pore sizes up to 7 nm in diameter.[12] The filtration barrier favors the passage of small (up to 35 nm) and uncharged or cationic molecules.[12]

Albumin is a 70 kD molecule with a diameter of 6 nm and anionic charge. Albumin is filtered by the glomerulus and is mostly reabsorbed by the proximal tubule by receptor-mediated endocytosis.[11,13] Under normal circumstances up to 20–30 mg of albumin is excreted each day.[11,13] Defects in the glomerular filtration barrier (glomerular proteinuria) or tubular reabsorption of filtered protein (tubular proteinuria) or an excessive overload of filtered proteins (overflow proteinuria) that overwhelms tubular reabsorptive capabilities can lead to pathologic levels of proteinuria.

Glomerular proteinuria mostly comprises albumin and occurs because of defects in the size and charge selective barrier.[9,13] This can occur from a variety of glomerular diseases that may result from inflammation, deposition, scarring, or genetic conditions that affect integral membrane proteins, including nephrin and podocin. The majority of the albumin that is filtered across the glomerulus is reabsorbed in the proximal tubule, such that only 4–7 mg of albuminuria is typically found in the urine of individuals with normal renal function.[9,13] Albuminuria above 30 mg/day and less than 300 mg/day (previously termed microalbuminuria) is now considered "moderate albuminuria" in the most recent KDIGO chronic kidney disease (CKD) staging guidelines.[14] Increasing levels of albuminuria are a marker of endothelial injury and are associated with increased risk of cardiovascular disease (CVD). Albuminuria over 300 mg/day is called "severely increased albuminuria" (previously termed macroalbuminuria) and is the level at which standard urine dipsticks are able to detect proteinuria.[14]

Tubular proteinuria is made up of low molecular weight proteins <25 kD, including beta-2 microglobulin, retinol-binding protein, immunoglobulin light chains, and breakdown products of albumin.[8,15] These proteins are generally freely filtered across the glomerular filtration barrier and undergo tubular reabsorption. Tubular proteinuria can be increased in both tubulointerstitial and glomerular diseases. Urine dipsticks detect albumin and are not sensitive for the detection of tubular proteins which are typically excreted in low levels.

Overflow proteinuria occurs with overproduction of proteins, including immunoglobulin light chains in multiple myeloma, myoglobin in the setting of rhabdomyolysis, lysozyme with acute myelomonocytic leukemia, and free hemoglobinuria with intravascular hemolysis that overwhelms the ability of haptoglobin to bind the hemoglobin.[16] The capacity of the proximal tubule to reabsorb the large quantities of proteinuria is often exceeded in these states, leading to nephrotoxic acute renal tubular injury.

PREVALENCE OF PROTEINURIA

Healthy adults excrete less than 150 mg of protein into their urine daily; approximately 20% of this is albumin and the remainder includes Tamm–Horsfall protein, immunoglobulin fragments, and low molecular weight proteins.[17,18] Previous studies estimate the prevalence of microalbuminuria or moderately increased albuminuria (urinary albumin:creatinine ratio [UACR] 30–300 mg/g) to be between 5.1% and 8.2% in the general population. The prevalence of severely increased albuminuria, previously known as macroalbuminuria, is estimated in the general population to be less than 2%.[19,20] However, many conditions are associated with increased risk of developing albuminuria, such as type 1 and type 2 diabetes,[21–23] obesity,[24] hypertension,[25] urologic disease,[26] and renal malignancy.[27]

SIGNIFICANCE

Proteinuria is a significant predictor of CKD progression, development of end-stage renal disease (ESRD), and is associated with cardiovascular mortality. Albuminuria is associated with worse prognosis at every stage of CKD.[20] According to the 2018 Center for Disease Control National Vital Statistic Report, proteinuric kidney disease (including nephritis, nephrotic syndrome, and nephrosis) was the ninth leading cause of death in 2015 and 2016.[28] Several trials have demonstrated the association of proteinuria with estimated GFR (eGFR) decline. In a subgroup analysis of the Modification of Diet in Renal Disease study, patients with greater than 3 g of proteinuria had an eGFR decline of 5.7–6.6 mL/min/year.[29,30] In the African American Study of Kidney Disease and Hypertension (AASK) trial, the median time to ESRD in patients with eGFR of 30 mL/min/min/1.73 m^2 varied by nearly 5 years for patients with lower vs. higher levels of proteinuria.[31] Conversely, reduction of proteinuria by angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin

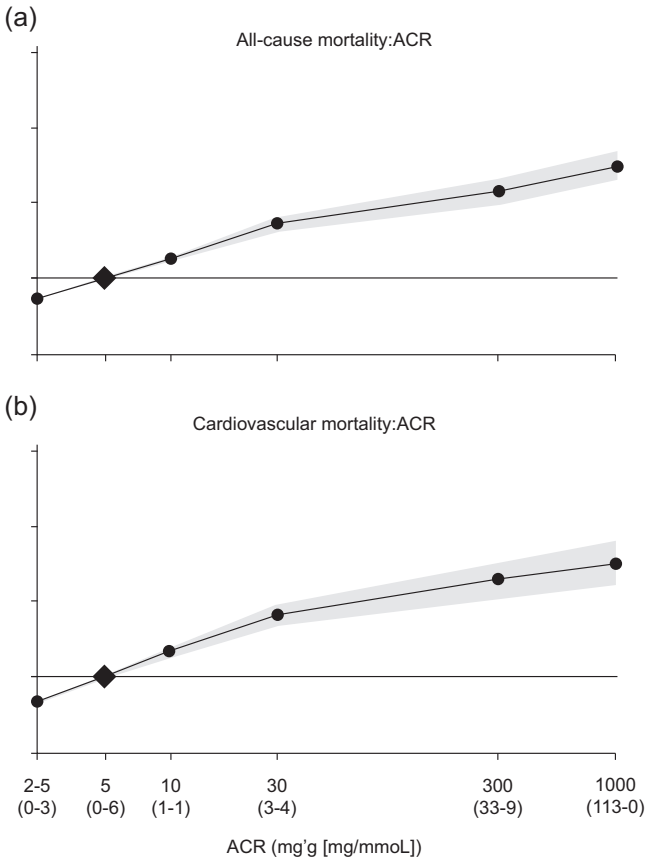

FIGURE 58.1 Relationship of albuminuria with mortality. Hazard ratios and 95% CIs (*shaded areas*) according to albumin:creatinine ratio (ACR) (a, b) adjusted for each other, age, sex, ethnic origin, history of cardiovascular disease, systolic blood pressure, diabetes, smoking, and total cholesterol. The reference (*diamond*) was ACR 5 mg/g (0·6 mg/mmol). Circles represent statistically significant and triangles represent not significant. ACR plotted in mg/g. To convert ACR in mg/g into mg/mmol multiply by 0·113. Approximate conversions to mg/mmol are shown in parentheses. *Reprinted with permission from reference 33 (Elsevier).*

receptor blockers (ARBs) was associated with reduction of the risk of both developing ESRD and with decline of GFR. In the Ramipril Efficacy in Nephropathy (REIN) trial, patients with 3 g or more of proteinuria were randomized to treatment with ramipril or a placebo plus conventional antihypertensives to achieve a goal diastolic BP less than 90 mm Hg.[32] At the end of the follow-up period, the mean absolute GFR was 12 mL/min higher in the ramipril group than the placebo group.[32]

Proteinuria is also significantly associated with CVD morbidity. In a meta-analysis of the CKD Prognosis Consortium, investigators demonstrated that UACR had a linear relationship to all cause and CVD mortality (Figure 58.1).[33] Similarly, a meta-analysis of 10 cohorts including 266,975 patients demonstrated that albuminuria and eGFR were multiplicatively associated with all-cause mortality and CVD mortality, independent of each other and of CVD risk factors.[34] Because of the important relationship between albuminuria and all cause and CVD mortality, as well as risk of CKD progression to ESRD, the KDIGO classification of CKD was updated to include albuminuria as well (Figure 58.2).

DIAGNOSTIC APPROACH TO NON-NEPHROTIC RANGE PROTEINURIA IN PATIENTS WITHOUT DIABETES

The approach to non-nephrotic range proteinuria in patients without diabetes is summarized in six steps (Table 58.1 and Figure 58.3).

History and Physical Examination

A comprehensive history and physical examination should be done with emphasis on signs and symptoms of primary and secondary renal disorders. Comorbidities such as hypertension, diabetes, inflammatory conditions, malignancies, and chronic infections may suggest etiologies of proteinuria. Family history of kidney disease may be positive in hereditary kidney disorders such as hereditary nephritis. A variety of renal diseases are caused or associated with medications. Therefore, a careful review of current and prior medications is essential. Patients may not report use of over-the-counter medications, supplements, or herbal medicines. Further questioning the patient about all medications and supplements and duration of therapy is useful. Physical examination should include blood pressure measurement and a thorough cardiopulmonary examination, as well as attention to skin lesions, which may be seen in some systemic disorders with renal involvement. Edema is an important finding, however, it is more likely in patients with nephrotic range proteinuria.

Obtaining a detailed history of comorbidities based on self-reported history and objective features can provide helpful information for the diagnostic approach. For example, duration of hypertension may not be clearly known for some patients. Objective features such as hypertensive retinopathy and left ventricular hypertrophy noted on ECG or echocardiogram may suggest chronic long-standing hypertension as a potential cause of kidney disease, in contrast to a recent onset of hypertension, which may be a consequence of acute or chronic kidney diseases. Absence of signs and symptoms of microvascular complications of diabetes, such as diabetic retinopathy and neuropathy, may indicate etiologies of proteinuria other than diabetic kidney

Percentage of US Population by eGFR and Albuminuria Category: KDIGO 2012 and NHANES 1999-2006				Persistent albuminuria categories Description and range			
				A1	A2	A3	
				Normal to mildly increased <30 mg/g <3 mg/mmol	Moderately increased 30-300 mg/g 3-30 mg/mmol	Severely increased >300 mg/g >30mg/mmol	
GFR categories (ml/min/ 1.73m²) Description and range	G1	Normal or high	≥90	55.6	1.9	0.4	57.9
	G2	Mildly decreased	60-89	32.9	2.2	0.3	35.4
	G3a	Mildly to moderately decreased	45-59	3.6	0.8	0.2	4.6
	G3b	Moderately to severely decreased	30-44	1.0	0.4	0.2	1.6
	G4	severely decreased	15-29	0.2	0.1	0.1	0.4
	G5	Kidney failure	<15	0.0	0.0	0.1	0.1
				93.2	5.4	1.3	100.0

disease. Non-nephrotic range proteinuria in a diabetic patient is not necessarily due to diabetic kidney disease, and other etiologies should be considered as well. Review of past recorded diagnoses and all comorbidities with attention to the onset and duration of the disorders can provide useful diagnostic clues. Questioning about the accuracy of past documented and "labeled" diagnoses may be necessary, and sometimes can change the entire diagnostic approach.

Urine Studies

The first step in the diagnostic approach to proteinuria is to confirm the result by performing a quantitative test for proteinuria on a random urine sample, followed by an additional test on an early morning urine sample excluding the possibility of orthostatic proteinuria. Orthostatic proteinuria and other benign functional causes of proteinuria are more likely with low grade levels of proteinuria (especially less than 1 g/day) and in younger individuals. The presence of hypertension, decreased GFR, microscopic hematuria, and cellular casts excludes benign functional causes of proteinuria and, therefore, obviates the need for an early morning urine sample to rule out orthostatic proteinuria. Obtaining the prior records of urine studies is helpful to understand the acuity of the process. Benign functional causes of proteinuria are mainly transient. Such transient proteinuria may be associated with fever, exercise, or urinary tract infection.[35–37] Transient proteinuria has been found in 11% of the school-age population, aged 8–15 years. In the absence of other signs of kidney disease, such as hematuria, isolated proteinuria (up to 1 g in 24 hours) may not warrant additional evaluation (such as renal biopsy).[38]

URINE DIPSTICK

Urine dipstick analysis is a common test performed as part of the initial evaluation of patients with renal diseases. Understanding the limitations of urine dipstick testing for proteinuria is important. A concentrated urine specimen or an alkaline urine or use of certain medications such as phenazopyridine may cause a false positive result for proteinuria. On the other hand, acidic urine or dilute urine may cause false-negative results. Therefore, urine-specific gravity and urine pH should be considered for interpretation of a urine dipstick result. Urine dipstick testing after iodinated contrast exposure may also result in a false-positive test for proteinuria.[39]

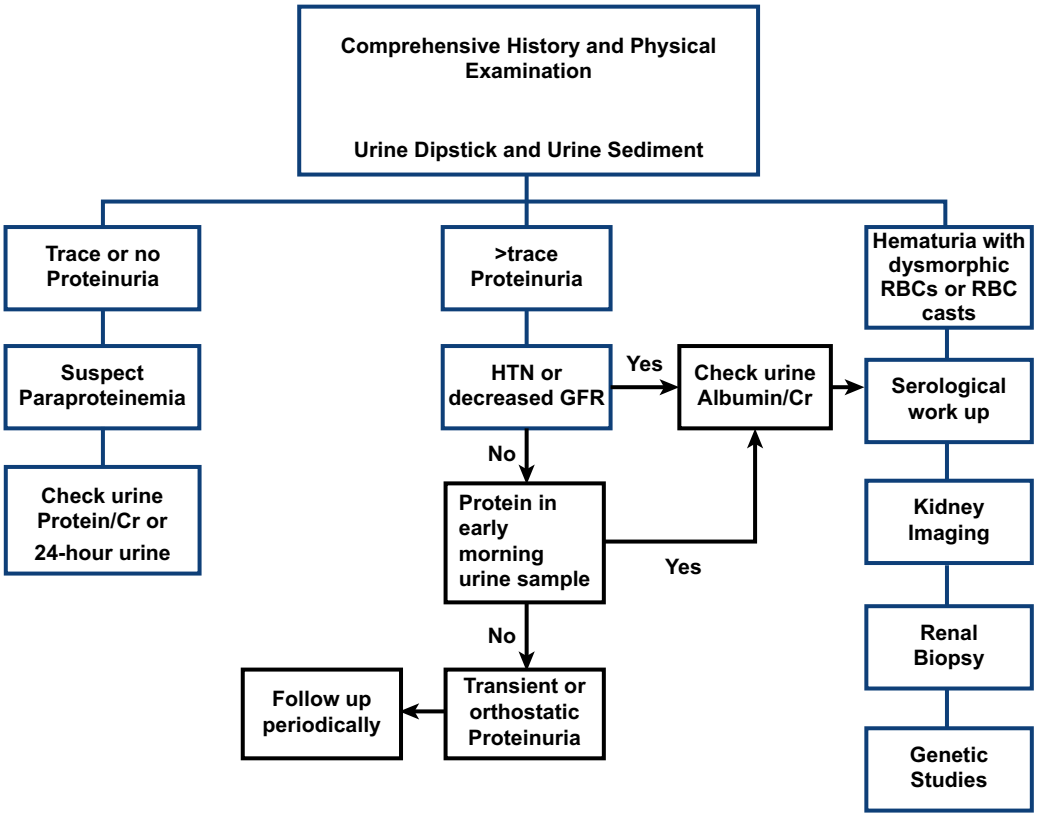

FIGURE 58.3 Approach to non-nephrotic proteinuria.

Urine dipstick cannot detect all proteins. It can only detect albuminuria. Therefore, another example of a false-negative urine dipstick result for proteinuria would be overflow proteinuria found in paraproteinemias, such as multiple myeloma. The presence or absence of other urine abnormalities, such as hematuria or leukocyturia, may also result in a positive test for proteinuria.

A negative urine dipstick for protein excludes proteinuria of a level of more than 1 g/g creatinine. Urine dipstick showing 4+ protein has a more than 90% chance of being associated with proteinuria more than 1 g/g creatinine on a random urine sample. Urine specific gravity and urine pH should be considered specifically in those individuals with 1+ proteinuria. A patient with concentrated and alkaline urine with 1+ proteinuria is less likely to have proteinuria more than 1 g/g creatinine.[40]

URINE ALBUMIN:CREATININE RATIO

Compared with urine dipstick, UACR has superior predictive ability for cardiovascular events.[41] UACR is helpful to identify glomerular damage. The potential pitfall of UACR is missing the overflow proteinuria found in paraproteinemias such as multiple myeloma. Measurement of total proteins by checking urine protein:creatinine ratio (UPCR) or by using 24-hour urine studies or urine protein electrophoresis can address this pitfall. Therefore, other urine studies in addition to UACR are required when paraproteinemia is suspected. Bone pain, anemia, hypercalcemia, and serum globulin gap may be diagnostic clues in patients suspected of having multiple myeloma.[42]

URINE PROTEIN:CREATININE RATIO

Close correlation between random UPCR and 24-hour urine protein excretion has been demonstrated.[43] Compared with UACR, UPCR (which includes albumin and nonalbumin proteins) has similar predictive ability for common complications of chronic kidney disease.[44] A protein gap between urine total protein and urine albumin suggests presence of paraproteins seen in disorders such as multiple myeloma.

UPCR and UACR may be influenced by race, sex, muscle mass, and nutritional status. Given that the urine creatinine concentration is in the denominator of these ratios, it may result in underestimation of proteinuria in patients with large muscle mass and overestimation of proteinuria in patients with poor nutritional status and lower muscle mass.[45,46]

24-HOUR URINE STUDIES

The 24-hour urine study is the gold standard for measurement of proteinuria, however, it is cumbersome and prone to overcollection and undercollection. Quantification of proteinuria based on a spot urine sample has become the common practice. 24-hour urine study is still performed for confirmation purposes or in cases of monitoring for high degree proteinuria when a spot urine sample may not be reliable. In patients with lupus nephritis, spot urine sample was found to be unreliable. 24-hour urine study is suggested for monitoring proteinuria in patients with lupus nephritis.[47] An alternative method is to check overnight 12-hour urine collection, which has been shown to be in agreement with 24-hour urine studies and is more convenient.[47]

URINE SEDIMENT

Microscopic examination of the urine sediment is helpful to narrow the differential diagnoses of non-nephrotic range proteinuria. The presence of dysmorphic RBCs, acanthocytes with blebs protruding from the cell membranes and RBC casts suggest glomerular hematuria. Acanthocyturia >5% is highly suggestive of glomerular hematuria. A patient with non-nephrotic range proteinuria and glomerular hematuria may have primary or secondary glomerulopathy. Identifying leukocytes with an associated negative urine culture (sterile pyuria) may suggest acute or chronic tubulointerstitial disease as the potential etiology for non-nephrotic range proteinuria.

SEROLOGIC EVALUATION

There is no "routine" serologic evaluation recommended for all patients with non-nephrotic range proteinuria. When no clear etiology for the proteinuria is established, however, serologic evaluation for infectious, autoimmune, or neoplastic etiologies would be warranted (Table 58.2). Such serologic evaluation should be guided and tailored based on a comprehensive history and physical examination. Investigation for infectious etiologies such as human immunodeficiency virus (HIV), syphilis, and hepatitis B and C viruses should be considered, especially in those individuals with risk factors, such as history of intravenous drug use, unsafe sexual practice, or exposure to blood products. Many patients with HIV infection may present with proteinuria, therefore, HIV infection should be screened in patients who have non-nephrotic range proteinuria with unclear etiology.[48,49] Patients with hepatitis B- and C-associated glomerulonephritides may present with non-nephrotic range proteinuria, usually with concomitant hematuria.[50,51] Patients with syphilis-associated membranous nephropathy may present with proteinuria ranging from mild to nephrotic range.[52] Autoimmune processes should be suspected in young patients and those with a family history of disorders such as lupus and vasculitis. Serologic tests, including evaluation of antinuclear antibody, anti-dsDNA antibody, antineutrophil cytoplasmic antibody, and serum complements, can be helpful in the diagnostic approach to non-nephrotic range proteinuria. Serologic evaluation for malignancies such as multiple myeloma may also be considered. A subset of patients with myeloma including those with amyloidosis and monoclonal immunoglobulin deposition disease may also present with non-nephrotic range proteinuria.[53,54]

TABLE 58.2 Serologic Evaluation of Non-nephrotic Proteinuria

Endocrine Disorders	Fasting Glucose or Hemoglobin A1c
Infectious etiologies	HIV antibody, hepatitis B surface antigen, hepatitis C antibody, RPR
Rheumatologic diseases	ANA, C3, C4, Anti-ds-DNA, Cryoglobulins, ANCA, anti-MPO, anti-PR3
Paraprotein-related diseases	Serum protein electrophoresis, kappa:lambda free light chain ratio, 24-hour urine protein electrophoresis
Primary renal diseases	Phospholipase A2 receptor antibody

Abbreviations: *ANA*, antinuclear antibodies; *ANCA*, antineutrophil cytoplasmic antibodies; *Anti-dsDNA*, antidouble stranded DNA; *Anti-MPO*, antibodies to myeloperoxidase; *anti-PR3*, antibodies to proteinase-3; *C3*, complement component C3; *C4*, complement component C4; *RPR*, rapid plasma reagin.

KIDNEY IMAGING

Renal ultrasonography is a common imaging modality for initial evaluation of kidney diseases. Other imaging modalities to investigate renal disorders include abdominal plain X-ray, computed tomography scan, magnetic resonance imaging, Doppler ultrasound studies, renal nuclear scans, and pyelography studies. All patients who have a decline in kidney function with unclear etiology should be evaluated with renal imaging studies, especially to exclude obstructive uropathy. Patients with proteinuria and preserved GFR should obtain renal imaging to exclude structural kidney diseases such as a single kidney, congenital anomalies, or cystic diseases. Ultrasonography is critical to assess renal size and echotexture before consideration of a kidney biopsy.

RENAL BIOPSY

Renal biopsy may be considered in the evaluation of non-nephrotic range proteinuria to establish the diagnosis, however, the therapeutic management may be changed in only a small percentage of patients (<15%).[55] Overall, patients with isolated non-nephrotic range proteinuria have a better prognosis than patients with nephrotic range proteinuria. In a Japanese study, 11% of 151 patients with asymptomatic proteinuria developed CKD stage 3 and/or a S[Cr] of more than 1.5 mg/dL within a mean follow-up of approximately 6 years. Proteinuria disappeared in 23% of patients. IgA nephropathy was the dominant diagnosis (68%).[56]

Many nephrologists proceed with renal biopsy in patients who have more than 1 g proteinuria. A lower threshold of 500 mg proteinuria may be used in the presence of systemic diseases such as systemic lupus erythematosus. Periodic follow-up visits are required for those patients with isolated non-nephrotic range proteinuria who do not undergo renal biopsy.

MOLECULAR GENETIC STUDIES

Genetic studies should be considered, especially in those patients with non-nephrotic range proteinuria and a family history of renal disease. Patients with a known family history of Fabry disease or Alport syndrome may proceed to genetic testing without the need for renal biopsy. Family counseling and prenatal diagnosis can be offered according to the genetic test results. Molecular genetic testing is accurate and noninvasive. Genetic study is confirmatory for Fabry disease.[57,58] Non-nephrotic range proteinuria may be the initial manifestation of Fabry disease in those individuals with renal limited disease.[57,58] In patients with a family history of Alport syndrome with a known mutation, molecular genetic testing can be done for that target gene.[59] A positive test for the same mutation will eliminate the need for renal biopsy. DNA sequencing is an option for those patients with other characteristics of Alport syndrome, without the family history of Alport syndrome.[59,60] Therefore, such genetic testing can be offered to a patient who presents with non-nephrotic range proteinuria (less than 1–2 g proteinuria) who does not wish to undergo renal biopsy, especially in cases with a positive family history or nonrenal characteristics of the disease. Genetic testing is also available for patients with FSGS. Absence of family history does not exclude the need for genetic testing, as many of the genes known to cause FSGS have incomplete penetrance.[61] Genetic testing for ApoL1 is also available to confirm the association with FSGS in patients of African descent. The result does not change the direct treatment of affected individuals, however it may affect family counseling, specifically in cases of potential kidney donor evaluation. Renal allograft outcomes have been associated with high-risk ApoL1 genotypes.[62]

TREATMENT

Control of blood pressure to a goal of at least <130/80 mm Hg remains the most important treatment for patients with proteinuria.[63–66] Inhibition of the renin–angiotensin–aldosterone system (RAAS) is first-line antihypertensive therapy for all patients with proteinuric renal disease unless contraindicated.[64] RAAS inhibitors, including ACEIs and ARBs, act to reduce glomerular filtration through vasodilatation of the efferent arteriole through inhibition of angiotensin II. These medications have been shown to decrease proteinuria independent of their effect to control hypertension. Other mechanisms which contribute to the antiproteinuric effect of ACEIs include increased levels of bradykinin, which vasodilates the efferent arteriole, restoration of the size and charge selectivity of the glomerular filtration barrier, and decreased production of transforming growth factor-β. Several clinical trials support the use of RAAS inhibition in the treatment of patients with nondiabetic kidney disease. Combination of a low sodium diet, diuretic therapy, and RAAS inhibition may lead to a greater reduction in proteinuria.[67]

The REIN study[68] evaluated whether administration of ACEI is more effective than conventional therapy at slowing progression of nondiabetic kidney disease. 352 patients were separated into two proteinuria strata. Stratum 1 was 1–3 g/24 h and stratum 2 was >3 g/24 h. Patients were randomly assigned to ramipril or placebo, including standard antihypertensive therapy to achieve a diastolic blood pressure <90 mm Hg. 186 patients in stratum 1 were randomized. The primary outcomes were a change in GFR and time to ESRD or nephrotic range proteinuria >3.5 g/24 h with a median follow-up of 31 months. The decline in GFR per month was not significantly different in patients with non-nephrotic proteinuria. Progression to ESRD, however, was significantly lower in patients who received ACEI with a relative risk reduction of 2.72 [1.27–4.52]. Progression to nephrotic range proteinuria was also significantly lower in the ramipril group. In subgroup analysis, patients with proteinuria >1.5 g/24 h or eGFR <45 m/min/1.73 m^2 benefited more from ACEI therapy.[69] Proteinuria decreased by 13% in the ACEI group and increased by 15% in the placebo arm.[69]

The AASK trial[70] included 1094 African-American patients with CKD secondary to hypertension. Mean protein excretion was 600 mg/24 h in men and 400 mg/24 h in women. Patients were randomly

assigned to ramipril 2.5–10 mg/day, amlodipine 5–10 mg/day, or metoprolol 50–200 mg/day. The primary outcome was the rate of change in GFR, and the secondary outcome was a composite of reduction in GFR of >50 percent or >25 mL/min/1.73 m^2, ESRD or death. Approximately 33% of patients had a UPCR >0.22 (mean protein excretion 1.5 g/24 h in men and 1.2 g/24 h in women). In this subgroup of patients, ramipril led to a 36% decrease in the rate of decline in GFR and a 48% decrease in the composite endpoint. However, patients with UPCR of 0.22 or less had no change in decline in GFR or composite endpoint. The AASK trial provides additional evidence for the benefit of ACEI in patients with non-nephrotic proteinuria.

Mineralocorticoid receptor antagonists (MRAs) can be added to therapy with ACEIs or ARBs to further decrease proteinuria when clinically indicated.[65,71,72] Caution should be used whenever combination RAAS blockade is employed, as rates of hyperkalemia are significantly higher. Combination of ACEI with ARB is no longer used as an antiproteinuric strategy due to higher rates of acute kidney injury and hyperkalemia.[73,74] MRAs should be avoided in patients with advanced CKD due to higher risk of hyperkalemia. A new MRA, finerenone,[75] has been shown to decrease proteinuria with lower rates of hyperkalemia compared with older formulations such as spironolactone and eplerenone.

Nondihydropyridine calcium channel blockers such as verapamil and diltiazem decrease proteinuria through reduction in glomerular filtration pressure. Dihydropyridine calcium channel blockers including amlodipine, felodipine, and nifedipine are effective antihypertensive medications, however, they do not lower proteinuria to the same extent as nondihydropyridine calcium channel blockers because of differential effects on the glomerular capillary bed.[76]

Vitamin D may also have a role in reducing proteinuria through decreasing prorenin gene expression, thus inhibiting the RAAS system.[77] Vitamin D may also decrease proinflammatory cytokines.[77] A randomized controlled trial of diabetic patients treated with the active vitamin D analogue paricalcitol showed a 20% reduction in proteinuria in the active treatment arm.[78] Another study found that treatment with an active vitamin D analogue has an additive effect to reduce proteinuria in patients already treated with RAAS inhibitors.[77]

Endothelin receptor antagonists are being studied to assess their antiproteinuric effects. Activation of the endothelin A receptor (ETA) leads to vasoconstriction of vascular smooth muscle. Inhibition of ETA causes vasodilation of the glomerular capillary bed, which leads to reduced permeability to albumin. Activation of the endothelin B receptor reduces arterial pressure by decreasing sodium and water reabsorption along the nephron. Avosentan, an ETA antagonist, was shown to reduce albuminuria but at the expense of causing edema and decompensated CHF.[79] Atrasentin is an alternative ETA antagonist which may cause less edema and still have similar antiproteinuric effects.[80]

Statin therapy is recommended for all patients with CKD older than age 50.[81] Statins have multiple pleiotropic effects. In some observational studies, statins may also have an antiproteinuric effect independent of their lipid lowering effects. In one retrospective controlled study,[82] 51 patients with Stages 3 and 4 CKD were evaluated over 53 weeks. Patients received treatment with simvastatin or no treatment. At the end of the treatment period, urine protein excretion decreased from 0.96 to 0.48 g/g creatinine in patients who received simvastatin in addition to an ACEI or ARB compared with no change in patients who did not receive statin therapy.

The role of limiting dietary protein intake to reduce proteinuria remains controversial. Some studies suggest that restricting dietary protein intake will help to reduce proteinuria and progression of CKD.[83,84] However, results are mixed. The National Kidney Foundation recommends restricting protein intake to 0.8–1.0 g/kg/day.[85]

Lifestyle modification including smoking cessation and weight reduction may also help to reduce proteinuria.[86,87] Obesity is associated with glomerular hyperfiltration. Obese patients (defined as a BMI >27 kg/m^2) who lost weight in an RCT had reduction in proteinuria compared with those patients who maintained the same weight.[86]

If a renal biopsy is performed, immunosuppression therapy may be a cornerstone of antiproteinuric therapy for patients with acute glomerulonephritis and tubulointerstitial nephritis. These patients often have subnephrotic proteinuria that will not respond to conservative therapy in the absence of specific treatment for the inflammatory renal disease. Immunosuppression options may include corticosteroids, calcineurin inhibitors, mycophenolate mofetil, and rituximab. Both cyclosporine and rituximab[88,89] have been shown to have direct effects on the podocyte to stabilize the actin cytoskeleton which helps to reduce proteinuria independent of their antiinflammatory properties.

CONCLUSION

The development of proteinuria has significant prognostic implications for progression of CKD and increased cardiovascular risk. The type of proteinuria may provide important diagnostic clues to the etiology

of CKD. Evaluation includes review of the urine sediment, serologic evaluation, and renal biopsy if appropriate. Lifestyle modification and antagonism of the RAAS form the cornerstone of conservative management for all patients with proteinuric kidney disease. Immunosuppressive therapy may be indicated depending on the etiology of the patient's renal disease. Additional specific therapies to reduce proteinuria and slow progression of CKD are eagerly awaited.

QUESTIONS AND ANSWERS

Question 1

A 47-year-old man is diagnosed with IgA nephropathy. Further evaluation reveals a 24-hour total protein excretion of 2900 mg, S[Cr] 1.4 mg/dL, and eGFR 51 mL/min/1.73 m^2. Which type of proteinuria is most predominant in this patient's 24-hour urine collection?

A. Albuminuria
B. Bence Jones protein
C. Beta-2 microglobulin
D. Tamm–Horsfall Protein

Answer: A

This patient has glomerulonephritis. Therefore, his proteinuria is glomerular in etiology. Albuminuria is the predominant protein seen in patients with diseases of the glomerular filtration barrier.[6,9]

Question 2

A 64-year-old woman presents with back pain, anemia, hypercalcemia, and progressive renal disease. S[Cr] increased from 1.2 mg/dL to 2.1 mg/dL over the past six months. Urinalysis reveals s.g. 1.010, pH 5.5, trace protein, negative heme, negative LE, and negative nitrite. Urine microscopy shows 0–3 rbc/hpf, 0–3 wbc/hpf. A UPCR was 1100 mg/g creat. Which of the following represents the type of proteinuria seen in this patient?

A. Glomerular
B. Tubular
C. Overflow
D. Postrenal

Answer: C

This patient has multiple myeloma and therefore has overflow proteinuria. The positively charged Bence Jones proteins are not detected by routine dipstick, which accounts for the discrepancy in finding only trace protein on dipstick and 1100 mg/g creatinine on the random urine sample.[9,41]

Question 3

A 58-year-old man with a history of hypertension presents for initial evaluation of "moderate albuminuria." UACR is 41 mg/g. At his primary care physician office, the urine albumin:creatinine was 54 mg/g and 36 mg/g on two prior occasions in the past 12 months. His blood pressure in the clinic is 142/91 mm Hg. His current medications include amlodipine 2.5 mg daily. His BMI is 31 kg/m^2. Examination is otherwise unremarkable. In addition to lifestyle modification, including weight reduction, which of the following management strategies is most appropriate for this patient?

A. Increase amlodipine to 5 mg once daily
B. Change from amlodipine to lisinopril
C. Discontinue amlodipine
D. Start chlorthalidone 12.5 mg once daily

Answer: B

Of the answer choices provided, option B is most appropriate in this patient with moderate albuminuria. Although answer choice A would improve blood pressure control, it is unlikely that increasing the dihydropyridiine calcium channel blocker will help reduce proteinuria to the same degree that adding an ACEI (lisinopril) would. Starting a thiazide diuretic may help with blood pressure control, but adding an ACEI would be standard of care given the proteinuria and hypertension. Discontinuation of amlodipine without substituting an alternative antihypertensive agent would not be appropriate therapy.[68,70]

Question 4

36-year-old woman comes to your office for evaluation of moderate albuminuria (38 mg/g) with preserved renal function, S[Cr] 0.7 mg/dL. She brings prior medical records which show UACR of 52 mg/g and 41 mg/g creatinine over the preceding two years. She has no significant past medical history. On physical examination, her BP is 127/80 mm Hg, HR 84 bpm, and BMI 24 kg/m^2. Otherwise, the physical examination is unremarkable. Which of the following is the most appropriate next step in the evaluation of this patient?

A. Start lisinopril 5 mg once daily and bring the patient back to the office in 4 weeks for blood pressure check
B. Review the urinalysis with microscopy
C. Renal biopsy
D. Send molecular genetic testing for Alport syndrome

Answer: B

Review of the urinalysis and microscopy is the next most appropriate step in management of this patient. The presence or absence of microscopic hematuria or cellular casts on urine microscopy will be essential in forming a differential diagnosis of this patient's moderate albuminuria. This patient is normotensive. Therefore, initiation of Lisinopril is not the most appropriate next step. The degree of moderate albuminuria does not warrant renal biopsy or molecular genetic testing, as it would not change management of this patient at this time.[6]

Question 5

Which of the following therapies has been shown to reduce proteinuria in some clinical trials?

A. Paricalcitol
B. Amlodipine
C. Fish oil
D. Vitamin E

Answer: A

Some studies have shown active vitamin D analogues have an additive effect to reduce proteinuria. A randomized controlled trial of diabetic patients treated with the active vitamin D analogue paricalcitol showed a 20% reduction in proteinuria in the active treatment arm. Another study found that treatment with an active vitamin D analogue has an additive effect to reduce proteinuria in patients already treated with RAAS inhibitors.[77,78]

CHAPTER

59

Nutritional Management of Patients with Chronic Kidney Disease

Maulin Shah[a,b], *William E. Mitch*[a]

[a]Nephrology Division, Baylor College of Medicine, Houston, TX, United States; [b]Nephrology Section, Michael E. DeBakey Veterans Affairs Medical Center, Houston, TX, United States

Abstract

Nutrition management can significantly ameliorate signs and symptoms of progressive chronic kidney disease (CKD). In this chapter, we illustrate how nondialytic, conservative treatment of CKD using protein-restricted diets is safe, improves protein stores, ameliorates toxin production, and delays CKD progression. Providing adequate and appropriate nutrition is much more likely to be successful with the assistance of a skilled dietitian. We describe methods to ascertain dietary compliance as monitoring caloric and protein intakes is essential to ensure utilization of other dietary constituents and to maintain protein stores without exacerbating uremia. Requirements for trace elements, minerals, and vitamins have been poorly studied but are critical for successful implementation of dietary restriction treatment.

INTRODUCTION

Chronic kidney disease (CKD) is a progressive disorder affecting an estimated 26 million American adults. CKD is characterized by disruption of metabolic processes producing electrolyte abnormalities and accumulation of unexcreted toxins. These abnormalities lead to the development of a uremic syndrome characterized by fatigue, loss of lean body mass, and a multitude of nonspecific symptoms.[1–6] We illustrate how nondialytic, conservative treatment of CKD using protein-restricted diets (low-protein diet [LPD]) is safe, improves protein stores, ameliorates toxin production, and delays CKD progression.

PATHOBIOLOGY

The intact nephron hypothesis helps explain why glomerular filtration rate (GFR) is the most accurate estimate of the remaining kidney function in CKD patients. The hypothesis states that each individual nephron functions as an independent unit, so the combined functions of all remaining nephrons will determine the "whole kidney" GFR. This is a useful concept because individual nephrons participate in all physiologic and metabolic functions of the kidney, including regulation of blood pressure, several endocrine functions, the concentrations of ions in extracellular and intracellular fluids, and the excretion of waste products. Losses of these functions produce direct consequences of CKD, including abnormalities arising from the accumulation of unexcreted waste products synthesized during the metabolism of proteins and amino acids. For example, CKD reduces the ability to excrete acid leading to hyperventilation with a compensatory decrease in P_{CO_2} and skeletal muscle metabolic process activation by a mechanism that activates the ubiquitin-proteasome enzymatic process to degrade muscle proteins, causing loss of muscle mass.[7] Accumulated acid is also buffered in bone, releasing calcium and phosphates to aggravate bone demineralization.[5]

PROTEIN

Metabolic Balance and Steady State

Metabolic balance in CKD patients occurs when the intake or production of a substance equals its elimination. The ability of CKD patients to achieve a balance between intake and the excretion plus metabolism of protein-derived compounds has a limit. Specifically, when CKD patients eat unrestricted/high-protein diets (HPDs), metabolism of the excess dietary protein exceeds the kidneys' capacity to excrete uremic toxins

Chronic Renal Disease, Second Edition

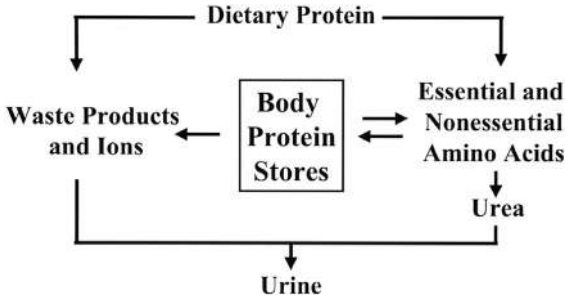

FIGURE 59.1 The summary figure indicates that increasing dietary protein raises the production of both urea and uremic toxins plus ions (such as H+, K+, Na+, and phosphates). The levels of toxins increase when kidney function is impaired. Contrariwise, overly restrictive diets will reduce the intake of essential amino acids and such responses stimulate the loss of body protein stores.

and inorganic ions (such as sodium, potassium, phosphate, etc.).[6] This imbalance is significantly responsible for the development of uremic symptoms (Figure 59.1).

The steady state is a concept related to metabolic balance. A CKD patient is in steady state when his/her internal environment is constant and the intake and/or production of ions or toxic compounds derived from dietary protein equal the excretion and/or metabolism of uremic toxins. CKD patients with a constant BUN and body weight may be in steady state; however, this does not necessarily mean that conditions are normal, as protein is still being converted into urea and toxic compounds. These considerations indicate why the amount of dietary protein being converted into urea must be accounted for when assessing changes occurring in response to alterations in dietary protein intake. Fortunately, this is possible because daily urea production in response to eating protein is either excreted or accumulated in body water. The concentration of urea is the same throughout body water, and the change in body water is calculated from changes in body weight.[8] Metabolic adaptations in response to CKD lead to accumulation of uremic toxins and ions affecting metabolism (such as phosphates, salt, etc.).[6]

The Trade-off Hypothesis

Another important principle, the trade-off hypothesis, refers to the activation of pathophysiologic responses which add to the severity of metabolic abnormalities while introducing consequences of the metabolic trade-off. For example, CKD patients will develop metabolic acidosis unless the source of acid namely dietary protein intake remains controlled. This is important because reducing dietary protein and amino acids limits acid generation in CKD and mitigates activation of pathophysiologic responses.[9,10] The trade-off for buffering acid is stimulation of the degradation of skeletal muscle proteins and amino acids resulting in protein wasting.[11] Furthermore, buffering of acid in bones and the release of phosphates from HPD contribute to the development of uremic bone disease.[5]

Protein Metabolism Contributes to Uremic Symptoms

The metabolism of amino acids and peptides plus pathophysiologic responses to ions that are associated with HPDs contribute to the development of uremia.[12,13] There are at least three major mechanisms that generate uremic toxicity. First, catabolism of dietary proteins, peptides, and amino acids occurs when proteases, amino acid oxidases, and other enzymes are produced by the gastrointestinal tract. Secondly, metabolic processes mediated by bacteria in the gastrointestinal tract can exert primary or secondary changes in the metabolism of proteins, peptides, and amino acids.[14] Investigating the experimental and clinical consequences of the influence of gastrointestinal bacteria is in its infancy. It is likely that this will provide new insights into the consequences of the metabolism of uremic toxins.[14] Third, indirect methods could produce toxic products from the metabolism of proteins, peptides, and amino acids. For example, an LPD improves insulin resistance in both diabetic and nondiabetic advanced CKD stages 4 and 5.[15,16] Lastly, the liver contributes to the metabolism of proteins, peptides, and amino acids. The liver modifies protein metabolism directly or secondarily and is largely responsible for the synthesis of urea.[17]

To date, no single compound or group of uremic toxins has been demonstrated to cause uremic symptoms, in part because identifying and measuring putative uremic toxins is difficult when patients have complex illnesses such as CKD. Generation of amino acid metabolites from eating a protein-rich diet has been implicated as an inducer of uremic symptoms. For example, phenylacetic acid and p-cresol are putative uremic toxins that are derived from the metabolism of phenylalanine that accumulate in CKD patients eating unrestricted amounts of dietary protein.[18,19] Experimentally, p-cresol contributes to inflammation, inhibits inducible nitric oxide synthase, and is linked to the development of atherosclerosis.[20] Another putative uremic toxin is indoxyl sulfate, which is derived from the metabolism of tryptophan. It can inhibit endothelial cell proliferation and interferes with endothelial-dependent wound repair.[19] Following extensive experimental information that indoxyl sulfate is a uremic toxin, a multicenter trial was undertaken to determine if inhibiting it would improve indices of CKD. The outcome of the trial was negative, indicating the complexity of identifying and then testing putative

biochemical mechanisms to determine if the experimental results will maintain the functions of the uremic toxins.[21] Arginine metabolism is another source of uremic toxins. When the mediator of toxicity, asymmetric dimethylarginine (ADMA), was initially examined, it was believed to contribute to impaired kidney functions in CKD patients *via* mechanisms that inhibit nitric oxide synthase and decrease nitric oxide production.[22] ADMA has also been associated with concentration-dependent pressor and bradycardia responses and vasoconstriction. Although these observations seem to identify that ADMA aggravates hypertension, the link between ADMA and blood pressure control has not been established. With ADMA, difficulties in identifying it as a uremic toxin include precise determination of the level of ADMA plus the influence of other mediators of blood pressure control such as the responses to dietary salt or the generation of other compounds that affect blood pressure control in CKD patients.[23] Other potential uremic toxins include guanidino-containing compounds that are present in the sera and tissues of uremic patients eating unrestricted diets. Guanidino compounds (e.g. methylguanidine) can exert neurotoxic responses and contribute to peripheral neuropathy, whereas others (such as γ-guanidinobutyric acid, taurocyamine, homoarginine, and α-keto-δ-guanidinovaleric acid) lower the seizure threshold in experimental animals.[13,24] Experimentally, these compounds are derived from excess dietary protein and, clinically, their metabolic and clinical responses are reduced by restricting dietary protein.

Consequences of High-Protein Diets

HPD contributes to the metabolic problems generated by CKD. Epidemiologically, uric acid production rises in patients eating an HPD. Experimentally increased uric acid levels are associated with the development of hypertension and inflammation.[25–27] Increased intake of protein is clearly associated with excessive intake of phosphates or salt, and these ions can negate the beneficial effects of ACEIs on slowing the progression of CKD.[28,29] Thirdly, an HPD generates metabolic acidosis in CKD patients, which in turn is associated with impaired function of bones, loss of protein stores, and more rapid loss of kidney function.[1–3,9,10,30]

Benefits of Dietary Protein Restriction in CKD

LPD can improve the symptoms and metabolic problems generated by CKD and slowing CKD progression.[12,13,31–34] In a study of almost 1600 CKD patients, Metzger et al. found that each 0.1 g protein/kg/day increase over the average value of 5.6 g protein/day was associated with an increase in the hazard ratio for end-stage renal disease (ESRD) of 1.05.[35] Secondly, Kelly et al. reviewed a meta-analysis of seven studies (~15,000 patients) and concluded that a reduced level of dietary protein was associated with a lower relative risk of death of 0.73, but the authors did not evaluate changes in the progression to ESRD.[36] Thirdly, an updated meta-analysis based on the Cochrane database provided evidence that LPD in nondiabetic CKD patients probably delays but does not halt progression to ESRD. In the latter analysis, LPD diets did not seem to reduce mortality.[37]

Unfortunately, compliance with LPD is difficult and has led to the evaluation of other types of protein substitutes. Substitutes for LPD for the treatment of CKD patients are largely based on supplying the nine essential amino acids (EAA) which are those that must be supplied because the body cannot synthesize them. Specifically, the estimated requirements for the recommended daily allowance (RDA) of the 9 EAAs provided as oral supplements can produce neutral nitrogen balance even when the 11 nonessential amino acids (NEAAs) are absent from the diets.

Alternative substitutes for dietary protein are abbreviated as Ketoacids. Ketoacids have the basic structures of different EAAs, but they have been treated to remove the nitrogen in EAAs. When provided in conjunction with a dietary prescription of 0.3 g protein/kg/day, the Ketoacid mixture improves nutritional indices and slows the progressive loss of kidney function.[38–49] For example, the responses to treating nondiabetic, Romanian, CKD patients for 15 months while they received a Ketoacid supplemented very low−protein diet (VLPD-KA) were favorably compared with results of nondiabetic control CKD patients fed a LPD (0.6 g protein/kg/day). The Ketoacid supplemented regimen was associated with slowing the loss of kidney function plus delaying need for dialysis. There was also evidence for improved nutritional status. There were difficulties in enrolling participants in this study as only about 14% of screened patients were recruited.[48]

There have been too few economic evaluations of the use of LPD to treat CKD patients. Scalone et al. randomly assigned 56 patients with advanced CKD to treatment with the VLPD-KA regimen compared with an equal number of control CKD patients assigned to standard dialysis strategies. At the initiation of the study, patients in both groups were >75 years of age and their creatinine clearances were <10 mL/min. During the first year of the study, the savings were >20,000 €uros and the clinical courses of the two groups of patients including nutritional indices were calculated to be noninferior.[50]

Recommendations for Protein Restriction in CKD

For healthy adults who undergo moderate physical activity and eat sufficient calories, nitrogen balance can be achieved. The minimal amount of dietary protein used to achieve nitrogen balance was similar to the requirements of normal adults according to the 1981 Food and Agriculture Organization/World Health Organization/United Nations University (FAO/WHO/UNU). Specifically, they recommended a dietary protein requirement for normal adults of 0.6 g protein/kg body weight/day. The source of proteins consists of high biological value proteins (i.e. proteins with both EAAs and NEAAs).[51] Two standard deviations from this level (i.e. 0.75 g protein/kg/day) were assigned as a "safe level of intake" because it should meet a protein requirement of 97.5% or more of healthy adults.[52,53] There are three caveats regarding these recommendations. Firstly, the number of patients studied was small. Secondly, some normal adults require less dietary protein and others require more than 0.75 g/kg/day. Thirdly, increasing the dietary protein of CKD patients beyond the safe level simply increases the production of urea and other waste products. For these reasons, the diet of CKD patients must be evaluated for each patient.

In normal individuals, a decrease in dietary protein from 1 to 0.6 g protein/kg/day activates adaptive metabolic responses. Specifically, dietary protein restriction will reduce the irreversible degradation of amino acids and slow the catabolism of muscle proteins. Changes in the rate of protein synthesis in these studies were small, indicating the major factor responsible for loss of protein stores was catabolism rather than changes in protein synthesis.[11,54] Notably, advanced CKD patients uncomplicated by metabolic acidemia, inflammation, or other catabolic conditions become remarkably efficient in adapting to dietary protein restriction.[55] Notably, similar responses were obtained when CKD patients were fed with the VLPD-KA regimen.[38] Furthermore, adaptations to an LPD in CKD patients occur *via* increased efficiency of muscle protein turnover.[56] These results indicate that diets based on 0.6 g protein/kg/day should be sufficient to maintain protein stores during long-term therapy. In our practice, we generally initiate nutritional therapy for patients with stable CKD using a regimen based on LPD to 0.8 g/kg/day as recommended by KDIGO.[57] However, if the patient is developing uremic symptoms or continues with a progressive increase in his/her S[Cr], we recommend dietary restriction to 0.6 g protein/kg/day because it can maintain protein stores and may slow the rate of progression. Unfortunately, Ketoacids are not available in the US. In Table 59.1, we have included our recommendations for different levels of dietary protein in CKD patients.

Despite the benefits discussed, compliance with LPD is low. For example, Moore et al. evaluated results in more than 16,000 adults participating in the National Health and Nutrition Examination Survey (2001–2008). Even at advanced stages of CKD, the dietary protein intake was about 1 g/kg/day.[58] To improve compliance with the change in diets, patients should have regular interactions with a dietician or nutritionist experienced in helping patients achieve compliance. Ignoring the implementation of dietary protein restriction can hasten the need to begin dialysis, which is expensive and interferes with the activities of patients. Moreover, several studies that have examined the outcomes of patients initiating dialysis "early" (at GFRs of 10–12 mL/min) have concluded that earlier dialysis initiation does not improve the mortality associated with CKD nor does it reduce the complications of CKD.[59,60]

Safety of LPD

Concern about the safety of LPD may contribute against routine implementation. Fortunately, there is increasing evidence LPDs are safe. Consequently, a critical goal of restricting dietary protein in CKD patients is to prevent loss of body protein stores. This will occur when there is an imbalance between the rates of protein synthesis and degradation. For example, an increase in the rate of protein synthesis to levels above the rate of protein degradation will produce improvements in protein stores. Alternatively, suppressing protein degradation below the level of protein synthesis will increase protein stores.

In the MDRD Study, 840 nondiabetic patients with different stages of CKD were examined regularly for an average of 2.2 years. Protein intakes were assessed from measurements of urea nitrogen excretion.[61,62] There also were evaluations of energy intake, but they were based on dietary diaries which can be inaccurate.[62,63] Notably, only two of 840 participants were removed from the trial because of concerns about their nutritional status. Overall, assignment to LPD was associated with a small loss of body weight and arm muscle area (an index of muscle mass). In contrast, the serum albumin (S[Alb]) increased significantly.[33,61,62] However, S[Alb] is not a reliable index of deteriorating protein stores.

Although reports indicate that CKD patients have been treated safely during restriction of dietary protein, some investigators have raised concern that LPD will be insufficient for maintaining protein stores.[37,62,64–68] Wolfe et al. used the amino acid turnover method and studied responses of elderly subjects to LPD.

TABLE 59.1 Recommended Nutrient Intake for CKD Patients

Nutrient	Nondialysis CKD	Dialysis ESRD
Protein	GFR 25–50 mL/min/1.73 m^2: 0.8 g/kg/day	>1.2 g/kg/day
	GFR <25 mL/min/1.73 m^2: 0.6 g/kg/day	
	Nephrotic: +1 g/day for each 1 g/day proteinuria	
	Systemic illness: 1.0 g/kg/day[a]	
Energy	30–35 kcal/kg/day[b]	30–35 kcal/kg/day[b]
Carbohydrates	35% of nonprotein calories	35% of nonprotein calories
Fat	Polysaturated to saturated ratio of 2:1	Polysaturated to saturated ratio of 2:1
Sodium	80–100 mmol/day	80–100 mmol/day
Potassium	<1 mmol/kg if elevated	<1 mmol/kg if elevated
Calcium	Should not exceed 2.5 g (dietary + calcium binders)	Should not exceed 2.5 g (dietary + calcium binders)
Phosphorus	800–1000 mg and phosphate binders if elevated	800–1000 mg and binders if elevated

Recommendations are based on ideal body weight.
[a]*>50% high biological value protein (rich in essential amino acids) is recommended.*
[b]*Based on physical activity level. In sedentary elderly adults, recommended energy intake is 30 kcal/kg/day.*

He concluded that elderly subjects exhibit defects in muscle protein synthesis, ultimately leading to loss of protein stores. The investigators concluded that the RDA of 0.8 g protein/kg/day in elderly subjects would be insufficient to maintain protein stores. Instead, the investigators recommended efforts to stimulate protein synthesis to a level that equals or exceeds protein degradation. To improve the rate of protein synthesis, they recommended that the dietary protein intake of elderly subjects be raised to 1.5 g protein/kg/day.[68] Wolfe et al. also reviewed treatment strategies for patients with other catabolic illnesses and concluded that the RDA for patients with CKD plus inflammation, obesity, and similar protein wasting disorders should be raised to 1.5 g/kg/day protein intake.[68] However, implementation of this HPD for CKD patients would be counterproductive as it would result in accumulation of unexcreted toxins, salt, phosphates, acid, and the metabolic consequences of these responses.[37,66]

Not all reports are positive. For example, Menon et al. reported that 10 years after closing the MDRD trial, there was information from the US Renal Data System (USRDS) indicating that random assignment to the VLPD-KA regimen was associated with an increased risk of death.[45] It should be pointed out, however, that during the 8 years after completing the 2-year MDRD Study, there were no data detailing compliance nor was there information about other illnesses, dialysis-related factors, or other treatments arising from the MDRD Study. In addition, there was no ongoing adherence to the Ketoacid regimen because Ketoacids were not supplied following closure of the MDRD trial. Other problems with the Menon et al. analysis have been detailed. In contrast, Chauveau et al. reached a markedly different conclusion about the safety of LPD. They examined the survival and characteristics of 220 stage 4–5 CKD patients who had been treated for an average of 33 months (range 4–230 months) with the VLPD-KA regimen. The outcomes of patients treated concurrently but with no education in LPD were compared with outcomes of patients treated with the VLPD-KA regimen. The latter group had a 1-year survival of 97% and 60% after 5 years of dialysis. Moreover, survival was not impaired following kidney transplantation and was 97% and 95% at 5 and 10 years, respectively.[31] These results were substantially better than those of dialysis patients based on analyses from the French Registry or in the USRDS. Another major advantage of outcomes of the Chauveau study is that compliance with dietary restriction was monitored during long-term therapy by measuring 24-hour urine urea nitrogen excretion. Finally, the influence of dialysis therapy on complications was included in the Chauveau report, but not by the Menon report. Based on these considerations, we conclude that LPDs, including the VLPD-KA regimen, maintain protein stores and do not jeopardize responses of CKD patients who require dialysis or transplantation.

Another special group of CKD patients includes those who excrete more than 5 g protein/day. These patients are special because their treatment requires reducing dietary protein. This is necessary because an HPD increases the degree of proteinuria.[69] In addition, an HPD can increase the likelihood of developing complications of CKD, including progressive kidney failure and cardiovascular disease.[69] It is fortunate nephrotic patients fed

an LPD can activate the adaptive responses to dietary protein restriction that are similar to responses that are activated when the dietary protein of normal adults or CKD patients is reduced. Nephrotic syndrome patients fed 0.8 (plus 1 g dietary protein for each gram of urinary protein excretion) and 35 kcal/kg/day maintained protein stores.[70] Although this amount generally suffices for patients excreting less than 10 g proteinuria, the limitations of LPD in the treatment of patients with excessive proteinuria have not been extensively explored.

In summary, patients with uncomplicated CKD, including those with nephrotic-range proteinuria, activate compensatory responses to dietary protein restriction. The responses include suppression of both amino acid oxidation and protein degradation, which act to preserve lean body mass during long-term dietary protein restriction. Patients eating restricted diets for >1 year can maintain indices of adequate nutrition.[6] It should be emphasized that the responses achieved required repeated monitoring to ensure patients eat a sufficient amount of protein and calories. Finally, if CKD is complicated by acidosis, inflammatory, or catabolic illnesses, patients may not be able to activate adaptive responses to dietary restriction. In these cases, the treatment should concentrate on correcting acidosis, inflammatory conditions, or chronic illnesses.

Diabetic patients may not activate adaptive changes to dietary protein restriction as efficiently as do normal adults or nondiabetic CKD patients, based on the importance of insulin in the regulation of protein and energy metabolism. These patients should emphasize maximizing glucose control to avoid loss of muscle proteins. A recent study of 197 advanced CKD patients with VLPD-KA showed improved uremic symptoms, diabetes control, and weight loss without negative effect on muscle mass or fitness.[71]

Diabetic nephropathy may interfere with the metabolism and progression of CKD. For example, a meta-analysis of 15 randomized controlled trials including nearly 2000 subjects showed LPD may not slow CKD progression in type II diabetic patients.[72] As we await further evidence, diabetic patients should be examined regularly to prevent loss of protein stores.

Plant-Based Dietary Protein Advantages

The source of dietary protein may influence CKD-induced changes in metabolism. In a study of only five patients, providing a vegetarian diet for 1 week led to a decreased S[P] and FGF-23 levels compared with eating meat-based meals.[73] In a study of nearly 3000 CKD patients, the CRIC study group concluded that plant proteins are associated with lower FGF-23 and higher serum bicarbonate levels.[74] Another observational study using the NHANES II database suggested that a diet with higher plant-based proteins is associated with lower mortality in CKD patients.[75]

Monitoring Protein Intake

A major requirement for the implementation of changing dietary proteins is the ability to obtain a regular assessment of the amount of protein eaten by CKD patients. This requirement can be met by collecting a 24-hour urine for the measurement of urea nitrogen, along with a simple calculation of the nitrogen excreted in forms other than urea. This is not a new concept, as Folin reported in 1905 that the principal response to a change in dietary protein is a parallel change in urinary urea excretion.[76] This concept has been confirmed in normal adults and CKD patients.[8,12,13,77] How can this be used to assess the intake of dietary protein (Box 59.1)? First, the patient should be in steady state, signified by constant values of BUN and body weight. Secondly, 24-hour urinary excretion of urea nitrogen is measured. We have noted that the rate of urea production exceeds the steady-state rate of urea excretion, because there is an extrarenal clearance of urea. The latter is presumably mediated by ureases that break down urea to ammonia and carbon dioxide.[12,78] Even when delivered to the liver, the nitrogen in ammonia does not contribute substantially to amino acid synthesis. Instead it is simply reincorporated into urea.[79,80]

BOX 59.1

NITROGEN BALANCE AND ESTIMATED DIETARY PROTEIN

$B_N = I_N - U - NUN$, where $NUN = 0.031$ g N/kg b.w.
If $B_N = 0$, then $I_N = U + 0.031$ g N/kg b.w.
When BUN is constant, $U = UUN$ and
$I_N = UUN + 0.031$ g N/kg b.w.

B_N, nitrogen balance (g N/day); BUN, blood urea nitrogen; I_N, nitrogen intake (g N/day); N, nitrogen; NUN, nonurea nitrogen (g N/day); U, urea nitrogen appearance (g N/day); UUN, 24-hour urinary urea nitrogen (g N/day).

We emphasize these findings because they simplify the evaluation of dietary protein compliance for two reasons. First, the rate of net urea production (i.e. urea appearance) closely parallels dietary nitrogen. Second, urea appearance is easily calculated because the concentration of urea is equal throughout body water.[8,81] Because water represents approximately 60% of body weight in nonedematous patients, changes in the urea nitrogen pool in a patient with CKD can be calculated by multiplying 60% of nonedematous body weight in kilograms by the serum urea nitrogen concentration in grams per liter. Thirdly, the nitrogen balance (B_N) is estimated by adding the urea excretion to the nonurea nitrogen excretion. The latter includes the amount of nitrogen in feces plus the nitrogen in urinary creatinine, uric acid, protein, etc. Note that the average excretion is estimated as 0.031 g nitrogen/kg/day. It does not vary significantly with changes in protein intake.[12] For this determination, nitrogen is used rather than protein weight because assessing changes in the intake/metabolism of all proteins would hopelessly complicate the calculation. Fortunately, the nitrogen content of all proteins is 16%, which avoids the pitfalls of measuring the nitrogen content of all the body's proteins. A neutral or positive B_N indicates that protein stores are maintained or increased, whereas a negative B_N indicates protein mass is declining. If the BUN is increasing more rapidly than the S[Cr], the amount of protein in the diet should be adjusted based on measurements of urea production.[12]

In summary, the urea appearance is calculated as the change in the urea nitrogen pool (positive or negative) plus urinary urea nitrogen excretion and the nonurea nitrogen excretion. If serum urea nitrogen and weight are stable, urea nitrogen accumulation is zero, and the urinary nitrogen appearance equals the excretion rate. The sum of urea nitrogen and nonurea nitrogen (i.e. 0.031 g nitrogen/kg/day) should equate to dietary intake of nitrogen unless there are complications (such as gastrointestinal bleeding). There are two caveats to the use of this method to estimate dietary protein. First, there must be completion of the 24-hour urine collection for urinary urea excretion because urea clearance varies throughout the day and an incomplete collection will underestimate dietary compliance. Secondly, the nonurea nitrogen average of 0.031 g N/kg/day is not reliable for patients receiving total parenteral nutrition or eating completely digestible foods (e.g. astronauts).[12] When the nitrogen balance has been calculated, the investigator must interpret the values. If the total amount of excreted nitrogen exceeds the prescribed protein intake by more than 20%, then the patient should be evaluated to determine if the increase in nitrogen excreted is due to dietary noncompliance, unexpected catabolism, or gastrointestinal bleeding.[12]

Another potential use of the method of assessing dietary protein would be to evaluate a patient's caloric intake. This is possible because a skilled dietitian can use a patient's dietary history to estimate the ratio of calories to protein. The second step is to calculate dietary protein intake from the 24-hour urea nitrogen production as described earlier. Third, the calories per protein intake can be used to estimate calorie intake from the ratio of protein to calorie intake. These simple calculations should be used regularly in patients treated with restricted diets because calorie intake must be sufficient to maintain body protein stores.[12]

Other methods of assessing intake, including dietary histories, are less accurate. For example, when the food records and anthropometry of CKD patients were evaluated, it was found that energy intake was seriously underestimated when assessed by diet records.[63,82]

Other methods of assessing the adequacy of the LPD for CKD patients include assessing amino acid turnover and repeated evaluations of anthropometric indices and/or levels of markers of nutritional status. There are problems with both methods. The amino acid turnover method requires an intravenous injection of a labeled amino acid, followed by repeated measurements of the dilution of the labeled amino acids in muscles. After the steady state is established, the rates of protein synthesis and degradation in skeletal muscles can be calculated during a day-long evaluation. Note that this technique, unlike the measurement of nitrogen balance, reflects only a portion of the metabolism for that day, while the nitrogen balance requires measuring metabolic responses throughout the body over 5–7 days. The most frequently used but least reliable method of evaluating changes in protein stores relies on estimating changes in protein stores from anthropometric measurements or from changes in serum protein levels. The accuracy of these methods has not been rigorously determined and their utility is limited.[12]

Protein-Energy Wasting Markers

There is no consensus about ideal markers of protein-energy wasting in CKD patients. Generally, a composite of health standards including body weight, S[Alb] or prealbumin levels, questions about general health status, and anthropometric measures are used to detect loss of protein stores. The problems in using these methods to detect loss of protein stores are the measurements. To interpret changes in body weight, the measurement should be obtained with the same amount of clothes and integrated with a dietary history plus estimates of dietary protein and caloric intake. There are also confounding interpretations of changes in S[Alb] because inflammation exerts a reciprocal reaction. Low

values of S[Alb] could be due to inflammation rather than an inadequate or unbalanced diet. The same problems affect the interpretation of serum prealbumin levels. Finally, anthropometric measurements are user-dependent, greatly increasing the variability in values, unless the same individual is measuring the same parameters (e.g. skinfold thickness and arm circumference).[83]

In determining whether patients are losing protein stores, we recommend a standardized assessment of body weight and dietary protein intake. S[Alb] can be measured with the caveat that low values should trigger evaluations for sources of inflammation.

INORGANIC DIETARY CONSIDERATIONS

Sodium

Diets rich in protein are also rich in sodium, chloride, potassium, phosphates, and precursors of uric acid and other acid equivalents. Excess dietary salt not only counteracts strategies to treat hypertension but also suppresses the benefits of ACEI therapy on the progression of CKD.[29,84,85] For these reasons, dietary salt should be included in evaluating patients with CKD. Specifically, the 24-hour excretion of sodium should stimulate an adjustment of the diet to achieve a daily sodium excretion less than 100 mEq/day (2–2.5 g sodium)[86] (Table 59.1).

Potassium

CKD patients with hyperkalemia should be initially screened for disorders that raise the S[K] (e.g. metabolic acidosis and insulin resistance), and there should be an estimate of daily potassium excretion from a 24-hour urine collection. Pathophysiological causes of hyperkalemia should be approached by restricting the 24-hour urinary potassium to 1.5 g/day (39 mEq/day, Table 59.1).[86] Fortunately, dietary potassium restriction for treating high levels of S[K] is generally unnecessary because responses to CKD include increases in gastrointestinal potassium excretion and aldosterone responses. We emphasize the benefits of these adaptations because diets planned for CKD patients are frequently based on fruits and vegetables, which have a high potassium content but also promote clinically important reductions in blood pressure. For example, the DASH (Dietary Approaches to Stop Hypertension) Study demonstrated that an increase in dietary potassium content and a decrease in dietary salt led to significant decreases in systolic and diastolic blood pressures, especially in African-American patients. The influence of the DASH diet has not been tested in CKD patients.[87–89]

Metabolic Acidosis

CKD patients frequently develop metabolic acidosis. As with other uremic toxins, restriction of dietary protein decreases acid production by limiting the intake of sulfur-containing and positively charged amino acids. These amino acids are metabolized to produce hydrogen ions.[1,2] Preventing this complication of CKD is beneficial because metabolic acidosis stimulates the degradation of muscle proteins and EAAs, and metabolic acidosis is associated with the development of several metabolic defects.[9,10] In normal individuals, the development of metabolic acidosis suppresses albumin synthesis and aggravates renal osteodystrophy,[5,90] while persistent acidosis in CKD patients can accelerate the loss of kidney function.[1–3] Considering the multiple adverse responses problems, it is not surprising that acidosis changes the metabolism of several hormones and vitamins and stimulates protein losses in CKD patients.[11,30,55,91–97]

These examples exhibit a recurring theme. CKD patients have a type of "protein intolerance" because meals with a high dietary protein content may lead to uremic toxicity due to the accumulation of unexcreted metabolites of protein and inorganic ions in patients with CKD. These problems can be largely avoided by manipulating the diet of CKD patients, but it is difficult to change dietary habits. At the minimum, patients require the assistance of a skilled dietitian. The dietitian can adjust components of the diet based on measuring compliance and provide "feedback" to help patients obtain a sufficient amount of dietary protein and calories to maintain body protein stores, while avoiding problems from excess dietary protein.

VITAMINS AND TRACE ELEMENTS IN CKD

Vitamins and trace elements are required for energy utilization, organ function, and cell growth and protection (for example, from oxygen radicals). Consequently, patients with CKD should receive a sufficient amount of these nutrients incorporated into their planned diets (Table 59.2). Besides an insufficient diet, inadequate supplies of vitamins and trace minerals can result from decreased intestinal absorption of micronutrients, or metabolic responses to uremia interfering with the influence of vitamins and minerals. In addition, there could be circulating inhibitors of vitamins, loss of protein-bound elements with proteinuria, and medicines that

TABLE 59.2 Recommended Vitamin and Trace Element Intake for CKD Patients

Nutrient	Nondialysis CKD
Thiamine (B_1)	1.2 mg/day
Riboflavin (B_2)	1.3 mg/day
Niacin (B_3)	16 mg/day
Pantothenic acid (B_5)	5 mg/day
Pyridoxine (B_6)	5 mg/day
Biotin (B_7)	30–100 μg/day
Folate (B_9)	1 mg/day
Cobalamin (B_{12})	2.4 μg/day
Ascorbic Acid (C)	70 mg/day
Vitamin A (retinoids)	No addition
Vitamin D	Individualized
Vitamin E	15 mg/day
Vitamin K	No addition
Zinc	No addition

antagonize some vitamins.[98] Unfortunately, the RDA for these nutrients has not been defined for CKD patients.

We recommend that CKD patients receive a supplement of the water-soluble vitamins containing B-complex and C vitamins.[98] These recommendations are based on reports that restricted protein diets may cause deficiency conditions. For example, riboflavin, found in meats and dairy products, acts as a cofactor for flavin mononucleotide and flavin adenine dinucleotide. Riboflavin deficiency can produce sore throat, stomatitis, or glossitis that may be mistaken for uremic symptoms.[98] Folic acid, found in fruits and vegetables, improves responses to erythropoietin treatment, and deficiency may suppress homocysteine production.[98] Pyridoxine, found in meats, vegetables, and cereals, contributes to amino acid metabolism. When deficient, problems similar to advanced uremia, such as peripheral neuropathy or altered immune function, are encountered. Consequently, it is recommended that patients with advanced CKD (stage 4 or 5) receive 5 mg pyridoxine daily.[98] Vitamin B_{12} is required for synthesis of nucleic acids and is available in meats and dairy products. There are large stores in the liver. As with other B vitamins, a supplement of vitamin B_{12} is recommended for CKD patients.[98] Vitamin C (ascorbic acid) is contained in meat, dairy, and many fruits and vegetables. A deficiency state is unusual. Ascorbic acid protects against antioxidant reactions and is involved in collagen formation. As high doses of vitamin C are metabolized to oxalate which can precipitate in soft tissues (including the kidney), we recommend limiting the dose of vitamin C to the RDA.[98] The remaining water-soluble vitamins, including biotin, niacin, and pantothenic acid, have not been extensively studied in CKD patients, leading us to limit their intake to the RDA.

The requirements for fat-soluble vitamins have not been established for CKD patients. There is a possibility that certain fat-soluble vitamins may cause complications. Plasma vitamin A (retinol) levels in CKD patients are frequently increased because there are high levels of retinol-binding protein. Vitamin A excess could explain the origin of the vitamin A-associated syndrome, consisting of anemia, dry skin, pruritis, bone reabsorption, and liver dysfunction, but the mechanisms underlying these problems have not be elucidated.[98] There is even less known about the requirements for vitamin E, but its plasma levels in CKD patients are apparently normal. It has been suggested that vitamin E might suppress lipid peroxidation/oxidant stress and block progression of arteriosclerosis.[99] Vitamin D relates to metabolic bone disease in CKD and will not be discussed in this chapter. There is inadequate information regarding vitamin K dosing in CKD patients.[98] Consequently, multivitamin preparations containing fat-soluble vitamins should be avoided in CKD, unless there is evidence of deficiency.

The requirements for trace elements in CKD patients also have not been sufficiently studied. One potential exception is zinc. Zinc is involved in gastrointestinal metabolic functioning following small intestine absorption. Zinc absorption is increased with HPD, and there is binding of zinc to proteins and various amino acids in foods. These relationships could contribute to zinc deficiency in patients who have zinc losses when urinary protein excretion is increased. Some but not all reports indicate that patients with CKD and poor taste discrimination (dysgeusia) or with impaired sexual function may be improved by giving zinc supplements.[98] Some of the commonly used medications for CKD patients (calcium and iron supplements and phosphate binders) can hinder the intestinal absorption of zinc. Finally, drugs such as ACEIs, ARBs, and thiazides can increase zincuria.[100,101]

The requirements for trace elements and the consequences of adverse reactions to their supplements have not been fully studied in CKD patients. Consequently, we do not recommend giving supplements of trace elements routinely to CKD patients unless there is evidence of low intake or deficiency. An exception would be for CKD patients receiving long-term parenteral or enteral nutrition. These individuals should routinely be given trace elements but still require careful monitoring of circulating levels. As with vitamins, the appearance of skin rashes, neurologic abnormalities, or unexplained problems in CKD patients should prompt a search for trace element deficiency conditions.[10]

ENERGY INTAKE OF CKD PATIENTS

In normal adults and CKD patients, inadequate energy intake leads to loss of body weight, but the mechanism resulting in this response is complex. First, the magnitude of the energy deficit is difficult to measure. Secondly, there are many possible metabolic defects such as changes in hormones (e.g. insulin). In detecting insufficient calories, the resting energy expenditure (REE), defined as the amount of energy expressed in Kcal required for a 24-hour period when the individual is at rest, is a reliable method. In 1981, a report of the results of about 11,000 REE determinations of healthy adults was analyzed by the FAO/WHO/UNU.[51] They reported that there was considerable variability in the determinations, and, hence, that caution is needed in making decisions about energy requirements. Besides the requirement for REE, energy requirements are also affected by physical activity, general health, and the presence of catabolic conditions (e.g. acidosis, high values of BUN or S[P], and the presence of insulin resistance). Generally, patients with stage 3 CKD or more advanced disease spontaneously limit daily physical activity. The contribution of uremia *per se* in increasing energy expenditure is controversial.[12] As a caveat, it has been noted that energy expenditure may not fall when caloric intake of CKD patients is reduced, indicating there is poor adaptation to a low-calorie intake.[102] In addition, obese CKD patients with S[Cr] values greater than 2.4 mg/dL or with metabolic acidosis can develop insulin resistance and impaired energy utilization.[103]

The contribution of a low energy intake to nutritional deficiencies in CKD patients is unclear. CKD patients who were eating 16–20 g/day of protein plus a supplement of EAA did not increase their protein stores (measured as nitrogen balance) when energy intake was varied between 22 and 50 kcal/kg/day.[104] Other investigators have concluded that energy requirements of CKD patients eating an LPD should be 35 kcal/kg/day, to utilize dietary protein maximally to maintain body protein stores.[102] Unfortunately, there are only a few studies of energy requirements of CKD patients. We believe that the energy intake of CKD patients who are at or below their ideal body weight should be 35 kcal/kg/day. Equally important, overweight patients should have energy intake restricted to lose adipose tissue. This is recommended because obesity causes insulin resistance, which impairs the utilization of protein and calories. In contrast, for patients who are losing weight, the number of dietary calories should be increased.[12] In all cases, energy intake of CKD patients should be monitored by assessing changes in body weight, calorie intake, and the presence of specific adipose sites. This is especially emphasized in patients with truncal obesity because calorie supplements will increase body fat rather than protein stores. Results from the MDRD Study of CKD patients revealed that when energy intakes were below 35 kcal/kg/day, loss of body mass was infrequent. Only two patients were withdrawn from the trial because of nutritional considerations.[63,82] Still, these conclusions must be considered tentative because energy intake was assessed from diet diaries, a method that can lead to erroneous results.[63,82]

CONCLUSIONS

CKD patients can respond to dietary modification with a reduction in the signs and symptoms of uremia. Dietary modification in CKD leads to reductions in waste product accumulation, plus mitigation of the uremic syndrome that includes correction of acidosis, amelioration of protein-energy wasting, suppression of uremic bone disease, and improvement in blood pressure control. There are remarkable similarities in the responses to dietary protein restriction when examined in normal adults and CKD patients, including activation of adaptive metabolic processes. This accounts, in part, for why restriction of diet proteins in patients with CKD is nutritionally safe unless there are complicating factors. Our recommendations for dietary management in CKD are summarized in Tables 59.1 and 59.2. Achieving compliance, however, can be difficult. Success and implementation is improved by the assistance of a skilled and interested dietitian.

Regarding initiation of LPDs, we recommend introducing dietary changes when signs/symptoms of CKD arise or when blood chemistry values indicate the presence of complications of CKD. We recognize that patients with CKD may spontaneously decrease their dietary intake, but this should not be a signal to increase protein in diets, as it would result in worsening complications of CKD. Whether dietary manipulation influences the progressive loss of GFR is still controversial. But instituting an LPD can substantially delay the need for dialysis, and there are other benefits including improved responsiveness to ACEI. The latter includes avoidance of excess dietary salt or phosphates that blunt ACEI responses.

QUESTIONS AND ANSWERS

Question 1

A 60-year-old man with stage 4 CKD with estimated GFR 20 mL/min/1.73 m^2 who weighs 65 kg is prescribed a 0.6 g protein/kg/day diet. His BUN and body weight are stable. Assess compliance if 24-hour urine collection contains 7 g of urea nitrogen.

Answer: Nitrogen balance (B_N) = nitrogen intake (I_N) − (urea nitrogen) UUN − (nonurea nitrogen) NUN

Assuming compliance $B_N = 0$ then I_N = UUN + NUN

UUN = 7 g N/day, NUN = 0.031 N/kg b.w. = 0.031 * 65 = 2.02 g N/day

I_N = 7 g N/day + 2.02 g N/day = 9.02 g N/day

Because protein is 16% nitrogen, protein intake = 9.02 g N/day/0.16% N/g protein = 56.38 g protein which is >20% of prescribed intake of 0.6 g protein/kg/day * 65 kg = 39 g protein.

He is not compliant with LPD.

Question 2

A 55-year-old woman with stage 3 CKD with estimated GFR of 45 mL/min/1.73 m^2 who weighs 80 kg presents for nutritional recommendations. She has nephrotic syndrome with 8 g proteinuria/day. What protein restriction do you prescribe?

Answer: Protein restriction for stage III CKD should be 0.8 g/kg/day. In this case, we also need to account for losses of 8 g/day from proteinuria. Her recommended protein intake should be 8 g/day + 0.8 g/kg * 80 kg = 72 g protein/day.

Question 3

An 85-year-old man with stage 5 CKD with estimated GFR 10 mL/min/1.73 m^2 presents for evaluation. He has mild symptoms of uremia. His serum electrolytes are within normal range. He is normotensive and euvolemic on examination. He asks your recommendation whether he should initiate dialysis. What are your recommendations?

Answer: Initiating hemodialysis earlier may be associated with higher cost and disease burden compared with medical management. There is no mortality benefit with dialysis compared with medical management. You can recommend a VLPD-KA regimen if available or LPD and assess his symptoms on follow-up.

Question 4

A 32-year-old woman with stage 3 CKD with estimated GFR 45 mL/min/1.73 m^2 asks you for vitamin supplementation to optimize nutrition. She follows an LPD of 0.8 g/kg/day and is not receiving parenteral nutrition. Which of the following do you recommend?

A. Prescribe fat-soluble vitamins (vitamin A, D, E, and K) but not water-soluble vitamins
B. Prescribe water-soluble vitamins (B-complex and C) but not fat-soluble vitamins
C. Prescribe trace elements only
D. Prescribe fat-soluble vitamins, water-soluble vitamins, and trace elements

Answer: B

Excessive vitamin C could lead to oxalate nephropathy so prescription should be lower than RDA.

Question 5

Which of the following are consequences of metabolic acidosis?

A. Stimulates muscle protein degradation
B. Improves protein stores
C. Suppresses albumin synthesis
D. Aggravates renal osteodystrophy
E. Ameliorates effects of uremia on bone
F. Accelerates CKD progression
G. Promotes insulin resistance and glucose intolerance
H. Leads to zinc accumulation
I. Impairs thyroid hormone responses
J. Aggravates trace element deficiencies
K. Impairs growth hormone
L. Impairs response to 1,25 dihydroxyvitamin D3

Answer: A, C, D, F, G, I, K, and L

Refer to section on metabolic acidosis.

Question 6

A 40-year-old man feels well but is concerned because his S[Cr] has increased from 2 to 3 mg/dL despite a prescribed diet of 0.8 g protein/kg/day and daily lisinopril. Which of the following factors must be evaluated?

A. The presence of edema and changes in body weight and blood pressure
B. Fluid ingestion at bedtime
C. Increased intake of phosphates
D. A 24-hour urine collection to measure intake of dietary protein
E. Urine sediment examination

Answer: A, C, D, and E

The presence of edema, hypertension, and higher blood pressure suggests the patient's salt intake has increased. This factor and/or an increase in phosphate intake can suppress the beneficial effect of ACEI in slowing the progression of CKD. If the dietary protein intake has increased, it might overcome the benefits of LPDs on the progression of CKD. The increase in S[Cr] could reflect kidney cell damage signified by granular casts in the urine sediment.

Abstract

Anemia is one of the most common complications of chronic kidney disease (CKD). As kidney disease advances, the incidence and prevalence of anemia increases. Anemia of CKD is multifactorial in etiology. The most common causes are erythropoietin deficiency, iron deficiency, and inflammation. Observational studies have suggested an increased risk of cardiovascular and renal complications, lower quality of life, and higher mortality as being associated with a lower hemoglobin (Hb) concentration. However, large randomized controlled trials have demonstrated that normalization of Hb concentration with an erythropoiesis-stimulating agent (ESA) is associated with either no benefit or an increased risk of cardiovascular complications and/or death, due to either the high Hb, the higher ESA doses needed to achieve this, or both. Contemporary approaches to anemia management embrace individualized therapy aimed at minimizing transfusions and use of the lowest possible dose of ESA together with treatment of iron deficiency and inflammation.

INTRODUCTION

Anemia is one of the most common complications of chronic kidney disease (CKD).[1,2] As kidney disease advances, the incidence and prevalence of anemia increases. Anemia of CKD is multifactorial in etiology. The most common causes are erythropoietin deficiency, iron deficiency, and inflammation. Observational studies, primarily in hemodialysis patients, suggested that an increased risk of cardiovascular and renal complications, lower quality of life (QoL), and higher mortality are associated with a lower hemoglobin (Hb) level.[3–7] Based on these observations, it became commonplace in both patients on dialysis and those with CKD not on dialysis to at least partially, if not fully, correct the anemia. In more recent years, however, large randomized controlled trials (RCTs) have demonstrated that complete, as opposed to partial, correction of anemia with an erythropoiesis-stimulating agent (ESA) is associated with either no benefit or an increased risk of cardiovascular complications and/or death compared with lower Hb levels, due either to these higher Hb levels, the higher ESA doses needed to achieve higher Hb concentrations, or some combination of both.[8–13] Thus, contemporary approaches to anemia management now more typically embrace using the lowest possible dose of ESA together with treatment of iron deficiency and inflammation with a goal of maintaining Hb levels around 10–11 g/dL in most patients.

DIAGNOSIS AND EVALUATION OF ANEMIA IN CKD PATIENTS

Evaluating patients both for the clinical effects of anemia and assessing potential causes of anemia is critical. The diagnosis of anemia of CKD rests on an appropriate clinical and laboratory evaluation. The evaluation is reviewed in more detail in two guideline documents from the Kidney Disease: Improving Global Outcomes (KDIGO) and the European Renal Best Practice groups.[14,15]

A diagnosis of anemia is generally made when the Hb concentration falls below about 13.5 g/dL in adult men and about 12.0 g/dL in adult children. As will be discussed below, however, these Hb concentrations should trigger an assessment of the cause of anemia but not necessarily treatment, and there is now a general consensus that an Hb concentration >10 g/dL does

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00060-7

not warrant specific therapy in most patients with anemia related to CKD. Screening for anemia should occur annually in patients with stage 3 CKD and at least twice a year in patients with stage 4 or 5 (nondialysis) CKD. Aside from a complete blood count, initial evaluation of anemia should include assessment of reticulocyte count, ferritin, transferrin saturation (TSAT), vitamin B_{12}, and red blood cell folate levels. Consideration should also be given to screening for fecal occult blood. Measurement of circulating erythropoietin levels is not useful in most patients with CKD and anemia and is not recommended. Once a patient has been diagnosed with anemia, but is not yet being treated with an ESA and/or iron therapy, monitoring of anemia should generally occur about every 3 months in patients with stages 3–5 who are not on dialysis.

The serum ferritin concentration is a commonly used indicator of storage iron. Ferritin is also an acute-phase reactant and, thus, is affected by inflammation. As such, ferritin values are of greatest predictive value when low (<100 ng/mL) but are of more limited value when elevated. TSAT measures circulating iron that is available for erythropoiesis. It is derived by dividing serum iron by total iron binding capacity and then multiplying by 100. Evaluating anemia based on serum iron alone is not recommended. Unfortunately, studies indicate that serum iron parameters poorly predict either tissue iron or Hb response to intravenous (IV) iron therapy.[16,17]

GENERAL APPROACH TO TREATMENT OF ANEMIA IN CKD

Before availability of recombinant human erythropoietin (epoetin alfa) in 1989, the treatment of CKD anemia comprises blood transfusions, iron, and, in patients on dialysis, anabolic steroids. Most patients were very anemic, with Hb concentrations commonly as low as 5–7 g/dL in advanced CKD and end-stage renal disease (ESRD). The goal of treatment was to raise the Hb to levels that afforded some improvement in symptoms such as lack of energy, fatigue, decreased physical functioning, and an inability to perform the daily activities of life. The introduction of epoetin alfa in 1989 had a transformative effect on the management of the anemia of CKD. Very soon thereafter, almost all anemic patients on dialysis were receiving epoetin alfa therapy and the numbers of nondialysis anemic patients with CKD receiving ESA treatment increased dramatically.

As noted above, observational studies, mostly among patients on hemodialysis, suggested an association between anemia and cardiovascular events and mortality in CKD patients with and without concurrent ESA treatment.[3–11] These studies found that lower levels of Hb were associated with worse outcomes, higher mortality risk, and increased rate of hospitalizations compared with patients with higher Hg concentrations.[3,7] Small studies also found that left ventricular hypertrophy was inversely associated with Hb concentrations.[18,19] Some studies indicated that patients with nondialysis CKD and anemia had a higher risk of progression of kidney disease and an increased risk of adverse cardiovascular events, congestive heart failure (CHF), and increased hospitalizations.[20–22] These observations led many physicians to use epoetin alfa to push Hb concentrations higher and higher toward the normal range with the expectation that doing so would improve patient well-being, cardiovascular outcomes, and mortality.

This began to change, however, with publication of the Normal Hematocrit Cardiac Trial (NHCT) trial in HD patients, in 1998. While this chapter is focused on patients with CKD who are not on dialysis, it is important to consider the NHCT study because its results informed future studies among patients who were not on dialysis. The NHCT was an RCT of HD patients with established heart disease, comparing a hematocrit target of 42% to one of 30%. The study was stopped by the Data Safety Monitoring Board because of concern for increased mortality in the patients randomized to the higher hematocrit group, although the observed difference was not statistically significant. Additionally, patients in the higher hematocrit group had a nearly statistically significantly higher rate of nonfatal myocardial infarction (MI) or death.[10] In a subsequent analysis, it was reported that randomization to the higher Hb target did increase the risk for the primary endpoint (RR 1.28; 95% CI = 1.06–1.56; p = 0.0112; 99.92% CI = 0.92–1.78), the risk of death (RR 1.27; 95% CI = 1.04–1.54), nonaccess thrombotic events (p = 0.041), and hospitalization rate (p = 0.04), while "physical function" did not improve (p = 0.88).[23,24] As discussed in the next section, subsequent studies in patients with CKD not on dialysis further informed our management of anemia in these patients.

ESA USE IN THE TREATMENT OF ANEMIA IN PATIENTS WITH CKD

The US Food and Drug Administration (FDA) approved epoetin alfa, a short-acting ESA, in 1989. Other short-acting ESAs are available in other countries, which differ in structure, dosing, safety, and immunogenicity. The epoetins are typically administered once weekly or every other week in patients with CKD who are not on dialysis. Darbepoetin alfa, approved in the US and elsewhere in 2001, is a hyperglycosylated erythropoietin analogue with a terminal half-life that is several fold

TABLE 60.1 Erythropoiesis-Stimulating Agents (ESAs)

	Commonly Used Initial Subcutaneous Dose
Short-Acting ESAs	
Various epoetins, including epoetin alfa-epbx	4000–10,000 weekly
Long-Acting ESAs	
Darbepoetin alfa	0.45 mcg/kg every 1–2 weeks or 0.75 mcg/kg every 2–4 weeks
Methoxy polyethylene glycol-epoetin	0.6 mcg/kg every 2–4 weeks

Adapted from reference 27.

longer than epoetin alfa. Darbepoetin alfa can be dose as infrequently as once or twice per month.[25] Methoxy polyethylene glycol-epoetin is another long-acting ESA with an extended half-life that can also be administered once or twice per month.[26] With expiration of patents for epoetin alfa has come the introduction of competitor products called "biosimilar" epoetins. Biosimilars are biologic therapeutic agents that are similar, but not identical, to the original biological agent. The epoetin biosimilar that is available in the US, epoetin alfa-epbx, is dosed the same as the original epoetin alfa formulation. Table 60.1 provides a comparison of dosing schedules of ESAs.[27,28] Unlike many hemodialysis patients, ESAs are administered subcutaneously in patients with CKD.

Treatment of anemia with an ESA in patients with CKD must balance the potential benefits of reducing blood transfusions and anemia-related symptoms against the risks of harm in individual patients. Current guidelines and consensus statements generally support the initiation of ESA therapy in many patients when Hb <10 g/dL, emphasizing though that whether to treat with an ESA should be individualized based on the rate of fall of Hb concentration, iron status and prior response to iron therapy, the risk of needing a transfusion, and the risks attributable to anemia and those related to ESA therapy. ESA treatment should generally not be undertaken until concurrent iron deficiency has been appropriately treated, with TSAT >20% and serum ferritin >100 ng/mL. On initiation of ESA therapy, the Hb concentration is often measured monthly until the target level has been achieved after which assessment monitoring every 2–3 months is appropriate, depending on clinical circumstances. ESA dose adjustments should typically be made no more often than once every 2–4 weeks because the effect of dose changes will generally not be seen within a shorter interval.

For most patients, ESA treatment is used to maintain Hb concentrations of 10–11.5 g/dL, with slightly higher concentrations targeted in selected patients who might benefit from higher levels and understand and are willing to accept the potential risks. The US FDA labeling for ESAs identifies avoidance of transfusion as the sole indication for ESA use and states that, for nondialysis CKD patients, one should consider ESA treatment only when the Hb level is <10 g/dL and reduce or interrupt the ESA dose if the Hb level exceeds 10 g/dL. Targeting Hb concentrations >13 g/dL is not recommended. KDIGO Guidelines recommend that ESAs be used with caution or not at all in patients with active malignancy (Grade 1B recommendation), a history of stroke (Grade 1B recommendation), or a history of malignancy (Grade 2C recommendation).[15] Individual responses to ESA treatment vary; those who do not respond as expected should be investigated for iron deficiency, infection, inflammatory conditions, and other disorders associated with ESA hyporesponsiveness.[29] Hyporesponsiveness has been associated with poorer outcomes compared with patients with better response to ESA treatment.[30,31] In all patients, the lowest possible dose that maintains the target Hb concentration should be used.

The above recommendations stem largely from results of three randomized controlled clinical trials in patients with CKD not on dialysis which found inconsistent effects on QoL and either no mortality benefit or risk of harm among patients randomized to treatment groups targeting higher compared with lower Hb concentrations. The Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta trial enrolled approximately 600 nondialysis CKD subjects who were randomized into either an early anemia treatment group or a delayed anemia treatment group.[9] The early treatment group received epoetin beta therapy immediately for a normal target Hb of 13–15 g/dL, whereas the delayed anemia treatment group did not receive treatment until their Hb was <10.5 g/dL with treatment aimed at maintaining an Hb of 10.5–11.5 g/dL. There was no improvement in time to first cardiac event in the early treatment/higher target Hb group compared with the delayed/lower target Hb group, but dialysis was required in more patients in the higher than the lower Hb group. QoL measure scores were improved for the higher compared with lower Hb group subjects.

The Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) trial was an open-label RCT that studied 1432 nondialysis CKD subjects who were randomized to receive epoetin alfa targeted to achieve an Hb of 13.5 g/dL or 11.3 g/dL.[11] The primary endpoint, a composite of death, MI, CHF, hospitalization (excluding hospitalization during which renal replacement therapy occurred), and stroke, occurred more often

in the high Hb group compared with the low Hb group (HR 1.34; 95% CI 1.03−1.74; p = 0.03). Among other secondary endpoints, QoL showed improvement in both groups but was not significantly better in the higher compared with lower Hb groups. More subjects in the high Hb group experienced at least one serious adverse event compared with the low Hb group. Secondary analyses from the CHOIR trial suggest the higher ESA doses needed to achieve and sustain higher Hb concentrations may contribute to the increased risk of adverse events in the high target Hb arm.[32,33]

The Trial to Reduce Cardiovascular Events with Aranesp Therapy study, the only large placebo-controlled study of ESAs in CKD, randomized 4038 subjects with type 2 diabetes mellitus and CKD (eGFR 20−60 mL/min/1.73 m^2) to receive darbepoetin alfa to achieve a target Hb of 13 g/dL or placebo with rescue darbepoetin administered if the Hb level was <9 g/dL.[8] The primary endpoints were composite outcomes of death or cardiovascular event (nonfatal MI, CHF, stroke, or hospitalization for myocardial ischemia) and death or ESRD. The median follow-up for this study was 29 months. Both groups had similar risks of death or cardiovascular event (HR 1.05; 95% CI 0.94−1.17; p = 0.41) and death or ESRD (HR 1.06; 95% CI 0.95−1.19; p = 0.29). There was a significantly higher risk of stroke in the group assigned to darbepoetin alfa compared with placebo, especially in patients with a prior history of a stroke. Death due to cancer in those with a prior history of cancer was also increased.

These three studies, along with changes in FDA-approved product labeling in the US, have led clinicians to avoid attempts at Hb normalization and tempered enthusiasm for use of ESAs to improve QoL. Instead, practice has evolved to use of lower ESA doses and targeting of Hb levels in the range of 10−11.5 g/dL in many patients.

EVALUATING AND CORRECTING PERSISTENT FAILURE TO REACH OR MAINTAIN TARGET HB

ESA hyporesponsiveness, which is much more common among hemodialysis patients than those with CKD not on dialysis, is diagnosed in patients who are not able to achieve or maintain the desired Hb concentration despite receiving higher than expected ESA doses.[29] Patients with initial ESA hyporesponsiveness during the first several months of treatment are more likely to experience an adverse cardiovascular outcome or die than patients who respond better to initial dosing.[30,34] In patients with initial or acquired ESA hyporesponsiveness, evaluation for specific causes of poor ESA response should be undertaken. The most common factors leading to ESA hyporesponsiveness are shown in Table 60.2.[35] It is now generally recommended, given concerns that high ESA doses may contribute to some of the adverse events noted in clinical trials, that ESA doses not be repeatedly increased in hyporesponsive patients beyond 2−3 times the initial dose.

IRON SUPPLEMENTATION TO TREAT CKD ANEMIA

Adequate iron stores and availability of iron to support erythropoiesis are essential, whether patients are receiving an ESA or not. Iron deficiency is common in patients with CKD.[36−38] Iron status (iron stores and available iron in the circulation) should be evaluated in anemic patients with CKD. The gold standard for evaluating iron stores is the assessment of stainable iron in a bone marrow biopsy, a test that is only very rarely performed for this purpose. Instead, measurement of serum ferritin, a marker of storage iron, is

TABLE 60.2 Factors Involved in Erythropoiesis-Stimulating Agent (ESA) Hyporesponsiveness

Easily Correctable	Potentially Correctable	Other Factors
Absolute iron deficiency	Infection/Inflammation	Hemoglobinopathies
Vitamin B_{12}/Folate deficiency	Malnutrition	
Inadequate dialysis	Hemolysis	
ACEI/ARB use (uncommon)	Bleeding	
	Severe hyperparathyroidism (uncommon)	
	Pure red cell aplasia	
	Malignancy	
	Bone marrow disorders	

ACEI, angiotensin-converting enzyme inhibitor; *ARB*, angiotensin receptor blocker.
Adapted from reference 35.

commonly used. A serum ferritin ≤30 ng/mL is consistent with an absence of bone marrow iron. Ferritin is also an acute-phase reactant, and because patients with CKD patients may have chronic inflammation, elevated serum ferritin levels must be interpreted cautiously. TSAT is the most common method for assessing iron availability in the circulation for incorporation into red blood cells.

Iron deficiency may be either absolute, i.e. there is an absence or deficiency of bone marrow iron which limits erythropoiesis, or functional, in which bone marrow iron is present but due to inflammatory blockade or other factors is not readily available to support erythropoiesis. Functional iron deficiency may also be seen in patients receiving ESAs with stimulation of erythropoiesis beyond that which available iron can support. Absolute iron deficiency in patients with CKD is typically characterized by TSAT <20% and serum ferritin levels <200 mg/dL. Functional iron deficiency, in contrast, is characterized by TSAT >20−30% and serum ferritin >200−300 mg/dL. Despite having adequate bone marrow iron stores, some patients with CKD and anemia will nonetheless experience an increased red blood cell production and Hb concentration when administered IV iron.[16,39]

Untreated iron deficiency is a major cause of hyporesponsiveness to ESA treatment.[40,41] As high ESA doses may contribute to adverse outcomes, maximizing ESA responsiveness with adequate iron stores is essential so that the lowest possible ESA dose can be used. Therefore, before initiating ESA therapy, a patient's iron status must be assessed and iron deficiency, if present, should be treated. Options for therapy depend on the stage of CKD and include oral and IV therapies. A trial of oral iron therapy is often undertaken in patients with CKD who are not on dialysis, although IV iron is more effective in repleting and maintaining sufficient iron stores and leads to greater Hb increases,[42] and thus should be used if oral iron is poorly tolerated or less effective than desired.

IRON AGENTS DOSING AND FREQUENCY IN CKD

Decisions to initiate iron therapy must weigh both the benefits (avoidance of transfusions and reduction of anemia-related symptoms) and potential adverse effects of iron supplementation. The 2012 KDIGO Clinical Practice Guidelines for anemia in CKD recommend initiation in nondialysis CKD patients not on ESA therapy if an increase in Hb concentration is desired and TSAT is ≤30% and ferritin is ≤500 ng/mL. A trial of oral iron therapy can be undertaken for 1−3 months before using IV iron therapy, although some use IV iron instead of oral iron to avoid adverse effects of oral iron and ensure adequate iron supplementation. Selection of route of iron therapy depend on severity of iron deficiency, availability of venous access, response to prior oral or IV iron therapy, tolerance of side effects with prior oral iron treatment, patient compliance, and cost.

Dosing strategies for oral iron generally provide approximately 200 mg of elemental iron daily, which is equivalent to ferrous sulfate 325 mg three times daily, the most commonly used oral iron preparation. Each pill provides 65 mg of elemental iron. Other oral iron formulations are available, but none has been convincingly demonstrated to be more effective or better tolerated than iron sulfate. Gastrointestinal side effects may limit use of oral iron. If goals of iron supplementation are not met with oral iron after a 1- to 3-month trial, it is appropriate to consider IV iron supplementation, as recommended (Grade 2C) in the 2012 KDIGO Anemia Guidelines.[15] IV iron can be administered as a single large dose or repeated smaller doses depending on the specific IV iron preparation used (discussed further below). The initial course of IV iron is typically prescribed to provide approximately 1000 mg initially, with additional doses if this fails to achieve the desired increase in Hb level and/or decrease in ESA dose. TSAT and ferritin are typically monitored every 3 months once anemia treatment with iron is initiated, with monthly monitoring of the Hb.

A new oral iron preparation, ferric citrate, was approved by the US FDA in 2017 for the treatment of iron deficiency anemia in patients with CKD who are not on dialysis. It had previously been approved as a phosphate binder for patients on dialysis. Ferric citrate contains the equivalent of 210 mg of ferric iron. Two double-blind RCTs comparing ferric citrate to placebo in subjects with nondialysis-dependent CKD demonstrated greater improvement in Hb and iron indices with ferric citrate and similar side effects compared with placebo.[43,44] Ferric citrate is more expensive than iron sulfate but may be useful in selected patients, although studies comparing the efficacy and side effects of these two oral iron preparations have not yet been reported.

USE OF INTRAVENOUS IRON IN THE TREATMENT OF CKD ANEMIA

Several IV iron preparations are available for treatment of iron deficiency among patients with CKD. A high molecular weight formulation of iron dextran, which was associated with more common occurrence of severe side effects compared with other agents, is no longer available. Alternatives include ferric carboxymaltose, ferric gluconate, ferumoxytol, iron sucrose, iron

isomaltoside (not available in the US), and low molecular weight iron dextran. Iron sucrose and ferric gluconate required repeated administration, whereas the other agents can provide a total iron dose of 1000 mg or more in one or two infusions, which is more convenient and preferred for patients with CKD who may be preserving veins for possible hemodialysis vascular access placement. Iron sucrose may be given in doses of 100–300 mg and ferric gluconate in doses of 125–175.5 mg. A 25-mg test dose before infusion of a full dose of iron dextran is required; test doses are not required with the other agents but are often recommended in patients with multiple drug allergies or history of prior reactions to IV iron.

IV iron can cause allergic reactions, including life-threatening anaphylaxis. Such reactions appear to be very uncommon and occur with roughly equal frequency with any of the currently available IV preparations. Other uncommon symptoms with iron infusion include urticaria, palpitations, and dizziness. Because of mostly theoretical concerns that bacterial infections may worsen following IV administration, it is generally recommended that iron infusions be deferred in patients with active bacterial infections or at least are on appropriate antimicrobial therapy.

CONCLUSION

Anemia is one of the most common complications of CKD. As kidney disease advances, the incidence and prevalence of anemia increases. Anemia of CKD is multifactorial in etiology with erythropoietin deficiency, iron deficiency, and inflammation being the most important contributing causes. Observational studies have suggested an increased risk of cardiovascular and renal complications, lower QoL, and higher mortality as being associated with a lower Hb level. While it is likely that this positive impact of anemia management is present comparing Hb concentrations of 9–11 g/dL with Hb concentrations prevalent before ESAs became available, large RCTs have demonstrated that correction of anemia with an ESA is associated with either no benefit or an increased risk of cardiovascular complications and/or death. Some studies have also suggested that exposure to high doses of ESA may contribute to some adverse events arising from anemia treatment. Contemporary approaches to anemia management now embrace individualizing anemia management using the lowest possible dose of ESA together with treatment of iron deficiency and any underlying inflammation. In the not too distant future, oral prolyl hydroxylase inhibitors that stabilize and prevent degradation of hypoxia-inducible factor leading to both enhanced erythropoietin production and improved iron utilization are likely to be approved for management of anemia in patients with CKD.[45,46] Their role in management of anemia in this patient population is likely to be determined based on their cost compared with already available agents and demonstration of long-term safety.

QUESTIONS AND ANSWERS

Question 1

A 60-year-old man with a history of hypertension, diabetes mellitus, and proteinuric CKD stage 4 is seen in follow-up. He has noticed increasing fatigue, without any other signs of uremia. He has had no changes in his medications, no recent illnesses. A recent echocardiogram demonstrated no acute changes. Current medications include lisinopril, aspirin, insulin, ferrous sulfate 325 mg three times a day, lansoprazole, and calcium acetate. Blood pressure is 120/80 mm Hg, heart rate 100 beats per minute. Lungs are clear, there are no murmurs, abdomen is soft, nontender, without evidence of hepatosplenomegaly, and there is trace peripheral edema. The following labs are obtained:

S[Na] 140 mEq/L
S[K] 4.4 mEq/L
S[Cl] 100 mEq/L
tCO2 22 mEq/L
BUN 38 mg/dL
S[Cr] 2.9 mg/dL
WBC 5.5/μL
Hb 8 g/dL
Hct 24%
Platelets 250/μL
TSAT 10%
Ferritin 20 ng/mL

What would be the next step in management?

A. Discontinue proton pump inhibitor
B. Discuss avoiding taking ferrous sulfate with meals or calcium acetate
C. Discontinue ACEI
D. Increase ferrous sulfate dose
E. Initiate IV iron therapy

Answer: E

The clinical presentation is consistent with severe iron deficiency anemia as evidenced by the symptoms and laboratory findings. The patient has a low Hb concentration with a low TSAT and a very low ferritin level. Although proton pump inhibitors, calcium phosphate, and ingesting iron with meals may interfere with iron absorption (A, B), the patient has symptomatic anemia; therefore, discontinuing the proton pump inhibitor and avoiding iron with meals and calcium acetate will not adequately address his severe anemia. Discontinuing his ACEI is not necessary, though ACEI are associated with ESA hyporesponsiveness (C). Increasing his ferrous sulfate dose (D), if he is indeed adherent, is also not correct as he is receiving the recommended daily dose of 200 mg of elemental iron (each 325mg of ferrous sulfate has 65mg of elemental iron). Given his symptoms, it would be best to initiate IV iron therapy (E) and measure his response to IV iron repletion following a dose of 1000 mg (in either split doses or one large dose). If his Hb does not improve and his TSAT remains $\leq$30% and his ferritin is $\leq$500 ng/mL, this dose may be repeated once. If there is no improvement following administration of 2 g of IV iron, then sources of ongoing blood loss should be investigated.

Question 2

A 45-year-old woman with a past medical history of systemic lupus, hypertension, and lupus nephritis (in remission), with CKD stage 3, presents for routine follow-up. She has no complaints and has been adherent with her medications, which include mycophenolate mofetil 1500 mg twice a day, plaquenil, lisinopril, and aspirin. Blood pressure is 110/70 mm Hg, heart rate is 70 beats per minute. Her physical examination demonstrates normal findings, clear lungs, no murmurs, no hepatosplenomegaly, and no evidence of peripheral edema. The following labs are obtained:

S[Na] 140 mEq/L
S[K] 4.0 mEq/L
S[Cl] 100 mEq/L
tCO2 24 mEq/L
BUN 25 mg/dL
S[Cr] 1.5 mg/dL
WBC 3.5/μL
Hb 9.8 g/dL
Hct 28.5%
Platelets 300/μL
TSAT 35%
Ferritin 250 ng/mL

What would be the next step in management of the anemia?

A. Decrease mycophenolate mofetil dose
B. Start oral iron therapy
C. Discontinue ACEI
D. Repeat CBC, TSAT, ferritin within 12 months and check B12/folate, TSH to investigate other causes of anemia
E. Initiate ESA therapy

Answer: D

This is an asymptomatic anemic patient with lupus nephritis which is in remission. Decreasing her mycophenolate mofetil dose may be indicated if she had leukopenia or infection, but not in this case (A). Her TSAT and ferritin levels are adequate and do not indicate iron deficiency (B). There is no indication to hold her ACEI in this case as it is not independently associated with a low Hb (C). In the absence of a clear

explanation for a low Hb, and in the absence of symptoms, there is no indication to initiate ESA therapy in this patient (E). Investigation of other underlying causes of anemia is indicated for this patient (D).

Question 3

A 55-year-old man with a history of hypertension and CKD stage 5 of unknown etiology has been followed regularly in renal clinic. He has not had any uremic symptoms but has noticed that his blood pressure, which had previously been well controlled, has become elevated recently to 160/90 mm Hg consistently. He denies headaches, change in vision, chest pain, and shortness of breath. He denies recent changes to his medications, and he does not take over-the-counter medications or recreational drugs. His medications include diltiazem, furosemide, darbepoetin alfa 40 μg monthly, sodium bicarbonate, ferrous sulfate 325 mg three times a day, sevelamer, calcitriol 0.5 μg three times a week, and simvastatin. Blood pressure is 170/100 mm Hg, heart rate is 75 beats per minute. His physical examination demonstrates jugular venous pressure 7 cm, clear lungs, no murmurs, no hepatosplenomegaly, and no evidence of peripheral edema. The following labs are obtained:

S[Na] 140 mEq/L
S[K] 4.5 mEq/L
S[Cl] 104 mEq/L
tCO2 21 mEq/L
BUN 49 mg/dL
S[Cr]5.5 mg/dL
WBC 6.5/μL
Hb 14 g/dL
Hct 42%
Platelets 300/μL
TSAT 30%
Ferritin 420 ng/mL
Chemistries have been stable for the last 6 months; however, the Hb has increased from 10 g/dL three months ago to 14 g/dL on the same dose of darbepoetin alfa.

What would be the next step in management?

A. Discontinue darbepoetin alfa
B. Decrease darbepoetin alfa dose
C. Discontinue iron
D. Increase antihypertensive therapy

Answer: A

This is a patient with hypertension likely related to therapy with ESA. Normal subjects and CKD patients (both treated and not treated with dialysis) on ESA therapy have demonstrated elevated systolic and diastolic blood pressures in previous studies. The correct answer would be A, stop the darbepoetin alfa and monitor blood pressure carefully. As it is likely that it will take some time to see an improvement in blood pressure in the short-term, it would also be prudent to increase antihypertensive therapy temporarily (D), but the patient would likely not need prolonged increased hypertensive therapy. Decreasing the darbepoetin alfa dose will not be beneficial as the Hb level is elevated and the patient does not need further therapy. Holding the iron therapy is also reasonable as the patient is not iron deficient (C), but the first thing to stop is the darbepoetin alfa.

Question 4

A 67-year-old woman with a history of hypertension, diabetes mellitus, and proteinuric CKD stage 5 presents with a history of increasing fatigue sustained an ankle fracture 6 months ago following a mechanical fall. She is having difficulty with walking up and down her stairs. On follow-up visit, her Hgb was 7.0 g/dL. She was sent to the hospital and had a blood transfusion. No evidence was found for ongoing blood loss. She subsequently had a cardiac stress test that was normal. Following the blood transfusion, her fatigue improved. She has returned for follow-up in renal clinic. Her medications have not changed since her hospitalization and include carvedilol, lisinopril, lansoprazole, calcitriol 0.5 μg on three times a week, sevelamer 1600 mg with meals, darbepoetin alfa 40 μg monthly, sodium bicarbonate, and simvastatin. Her blood pressure is 110/75 mm Hg, heart rate is 70 beats per minute. The rest of her physical examination demonstrates clear lungs, no murmurs, no hepatosplenomegaly, and no evidence of peripheral edema. The following labs are obtained:

S[Na] 140 mEq/L
S[K] 5.0 mEq/L
S[Cl] 110 mEq/L
tCO2 22 mEq/L
BUN 40 mg/dL
S[Cr] 5.0 mg/dL
S[Ca] 8.5
S[P] 8.0 mg/dL
iPTH = 2000 pg/mL
WBC 7.5/μL
Hb 8.5 g/dL
Hct 26%
Platelets 228/μL
TSAT 30%
Ferritin 420 ng/mL

What would be the next step in management?

A. Discontinue lisinopril
B. Discontinue lansoprazole

C. Control hyperparathyroidism by discontinuing calcitriol, discussing adherence to low phosphorus diet and binders, and starting cinacalcet
D. Increase darbepoetin alfa frequency

Answer: C

This is a patient with severe hyperparathyroidism with symptomatic anemia despite normal iron stores and ESA therapy who subsequently required a blood transfusion. Hyperparathyroidism is a cause of ESA hyporesponsiveness; therefore, C is the correct answer: control hyperparathyroidism. Although lisinopril may be a cause of ESA hyporesponsiveness and may also be held if her blood pressure is monitored (A), it is not the first step in this patient's management. Lansoprazole does not affect ESA response (B), and increasing darbepoetin will not improve this patient's Hb until the hyperparathyroidism is under control (D).

Question 5

A 70-year-old woman with a history of hypertension, hypothyroidism, and IgA nephropathy with CKD stage 4 who presents with a history of progressive fatigue returns to renal clinic. She has an Hb of 6 g/dL. Three months ago, her Hb was 9.5 g/dL. She denies shortness of breath or chest pain but does have dyspnea on exertion and has noticed some light-headedness at times. Her medications include labetalol, synthroid, epoetin alfa three times a week, calcium acetate 500 mg with meals, and calcitriol 0.25 μg three times a week. Her blood pressure is 100/70 mm Hg, heart rate is 70 beats per minute. The rest of her physical examination is unremarkable. The following labs are obtained STAT:

S[Na] 140 mEq/L
S[K] 4.0 mEq/L
S[Cl] 105 mEq/L
tCO2 22 mEq/L
BUN 40 mg/dL
S[Cr] 4.0 mg/dL
S[Ca] 8.5 mg/dL
S[P] 5.0 mg/dL
WBC 8.0/μL
Hb 6 g/dL
Hct 18%
Platelets 228/μL

Before a blood transfusion, you request the following labs be obtained. Which laboratory test is most likely to be abnormal?

A. TSH
B. Parvovirus PCR
C. Anti-EPO antibodies
D. iPTH
E. Iron studies to include TSAT, ferritin

Answer: C

The dramatic drop in Hb level in this patient raises concerns about ongoing blood loss, but in the absence of bleeding, the more likely cause of this dramatic decrease in hematocrit is anti-EPO antibodies (C) developing as a consequence of ESA therapy. Although pure red blood cell aplasia is rare, it has been seen in patients who have been on formulations of epoietin alpha. The other causes of ESA hyporesponsiveness should also be investigated. If the first set of studies is normal, evaluation by a hematologist will be necessary as bone marrow disorders, and malignancy could also be a cause of severe anemia in this patient.

Question 6

A 75-year-old woman with a past medical history of Hodgkin lymphoma successfully treated with chemotherapy and radiation 20 years ago, with hypertension and CKD stage 4 presents for follow-up in renal clinic. Her labs have been stable over three years, except at her last visit 6 months ago, she was found to be anemic with an Hb of 7.5 g/dL. She was initiated on oral iron for iron deficiency anemia, and once her iron stores had improved, she was started on darbepoetin alfa monthly. She has been on ESA therapy for 3 months now, and each month, her TSAT and ferritin have been adequate, yet her Hb has not substantially improved and is still 7.8 g/dL. Her current dose of darbepoetin is twice the initial dose recommended by the manufacturer. She is fatigued but has not had shortness of breath or dyspnea on exertion, and she denies light-headedness.

What is the next step in this patient's management?

A. Increase her darbepoetin dose
B. Initiate a trial of IV iron therapy
C. Initiate Vitamin C therapy
D. Referral to hematology for evaluation of anemia

Answer: A

Attempting an increase in darbepoetin dose sounds reasonable (A), given the lack of response to the current dose of ESA. The darbepoetin dose should be adjusted monthly but should not exceed four times the initial dose recommendations based on weight. Given her history of Hodgkin lymphoma, she is at increased risk for developing myelodysplastic syndrome, which is a cause of ESA hyporesponsiveness, as is any bone marrow disorder. If there is no improvement in her Hb within one month with the increased dose of darbepoetin, then referral to a hematologist is indicated (D). Answer B is not correct because her TSAT and ferritin are adequate. Answer C, Vitamin C adjuvant therapy, is associated with Hb improvements in patients treated with dialysis who are on ESA therapy; however, the effects of Vitamin C on predialysis CKD patients are unknown.

CHAPTER

Management of Hypertension in Chronic Kidney Disease

Mahboob Rahman[a], *Paul Drawz*[b], *George Thomas*[c], *Jeffrey Turner*[d]

[a]University Hospitals Cleveland Medical Center, Case Western Reserve University, Louis Stokes Cleveland VA Medical Center, Cleveland, OH, United States; [b]Division of Renal Diseases and Hypertension, University of Minnesota Medical School, Minneapolis, MN, United States; [c]Cleveland Clinic Foundation, Cleveland, OH, United States; [d]Yale University, New Haven, CT, United States

Abstract

Hypertension is common in patients with chronic kidney disease (CKD) and contributes to risk of progression of CKD and cardiovascular disease. Many factors including alterations in salt and water balance, the sympathetic nervous system, and the renin–angiotensin–aldosterone system underlie the pathophysiology of hypertension in this setting. Careful measurement of blood pressure, including out-of-office measurement, is important. Goal blood pressure for patients with CKD is less than 130/80 mm Hg. Restriction of dietary salt intake is an important nonpharmacologic intervention, and inhibitors of the renin–angiotensin axis are the cornerstone of drug therapy, especially in patients with proteinuria.

Hypertension is common in patients with chronic kidney disease (CKD) with a prevalence rate of 60–90% in several studies.[1] Hypertension contributes to the high risk for cardiovascular disease and to progressive loss of kidney function over time in this population. Therefore, optimal management of hypertension is an important aspect of the care of the patient with CKD. However, blood pressure (BP) control rates remain suboptimal. Only 34–67% of adults with hypertension and CKD have controlled BP (<140/90 mm Hg).[2,3]

MECHANISMS OF HYPERTENSION IN CKD

The kidneys play a central role in regulating BP by maintaining sodium and water homeostasis and through regulation of the renin–angiotensin–aldosterone system (RAAS). In addition, factors that affect the sympathetic nervous system and endothelial function are important contributors to the pathogenesis of hypertension in CKD patients.

Salt and Water Balance

Hypertension due to impaired sodium and water retention is a final common pathway of several interconnected pathologies that occur in CKD. In the steady state, salt and water intake is precisely balanced with salt and water excretion by the kidneys. When salt and water intake is increased, such that it exceeds the steady state excretion rate, a transient period of positive sodium balance will occur. This results in an increase in total body water, extracellular water, and arterial BP. The rise in BP stimulates an increase in sodium and water excretion by the kidneys, such that homeostasis is achieved, and sodium and water intake will again be balanced by salt and water excretion.[4,5] In this system, the BP costs of achieving sodium balance with increasing amounts of sodium intake varies among individuals. In some a rise in BP is minimal or nonexistent, whereas in others, significant sustained hypertension occurs.[6] The latter is referred to as salt-sensitive hypertension. The magnitude of salt-sensitive hypertension increases with increasing loss of kidney function.[7–9] In these settings, there is an increase in mean arterial pressure required to achieve sodium balance with higher levels of sodium intake. This salt-sensitivity phenomenon is due to an inability to adequately downregulate neurohormones that promote increased renal sodium reabsorption in these pathologic settings. On the other hand, in some models of CKD, salt sensitivity is not demonstrated, due to a homogenous increase in preglomerular resistance. Representative clinical scenarios

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00061-9

include bilateral renal artery stenosis and coarctation of the aorta, in which hypertension is a significant feature; however, salt sensitivity is not present. This is due to the preservation of the ability to downregulate neurohormones that promote renal sodium reabsorption with increased salt intake.

The mechanisms that result in a shift to the right of the pressure natriuresis curves, the so called "resetting of pressure natriuresis," are less well understood. This response is critical in any form of sustained hypertension, whether essential hypertension or hypertension in the setting of CKD is considered.[10] Resetting in pressure natriuresis is not due to changes in renal blood flow or glomerular filtration. Rather, increases in renal interstitial hydrostatic pressure lead to the downregulation of proximal tubule sodium transporters, particularly Na+ H+ isoform 3.[11] In addition, it has been speculated that sustained abnormalities in pressure natriuresis may be related to abnormalities in renal vasoconstriction[12] and endothelial dysfunction related to abnormalities in nitric oxide.[13]

Renin–Angiotensin–Aldosterone System

The RAAS is a major regulator of BP due to its effects on salt and water retention and due to its direct effects on vasoconstriction. Key concepts have emerged regarding the role of RAAS in the pathogenesis of hypertension in CKD. The presence of an intrarenal RAAS that operates independently of systemic RAAS plays an important pathophysiologic role. Important signaling pathways for the intrarenal RAAS include the Wnt/β-catenin pathway and sympathetic nervous system stimulation of β-1 adrenergic receptors.

The RAAS is tightly regulated in health and responds to dietary sodium intake. In the presence of high salt intake, there is increased delivery of sodium and chloride to the macula densa of the thick ascending limb. This signals inhibition of renin production by the juxtaglomerular cells of the afferent arteriole, which then inhibit the downstream production of angiotensin II and aldosterone, potent stimuli for vasoconstriction and renal tubular sodium reabsorption. However, in CKD there is hyperactivation of the RAAS that is stimulated independently of sodium intake.[14,15] Mounting evidence demonstrates that this is mediated through the intrarenal RAAS system.[16,17] The kidney is unique compared to most other organs in the body, in that it has all the necessary components to generate intrarenal angiotensin II along the cells of the nephron. Much higher tissue concentrations of angiotensin II in the kidney have been demonstrated that could not be explained by delivery of systemically produced angiotensin II *via* the arterial blood flow alone.[14,18] In addition, several kidney disease models have demonstrated activation of intrarenal RAAS as opposed to systemic RAAS.[19–24] Therefore, it appears that intrarenal RAAS is an important mechanism by which hypertension is both initiated and maintained in CKD.

Sympathetic Nervous System

Activation of the sympathetic nervous system is an important contributor to the development of hypertension in CKD patients. The kidneys are both the source (*via* afferent pathways) and the target (*via* efferent pathways) of this activity, and higher sympathetic nervous system activity is associated with increased vascular tone and BP.[25] Direct stimulation of renal afferent pathways by uremic solutes[26,27] may also mediate increased sympathetic nervous system activity in CKD.[28] Sympathetic overactivity is also transmitted back to the kidney *via* efferent neural pathways resulting in β1 adrenergic receptor–mediated renin release in the juxtaglomerular cells and α1 adrenergic receptor–mediated renal arteriole vasoconstriction. Both of these mechanisms are important in sustaining hypertension in CKD patients.

Vascular Endothelial Dysfunction

Endothelial dysfunction is common in CKD, contributing to hypertension as well as end-organ damage. Although there are numerous pathways by which endothelial function is affected, two important mechanisms include impairments in nitric oxide, a potent vasodilator, and deficiencies of renalase, a secreted amine important for catecholamine metabolism.[29–31]

MEASUREMENT OF BLOOD PRESSURE IN CKD

Office Blood Pressure

For over 100 years, BP measurement in the office has been the preferred method for assessing BP, diagnosing hypertension, and evaluating response to therapy. The original auscultatory method has been mostly replaced by oscillometric devices that detect pulsatile blood flow and indirectly calculate BP.[32] Many modern oscillometric devices are programmable to enable a defined rest period, and multiple measurements are typically taken at one minute intervals. BP measured using one of these newer devices is referred to as automated office BP. Although the evidence is limited, automated office BP may be slightly lower than manual office BP, and automated office BP may correlate better with ambulatory daytime BPs.[33] Most recent clinical trials use automated office BP.[34] Regardless of the technique (manual vs. automated), measurement of BP in the office should

follow guidelines from the American College of Cardiology/American Heart Association.[32,35] Important considerations include preparing the patient (including about five minutes of quiet rest, and proper positioning with the arm supported at heart level), use of an approved device with the proper cuff size, and averaging two or more readings used to estimate the BP for that clinic visit.

Home BP

Measurement of BP outside the office setting has been increasingly recognized as a valuable adjunct in the management of hypertension.[32,36] This can be done by monitoring BP at home, or by 24-hour ambulatory BP monitoring. Although it does require some patient education, home BP monitoring is typically less cumbersome than ambulatory BP monitoring. Patients should be instructed on proper technique, including use of a validated monitor, proper positioning, and the necessity of adequate quiet rest prior to taking readings.[32] Patients should bring their monitor to clinic to assess their technique using their home device compared to clinic BP. Patients are typically instructed to take two BP readings in the morning before taking medications and two BP readings in the evening. The average of all readings over a week is then used to assess BP control.[32] Home BP monitoring may improve BP control. In the Targets and Self-Management for the Control of Blood Pressure in Strokes and at Risk Groups (TASMIN-SR) study, 552 patients with a BP $\geq$130 mm Hg were randomized to usual care or self-management (which included measurement of BP in the home and self-titration of medications).[37] After 12 months, among the 146 patients with CKD, the systolic BP in the intervention group at 12 months was 8.4 mm Hg (95% CI 1.1−15.8) lower than the control group.[37] A recent meta-analysis found a similar benefit to home BP monitoring but indicated that combining home BP monitoring with other interventions, such as a plan for medication titration and education, may be necessary to achieve lower BPs.[38] In summary, home BP monitoring should be considered in the diagnosis (to identify white coat and masked hypertension) and management of hypertension in patients with CKD.

Ambulatory BP Monitoring

Ambulatory BP monitoring (ABPM) is considered the gold standard for assessing out-of-office BP. The monitors are similar to automated oscillometric devices used in the clinic and are programmed to record BP throughout the day and night for a 24-hour period.[32] ABPM provides an estimate of daytime, 24 hour, and nighttime BP, and the relative decrease in BP from day to night, which is referred to as dipping status.[39] Compared to daytime BP, nighttime BP is more strongly associated with all-cause mortality, cardiovascular mortality, and cardiovascular events.[40−42]

White-Coat and Masked Hypertension

Out-of-office BPs, either home or ambulatory, can be combined with clinic BPs to categorize patients as normotensive (normal clinic and out-of-office BP), white-coat hypertension (elevated clinic BP with normal out-of-office BP), masked hypertension (normal clinic BP with elevated out-of-office BP), and sustained hypertension (elevated clinic and out-of-office BP). In observational studies in the general population, patients with white-coat hypertension have risk of cardiovascular outcomes that are similar to those with controlled clinic and out-of-office BPs, whereas masked hypertension is associated with increased risk for adverse outcomes.[43,44]

Patients with low estimated glomerular filtration rate (eGFR) and proteinuria are more likely to have elevated nighttime BP and a nondipping pattern.[45] Similarly, masked and sustained hypertensions are associated with lower eGFR and proteinuria.[46] Masked hypertension is associated with higher risk of target organ damage and clinical cardiovascular disease outcomes. In 1492 patients with CKD enrolled in the Chronic Renal Insufficiency Cohort study, 28% had masked hypertension. Compared to controlled clinic and ambulatory BP, masked hypertension was associated with higher left ventricular mass index (+2.52 g/m^2; 95% CI 0.9−4.1) and pulse wave velocity (+0.92 m/s; 95% CI 0.5−1.3).[46] In a longitudinal study of 489 hypertensive patients seen in a nephrology clinic in Italy, compared to controlled clinic and ambulatory BP, white-coat hypertension was associated with similar risk for cardiovascular outcomes, end-stage renal disease (ESRD), and all-cause mortality while masked hypertension was associated with increased risk of cardiovascular outcomes (hazard ratio [HR] 3.17; 95% 1.5−6.7), ESRD (HR 3.93; 95% CI 1.8−8.7), and all-cause mortality (HR 3.45; 95% CI 1.5−7.9).[47] Based on these studies and others, it appears that the well-established increased risk associated with masked hypertension in the general population also applies to patients with CKD.

Current national guidelines recommend out-of-office BP to confirm the diagnosis of hypertension prior to initiating treatment and to guide therapy in patients receiving antihypertensive medications.[32,36]

TREATMENT OF HYPERTENSION IN CKD PATIENTS

The goal of hypertension management in patients with CKD is to achieve and maintain BP less than 130/80 mm Hg[32] (Figure 61.1). This is supported by

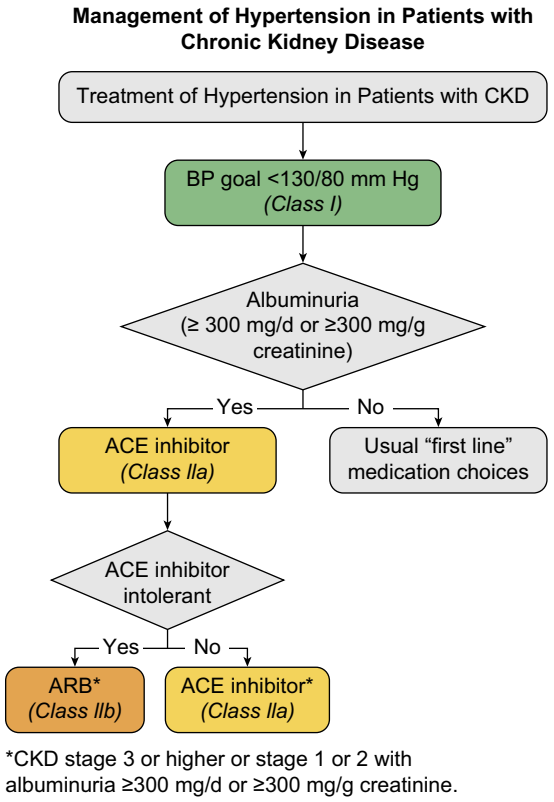

FIGURE 61.1 Overview of management of hypertension in CKD.[32] *Reprinted with permission from the Journal of the American College of Cardiology.*

observational data that suggest there is a linear relationship between BP and clinical outcomes in patients with CKD.[48] More importantly, intensive treatment of BP has been shown to reduce risk of cardiovascular disease and mortality in this patient population.[34,49] The Systolic Blood Pressure Treatment Trial (SPRINT) provided valuable information about intensive BP control in patients with CKD. SPRINT was a multicenter clinical trial that randomized 9361 hypertensive patients to a standard treatment arm (target systolic BP less than 140 mm Hg) or an intensive treatment arm (target systolic BP less 120 mm Hg). Of study participants, 28% had CKD at baseline. In the CKD participants[50] the mean BP over the duration of follow-up (3.2 years) was 123/66 mm Hg, requiring an average of 2.9 antihypertertensive medications. Participants assigned to the intensive treatment group had lower risk of all-cause mortality (HR, 0.72; 95% CI, 0.53–0.99) and of developing the primary cardiovascular outcome (HR, 0.81; 95% CI, 0.63–1.05), consistent with findings in the overall study population. However, there was no difference in the primary renal outcome (ESRD or 50% decline in eGFR), perhaps due to the small number of patients who reached this endpoint. There was an acute decline in glomerular filtration rate (GFR) in the first six months in the intensive treatment group, suggestive of a hemodynamic effect of lowering BP, seen in previous clinical trials. The urinary biomarker profile measured in SPRINT supported a hemodynamically mediated decline in GFR rather than tubular injury. In summary, the SPRINT study demonstrated that intensive BP control can be achieved and maintained and is associated with lower risk of mortality and cardiovascular disease in patients with CKD.

Other studies have shown that benefits of intensive treatment of BP on preserving renal function are seen after long-term follow-up in patients with proteinuria.[50,51] Whether intensive treatment of BP slows decline in kidney function in patients without significant proteinuria remains unclear.[50]

Nonpharmacologic Interventions

Patients with CKD and hypertension should be advised to lose weight, follow a healthy diet, reduce salt intake, participate in regular physical activity, not smoke, and have moderate alcohol intake.[32,52] Most of these recommendations are based on expert opinion, observational data, and randomized trials in the general population. However, there is some evidence of the effectiveness of these interventions in patients with CKD. A meta-analysis of 11 observational studies and 2 randomized trials demonstrated that weight loss interventions resulted in lower systolic BP along with a reduction in proteinuria.[53] Dietary sodium restriction is especially important to consider given CKD patients' decreased ability to excrete sodium. Among CKD patients with proteinuria, randomized trials have shown that decreased sodium intake reduces BP and proteinuria.[54,55] The Dietary Approaches to Stop Hypertension diet is recommended to lower BP in the general population. It should be considered with caution, however, in patients with advanced CKD, especially those with elevated serum potassium concentration (S[K]).[56]

Antihypertensive Drug Therapy in CKD

Selection of antihypertensive medications for CKD patients should take into account the presence of proteinuria, comorbid conditions, individual patient characteristics, and side-effect profile. Each specific class of antihypertensive medication has advantages and disadvantages, as well as indications and contraindications.

RAAS Blockers

RAAS blockers including angiotensin-converting enzyme inhibitors (ACEI) and angiotensin-receptor blockers (ARB) are recommended as first-line therapy for treatment of hypertension in patients with

proteinuric CKD.[32] These agents are effective in reducing proteinuria and slowing progression of CKD by improving glomerular hemodynamics, restoring the altered glomerular barrier function, and limiting the nonhemodynamic effects of angiotensin II and aldosterone, such as fibrosis and vascular endothelial dysfunction. These protective effects are, at least in part, independent of the reduction in systemic BP.[57] In patients with nondiabetic kidney disease, there is good evidence that treatment with ACEI results in slower decline in GFR, and this risk reduction is more pronounced in patients with higher degrees of proteinuria.[58] In patients with type 1 diabetes, treatment with captopril in those with overt proteinuria was associated with a 50% decrease in the risk of the combined endpoint of death, dialysis, or renal transplantation.[59] Patients with moderately increased albuminuria and treated with an ACEI also had reduced incidence of progression to overt proteinuria.[60] In type 2 diabetes, treatment with an ARB in patients with overt nephropathy was associated with a significant 20% and 16% decrease in risk, respectively, of the combined endpoint of death, ESRD, or doubling of serum creatinine concentration (S[Cr]).[61] Side effects of ACEI and ARB include cough (more with ACEI), angioedema (more with ACEI), and development of hyperkalemia. ACEI or ARB therapy can cause a modest rise in S[Cr] due to reduction in intraglomerular pressure. An elevation in S[Cr] up to 30% that stabilizes in the first 2 months is not necessarily a reason to discontinue therapy. Continued rise in S[Cr] should prompt evaluation for excessive fall in BP (especially with volume depletion due to concomitant diuretic use) and/or possible bilateral renal artery stenosis. There is no level of GFR or S[Cr] at which ACEI or ARB is absolutely contraindicated. This decision should be made on an individual basis. Risks for hyperkalemia should always be kept in mind at lower GFR levels. It would be prudent to check S[Cr] and S[K] within the first week or two after initiation or intensification of RAAS inhibition in CKD patients. RAAS blockers are contraindicated in pregnancy due to known teratogenic effects.

Aliskiren is a direct renin inhibitor that prevents conversion of angiotensinogen to angiotensin I. There are limited data to support the use of aliskiren in patients with CKD. Combination therapy with ACEI, ARB, or direct renin inhibitors is not recommended. Studies demonstrated worse renal outcomes, hypertension, and hyperkalemia with use of dual RAAS blockade.[62,63]

Diuretics

Because patients with CKD are particularly sensitive to sodium and water retention, diuretics are an integral component of management of hypertension. Diuretics may also help to reduce the risk of hyperkalemia in CKD patients treated with an ACEI or ARB. Many patients with CKD have resistant hypertension, and diuretics are important in this setting to achieve BP control. Thiazide diuretics also likely decrease peripheral vascular resistance and contribute to long-term benefit in BP control, in addition to acute benefits in volume expansion.

Thiazide-type diuretics include hydrochlorothiazide, chlorthalidone, indapamide, and metolazone. Chlorthalidone is more potent and has a longer duration of action compared to hydrochlorothiazide.[64] Chlorthalidone may be associated with a higher risk of developing hyponatremia and hypokalemia, particularly in the elderly.[65] Thiazide diuretics are generally considered to be ineffective when estimated GFR is less than 30 mL/min/1.73 m^2, due to decreased filtered sodium load reaching the distal tubule. Loop diuretics are preferred in this setting. However, some studies indicate that chlorthalidone is effective in lowering BP even in patients with low GFR.[66] Metolazone remains effective in patients with renal dysfunction, but due to unpredictable bioavailability, it is generally used for short durations of treatment, in combination with loop diuretics. Short-acting loop diuretics (such as furosemide) should be dosed at least twice daily to be effective. Patients with CKD may require higher doses of diuretics due to decreased secretion of diuretics by renal tubules in the setting of impaired renal function. Electrolytes should be monitored while patients are on diuretic therapy. Diuretics should be used cautiously in patients with a history of acute gout, unless already on uric acid-lowering therapy.

Mineralocorticoid Antagonists

There is now strong evidence supporting the use of spironolactone as add-on therapy in patients with resistant hypertension.[67] In patients with CKD, studies have shown enhanced antiproteinuric effects of an ACEI or ARB when combined with mineralocorticoid antagonists.[68] This added benefit is likely due to the impact on aldosterone escape (non−ACE-mediated activation of angiotensin II and production of aldosterone) and attenuation of aldosterone-mediated renal fibrosis. Combination therapy entails the risk of hyperkalemia and therefore should be used with caution in patients with significant renal dysfunction, with close monitoring of renal function and S[K]. Side effects specific to spironolactone include gynecomastia and breast tenderness due to estrogen-like effects, which are not seen with eplerenone.

Calcium Channel Blockers

Calcium channel blockers include dihydropyridines (such as amlodipine, nifedipine) and nondihydropyridines (such as verapamil and diltiazem).

Dihydropyridines act on vascular smooth muscle causing vasodilation. They also have a preferential effect on afferent glomerular arteriolar vasodilation, which can result in increased albuminuria when used as monotherapy.[69] Nondihydropyridines act on the myocardium, with negative chronotropic and inotropic effects. They have a vasodilatory effect on both afferent and efferent glomerular arterioles, resulting in decreased albuminuria. Although both classes of calcium channel blockers can lower BP, nondihydropyridines may be preferable in patients with albuminuria, especially when there is a contraindication to use of an ACEI or ARB. Although combination therapy with dihydropyridine and nondihydropyridine calcium channel blockers has been proposed due to differential mechanisms of action, this has not been studied in CKD patients.

Pedal edema may be a limiting factor to use of dihydropyridine calcium channel blockers due to arteriolar dilation and redistribution of fluid from the vascular space into the interstitium. The risk of edema is dose-dependent. Diuretic therapy may not be beneficial for calcium channel blocker-induced edema because it is not plasma volume mediated. The addition of an ACEI or ARB, on the other hand, may reduce the severity of edema.[70] Nondihydropyridines may increase the risk of atrioventricular block or bradycardia and should not be combined with beta blocker therapy.

Beta Blockers

Beta blockers are not recommended as first-line therapy for hypertension management in the absence of specific indications. They are useful in the setting of cardiac comorbidities including ischemic heart disease, congestive heart failure, and tachyarrhythmias. Extended release metoprolol and vasodilating beta blockers such as carvedilol have been shown to have mortality benefits in patients with congestive heart failure.[71] Abrupt cessation of beta blockers should be avoided, and concomitant use with nondihydropyridine calcium channel blockers is not recommended due to the risk of bradycardia and heart block.

Alpha Blockers

Alpha-1 blockers act by peripheral vasodilation and may be particularly useful in men with symptomatic benign prostatic hyperplasia. Therapy with the alpha-1 blocker doxazosin was associated with increased risk of cardiovascular events (especially congestive heart failure), compared to therapy with chlorthalidone.[72] Therefore, alpha-1 blockers are not recommended as first-line therapy for hypertension in CKD patients. Adverse effects include postural hypotension and risk of falls, particularly in the elderly.

Centrally Acting Alpha Agonists

Centrally acting alpha agonists include clonidine, methyldopa, and guanfacine. Centrally acting alpha agonists act by decreasing central sympathetic outflow, resulting in vasodilation. Centrally acting alpha agonists are generally used as adjunctive therapy in CKD patients with resistant hypertension who are already treated with multiple medications. Methyldopa has a long record of safety in pregnancy and is therefore widely used in this setting. Abrupt discontinuation of clonidine should be avoided because of the risk of rebound hypertension.

Vasodilators

Vasodilators, such as hydralazine and minoxidil, have direct vasodilatory effects on vascular smooth muscle, resulting in BP reduction. These agents are often third- or fourth-line agents after other medications have resulted in inadequate BP control or have intolerable side effects. Hydralazine has a short duration of action and frequent dosing is needed. Use of hydralazine is also associated with a drug-induced lupus-like syndrome in some patients treated with higher doses. Minoxidil is associated with pericardial effusion and severe volume expansion. Minoxidil should ideally be used with a high dose of a loop diuretic.

Choice of Drug Therapy and Combination Antihypertensive Drug Therapy in CKD

In proteinuric CKD, an ACEI or an ARB should be used as first-line therapy to lower BP and slow rate of progression of CKD.[32] The antihypertensive effect of an RAAS blocker may be enhanced by diuretic use. As a next step, a nondihydropyridine calcium channel blocker can be added for additional reduction in proteinuria. In patients with proteinuric CKD without overt edema, a diuretic or a nondihydropyridine calcium channel blocker can be considered as second-line therapy.

In patients with nonproteinuric CKD, there is no strong evidence that RAAS blockers are more beneficial than other agents. Any of the first-line agents for the treatment of hypertension can be used.[32] Diuretics remain useful as a part of combination therapy.

RESISTANT HYPERTENSION

Resistant hypertension is defined as BP that is not at goal despite the use of at least three antihypertensive medication classes, preferably including a diuretic, or BP that is at goal but requires prescription of four or

more medications.[73] The prevalence of apparent treatment resistant hypertension has been estimated to be as high as 40% in patients with CKD.[74] Patients with resistant hypertension are at higher risk for decline in kidney function (28% increased risk for decline in GFR and ESRD) and developing cardiovascular events (38% increased risk of composite of myocardial infarction, stroke, peripheral arterial disease, congestive heart failure, and all-cause mortality) compared with those without treatment-resistant hypertension.[74]

A careful and systematic evaluation of patients can result in identification of barriers to BP control and aid in the crafting of an optimal antihypertensive medication regimen in a given patient.[73] This starts with excluding factors that cause "pseudo-resistance," by obtaining standardized measurement of BP as described above and measuring out-of-office BP readings to exclude a "white-coat" effect. Assessment of the patient's adherence to the therapeutic regimen is very important. Some studies have indicated medication nonadherence rates as high as 50%.[75] Patients with CKD have complex medication regimens that may predispose them to more side effects. A high pill burden increases the possibility of nonadherence. It is also important to identify use of any pharmacologic agents that may increase BP, such as erythropoietin or cyclosporine, and reinforce lifestyle factors including dietary sodium reduction, moderation in alcohol use, engagement in regular physical activity, and weight management. An evaluation for causes of secondary hypertension may be needed if indicated by clinical features or initial laboratory assessments.

Several pharmacologic principles should be considered in the management of the patient with resistant hypertension. Dosing regimens should be optimized to maintain antihypertensive efficacy. Agents with complementary mechanisms of action should be used in combination to obtain maximum BP reduction. It is particularly important to choose the appropriate diuretic. In general, patients with preserved kidney function (GFR >30 mL/min) respond better to thiazide diuretics. Loop diuretics are preferred in patients with more advanced CKD (GFR <30 mL/min). The use of mineralocorticoid antagonists such as spironolactone is now standard as the fourth-line agent in patients with resistant hypertension. However, special considerations in CKD patients include the risk of hyperkalemia especially if used in combination with an ACEI or ARB. Ultimately, patient characteristics will determine the best combination of antihypertensive drug therapy. Consultation with a hypertension specialist may be considered in patients with true refractory hypertension.

Suboptimal control rates of hypertension and limited advances in pharmacologic options have increased interest in the use of device therapy as potential complementary or alternative treatment modalities for patients with hypertension. Experimental device therapies have included catheter-based renal denervation and baroreceptor-activation therapy.[76,77] Better understanding is needed regarding the safety, efficacy, and durability of their effects. This is especially true in CKD patients, as all large clinical trials studying device therapy have excluded patients with moderate to severe CKD and ESRD. Additionally, studies do not show a uniform BP lowering response with device therapy. Patient subgroups that are more likely to respond need to be identified, and practical clinical markers that can assess adequacy of the intervention are needed. None of the device therapies are currently approved for clinical use in the US. Appropriate evaluation of patients with resistant hypertension, with emphasis on lifestyle modifications and appropriate antihypertensive medication use, remain the cornerstone of management of these patients.

CONCLUSION

Hypertension is common in patients with CKD and contributes to the high risk of morbidity and mortality in this population. Many factors including abnormalities in salt and water balance, renin–angiotensin–aldosterone axis, and sympathetic nervous system contribute to hypertension in patients with CKD. A systematic and thorough approach is required to manage hypertension. This includes careful measurement of office BP, consideration of out-of-office BP measures, and reinforcement of nonpharmacologic interventions to lower BP. The target BP of less than 130/80 mm Hg can often be achieved and maintained with combination antihypertensive drug therapy, including RAAS inhibitors and diuretics. Importantly, good BP control can reduce risk of cardiovascular and progressive kidney disease in patients with CKD.

QUESTIONS AND ANSWERS

Question 1

A 74-year-old woman presents to hypertension clinic. She is a retired physician and is concerned about her risk for cardiovascular disease. She asks which type of BP measurement is best for assessing hypertension-related cardiovascular risk. You recommend:

A. Clinic BP
B. Home BP
C. Ambulatory BP
D. Kiosk BP at pharmacies

Answer: C

Ambulatory BP has the advantage of estimating 24-hour BP, nighttime BP, and the relative decrease in BP from day to night, which is referred to as dipping status. Nighttime BP is of particular interest. Compared to daytime BP, nighttime BP is more strongly associated with all-cause mortality, cardiovascular mortality, and cardiovascular events (C is correct). Although clinic BP has been used to assess eligibility for nearly all randomized controlled trials in hypertension and as the target BP in treat to target studies, ambulatory BP is more strongly associated with adverse outcomes than clinic BP (A is incorrect). Home BP allows for identification of white-coat and masked hypertension but does not assess nighttime BP (B is incorrect). Most kiosk BP monitors are not well validated (D is incorrect).

Question 2

A 62-year-old woman with CKD stage 4 from diabetic nephropathy presents to clinic for follow-up. She reports an increase in dietary sodium intake in recent weeks. An average of her recent home BP measurements is 154/92 mm Hg. Her current medications include furosemide 40 mg daily and lisinopril 20 mg daily. Her examination is notable for an elevated jugular venous pressure at 10 cm, crackles at her lung bases bilaterally, and 2+ edema of her lower extremities. Which of the following statement is most correct about hypertension in CKD?

A. Net sodium intake is always greater then net sodium excretion in CKD
B. Pressure natriuresis response does not change in CKD
C. Upregulation of the renin−angiotensin−aldosterone system and the sympathetic nervous system commonly impair sodium excretion in CKD
D. Low plasma renin activity and high serum aldosterone is a typical finding in CKD patients with hypertension

Answer: C

Impaired sodium excretion due to the upregulation of the renin−angiotensin−aldosterone system and the sympathetic nervous system is a common mechanism underlying hypertension in CKD (Answer C is correct). Typically the severity of these abnormalities associates with the severity of CKD. Despite this, sodium homeostasis is still maintained (at the cost of elevated BP and volume overload) in CKD except for ESRD patients (Answer A is incorrect). Pressure natriuresis is defined by the relationship of BP and sodium excretion. Typically, the pressure natriuresis curve is shifted to the right in CKD, such that a higher BP is required to reach sodium homeostasis (Answer B is incorrect). Finally, low plasma renin activity, and high serum aldosterone is typical of primary hyperaldosteronism, but this is not a typical finding in CKD (Answer D is incorrect).

Question 3

A 45-year-old man is seen for routine follow-up. He has a history of dyslipidemia and takes atorvastatin once daily. He is otherwise well. On physical examination his BP is 138/78 mm Hg and pulse is 74 bpm. He has a regular rhythm without murmurs, gallops, or rubs; no bruits; and peripheral pulses are equal. You instruct him on lifestyle modifications including exercise and a low-salt diet. Three months later, he returns and his BP is 136/76 mm Hg. According to the 2017 American College of Cardiology/American Heart Association guidelines, the next step in the diagnosis and management of this patient's elevated BP is

A. Initiate antihypertensive therapy with chlorthalidone 12.5 mg once daily
B. Initiate antihypertensive therapy with carvedilol 6.25 mg twice daily
C. Obtain out-of-office BP and initiate treatment if daytime ambulatory or home BP is $\geq$130/80 mm Hg
D. Make a diagnosis of elevated BP

Answer: C

This patient presents with elevated BP on two occasions separated by 3 months. The ACC/AHA guidelines recommend confirming elevated clinic BP with out-of-office measurements (correct Answer C) prior to initiating antihypertensive therapy (A and B are incorrect). The recommendation for out-of-office BPs is based on observational evidence of low risk for adverse outcomes with white-coat hypertension (elevated clinic BP with normal ambulatory/home BP). Similarly, the guidelines recommend out-of-office BP measurement in patients with elevated office BP (120−129/<80 mm Hg) to screen for masked hypertension (normal clinic BP with elevated ambulatory/home BP). The ACC/AHA guidelines define elevated BP as a systolic BP of

120−129 mm Hg and a diastolic BP <80 mm Hg (D is incorrect).

Question 4

A 50-year-old man with a past medical history of CKD stage 3 presents because he was found to have elevated BP readings on a routine physical examination a month ago and on subsequent home readings. His BP today in the office is 148/93 mm Hg. A complete physical examination is otherwise unremarkable. Renal function panel obtained today reveals S[Cr] 1.4 mg/dL (stable over the last 2 years). Urinalysis indicates proteinuria. You recommend the following:

A. Repeat the BP measurement in a week to confirm the diagnosis of hypertension
B. Start carvedilol
C. Start chlorthalidone
D. Start lisinopril
E. Start clonidine

Answer: D

This patient's diagnosis of HTN is already established based on more than one office visit and out-of-office readings. He does not need further measurement for confirmation (Answer A is incorrect). Per 2017 ACC/AHA guideline recommendations, in patients with proteinuric CKD, treatment with ACEI or ARB is recommended to improve renal outcomes (Answer D is correct; Answer C is incorrect). Beta blockers are no longer considered first-line antihypertensive in the absence of heart failure or coronary artery disease (Answer B is incorrect). Clonidine is not a first-line agent for hypertension management (Answer E is incorrect).

Question 5

A 65-year-old man is referred for further management of hypertension. He was just diagnosed with stage 1 hypertension and started on hydrochlorothiazide 25 mg daily with excellent BP control. His examination today is unremarkable. His BP is 129/79 mm Hg. His renal function panel shows a S[Cr] 1.0 mg/dL, Na of 138 mEq/L, and K of 4 mEq/L. He has done extensive reading about hydrochlorothiazide vs. chlorthalidone. He asks you about your recommendations. When comparing hydrochlorothiazide and chlorthalidone, which one of the following is correct?

A. Hydrochlorothiazide has a longer duration of action
B. Chlorthalidone may be associated with a higher risk of hyponatremia and hypokalemia in the elderly
C. Hydrochlorothiazide has been associated with a mortality benefit
D. Hydrochlorothiazide is a more potent BP medication
E. Chlorthalidone was not used in large hypertension studies

Answer: B

Chlorthalidone is more potent and has a longer duration of action compared to hydrochlorothiazide, including lowering nighttime BP (Answer A and D are incorrect). Mortality benefits and reduced cardiovascular morbidity have also been reported with use of chlorthalidone compared to hydrochlorothiazide (Answer C is incorrect). One study showed an increased risk of hospitalization for hyponatremia and hypokalemia with the use of chlorthalidone in the elderly (Answer B is correct). Chlorthalidone has been used in large hypertension trials, including the SPRINT trial, where the preferred thiazide diuretic was chlorthalidone (Answer E is incorrect).

Question 6

A 75-year-old man with hypertension and stage 3 CKD who is in good overall health is seen in your office. He has recently read online that new guidelines recommend lower BP goals (<130/80 mm Hg) compared to previous guidelines (<140/90 mm Hg). He asks about your opinion regarding more intensive compared to "usual" BP control targets.

Which of the following is NOT true about intensive compared to standard BP treatment goals?

A. Intensive treatment BP goals are associated with lower risk of heart disease and mortality in older patients
B. Intensive treatment BP goals will likely require use of more antihypertensive medications than standard goals
C. Intensive treatment BP goals will reduce the risk of progression of kidney disease in all patients with CKD
D. Intensive treatment goals of BP may be associated with more side effects

Answer: C

The SPRINT study rigorously compared a standard BP goal (<140 mm Hg systolic) with an intensive treatment goal (<120 mm Hg). Participants assigned to the intensive treatment goal had lower risk of cardiovascular outcomes and mortality (Option A is correct). Intensive BP therapy was associated with more use of antihypertensive drug therapy and higher risk of some side effects (Options B and D are correct). However, there was no difference in risk of progression of kidney disease between the two groups. This is consistent with other studies that do not show a benefit of intensive BP control in CKD patients without proteinuria (Option C is incorrect).

Management of Mineral and Bone Disorders in Chronic Kidney Disease

Kristen L. Nowak, Michel Chonchol

Division of Renal Diseases and Hypertension, University of Colorado Denver Anschutz Medical Campus, Aurora, CO, United States

Abstract

The pathophysiology of chronic kidney disease—mineral and bone disorder (CKD-MBD), a common clinical syndrome in patients with CKD with consequences affecting mineral metabolism, bone mineralization, and extracellular calcification, is complex. Diagnosis and management of CKD-MBD requires particular attention to the biochemical/hormonal factors affecting calcium, phosphorus, vitamin D, parathyroid hormone, and fibroblast growth factor-23 metabolism, as well as consideration of bone and vascular calcification. Nephrologists, patients, and the public need future well-designed randomized trials to further guide the diagnosis and management of CKD-MBD.

SCOPE OF THE PROBLEM AND PUBLIC HEALTH IMPLICATIONS

With declining kidney function, mineral homeostasis becomes progressively dysregulated, including alterations in serum concentrations of calcium, phosphate, intact parathyroid hormone (iPTH), and fibroblast growth factor-23 (FGF-23).[1] These biochemical abnormalities are tightly associated with cardiovascular mineralization and paradoxical skeletal demineralization (Figure 62.1).[2] In 2005, Kidney Disease: Improving Global Outcomes (KDIGO), an international organization with the mission of developing clinical practice guidelines in CKD, formally classified this clinical syndrome as chronic kidney disease—mineral and bone disorder (CKD-MBD).[3] This terminology replaced "renal osteodystrophy" to better describe the broader consequences of CKD complications on mineral metabolism, the bones, and the cardiovascular system.[1] The term renal osteodystrophy is now restricted specifically to the alterations in bone morphology or pathology that can result from complications of CKD, as CKD-MBD better reflects the systemic consequences of kidney disease, beyond bone alone.[1]

CKD-MBD is a common complication in CKD, occurs early in the disease, and both persists and progresses across all stages of CKD.[1] The interactions between abnormal mineral metabolism, extraskeletal calcification, and skeletal demineralization may increase morbidity and mortality in patients with CKD.[4] Thus, management of CKD-MBD may influence important clinical outcomes in this patient population. However, much is still unknown, and there is an overall lack of large randomized controlled trials (RCTs) providing direction for clinical practice. The major basis of the recommendations in this chapter are the KDIGO CKD-MBD guidelines originally released in 2009,[1] with select updates included in the 2013 KDIGO guideline on the Evaluation and Management of Chronic Kidney Disease[4] and the 2017 CKD-MBD guidelines update.[5] The recommendations of the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI), released in 2010[6] and 2017[7] to adapt the 2009 and 2017 KDIGO guidelines for use in the US, are consistent with the KDIGO guidelines, except where noted.

PATHOPHYSIOLOGY

Biochemical and hormonal abnormalities affect calcium, phosphate, vitamin D, iPTH and FGF-23 metabolism and handling, and bone and vascular calcification alterations occur in patients with CKD-MBD.

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00062-0

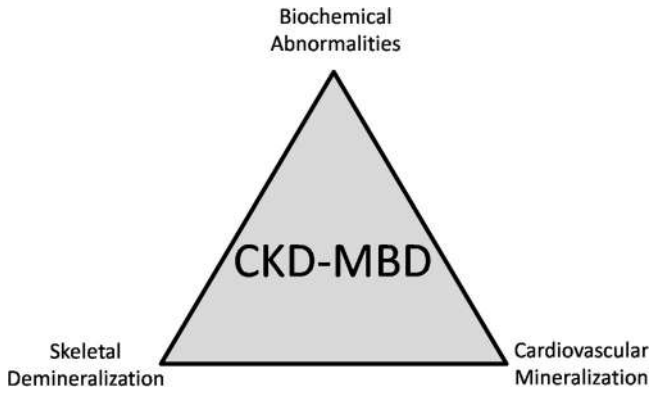

FIGURE 62.1 Components of chronic kidney disease—mineral and bone disorder (CKD-MBD). The clinical syndrome CKD-MBD was formally classified by Kidney Disease: Improving Global Outcomes in 2005 to reflect the adverse consequences of CKD complications on mineral metabolism, skeletal demineralization, and paradoxical extraskeletal cardiovascular mineralization.

Calcium

CKD is characterized by moderate hypocalcemia, although serum calcium concentration (S[Ca]) remains relatively stable in most patients with nondialysis-dependent CKD (Figure 62.2).[8,9] The mechanisms associated with the development of modest hypocalcemia in CKD patients are multifactorial but include decreased intestinal absorption and reduced 1,25 dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) levels (Figure 62.3).[10] An additional concern in patients with CKD, particularly those requiring dialysis, is increased S[Ca] resulting from pharmacological agents such as calcium-based phosphate binders. However, there are currently no data to support an increased risk of either fracture or mortality with increasing S[Ca] in patients with stage 3–5 CKD,[1] although observational studies suggest that hypercalcemia may increase the relative risk of mortality in dialysis-dependent CKD.[11–13] Based on meta-analysis in the general population, calcium supplements may increase the risk of cardiovascular events.[14] Although the applicability to patients with CKD is unclear, this is biologically plausible.

Phosphorus

In CKD stages 3–5, serum phosphate concentration (S[P]) remains normal until estimated glomerular filtration rate (eGFR) falls below 40 mL/min/1.73 m^2 and is still relatively stable until eGFR is <20 mL/min/1.73 m^2[9,15] (Figure 62.2). S[P] is maintained within the normal laboratory range until later stages of CKD mainly by FGF-23, which increases phosphate excretion to maintain normal S[P].[16] Increased S[P] is a stimulus for secondary hyperparathyroidism and a mediator of vascular calcification.[17]

Observational studies suggest that even in the normal range, increased S[P] is associated with increased risk of all-cause mortality in patients without CKD,[18,19] nondialysis-dependent CKD,[20,21] as well as consistently in patients treated with chronic dialysis.[21,22] However, the review of literature for the 2017 KDIGO guidelines update concluded that the majority of studies found this association to be consistent for S[P] above normal limits but not within the normal range. Additionally, correction of mildly elevated phosphate in the normal range with a phosphate binder in stage 3b and 4 CKD

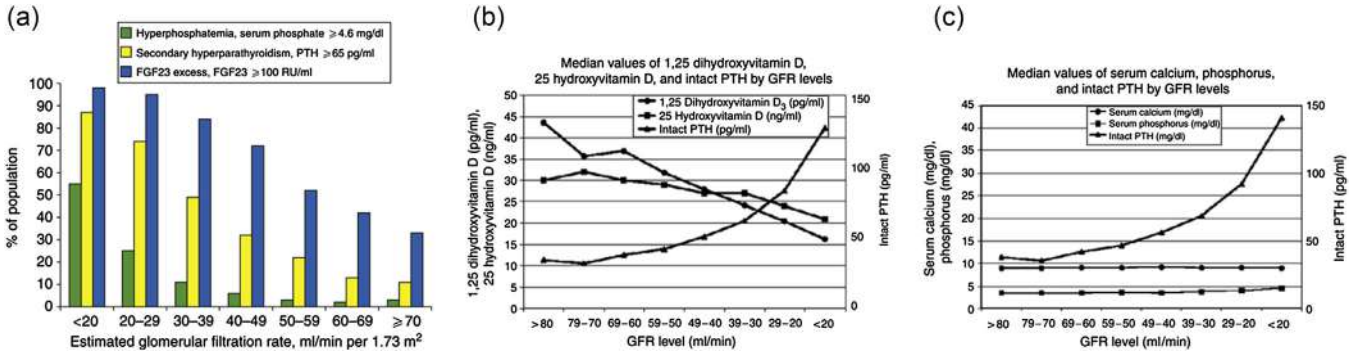

FIGURE 62.2 Alterations in biochemical and hormonal parameters with declining glomerular filtration rate (GFR) in chronic kidney disease (CKD). One of the earliest detectable changes in chronic kidney disease—mineral and bone disorder (CKD-MBD) is rising fibroblast growth factor-23 (FGF-23) levels, which increases when GFR is approximately 70 mL/min/1.73 m^2 and progressively rises further as estimated glomerular filtration rate continues to decline (Panel a, right bars. Left bars indicate hyperphosphatemia; middle bars indicate secondary hyperparathyroidism). Increasing FGF-23 contributes to a decline in calcitriol (1,25 dihydroxyvitamin D_3) levels by inhibiting 1α-hydroxylase activity and stimulating 24-hydroxylase, which is responsible for the degradation of calcitriol (Panel b). Intact parathyroid hormone (iPTH) also rises as GFR declines, although not significantly until GFR falls below 45 mL/min/1.73 m^2 (Panels b and c). In contrast, S[Ca] remains relatively stable in most patients with nondialysis-dependent CKD (Panel c). S[P] remains normal until GFR falls below 40 mL/min/1.73 m^2 and is still relatively stable until GFR is <20 mL/min/1.73 m^2 (Panels a and c). *Reprinted by permission from Macmillan Publishers Ltd: [Kidney International][6], copyright (2011) [Panel a] and Macmillan Publishers Ltd: [Kidney International][13], copyright (2007) [Panels b and c].*

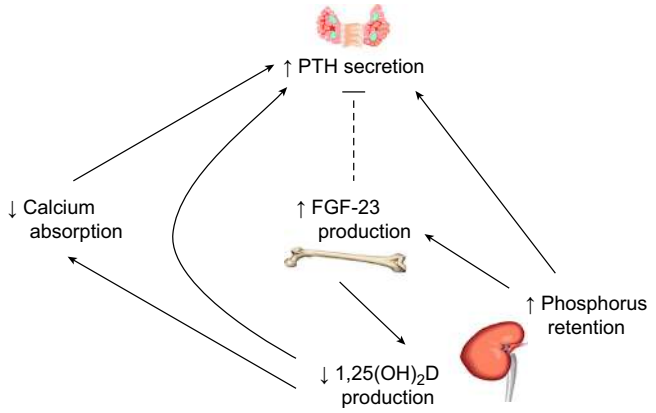

FIGURE 62.3 Biochemical and hormonal abnormalities in chronic kidney disease–mineral and bone disorder (CKD-MBD). In CKD-MBD, production of fibroblast growth factor-23 (FGF-23), the principal hormone regulating phosphorus, is elevated to counter a rise in S[P]. FGF-23 also inhibits synthesis of 1,25 dihydroxyvitamin D_3 ($1,25(OH)_2D_3$), by decreasing renal 1α-hydroxyase expression and increasing 24-hydroxylase expression. FGF-23 also initially suppresses parathyroid hormone (PTH) release and secretion, although the parathyroid glands may become resistant and the relationship may change with advancing kidney disease. PTH release and secretion also increase in response to hypocalcemia, hyperphosphatemia, and/or decreased $1,25(OH)_2D_3$. Both decreased intestinal absorption of calcium and reduced $1,25(OH)_2D_3$ levels contribute to the development of modest hypocalcemia.

resulted in minimal decline in S[P] and increased coronary calcification score.[23]

Vitamin D

25-Hydroxyvitamin D ($25(OH)D_3$; calcidiol) is considered the best measure of vitamin D nutritional status because of its long half-life in the circulation of approximately 3 weeks. $25(OH)D_3$ is converted in the kidney by 1α-hydroxylase to $1,25(OH)_2D_3$ (calcitriol), the active form of vitamin D, although extrarenal conversion can also occur.[1] $1,25(OH)_2D_3$ is an important regulator of mineral homeostasis and musculoskeletal function, in addition to having pleiotropic extracellular effects.

Most patients with CKD have low levels of $1,25(OH)_2D_3$.[22,24] This decline occurs early in the disease, and the severity increases as CKD progresses[8,25] (Figure 62.2). Classic teaching was that the decline in $1,25(OH)_2D_3$ was the result of loss of nephron mass. It is now known that increased serum FGF-23 in the early stages of kidney disease is also an important contributor, by inhibiting 1α-hydroxylase activity and stimulating 24-hydroxylase, which is responsible for the degradation of $1,25(OH)_2D_3$[26] (Figure 62.3).

Several observational studies have shown inverse associations between vitamin D metabolites and adverse outcomes in patients with CKD, as well as in the general population. Low serum $25(OH)D_3$ level is independently associated with all-cause mortality in both nondialysis and dialysis-dependent CKD patients[27,28] and in the general population.[15,29,30] $1,25(OH)_2D_3$ levels are also inversely associated with mortality in nondialysis-dependent CKD patients. Low serum $25(OH)D_3$ and/or $1,25(OH)_2D_3$ are also independently associated with cardiovascular events and mortality in individuals with[4] and without CKD.[15,30,31] In addition, both $1,25(OH)_2D_3$[32] and $25(OH)D_3$[29] levels are inversely associated with kidney disease progression. Low $25(OH)D_3$ levels are associated with increased risk of coronary artery disease progression in the general population.[33]

Parathyroid Hormone

Under physiological circumstances, parathyroid hormone (PTH) maintains S[Ca], increases phosphate excretion, and stimulates production of $1,25(OH)_2D_3$. Production increases in response to hypocalcemia, hyperphosphatemia, and/or decreased $1,25(OH)_2D_3$ (Figure 62.3).[1] FGF-23 can also suppress PTH, although the parathyroid glands may become resistant and the relationship may change with advancing kidney disease.[26,34]

iPTH rises as GFR declines, although not in a significant way until eGFR falls below 45 mL/min/1.73 m^2 (Figure 62.2).[8] This is initially an adaptive response to maintain calcium, phosphorus, and $1,25(OH)_2D_3$ homeostasis.[1] Decreased S[Ca] was once thought to be central in the development of secondary hyperparathyroidism. It is now accepted that FGF-23 is a key player in this process, initially inhibiting PTH, although this is compromised as CKD progresses.[16]

Most observational evidence on the relationship between PTH and clinical outcomes was generated from chronic HD patients. When iPTH is elevated beyond an inflection point ranging from 480 to 600 pg/mL,[12,35,36] there is an increased mortality risk, but this finding is not consistent and the relationship may be U-shaped, inverse, or nonsignificant.[37–39] Increased iPTH may also be associated with risk of cardiovascular events in this population.[1] In general, iPTH fails to correlate with fracture risk, and the relationship of PTH levels with bone formation rates varies greatly.[1]

FGF-23

FGF-23 was first identified in 2000,[40] and the discovery has led to a reconsideration of the mechanisms driving secondary hyperparathyroidism.[16] FGF-23 is secreted by skeletal osteocytes in response to changes in bone formation and S[P] (Figure 62.3). However, the mechanisms underlying the direct regulation of

FGF-23 production are largely unknown.[41] FGF-23 is the principal-regulating hormone of phosphorus and also inhibits synthesis of $1,25(OH)_2D_3$ and suppresses PTH, at least initially.[26,34] These functions are accomplished by reducing the activity and/or expression of sodium phosphate cotransporters, possibly reducing intestinal phosphate absorption, decreasing renal 1α-hydroxylase expression, and increasing 24-hydroxylase expression.[26,34] FGF-23 acts by binding to receptors that are part of the tyrosine kinase superfamily[42] in the presence of the membrane-bound coreceptor klotho,[34] but animal studies support that FGF-23 can also act independently of klotho, at least in the heart.[43]

Increasing FGF-23 levels may be one of the earliest detectable changes in CKD-MBD. FGF-23 levels begin to increase when eGFR is approximately 70 mL/min/1.73 m^2 and progressively rise as eGFR declines further (Figure 62.2).[16,44] Small elevations in FGF-23 are initially required, as this increases renal phosphate excretion, thus maintaining S[P] within normal limits. With CKD progression, circulating FGF-23 levels continue to rise, the phosphaturic response declines, and eventually S[P] increases. It is presently unknown why FGF-23 rises early in CKD, before a rise in S[P].

In nondialysis-dependent CKD patients, FGF-23 levels are independently associated with mortality,[45,46] cardiovascular events,[45–47] CKD progression,[45,46,48] and infection-related hospitalization.[49] Very large hazard ratios support the contention that FGF-23 is a key outcome predictor. FGF-23 levels are also independently associated with left ventricular hypertrophy in nondialysis-dependent CKD patients,[43,50] chronic HD patients,[51] and in the general population.[52] Evidence in animals indicates that blocking FGF-23 can prevent the development of left ventricular hypertrophy.[43] One of the strongest working hypotheses regarding why FGF-23 predicts cardiovascular events and mortality is its causal effect on left ventricular hypertrophy.

Bone

Traditionally, renal osteodystophy has been characterized based on bone turnover and mineralization. In CKD-MBD, alterations in these parameters vary greatly. The spectrum of bone turnover ranges from abnormally low to very high, and mineralization may or may not be present.

A systematic review of bone biopsies in patients with CKD stages 3–5 showed 32% had osteitis fibrosa (increased turnover and normal mineralization), 18% adynamic (decreased turnover and acellularity), 16% were normal, 8% had osteomalacia (decreased turnover and abnormal mineralization), and 20% had mixed disease (increased turnover with abnormal mineralization).[1]

Alterations in bone are important, as this can lead to increased bone fragility and fracture. Hip fractures are two to three times more common in elderly patients with stage 3–4 CKD.[1] Although the risk in early stage CKD is unclear, chronic dialysis patients with adynamic bone disease and/or osteomalacia have an increased risk of fracture.[53,54] Dual-energy X-ray absorptiometry (DXA) bone mineral density (BMD) predicts risk of fracture across the spectrum in CKD.[55–58]

Vascular Calcification

Extraskeletal calcification of the vasculature increases progressively with declining eGFR and is more prevalent, severe, and accelerated in CKD compared to the general population.[17] Calcification can occur in both the intimal and medial layers of the vasculature, but medial calcification is considered the more common and major form of calcification in CKD.[59] Medial calcification is characterized by diffuse mineral deposition throughout the vascular tree[60] and is associated with increased large-elastic artery stiffness. This promotes increased systolic blood pressure, reduced diastolic blood pressure, increased cardiac afterload, compromised perfusion of the coronary arteries, and left ventricular remodeling.[61,62] Accordingly, vascular calcification is a major contributor to CVD in CKD patients. Observational data indicate vascular calcification predicts cardiovascular events and mortality.[17,59] However, it is presently unclear if intervening to slow progression of vascular calcification alters outcomes in CKD patients.[1]

DIAGNOSIS

The basis of these recommendations is primarily the KDIGO guidelines[1,4] (mentioning differences from KDOQI[6,7] when applicable). Traditionally, biochemical parameters have been the primary indicators for the basis of diagnosis, identifying therapeutic targets, and managing CKD-MBD. When considering biochemical values, it is recommended that all therapeutic decisions are based on serial circulating levels of calcium, phosphate, and PTH considered together, given the interdependence of these parameters and variations in levels due to food, drugs, diet, assays, and diurnal variation.[5]

Clinically significant biochemical manifestations of CKD-MBD may begin in stage 3 (a GFR of approximately 40–50 mL/min/1.73 m^2),[8] but the rate and degree of changes are highly variable. Therefore the frequency of assessment must consider the individual patient.[1]

KDIGO guidelines recommend measuring S[Ca], S[P], iPTH, and alkaline phosphatase (ALP), at least

once in all adults with an eGFR less than 45 mL/min/1.73 m^2, to establish a baseline.[4] At least one of these biochemical abnormalities must be present for the diagnosis of CKD-MBD.[1] Most observational data on these parameters were generated in HD populations. Much less is known about stage 3−5 CKD. This makes establishing diagnostic criteria as well as treatment recommendations challenging. Furthermore, there are no clear data available supporting the notion that routine measurement improves outcomes, but these are the best recommendations based on the currently available data.[1]

Calcium

KDIGO recommends monitoring S[Ca] beginning in stage 3 CKD. Although the frequency of monitoring should consider the individual patient, a reasonable monitoring schedule is every 6−12 months in stage 3, every 3−6 months in stage 4, and every 1−3 months in stage 5 (Table 62.1).[1] Ideally, ionized calcium should be used, as this is the physiologically active form. However, this is not a routinely available, practical, or cost-effective option, thus total calcium is most frequently measured.

Phosphorus

Recommendations for monitoring S[P] parallel those for S[Ca] (Table 62.1).[1] S[P] varies diurnally, although this variation is less in patients with CKD.[63]

Vitamin D

$25(OH)D_3$ is considered the best measure of vitamin D nutritional status, as it has a long half-life (approximately 3 weeks). $1,25(OH)_2D_3$ has a much shorter half-life (approximately 4−6 hours).[1] Epidemiological studies have found both $25(OH)D_3$ and $1,25(OH)_2D_3$ to be independent predictors of all-cause and cardiovascular mortality in both patients with CKD and in the general population.[27−30] Vitamin D status refers to whether or not circulating levels of $25(OH)D_3$ are considered adequate. Although there is no consensus on what are considered adequate levels, the 2013 update from KDIGO recommended using the international definition of <20 ng/mL as a cut-off for vitamin D deficiency.[4] Serum $25(OH)D_3$ levels are inversely associated with serum PTH levels in CKD[64] and non-CKD[65,66] patients, until $25(OH)D_3$ increases to 30−40 ng/mL, at which point PTH level plateaus at its nadir.[67] Such data provide the basis for the term vitamin D status, which refers generally to whether an individual has deficient, insufficient, or sufficient serum levels of $25(OH)D_3$. KDIGO recommends considering monitoring $25(OH)D_3$ in CKD stages 3−5, with repeat testing intervals commensurate with both baseline levels and current treatment (Table 62.1).[1] KDOQI also recommends periodic testing of $25(OH)D_3$ and initiating treatment if levels are low.[6] However, there is still some debate in the nephrology community regarding whether $25(OH)D_3$ levels should be measured and monitored, as there is a lack of evidence that vitamin D supplementation indeed improves clinical outcomes. The assays used to measure $25(OH)D_3$ are not well standardized. The DiaSorin assay is most commonly used in clinical practice.[1]

PTH

KDIGO recommends monitoring serum iPTH levels beginning in stage 3 and considering these levels and progression in determining repeat testing intervals. A reasonable monitoring schedule in stages 4 and 5 is every 6−12 and 3−6 months, respectively (Table 62.1). The optimal level of iPTH in stages 3−5 CKD is currently unknown, and difficult to establish, because the range of values widens as CKD progresses. In addition, there are methodological challenges to measurement associated with assay type, sample type, technique used, and variability. The second generation assay (iPTH) is most commonly used in clinical practice. There are also normally minute-to-minute oscillations in levels, although this is blunted in CKD. Thus, KDIGO does not provide a specific target recommendation, but instead recommends interpretation on the basis of the specifics of each individual laboratory. Therapy should be based on a persistent rise in levels, rather than an absolute value.[1]

FGF-23

FGF-23 is not currently considered in the diagnosis of CKD-MBD, as it is still a relatively new, but very important, component of CKD-MBD. Thus, FGF-23 is not discussed in the KDIGO or KDOQI guidelines, and FGF-23 is currently more commonly assessed in research. There are two enzyme-linked immunoassays used to measure FGF-23: the intact FGF-23 assay (primarily serum) and the C-terminal FGF-23 assay (primarily plasma). Initial studies showed a good correlation between the two, although this has been questioned.[68,69] Values for FGF-23 are skewed to the right; therefore, median levels are typically reported in research. Using the C-terminal assay, typical levels in healthy adults are 17.8−197.0 RU/mL (median 76.5 RU/mL) (Table 62.1).[70] In nondialysis-dependent CKD patients, the typical elevation is two- to fivefold higher (63.6−5592 RU/mL; median 188 RU/mL); in dialysis

TABLE 62.1 Biochemical Diagnosis of Chronic Kidney Disease–Mineral and Bone Disorder (CKD-MBD)*

Parameter	Normal Range (Serum)	Physiological Triggers and Consequences	Changes in CKD	KDIGO Monitoring Recommendations
Calcium*	8.5–10.5 mg/dL#	Low $1,25(OH)_2D_3$, decreased intestinal absorption, and phosphate retention	Most often moderate hypocalcemia, although hypercalcemia can occur (rare)	Stage 3: every 6–12 months† Stage 4: every 3–6 months†
		Favors the development of SHP	Remains normal until eGFR <40 mL/min/1.73 m^2 and stays relatively stable until eGFR <20 mL/min/1.73 m^2	Stage 5: every 1–3 months†
Phosphorus*	2.5–4.5 mg/dL	Impaired phosphate excretion promotes a rise in S[P]	Remains normal until eGFR <40 mL/min/1.73 m^2 and stays relatively stable until eGFR <20 mL/min/1.73 m^2	Stage 3: every 6–12 months† Stage 4: every 3–6 months†
		Increased levels stimulate SHP, promote vascular calcification	Does not rise until later stages because FGF-23 initially maintains the normal range by increasing renal phosphate excretion	Stage 5: every 1–3 months†
Vitamin D*	Deficient = $25(OH)D_3$ <20 ng/mL	$1,25(OH)_2D_3$ synthesis in the kidney is compromised	Insufficiency and deficiency are highly prevalent, possibly approximately 50% of CKD patients	Baseline testing in stages 3–5, with repeat intervals commensurate with baseline levels and treatment
	Insufficient = 20–30 ng/mL	May be an underlying cause of elevated PTH		
	Sufficient >30 ng/mL			
PTH*	Abnormal if eGFR is <45 mL/min/1.73 m^2 and iPTH is persistently above upper limit of normal for the given assay and progressively rising	Increases in response to hypocalcemia, hyperphosphatemia, and/or decreased $1,25(OH)_2D_3$	Approximately 60% of patients with eGFR <60 mL/min/1.73 m^2 have elevated iPTH levels	Stage 3: based on baseline levels and CKD progression† Stage 4: every 6–12 months†
		Hypercalcemia, high $1,25(OH)_2D_3$ and FGF-23 can suppress		Stage 5: every 3–6 months†
FGF-23	In one small study: healthy adults: 17.8–197.0 RU/mL (median 76.5 RU/mL); Nondialysis-dependent CKD: 63.6–5592.0 RU/mL (median 188.0 RU/mL)	Secreted by skeletal osteocytes in response to changes in bone formation and S[P], principal regulating hormone of phosphorus	Increases very early in CKD (eGFR approximately 70 mL/min/1.73 m^2) and progressively increases as GFR declines	No recommendation given
	Maintenance HD: 150–115,000 RU/mL (median 4715.0 RU/mL)	High FGF-23 inhibits $1,25(OH)_2D_3$ and favors increased PTH		

All therapeutic decisions should be based on trends rather than a single laboratory value. *$1,25(OH)_2D_3$*, 1,25D dihydroxyvitamin D_3; *$25(OH)D_3$*, 25 hydroxyvitamin D_3; *eGFR*, estimated glomerular filtration rate; *FGF-23*, fibroblast growth factor-23; *iPTH*, intact parathyroid hormone; *S[P]*, serum phosphate concentration; *SHP*, secondary hyperparathyroidism.

\# *May vary by laboratory.*

† *Frequency of monitoring should consider the presence and magnitude of abnormalities.*

patients, levels can reach an exponential 1000-fold increase (150−115,000 RU/mL; median 4175 RU/mL).[16,68,70] It is also important to consider the fractional excretion of phosphate in the interpretation of these values, as FGF-23 is the principal hormone-regulating phosphorus.

Bone

Bone biopsy−based histology is considered the gold standard technique for the diagnosis of the bone component of CKD-MBD, as it provides information regarding bone turnover, mineralization, and volume.[1] KDIGO asserts that bone biopsy is reasonable in stage 3−5 CKD if knowledge of type of renal osteodystrophy will impact treatment, but it is no longer required prior to antiresorptive therapy, based in increased experience with osteoporosis medications in CKD and growing evidence that they are effective at preventing fractures in stage 3−4 CKD.[71] DXA BMD testing is now recommended for stage 3−4 CKD with evidence of CKD-MBD and/or risk factors for osteoporosis if results will impact treatment decisions.[5] KDOQI agrees with this new recommendation, but stressed that BMD does not predict bone turnover type, which is an important determinant of pharmacological treatment and that there is a lack of data on osteoporosis medications and BMD and fracture in CKD.[7]

Vascular Calcification

Although extraskeletal calcification is a component of diagnosis of CKD-MBD, KDIGO does not recommend indiscriminate screening of all patients with CKD-MBD for vascular calcification, as it is unclear if intervention will alter outcomes.[1] KDOQI also does not recommend screening asymptomatic patients with CKD for calcification.[6] At this time, there is consensus among the nephrology community that screening for vascular calcification will increase the cost−benefit ratio, as there is a lack of potential therapeutic interventions to reverse vascular calcification. However, when vascular calcification is detected, the patient should be considered to have high cardiovascular risk.

TREATMENT

To date, the focus in the literature has been on the association between disordered mineral metabolism in CKD and adverse outcomes, including mortality, cardiovascular disease, and fractures. This has led to targeting these parameters in clinical practice to potentially improve these outcomes, but large RCTs supporting clinical practice are presently very limited.[1] Most of the available literature consists of observational data or surrogate outcomes, rather than therapeutic options associated with hard outcomes. In general, therapy has typically focused on correcting biochemical and hormonal abnormalities to limit their potentially adverse consequences. This section focuses largely on treatments targeting correction of biochemical and hormonal abnormalities.

Calcium

There is little observational or interventional evidence that targeting S[Ca] alters clinical outcomes in CKD, although calcium supplementation may increase risk of CVD in the general population.[72] KDIGO recommends avoiding hypercalcemia in stage 3−5 CKD patients,[5] based on evidence from the EVOLVE (Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events) study that mild hypocalcemia can be tolerated[73] (Table 62.2). KDOQI agrees with this recommendation, emphasizing that it allows for greater individualization of treatment strategies and use of calcimimetics to lower elevated PTH in the setting of mild hypocalcemia.[7] To avoid hypercalcemia, limiting the use of calcium-based binders, calcitriol, and/or its analogs in patients with known hypercalcemia is recommended.[5] Figure 62.4 provides an algorithmic approach to the treatment of hypercalcemia and other abnormalities of mineral metabolites in patients with CKD-MBD. An individualized approach should be used for correction of hypocalcemia, particularly for cases of severe or symptomatic hypocalcemia rather than recommending correction for all patients.[5]

Phosphorus

The data on normalizing S[P] in those patients with CKD not requiring chronic dialysis are conflicting.[23] Treatment should be aimed at lowering elevated phosphate levels in cases of overt hyperphosphatemia toward the normal range. Figure 62.4 provides a suggested approach to correcting S[P] abnormalities in nondialysis-dependent CKD patients.

Observational data suggest that phosphate binders of any type may reduce mortality in both dialysis-[74] and nondialysis-dependent CKD patients.[75] Most RCTs have been completed in chronic HD populations, with only one trial available in patients with stage 3−5 CKD.[76] The phosphate binder sevelamer slowed vascular calcification in this study, which is largely consistent with studies in dialysis patients,[22,77] although not all trials have been positive.[78,79] The efficacy of phosphate binders for reducing cardiovascular events or

TABLE 62.2 Treatment of Biochemical Abnormalities in Chronic Kidney Disease–Mineral and Bone Disorder (CKD-MBD)

Parameter	KDIGO/KDOQI Treatment Recommendations	Therapeutic Options
Calcium	Stage 3–5: avoid hypercalcemia	Limit calcium-based binders and/or 1,25(OH)$_2$D$_3$ or active vitamin D treatment if known hypercalcemia
Phosphorus	In stage 3–5 CKD, elevated S[P] should be lowered toward the normal range	Dietary phosphate restriction Phosphate binders
	Choice of binder should consider other components of CKD-MBD, other therapies, and side-effects In stage 3–5, lower elevated S[P] toward the normal range	• Aluminum hydroxide (not recommended) • Calcium carbonate and calcium acetate (restricted use) • Magnesium hydroxide and magnesium carbonate • Sevelamer hydrochloride and sevelamer carbonate • Lanthanum carbonate
Vitamin D	Only indicated to correct 25(OH)D$_3$ deficiency, follow recommendations for general population (1000–2000 IU/day cholecalciferol [D$_3$])	Nutritional vitamin D
	Recommend using 50,000 IU/week or per month ergocalciferol (D$_2$) to correct deficiency to >30 ng/mL	• Ergocalciferol (D$_2$) • Cholecalciferol (D$_3$)
PTH	Stages 3–5: optimal levels unknown	First evaluate for hyperphosphatemia, hypocalcemia, and vitamin D deficiency
	Suggest lowering PTH threshold in CKD stages 4–5 to prompt evaluation and possible treatment	Initial options • Limit dietary phosphate • Phosphate binders • Calcium supplements • Nutritional vitamin D (only if 25(OH)D$_3$ deficient)
		Calcitriol or vitamin D analogs should be reserved for stage 4–5 CKD with severe and progressive hyperparathyroidism
		Cinacalcet—not recommended by KDIGO in nondialysis CKD patients
		Severe HPT without response to other therapy: parathyroidectomy
FGF-23	Optimal levels unknown. KDIGO and KDOQI do not make recommendations	KDIGO does not make a recommendation
		Only therapeutic option at this time is dietary phosphate reduction
		Sevelamer and lanthanum carbonate may lower FGF-23

1,25(OH)$_2$D$_3$, 1,25D dihydroxyvitamin D; *25(OH)D$_3$*, 25 hydroxyvitamin D; *eGFR*, estimated glomerular filtration rate; *FGF-23*, fibroblast growth factor-23; *HPT*, hyperparathyroidism; *PTH*, parathyroid hormone; *S[Ca]*, serum calcium concentration; *S[P]*, serum phosphate concentration. See Figure 62.4 for an approach to treating biochemical abnormalities in patients with CKD-MBD.

mortality in nondialysis-dependent CKD is currently unknown. In dialysis patients, both an RCT[80] and secondary analysis of an open-label study[81] showed no difference in mortality based on allocation to sevelamer compared to calcium-based binders. A third study performed in incident HD patients found increased mortality in the calcium-based binder compared to the sevelamer group, although the KDIGO work group[1] raised a concern of a possibly unsuccessful randomization.[22] RCTs using phosphate binders with cardiovascular endpoints are also lacking in the chronic dialysis population. The effects of calcium-based binders compared to either sevelamer or lanthanum on bone histology are unclear, with some studies in chronic dialysis patients showing improvements and some showing worsening.[79,82,83]

Sevelamer and calcium-based binders appear to be equally effective at lowering S[P] in RCTs with stage 3–5 CKD patients.[76] However, it is suggested to restrict calcium-based phosphate binders in all hyperphosphatemic adult patients with stage 3–5 CKD.[5] Lanthanum also appears to be effective at lowering S[P] in chronic dialysis patients[84,85] and nondialysis-dependent CKD in the setting of elevated S[P].[86,87] New iron-based binders were also effective in phase 3 trials in chronic dialysis patients.[88–90]

The most recent KDIGO guidelines recommend lowering S[P] toward the normal range in stage 3–5

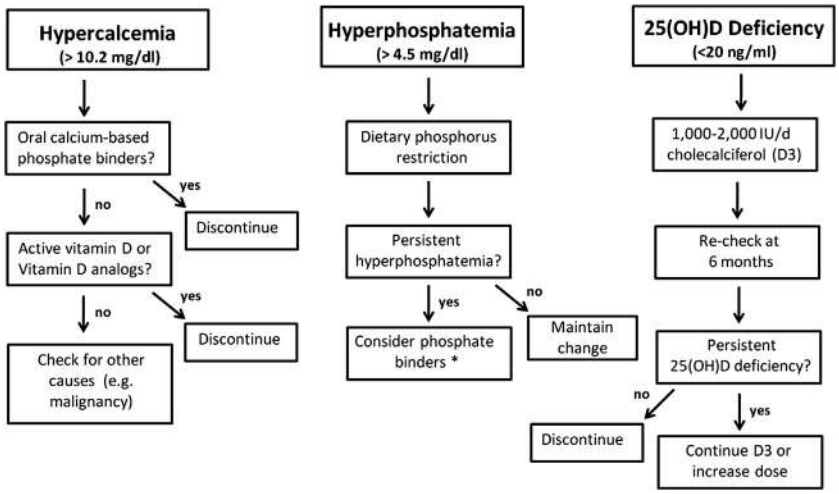

FIGURE 62.4 Algorithmic approach to treating biochemical and hormonal abnormalities in chronic kidney disease—mineral and bone disorder (CKD-MBD). The first step in the treatment of hypercalcemia is to check if the patient is taking oral calcium-based phosphate binders. If so, the binder should be discontinued. The same question should be asked regarding therapy with active vitamin D or vitamin D analogs. If neither is a potential cause of hypercalcemia, other potential causes should be evaluated, such as malignancy. To treat hyperphosphatemia, dietary phosphate restriction should first be attempted. If hyperphosphatemia persists, phosphate binders should be considered. However, phosphate binders are not FDA-approved for the treatment of hyperphosphatemia in nondialysis-dependent chronic kidney disease (indicated by *). Consistent with KDIGO recommendations, we recommend treatment of 25(OH)D_3 deficiency with 1000–2000 IU/day of cholecalciferol (D3). Serum 25(OH)D_3 should be rechecked after 6 months, with supplementation continued or increased according to repeat test levels.

CKD patients, with an emphasis on treating overt hyperphosphatemia[5] (Table 62.2). This recommendation is based on an overall lack of evidence and potential for harm in the normophosphatemic range. KDOQI recommendations noted that this recommendation could have an unintended consequence of discouraging dietary phosphorus restriction, with gradually increasing phosphorus levels in the normal range.[7] Overall, a phosphate-restricted diet combined with oral phosphate binders is a well-established recommendation for controlling hyperphosphatemia in patients with stage 3–5 CKD.[1,6] Treatment should be based on progressively or persistently elevated S[P], rather than preventive phosphate-lowering. The choice of phosphate binder should consider other components of CKD-MBD, concomitant therapies, and side effects.[5] There is currently insufficient evidence on comparative clinical efficacy to recommend a specific binder for all patients.

Dietary phosphate restriction is important in the treatment of CKD-MBD because 60–70% of ingested phosphate is absorbed.[91] Dietary phosphate intake should be limited either alone or in combination with other treatments for the treatment of hyperphosphatemia, with consideration of the source of phosphate (e.g. animal, vegetable, additives).[5] However, there are numerous challenges to achieving treatment goals, including patient compliance, issues with food labels, and the presence of abundant food additives (Table 62.3).

Phosphate binders available for the treatment of CKD-MBD have particular advantages and disadvantages (Table 62.3). Aluminum hydroxide is not recommended for use, as there is a risk of serious hematological, neurological, and skeletal adverse events as a consequence of aluminum toxicity.[91] Calcium carbonate and calcium acetate are both calcium-based phosphate binders that are inexpensive and effective at lowering S[P], but increase risk of calcium overload, which may promote vascular calcification or adynamic bone disease (although there is less calcium exposure with calcium acetate than calcium carbonate).[91] Accordingly, KDIGO suggests restricting use of calcium-based phosphate binders in stage 3–5 CKD patients.[5] Magnesium-based binders include magnesium hydroxide and magnesium carbonate. Both magnesium-based binders are associated with a lower calcium load than pure calcium-based phosphate binders. However, they have gastrointestinal side effects, are not well studied, and have lower efficacy, which may necessitate prescription of higher doses that could induce hypermagnesemia in CKD patients.[91]

Sevelamer hydrochloride is a noncalcium, nonmetal, nonabsorbable phosphate binder. Sevelamer carbonate is similar to sevelamer hydrochloride and is assumed to have equal efficacy and potentially improved acid–base balance and lower risk of acidosis.[1,92] Both have the advantages of avoiding calcium overload, metal exposure, and absorption, and have also been shown to lower

TABLE 62.3 Advantages and Disadvantages of Available Therapies to Treat Chronic Kidney Disease—Mineral and Bone Disorder (CKD-MBD)—Associated Biochemical Abnormalities

Therapeutic Options	Pros	Cons
Dietary phosphate restriction, with consideration of source	Important modulator of S[P] because 60–70% of all ingested dietary phosphate is absorbed	Challenging to adhere to (food choices, food labeling, additives, etc.)
		Not enough data available to strongly endorse as the sole therapy for treatment hyperphosphatemia
Aluminum hydroxide	Very effective phosphate binding	Not recommended due to risk of serious hematological, neurological, and skeletal adverse events resulting from aluminum toxicity
Calcium carbonate	Inexpensive, effective, and readily available	Potential of hypercalcemia-associated risks (e.g. vascular calcification, adynamic bone disease)
		KDIGO suggests restricting calcium-based phosphate binders in stage 3–4 CKD
Calcium acetate	Potentially less calcium exposure and better phosphate-binding capacity than calcium carbonate	Risk of hypercalcemia
		More costly than calcium carbonate
		KDIGO suggests restricting calcium-based phosphate binders in stage 3–4 CKD
Magnesium hydroxide and magnesium carbonate	Potentially less calcium exposure than calcium-based binders	Gastrointestinal side effects
		Lower efficacy, which may necessitate higher doses and potentially hypermagnesemia
		Not well studied
Sevelamer hydrochloride	Effective	High cost
	Avoids calcium overload	Gastrointestinal side effects
	Avoids metal exposure	High pill burden
	Not absorbed	Potential for decreased serum bicarbonate levels (acidosis)
	May have benefits beyond lowering S[P] (such as lowering LDL, slowing vascular calcification, and lowering FGF-23)	
Sevelamer carbonate	Assumed to have similar advantages to sevelamer hydrochloride with improved acid–base balance	High cost
		Gastrointestinal side effects
		High pill burden
Lanthanum carbonate	Effective	High cost
	Avoids calcium overload	Gastrointestinal side effects
	Chewable	Long-term clinical consequences unknown
	Eliminated by the liver thus metabolism not dependent on renal function	
	May have benefits beyond lowering S[P] (such as improving bone remodeling, lowering FGF-23 levels)	
Iron-based phosphate binders (ferric citrate, sucroferric oxyhydroxide)	Consistent rapid reduction in S[P]	Not yet FDA approved for phosphate lowering in nondialysis-dependent CKD
	Reduced intravenous iron and erythropoietin-stimulating agent use	Long-term clinical consequences unknown
	Lower pill burden than sevelamer	Gastrointestinal side effects
	Favorable safety profile	

TABLE 62.3 Advantages and Disadvantages of Available Therapies to Treat Chronic Kidney Disease–Mineral and Bone Disorder (CKD-MBD)–Associated Biochemical Abnormalities—cont'd

Therapeutic Options	Pros	Cons
Nutritional vitamin D (D_2 and D_3)	Effective at raising $25(OH)D_3$ and $1,25(OH)_2D_3$ levels	Lack of RCTs in CKD patients
	Extra-renal conversion to $1,25(OH)_2D_3$ may confer extra-renal benefits	Less studied in CKD patients
	Can also suppress PTH	Some question as to whether it is adequate to raise $25(OH)D_3$ to sufficient levels in all CKD patients
	Inexpensive	
	Incidence of hypercalcemia and hyperphosphatemia is low	
Calcitriol (1,25D3)	Effective at raising $1,25(OH)_2D_3$ levels	May promote hypercalcemia (risk of adynamic bone disease, vascular calcification) and/or raise S[P]
	Decreases PTH production by the parathyroid glands	
Vitamin D receptor activators ($1,25(OH)_2D_3$ analogs: e.g. paricalcitol, doxercalciferol)	Effective at raising $1,25(OH)_2D_3$	May promote hypercalcemia (risk of adynamic bone disease, vascular calcification) and/or raise S[P]
	Decreases PTH production by the parathyroid glands	Failed to reduce left ventricular mass index in the PRIMO and OPERA trials
	Newer analogs are more selective for PTH suppression with fewer effects on S[Ca] and S[P]	
Cinacalcet	Effectively lowers PTH	Did not reduce mortality in EVOLVE trial
	May also lower S[P]	Gastrointestinal side effects
		Risk of hypocalcemia
		Not FDA approved for use in patients with CKD not requiring dialysis
Parathyroidectomy	Generally reduces PTH, S[Ca], and S[P]	Last choice therapy
		Lack of RCTs on the benefits and risks

$1,25(OH)_2D_3$, 1,25D dihydroxyvitamin D; *$25(OH)D_3$*, 25 hydroxyvitamin D; *FGF-23*, fibroblast growth factor-23; *PTH*, parathyroid hormone; *RCT*, randomized controlled trial; *S[Ca]*, serum calcium concentration; *S[P]*, serum phosphate concentration.

low-density lipoprotein (LDL) cholesterol.[91] Sevelamer also has potential benefits on vascular calcification and mortality,[76,80] and treatment can lower FGF-23 levels. Disadvantages of sevelamer include high cost, gastrointestinal side effects, a high pill burden, and the risk of decreased bicarbonate levels with sevelamer hydrochloride.[91]

Lanthanum carbonate is a noncalcium, naturally occurring metal-based binder first approved for use in 2004.[93] Advantages include effective phosphate lowering, avoidance of calcium overload, lesser pill requirement than sevelamer, and chewable delivery. Lanthanum is eliminated by the liver and therefore its handling is not dependent on renal function.[91] Lanthanum may also have benefits beyond lowering S[P], such as improving bone remodeling or lowering FGF-23 levels.[84,94] However, the cost of lanthanum carbonate is high, gastrointestinal side effects are common, and the long-term clinical consequences of its use are still largely unknown.[1,91,95]

Iron-based phosphate binders (ferric citrate, sucroferric oxyhydroxide) are new intestinal phosphate binders that can replete iron stores, increase hemoglobin, and reduce S[P] in phase 3 trials in chronic dialysis patients.[88–90] Advantages include reduced intravenous iron and erythropoietin-stimulating agent use, lower pill burden than sevelamer, and a favorable safety profile. However, they are not yet Food and Drug Administration (FDA)-approved for phosphate lowering in

nondialysis-dependent CKD, long-term data on clinical outcomes are lacking, and gastrointestinal side effects can occur.

Vitamin D

KDIGO recommends treating CKD patients with low circulating levels of 25(OH)D_3, with supplementation with 1000−2000 IU/day of cholecalciferol, consistent with repletion recommendations for the general population.[4] KDOQI recommends using ergocalciferol (50,000 IU weekly or monthly) to correct 25(OH)D_3 deficiency if levels are lower than 30 ng/mL.[6] Both forms of vitamin D supplementation have been shown to increase serum 25(OH)D_3 levels. However, there is a lack of data regarding the impact of these nutritional vitamin D supplements on clinical management issues, including pill burden and the cost related to treatment and monitoring. 1,25$(OH)_2D_3$ levels are usually not monitored throughout the course of CKD. Therefore, treatment should not be administered in response to low 1,25$(OH)_2D_3$. Figure 62.4 provides an algorithmic approach to treating CKD patients with low circulating levels of 25(OH)D_3, with the available evidence supporting this overall approach.

Observational data in chronic dialysis patients support increased survival with treatment with 1,25$(OH)_2D_3$ analogs,[13,27] but this finding is likely confounded by indication, and results are not consistent.[96,97] Data are limited in nondialysis-dependent CKD patients, as well as for nutritional vitamin D therapy. Observational data suggest that active vitamin D therapy is also associated with reduced risk of progression to end-stage renal disease (ESRD).[98] In a meta-analysis of trials in non-CKD patients, nutritional vitamin D supplementation was shown to decrease mortality.[99] One small observational study in chronic HD patients showed an association between cholecalciferol use and reduced left ventricular mass index.[100]

A recent trial comparing 6 months of calcitriol and cholecalciferol in participants with stage 3b and 4 CKD found no improvement in vascular endothelial function, measured by brachial artery flow-mediated dilation.[101] Similary, in an open-label randomized clinical trial in patients with secondary hyperparathyroidism receiving maintenance hemodialysis, the vitamin D receptor activator alfacalcidol failed to reduce cardiovascular events.[102] Additionally, the recently completed NIH-funded Vitamin D and Omega-3 Trial (VITAL) found no reduction in major cardiovascular events with nutritional vitamin D supplementation in the general population.[103] The PRIMO (Paricalcitol Capsule Benefits in Renal Failure-Induced Cardiac Morbidity) trial showed no change in left ventricular mass index in stage 3−4 CKD patients treated with 2 μg/day paricalcitol for 48 weeks.[104] Results were similar in the OPERA (Oral Paricalcitol in Stage 3−5 CKD) trial with 52 weeks of paricalcitol in stage 3−5 CKD patients.[105] These findings were in contrast to earlier evidence that vitamin D analogs reduce LVH in rats.[106] Both studies also demonstrated more frequent hypercalcemia with paricalcitol.

Studies on vascular calcification are inconclusive, and mouse models of CKD suggest that there is a balance needed between high and low levels of 1,25$(OH)_2D_3$ to protect against vs. induce vascular calcification.[107] It is currently unknown if vitamin D treatment reduces fracture risk in patients with CKD, and the effects on bone are inconclusive. Randomized trials have shown possible improvements in osteitis fibrosa and mineralization, but also reduced bone turnover, which could increase the risk of developing adynamic bone disease.[108,109]

In stage 3−5 CKD patients, RCTs support that calcitriol and vitamin D analogs both lower serum iPTH compared to placebo,[110−112] may increase S[Ca][110−112] or S[P],[110] or may not change either.[110] Additionally, vitamin D analogs may reduce proteinuria[113−115] and lower the inflammatory acute phase protein C-reactive protein. Nutritional vitamin D treatment may also lower iPTH in this population, and the associated incidence of hypercalcemia and hyperphosphatemia is low.[116]

KDIGO currently recommends correcting 25(OH)D_3 deficiency to >30 ng/mL using treatment strategies similar to those used in the general population (Table 62.2).[1,4] Calcitriol and vitamin D analogs should not be routinely used in stage 3−5 CKD but reserved for patients with CKD stage 4 and 5 and severe and progressive hyperparathyroidism.[5] KDOQI recommends using vitamin D2 (ergocalciferol) to correct serum 25(OH)D_3 levels that are <30 ng/mL.[6] Overall, there is no consensus regarding the optimal treatment type, dose, or target levels of 25(OH)D_3. More research is needed to help answer these questions.

Nutritional options to treat 25(OH)D_3 deficiency are ergocalciferol (D2) and cholecalciferol (D3) (Table 62.3), which must undergo conversion in the liver to 25(OH)D_3. Nutritional vitamin D is effective at raising both serum 25(OH)D_3 and 1,25$(OH)_2D_3$ levels in CKD patients in both observational studies[117,118] and RCTs.[119,120] There is currently debate regarding whether ergocalciferol or cholecalciferol is better at raising and maintaining serum 25(OH)D_3 levels.[121,122] There is overall a lack of large observational cohort studies and RCTs using nutritional vitamin D in CKD patients. However, there has been greater interest in its use in addition to or instead of active vitamin D in CKD patients more recently. There is still some question regarding whether nutritional vitamin D can adequately raise 25(OH)D_3 to sufficient levels in all CKD patients.[117,118] Nutritional vitamin D

is also effective at lowering PTH,[119,120] although the evidence is not as strong as for active vitamin D therapy.[123] An additional advantage of ergocalciferol and cholecalciferol is that they are relatively inexpensive.

Active ($1,25(OH)_2D_3$) vitamin D and $1,25(OH)_2D_3$ analogs have been more traditionally used as therapeutic options in patients with CKD. These are no longer recommended for routine use in stage 3−5 CKD, given failure to improved clinical outcomes in the PRIMO and OPERA trials and increased risk of hypercalcemia. Use should be reserved for patients with stage 4 and 5 CKD and progressive hyperparathyroidism.[5] Calcitriol ($1,25(OH)_2D_3$) is effective at raising serum $1,25(OH)_2D_3$ levels, as well as decreasing PTH production by the parathyroid glands. Calcitriol also increases S[Ca], which further suppresses PTH secretion.[124] Normalization of S[P] should occur before initiation of therapy with active vitamin D or vitamin D analogs. Observational evidence supports that calcitriol use may be associated with reduced risk of death or dialysis in patients with secondary hyperparathyroidism.[98] However, there are concerns that calcitriol use may lead to adynamic bone disease, hypercalcemia, and/or hyperphosphatemia, as well as vascular calcification.[91,124] Paricalcitol (19-nor-1α,$25(OH)_2D_2$) and doxercalciferol (1α,$25(OH)D_2$) are analogs of $1,25(OH)_2D_3$ that activate the vitamin D receptor. Vitamin D analogs are also effective at raising serum $1,25(OH)_2D_3$ levels, and newer analogs are more selective for PTH suppression with less effect on S[Ca] and S[P].[110,125] Observational evidence suggests that vitamin D analog use may improve survival in dialysis patients[13,27] and slow progression to ESRD in earlier stages.[98]

Parathyroid Hormone

The EVOLVE study raised questions regarding the utility of lowering PTH for improving cardiovascular outcomes in patients with CKD.[73] Prior to EVOLVE, observational data supported notions that lowering PTH with cinacalcet is associated with decreased all-cause and cardiovascular mortality in chronic HD patients.[11] RCTs with therapeutic agents to lower PTH (testing calcium supplementation, phosphate binders, nutritional vitamin D, $1,25(OH)_2D_3$ analogs, and calcimimetics) were mostly limited to the effects on biochemical parameters and surrogate outcomes. In a single trial in stage 3−5 CKD patients, calcium binders did not lower iPTH but increased coronary calcification score.[126] In three other clinical trials in stage 3−4 CKD, sevelamer and lanthanum also failed to lower iPTH.[23,127,128] Treatment with active vitamin D and its analogs lowers serum iPTH but may also increase S[Ca] or S[P],[110−112] as highlighted by increased risk of hypercalcemia in the PRIMO and EVOLVE studies.[104,105] Active vitamin D and vitamin D analogs have been shown to improve histological indices of bone turnover. Although most studies have been in chronic dialysis populations,[129,130] calcimimetics did lower iPTH in prospective trials of stage 3−5 CKD patients, as well as induce an asymptomatic decrease in S[Ca] and S[P].[131,132] In the ADVANCE study, a randomized trial to evaluate the effects of cinacalcet plus low-dose vitamin D on vascular calcification in HD patients, cinacalcet, a calcimimetic, plus low-dose paricalcitol did not significantly change the primary endpoint, the Agatston coronary calcification score.[133]

The EVOLVE study was a randomized, double-blinded, placebo-controlled study in 3883 chronic HD patients with moderate to severe secondary hyperparathyroidism.[73] In the unadjusted intent to treat analysis, there was no significant change in mortality or cardiovascular events with cinacalcet, despite effective lowering of iPTH.

Optimal levels of iPTH for patients with stage 3−5 CKD are unknown, thus KDIGO does not recommend targeting a specific range (Table 62.2).[1] KDOQI suggests lowering the iPTH threshold in stage 4−5 CKD for prompting evaluation and possible treatment of hyperparathyroidism.[6] This is one of the most debated recommendations, as there is a lack of studies relating serum iPTH levels to bone disease. There is some consensus, however, that trends in iPTH levels should be considered before initiating a therapeutic intervention, as reflected by the newest KDIGO guidelines emphasizing progressively rising or persistently elevate iPTH as indications for treatment.[5] KDIGO considers any of the following to be reasonable first-line therapies for the treatment of hyperparathyroidism: reduced phosphate intake, phosphate binders, calcium supplements, and if the patient is also $25(OH)D_3$ deficient, nutritional vitamin D.[1,4] If these options are not effective, iPTH is progressively rising and remains above the upper limit of normal, and $25(OH)D_3$ deficiency is present, then treatment with $1,25(OH)_2D_3$ or $1,25(OH)_2D_3$ analogs should be considered in stage 4 and 5 CKD.

Calcimimetics are not currently recommended for treatment of hyperparathyroidism in nondialysis-dependent CKD, as the work group felt more data were still needed, nor are they approved by the FDA in this population. In circumstances of severe hyperparathyroidism that fails to respond to other therapy, parathyroidectomy is recommended.

There are advantages and disadvantages associated with calcimimetics compared to parathyroidectomy for treatment of hyperparathyroidism in CKD patients (Table 62.3). By mimicking an increase in extracellular calcium concentration, calcimimetics increase intracellular calcium levels, which decreases PTH release.[1] Cinacalcet, which acts as a positive allosteric modulator by inducing a conformational change in the calcium-sensing receptor

to increase sensitivity to extracellular calcium,[91] is the only type II calcimimetic currently available for clinical use. Although cinacalcet is effective at lowering iPTH in both chronic dialysis patients[129,130] and nondialysis CKD patients,[131,132] its use is associated with gastrointestinal side effects.[73] In the EVOLVE study, there was also an increased occurrence of hypocalcemia with use of cinacalcet, without any reduction in cardiovascular events or mortality.[73]

There is a lack of RCTs to show either the benefits or risks associated with parathyroidectomy to treat secondary or autonomous hyperparathyroidism, as well as studies specifically comparing surgical to medical therapy for treatment of secondary hyperparathroidism. However, it is generally accepted that a well-performed parathyroidectomy reduces serum iPTH concentrations, S[Ca], and S[P] in CKD patients with secondary or autonomous hyperparathyroidism. In addition to a last resort therapy when patients fail to respond to medical therapy, parathyroidectomy could also be considered if the medical management of hyperparathyroidism leads to an unacceptable rise in S[Ca] and/or S[P], or if there are other intolerable adverse events.[1]

FGF-23

The discovery of FGF-23 is relatively recent; and therefore, its role in the treatment of CKD-MBD is not yet well understood or targeted. There are some small diet manipulation studies and observational evidence that suggest that manipulating dietary phosphate intake can alter FGF-23 levels, which is dependent on the source of phosphate (animal vs. plant).[63,134,135] Several small studies have also shown that phosphate lowering with the binders sevelamer[136,137] and lanthanum (plus a low-phosphate diet)[138] can also reduce levels of FGF-23 in patients with stage 3–4 CKD. FGF-23 levels may also be reduced in stage 3–5 CKD with ferric acid treatment.[139] However, the degree of change in FGF-23 in response to phosphate binders or dietary phosphate restriction is minimal compared to the magnitude of change seen with progression of CKD. Thus manipulating phosphorus alone, either through dietary intake or with phosphate binders, may not be enough to modify FGF-23 levels in a meaningful way.

Secondary analysis of the EVOLVE study showed reductions in FGF-23 with the calcimimetic cinacalcet, which was associated with reduced rates of cardiovascular death and major cardiovascular events.[140] A recently completed phase 3 trial in stage 3b–4 CKD patients (The COMBINE [CKD Optimal Management with Binders and NicotinamidE] study) failed to demonstrate effective lowering of FGF-23 or phosphate levels with 12 months of nicotinamide, which inhibits intestinal NPT2b, with or without lanthanum carbonate.[141]

FGF-23 receptor blockers are currently being tested in animal models to suppress FGF receptor signaling.[142] An FGF-23 antibody (burosumab-twza) was recently approved by the FDA for the treatment of X-linked hypophosphatemia in adults and pediatric patients. There are also ongoing phase I/II oncology clinical trials using FGF receptor (1–4) tyrosine kinase inhibitors. This may represent a potential pharmacological target in the treatment of CKD-MBD. However, there are potential concerns regarding possible negative or unknown consequences of lowering FGF-23 that will need to be carefully considered.

Bone

KDIGO recommends that in patients with stage 1–2 CKD and osteoporosis or a high risk of fracture, and patients with stage 3 CKD with osteoporosis or a high risk of fracture and iPTH in the normal range, management should be the same as in the general population.[1] In patients with stage 3–5 CKD, biochemical abnormalities, and low BMD and/or fragility fractures, treatment options should include consideration of the magnitude and reversibility of biochemical abnormalities, as well as CKD progression; performance of bone biopsy should also be considered.[5] Bone biopsy is no longer required (although can be considered) prior to beginning an antiresorptive agent, as there is growing evidence that antiresorptive therapies are effective at preventing fractures and there is a lack of robust evidence that medications induce adynamic bone disease.[71] It is recommended that secondary hyperparathyroidism be corrected first.[1]

The risks of treatment must be weighed against potential side effects and the accuracy of the diagnosis of the underlying bone phenotype. Biphosphonates are effective at decreasing fractures in non-CKD patients with osteoporosis, and *post hoc* analyses of RCTs support they may be as effective in stage 3 CKD patients. Teriparatide is an anabolic drug that increases the formation of new bone. Teriparatide is a recombinant human 1–34 PTH, and therefore is contraindicated in patients with hyperparathyroidism.[1] Teriparatide does not appear to be contraindicated in women with stage 2–3 CKD and normal biochemistry, based on a *post hoc* analysis.[143] Desosumab is an antiresorptive agent that is a monoclonal antibody against the receptor activator of nuclear factor κB ligand. Recent studies suggest it can be safely administered in patients with CKD-associated osteoporosis, with careful monitoring for hypocalcemia, adequate calcium intake, and vitamin D supplementation.[71]

Raloxifene is a selective estrogen receptor modulator approved for the treatment of postmenopausal osteoporosis. Raloxifene reduces vertebral fracture risk in this population, although there are concerns common to

estrogen therapy, including increased risk of fatal stroke.[1] A *post hoc* analysis including participants from a trial who had mild to moderate CKD and normal biochemistry suggests raloxifene may be as safe and effective for these patients as the general population, although this cohort in not likely representative of the typical CKD population.[144]

Vascular Calcification

There is no clear evidence-based protocol established for treatment given a positive calcification test. In general, the KDIGO recommendations focus on strategies to minimize the progression of vascular calcification in patients with known calcification.[1] Noncalcium-based binders are recommended for the treatment of hyperphosphatemia in CKD patients with known vascular calcification. There is currently a lack of interventional data on the effects of calcimimetics, nutritional or active vitamin D/analogs, or parathyroidectomy on vascular calcification progression.

CONCLUSION

The pathophysiology of CKD-MBD, a common clinical syndrome in patients with CKD with consequences affecting mineral metabolism, bone mineralization, and extracellular calcification, is complex. Treatment of CKD-MBD, especially in early stages of disease, with a focus on the biochemical and hormonal factors, and calcium, phosphorus, vitamin D, iPTH and FGF-23 metabolism, as well as consideration of bone and vascular calcification, is often not evidence-based because of the lack of information from observational studies as well as RCTs performed in specific patient populations. There is great need for additional well-designed RCTs to further guide the diagnosis and complex management of patients with CKD-MBD.

QUESTIONS AND ANSWERS

Question 1

A 50-year-old man with stage 3b CKD (eGFR 44 mL/min per 1.73 m^2) presents for a biannual checkup. He is mildly obese (body mass index [BMI], 32 kg/m^2), with a medical history that shows a 5-year history of insulin-dependent type 2 diabetes (poorly controlled; hemoglobin A_{1c} [HbA_{1c}] 8.0%), and hypertension and hypercholesterolemia diagnosed 7 years previously. He is currently on an angiotensin converting enzyme inhibitor (ACEI) for hypertension (lisinopril 40 mg/day) and a statin (atorvastatin 40 mg/day) for hypercholesterolemia.

His BP is well controlled (120/85 mm Hg) and previous blood work shows a LDL cholesterol level of 120 mg/dL. Biochemical tests show the following: S[Ca] 8.9 mg/dL, S[P] 4.8 mg/dL, and serum iPTH 100 pg/mL. Which of the following is a nontraditional risk factor for the development of cardiovascular disease (CVD) in patients with CKD and diabetes?

A. Hypertension
B. Dyslipidemia
C. Disorders of mineral metabolism
D. Diabetes

Answer: C

Risk factors for the development of CVD in patients with CKD or ESRD may be either traditional or nontraditional. Traditional risk factors for CVD include hypertension, dyslipidemia, diabetes, and obesity, among others, all of which may or may not be present in patients with CKD. Patients with CKD are also prone to the development of vascular calcification or atherosclerosis that results from declining kidney function and disorders of mineral metabolism (a nontraditional risk factor) that may be in the causal pathway of arterial thickening and calcification. Evidence suggests that vascular calcification occurs as a result of abnormal mineral metabolism and the deposition of calcium phosphate complexes in soft tissues, blood vessels, the myocardium, and cardiac valves, which begins in early CKD. Patients with CKD are susceptible to the development of cardiovascular disease and vascular calcification, both of which can be caused by traditional and/or nontraditional risk factors. Disorders of mineral metabolism may play a major role in the development of CVD in patients with CKD.[17,145]

Question 2

According to KDIGO guidelines for the evaluation and management of patients with CKD, how often should monitoring of biochemical and blood mineralization levels be performed in stage 3 CKD patients?

A. Testing should only be performed at baseline without consideration of disease progression
B. S[Ca]/S[P] every 6–12 months and PTH based on baseline level and CKD progression
C. S[Ca] and S[P] every 3–6 months, and PTH every 6–12 months.
D. S[Ca]/S[P] every 1–3 months and PTH every 3–6 months

Answer: B

The KDIGO recommendations for monitoring biochemical and blood mineralization values, from initial injury to ESRD, reflect the recommendation for increased frequency of testing for patients whose stage of CKD progresses with declining renal function.[1] Current KDIGO guidelines recommend monitoring S[Ca], S[P], serum PTH level, and serum ALP beginning in CKD stage 3. Thereafter, for CKD stages 3–5, the frequency of monitoring S[Ca], S[P], and PTH should be based on the presence and magnitude of abnormalities and the rate of progression of CKD. In patients with stage 3 CKD, S[Ca] and S[P] should be tested every 6–12 months. Evaluation of PTH should be based on baseline level and rate of CKD progression.[1]

Question 3

A 65-year-old man with stage 4 CKD (eGFR 24 mL/min/1.73 m^2) presents to his nephrologist for a scheduled follow-up visit. The physician orders several laboratory tests to determine his S[Ca], S[P], iPTH, and 25-hydroxyvitamin D (25(OH)D) levels, and a test for bone-specific ALP. The results show some significant changes since his last visit, with his iPTH increasing from 75 pg/mL to 150 pg/mL and his S[Ca] decreasing from 9.4 mg/dL to 8.6 mg/dL. Serum vitamin D level is 15 ng/mL, S[P] is 4.6 mg/dL, and S[Cr] is 3.2 mg/dL. ALP is 152 IU/L. What mineralization test would you consider to justify intervention to normalize iPTH?

A. S[Ca]
B. 25-Hydroxy vitamin D [25(OH)D]
C. S[P]
D. S[Cr]
E. ALP

Answer: B

Sustained elevations in serum iPTH occur in response to declining renal function, impaired phosphate excretion, and an inability to activate vitamin D to calcitriol, the hormonally active form of vitamin D. Abnormalities of vitamin D metabolism play a significant role in the cascade of events leading to the development of sustained elevated levels of serum iPTH. In the body's attempt to maintain calcium homeostasis, there is an increase in the secretion of PTH to stimulate the

production of calcitriol, eventually leading to secondary hyperparathyroidism. In response to excessive levels of iPTH, there are further increases in S[P] and a vicious cycle ensues.

The goal of therapy in CKD is to reduce iPTH to normal levels, with an eventual return to homeostasis of all biochemical and blood minerals. Patients with CKD typically do not have changes in their S[Ca] and S[P], and only mild increases in serum iPTH. Therefore, testing for serum 25 (OH)D concentrations should be performed and replacement should be attempted with the objective of improving iPTH before initiating therapy with active form of vitamin D.[8,146] S[Cr] and levels of ALP are not indications for therapy.

Question 4

On a subsequent visit, the patient's S[P] has increased to 6 mg/dL. S[Ca] continues to fall, albeit slightly, and is now at 8.2 mg/dL. 25(OH)D level is 35 ng/mL after having started treatment with cholecalciferol 2000 IU/daily. Serum iPTH has also risen slightly, to 170 pg/mL. The patient remains at stage 4 CKD, with a stable GFR of 24 mL/min per 1.73 m^2.

Which of the following interventions would be an acceptable course of action in this patient based on the lab values obtained from his last two visits?

A. Decreased dietary intake of phosphorus and dietary consultation
B. Phosphate binders
C. Vitamin D sterols
D. Cinacalcet

Answer: A

Elevated S[P] levels may contribute to the development of vascular calcification through several mechanisms, which include osteochondrogenic phenotypic changes in vascular smooth muscle cells (VSMCs), phosphate-induced apoptosis of VSMC, phosphate inhibition of osteoclast differentiation, and Klotho deficiency.[17] KDIGO guidelines recommend that S[P] be maintained in the normal range in patients with CKD stages 3–5. However, the evidence that supports the use of calcium and noncalcium-based phosphate binders for the treatment of patients with elevated S[P] in patients with predialysis CKD is inconclusive.[23]

Question 5

A 66-year-old man is referred for evaluation and treatment of nephrotic syndrome. Laboratory evaluation reveals a GFR 42 mL/min/1.73 m^2, urinary protein excretion of 10 g/day, serum albumin 2 g/dL, intact parathyroid hormone level of 180 pg/mL, and a 25(OH)D level <10 ng/mL. Which one of the following statements is most accurate?

A. Vitamin D status is reflected by the serum levels of calcitriol and not 25(OH)D
B. 25(OH)D deficiency and insufficiency are highly prevalent in patients with CKD
C. Low levels of 25(OH)D are not associated with increased parathyroid hormone
D. Proteinuria does not contribute to vitamin D deficiency

Answer: B

It is being increasingly recognized that kidney disease, especially proteinuric kidney disease, is a risk factor for vitamin D insufficiency and deficiency. Increased levels of PTH are associated with the low levels of 25-hydroxyvitamin D. Current practice guidelines suggest that this should be corrected if PTH levels are elevated.[64,147]

Question 6

A 49-year-old woman is referred with stage 4 CKD that has been attributed to long-standing and poorly controlled hypertension. Her eGFR is 25 mL/min/1.73 m^2. In a previous echocardiogram, it was noted that her mitral valve was calcified. A kidney–ureter–bladder radiograph revealed aortic calcification. Which one of the following statements is most accurate?

A. Vascular calcification is always present with advanced CKD
B. Vascular calcification tends to be progressive
C. Vascular calcification is only seen in patients with diabetes and in patients who have prolonged periods of hyperphosphatemia
D. Vascular calcification would be expected to regress with control of secondary hyperparathyroidism

Answer: B

Vascular calcification in the setting of advanced CKD is virtually always progressive. In this case, the calcification is most likely medial calcification. Although common in patients with advanced CKD, it is not invariable. Vascular calcification is very common in patients with diabetic kidney disease. Efforts should be made to slow the progression of calcification by aggressive control of hyperphosphatemia, but it may occur in patients who have adequate control of S[P]. Vascular calcification typically does not regress with reduction in iPTH levels; in fact, patients with the low iPTH levels may be more prone to such calcification.[148]

Abstract

Patients with chronic kidney disease (CKD), which is typically accompanied by several comorbid conditions, require multiple medications on a daily basis to treat their underlying disease. Decreased renal excretion of drugs is a well-documented consequence of CKD. In addition, there now is abundant evidence indicating that the function of drug metabolizing enzymes and transporters, which collectively determine net nonrenal drug clearance, is differentially altered in CKD. Basic principles of drug metabolism and transport are reviewed and discussed in the context of drug therapy in patients with CKD. Evidence is presented from preclinical to clinical studies, and important clinical examples are highlighted.

SCOPE OF THE PROBLEM

The prevalence of chronic kidney disease (CKD) in adults between 2011 and 2014 was 14.8% of the US population, and at the end of 2015 there were over 700,000 patients with end-stage renal disease (ESRD).[1] The number of patients progressing to ESRD continues to rise by approximately 20,000 cases per year, and there are now over 1 million patients globally that have ESRD and are treated with renal replacement therapies such as dialysis.[2] CKD is commonly accompanied by several comorbidities, including diabetes, hypertension, anemia, and cardiovascular disease. These comorbidities significantly increase the risk of serious events and decrease life expectancy. For example, the life expectancy at age 55 is reduced from 19.9 years with normal or slightly reduced kidney function to 5.6 years with severe CKD.[3] The increased risk of adverse events is at least partly mediated by decreased clearance of uremic toxins, molecules that accumulate in the blood of CKD patients as their kidney function declines.[4–6]

CKD patients are prescribed a disproportionately high number of medications to treat their underlying kidney disease and the large number of comorbidities. For example, ESRD patients treated with maintenance hemodialysis (HD) have a median daily pill burden of 19, with one quarter of patients exceeding 25 pills per day.[7] Collectively, HD patients take an average of 12 different medications in an attempt to control their various comorbidities.[8] A consequence of both their CKD and large pill burden is heightened risk for adverse drug events. This is highlighted by a report that indicates there is one medication-related problem for every 2.7 medication exposures in maintenance HD patients.[9] Dosing of medications in CKD continues to be a challenge, with rates of inappropriate dosing reported to be as high as 68 per 100 prescriptions for antibiotics.[10]

Changes in the pharmacokinetics of many drugs induced by kidney disease further complicates pharmacotherapy in CKD. The kidney is the primary organ responsible for drug excretion so it is not surprising that decreased kidney function decreases the excretion of many drugs. Drugs are typically designed and tested for use in healthy patients with normal kidney function with minimal to no testing in patients with impaired kidney function. Traditional strategies for prescribing drugs in CKD patients include selection of medications that exhibit minimal to no renal excretion under the premise that they may be administered in normal unadjusted doses, or using nomograms or equations to adjust the dosing of drugs that are excreted by the kidney. The revised Food and Drug Administration (FDA) guidance for industry on pharmacokinetics in patients with impaired kidney function highlights the need for

Chronic Renal Disease, Second Edition

pharmacokinetic studies in CKD patients.[11] An additional important consideration is the impact of dialysis on drug clearance and pharmacokinetics. It is clear that dialysis does not replace the functioning kidney as several highly protein bound substrates removed *via* renal tubular secretion are inefficiently removed by dialysis, and dialytic clearance can vary substantially among drugs from within the same class.[12]

In addition to directly impacting renal drug clearance, CKD has pronounced effects on nonrenal clearance of drugs. Nonrenal drug clearance comprises hepatic and extrahepatic metabolism (collectively metabolic clearance) and drug transport. The nonrenal clearance of many drugs is altered in patients with impaired kidney function, often translating into clinically relevant changes in systemic exposure (Table 63.1). Hepatic metabolism and transport are the largest contributors to nonrenal drug clearance, although other organs such as the intestine, heart, and lung contribute to varying degrees. Changes in hepatic metabolism induced by CKD are especially important to consider because approximately 73% of drugs undergo metabolism prior to being eliminated.[13] Similarly, hepatic transporters are essential for delivering substrate drugs to the liver for subsequent metabolism and/or transporter-mediated biliary excretion. The objective of this chapter is to highlight CKD-mediated changes to drug metabolism and transport and to discuss the implications of these changes on the pharmacokinetics of drugs in CKD patients. Several excellent review articles have also addressed this area.[14–26]

TABLE 63.1 Selected Drugs With Evidence of Altered Nonrenal Clearance in Humans With Chronic Kidney Disease

Acyclovir	Ciprofloxacin	Ketorolac	Propoxyphene
Alfuzosin	Cyclophosphamide	Lanthanum	Propranolol
Aliskiren	Darifenacin	Lidocaine	Quinapril
Aprepitant	Desmethyldiazepam	Lomefloxacin	Raloxifene
Aztreonam	Dextromethorphan	Losartan	Ranolazine
Bufurolol	Diacerein	Lovastatin	Reboxetine
Bupropion	Didanosine	Metoclopromide	Repaglinide
Captopril	Dihydrocodeine	Metoprolol	Rosuvastatin
Carvedilol	Doxorubicin	Midazolam	Roxithromycin
Caspofungin	Duloxetine	Minoxidil	Sildenafil
Cefepime	Encainide	Morphine	Simvastatin
Cefmenoxime	Eprosartan	Moxalactam	Solifenacin
Cefmetazole	Erythromycin	Naltrexone	Sparfloxacin
Cefonicid	Felbamate	Nebivolol	Tacrolimus
Cefotaxime	Fexofenadine	Nefopam	Tadalafil
Cefsulodin	Fluorouracil	Nicardipine	Telithromycin
Ceftibuten	Fluvastatin	Nimodipine	Valsartan
Ceftizoxime	Guanadrel	Nitrendipine	Vancomycin
Ceftriaxone	Idarubicin	Nortriptyline	Vardenafil
Cerivastatin	Imatinib	Oxcarbazepine	Verapamil
Cibenzoline	Imipenem	Oxprenolol	Warfarin
Cilastatin	Isoniazid	Paroxetine	Zidovudine
Cimetidine	Ketoprofen	Procainamide

DRUG METABOLISM AND TRANSPORT

The majority of medications are xenobiotics, or substances foreign to the human body. Organs such as the liver, intestine, kidney, and lung have evolved a complex network of enzymes and transporters that facilitate systemic exposure and elimination of xenobiotics from the body. Drug-metabolizing enzymes are classified into phase 1 (oxidation, reduction, hydrolysis) or phase 2 (conjugation) reactions (see Figure 63.1). Drug-metabolizing enzymes usually convert lipophilic drugs into more polar metabolites to facilitate their excretion.

Drug transporters are expressed on cell membranes and mediate the uptake and efflux of drugs (Figure 63.1). The most important uptake transporters that impact drug disposition are the solute carrier (SLC) transporters. SLC transporters are typically facilitated transporters and ion-coupled secondary active transporters. There are 43 known SLC families and approximately 300 SLC transporters, many of which are determinants of drug absorption and disposition.[27] Similarly, the ATP-binding cassette (ABC) family of transporters is the most relevant efflux transporter family for drug disposition. ABC transporters are largely primary active transporters that use ATP hydrolysis as an energy source to pump substrates out of cells, often against a concentration gradient. There are 49 known ABC genes and 7 families of ABC transporters.[27]

Collectively, drug-metabolizing enzymes and transporters are key mediators of both renal and nonrenal drug clearance and act in a concerted manner to determine the pharmacokinetics of drugs. A change in the expression or activity of drug metabolizing enzymes or transporters can profoundly alter the pharmacokinetics of substrate drugs. The interplay between drug metabolizing enzymes and drug transporters is demonstrated in Figure 63.1.

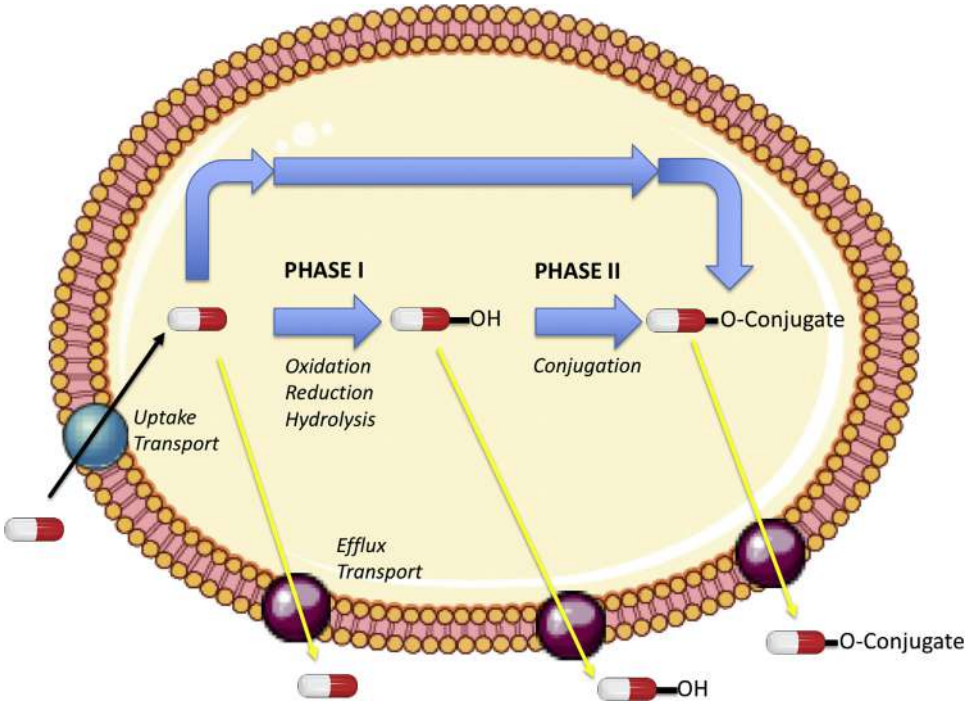

FIGURE 63.1 **The interplay between drug metabolism and transport.** Drugs may enter the cell by passive diffusion (not shown) or *via* an uptake transporter (depicted by *blue sphere*). Once inside the cell, the drug may be 1) removed from the cell by an efflux transporter (*purple sphere*) or metabolized by phase I (oxidation, reduction, hydrolysis) or phase II (conjugation) drug-metabolizing enzymes. Although drugs are typically metabolized first by phase I enzymes prior to phase II metabolism, some drugs are directly metabolized by phase II enzymes. Metabolites (phase I or II) may also be subject to efflux from the cell. *Images used to generate this figure were modified from Servier Medical Art, licensed under Creative Commons Attribution 3.0 Generic License, http://smart.servier.com/.*

DRUG METABOLISM IN PRECLINICAL MODELS OF CKD

The earliest reports of altered drug metabolism in CKD were published in the 1970s and 1980s in experimental (mostly rat) models of CKD.[28–31] These pioneering studies used probes of global cytochrome P450 activity (i.e. substrates metabolized by multiple enzymes), such as aminopyrine, acetanilide, and *p*-nitroanisol. Experimental kidney disease was typically induced in these studies by a 5/6 nephrectomy. In this procedure, 2/3 of the kidney mass is surgically resected and one week later a complete nephrectomy is performed, resulting in only 1/6 of the total kidney mass remaining. Although the remaining kidney mass undergoes hyperfiltration in an attempt to compensate for the nephron loss, the animals ultimately experience kidney disease as evidenced by increases in serum creatinine concentration (S[Cr]) and blood urea nitrogen (BUN). These early preclinical studies demonstrated a 32% reduction in total cytochrome P450 (CYP) content in CKD animals along with a 35%, 37%, and 31% decrease in the CYP-mediated metabolism of aminopyrine, *p*-nitroanisol, and acetanilide, respectively,[31] substrates that are broad probes of CYP enzymes. For example, antipyrine is metabolized by CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C18, and CYP3A4 in humans.[32] Accordingly, these studies suggested that hepatic drug metabolism is decreased in CKD but provided little information on the specific pathways that are altered by kidney disease.

Subsequent research focused on delineating the specific metabolic pathways altered in CKD. Uchida and colleagues used a 5/6 nephrectomy model to evaluate the effect of CKD on hepatic drug-metabolizing enzymes.[33] A negative correlation between BUN and cytochrome P450 content as well as multiple hepatic specific activities (e.g. aminopyrine demethylase and δ-aminolevulinic acid synthetase) was observed. In addition, hepatic Cyp2c6, Cyp2c11, and Cyp3a2 were downregulated in CKD (note lower case letters in Cyps represent rodent). Leblond, Pichette, and colleagues, who systematically investigated the effect of CKD on drug metabolism in elegant studies that spanned over a decade,[34–40] demonstrated that total hepatic CYP content was negatively correlated with creatinine clearance. Although there was no change in the activity of Cyp1a or Cyp2d enzymes, a pronounced decrease in the mRNA and protein expression of Cyp2c11, Cyp3a1 (Cyp3a23), and Cyp3a2 in the 5/6

nephrectomy rat model was shown.[39] Collectively, these represent the rat orthologs of human CYP2C9 and CYP3A4, respectively. The *in vivo* relevance of these observations was also reported. Specifically, a caffeine breath test (Cyp1a probe) revealed no change in Cyp1a metabolic activity in CKD animals *in vivo* compared to controls, confirming *ex vivo* observations.[40] Similarly, *in vivo* breath tests for aminopyrine (Cyp2c11 probe) and erythromycin (Cyp3a probe) revealed a 35% decrease in the activities of Cyp2c11 and Cyp3a in CKD animals compared to controls, again confirming *ex vivo* microsomal studies.

Although this collection of work clearly indicates hepatic drug metabolism is significantly impaired in severe kidney disease induced by 5/6 nephrectomy, it raised the question of whether drug metabolism is impacted in earlier stages of disease. Velenosi and colleagues used a modified surgical/vessel ligation technique to generate a model of moderate kidney impairment[41] that demonstrated even moderate kidney disease (1.7-fold increase in S[Cr]) was able to induce a greater than 60% decrease in Cyp2c11 and Cyp3a2 mRNA and protein expression. In addition, the catalytic activity of midazolam (Cyp3a) and testosterone (Cyp2c11 and Cyp3a) were significantly decreased in both moderate and severe kidney disease. There was an exponential decline in hepatic drug metabolizing enzyme activity as kidney disease progressed, suggesting that a small change in kidney function has a profound impact on drug metabolism.[41] The dietary adenine model of CKD, which has gained popularity as it provides less variability in degree of kidney disease,[42] has also been used to study the impact of CKD on drug metabolism. Similar to the 5/6 nephrectomy model, adenine-induced CKD causes a pronounced decrease in hepatic Cyp2c11 and Cyp3a2 expression and activity in rats, but no significant differences in hepatic Cyp1a or Cyp2d.[43]

CKD also elicits changes in extra-hepatic drug metabolism. Although the liver is the body's primary metabolic organ, substantial drug metabolism occurs in both intestinal enterocytes and renal tubular cells. Expression of Cyp1a1 and Cyp3a2 mRNA and protein are significantly downregulated in rats with CKD.[44] Moreover, enzymatic activity assays using ethoxyresorufin O-dealkylation (Cyp1a) and erythromycin demethylation (Cyp3a) confirm that Cyp1a and Cyp3a activity is decreased. These changes suggest that altered intestinal drug metabolism in CKD may impact the bioavailability of drugs. Cytochrome P450 expression was also evaluated in the remnant kidney from rats that underwent 5/6 subtotal nephrectomy.[45] In contrast to liver and intestine, there was no change in renal Cyp3a2, but Cyp1a1 was significantly downregulated in CKD compared to control.[44]

Although cytochrome P450s are the most widely studied phase I drug metabolizing enzymes, hepatic reductases are also important phase I drug metabolizing enzymes relevant to drug disposition. One of the most important and widely used drugs impacted by hepatic drug reduction is the anticoagulant warfarin, which is used extensively in patients with CKD. In addition to CYP-mediated phase I metabolism, the acetonyl functional group of warfarin is reduced by hepatic reductases to form warfarin alcohols. The reduction of warfarin generates a second chiral center, such that two diastereoisomers of warfarin alcohols may be generated: warfarin alcohol 1 (*RS/SR*) and warfarin alcohol 2 (*RR/SS*). Warfarin reduction is mediated by the cytosolic enzymes carbonyl reductase 1 (CBR1) and aldo-keto reductase family 1 member C3 (AKR1C3) and by the microsomal enzyme 11 β-hydroxysteroid dehydrogenase 1 (11 β-HSD1). Alshogran and colleagues used the 5/6 nephrectomy model of CKD to evaluate the expression and activity of hepatic reductase enzymes,[46] and demonstrated that the mRNA expression of CBR1, AKR1C3, and 11 β-HSD1 were downregulated by 34%, 93%, and 35%, respectively, in CKD compared to controls. Similarly, protein expression of CBR1, AKR1C18 (encoded by the AKR1C3 gene), and 11 β-HSD1 were downregulated by 43%, 76%, and 70% in CKD compared to controls, respectively. The downregulation of these reductases resulted in a 39% decreased formation of warfarin alcohol 1 in the cytosol and a 43% decrease in microsomes from CKD rats compared to sham controls.

Phase II drug-metabolizing enzymes serve to conjugate drugs, typically by adding endogenous substances such as glutathione, sulfate, glycine, or glucuronic acid that make the parent drug more polar and/or less toxic (Figure 63.1). The predominant phase II drug-metabolizing enzymes include acetylation (by N-acetyltransferases; NAT), glucuronidation (by uridine 5′-diphospho glucuronosyltransferases; UGT), methylation (by thiopurine methyltransferases; TPMT), and conjugation with glutathione (glutathione S-transferases; GST). Although the 5/6 nephrectomy model of CKD shows no difference in expression or activity in the major UGT enzymes,[47] pronounced differences in hepatic acetylation have been described in this model.[48] Specifically, a 33% and 50% decrease in Nat1 and Nat2 expression, respectively, is apparent in CKD rats compared to controls. In addition, there is a 50% reduction in Nat2-mediated acetylation of *p*-aminobenzoic acid in CKD rat liver cytosol compared to controls.

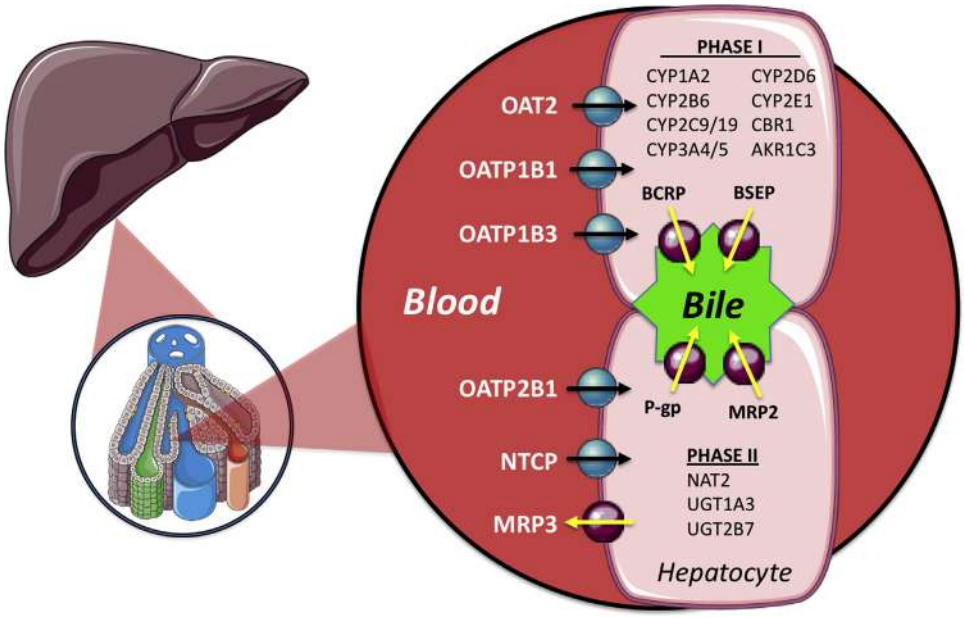

FIGURE 63.2 **Hepatic drug metabolism and transport pathways.** Hepatic sinusoids within the liver connect the portal and hepatic circulation and facilitate the formation of bile. The hepatocytes are the primary functional cells in the liver. In the context of drug therapy, drug can be taken up in hepatocytes by uptake transporters (*blue spheres*). Once within the cell, drugs can be metabolized by phase I (e.g. CYPs) or phase II drug-metabolizing enzymes. Parent drug or metabolite may be removed from the hepatocyte into the blood or excreted into the bile *via* efflux transporters (*purple sphere*). Representative transporters and enzymes are shown for reference. Note this is not a complete list. *Images used to generate this figure were modified from Servier Medical Art, licensed under Creative Commons Attribution 3.0 Generic License, http://smart.servier.com/.*

DRUG METABOLISM IN HUMANS WITH CKD

The impact of CKD on drug metabolism in humans is complex, largely owing to the multiple enzymes that metabolize drugs and the complex interplay between drug-metabolizing enzymes and drug transporters (Figure 63.1). The most common approach to assessing drug metabolism in patients with kidney disease is to evaluate the pharmacokinetic parameter clearance (CL). Clearance is the volume of blood (or plasma) from which a substance is removed per unit time. Oral drug clearance is calculated as:

$$CL_{oral} = CL/F = dose * F/AUC$$

where F = bioavailability and AUC = the area under the plasma concentration time curve. In general, oral drug clearance can be considered the sum of renal clearance, hepatic clearance, and clearance from other routes as follows:

$$CL_{oral} = CL_{renal} + CL_{hepatic} + CL_{other}$$

For highly metabolized drugs with a fractional excretion less than 10%, a change in oral clearance is typically assumed to be a change in hepatic clearance because the drug is minimally excreted in the urine and usually other clearance routes (e.g. respiratory and sweat) contribute minimally to total oral clearance. This is commonly termed nonrenal clearance (CL_{NR}) and refers to clearance by all routes other than the kidney. As described above, multiple enzymes metabolize many drugs and many are also subjected to hepatic transport (Figure 63.2). For these reasons, it is often difficult to link changes in clearance to a specific pathway (e.g. a specific cytochrome P450 isozyme). Fortunately, there are a number of fairly specific probe substrates that have been characterized that allow direct phenotypic characterization of specific metabolic pathways. These include bupropion (CYP2B6), warfarin (CYP2C9), mephenytoin (CYP2C19), sparteine (CYP2D6), midazolam (CYP3A4), and chlorzoxazone (CYP2E1). The function of several cytochrome P450 enzymes has been studied in humans with CKD using these and other probe substrates and is summarized in Table 63.2.

CYP2B6

CYP2B6 is highly expressed in human liver and metabolizes several antidepressants, anticonvulsants, and chemotherapeutic agents. The antidepressant bupropion is extensively metabolized by CYP2B6 and is the most widely used probe of this CYP isozyme. In an open-label pharmacokinetic study, healthy controls and CKD patients (mean eGFR 30.9 mL/min/1.73 m^2) were given a single 150 mg oral dose of sustained release

TABLE 63.2 Impact of Chronic Kidney Disease (CKD) on Drug Metabolizing Enzymes in Humans

Enzyme	Probe	Effect of CKD	Interpretation
CYP2B6	Bupropion	↑AUC, ↓CL/F	↓ activity in CKD
CYP2C9	Warfarin	↓*S/R* warfarin ratio	↓ activity in CKD
CYP2C19	Mephenytoin	=AUC, =CL/F	No Change in CKD
CYP2D6	Sparteine	Unclear	= or ↓ activity in CKD
	Dextromethorphan	Unclear	= or ↓ activity in CKD
	Nebivolol	↑AUC, ↓CL/F	↓ activity in CKD
CYP2E1	Chlorzoxazone	= CL	No Change in CKD
CYP3A4	Erythromycin	↓Breath test	↓ activity in CKD*
		↓CL	↓ activity in CKD*
	Midazolam		
	Oral	= AUC, CL/F	No change in CKD
	IV	↑AUC, ↓CL/F, =t1/2	No change in CKD or modest ↓
CBR1 & AKR1C3	Doxorubicin	↑AUC, ↓CL	↓ activity in CKD
	Idarubicin	↑AUC, ↓CL	↓ activity in CKD
NAT2	Isoniazid	↓CL	↓ activity in CKD
UGT1A3 & UGT2B7	Morphine	↑AUC, ↓CL	↓ activity in CKD

** Also extensively transported so unclear if changes are related to altered transport, metabolism, or both.*

bupropion. CKD patients had a 126% increase in the AUC and a 63% decrease in CL/F.[49] In a different study, patients with biopsy confirmed glomerular disease (lupus nephritis or antineutrophil associated [ANCA] vasculitis) received a single oral 150 mg dose of sustained release bupropion.[50] Patients with glomerular disease had a twofold increase in bupropion AUC and CL/F was approximately half compared to subjects without glomerular disease. Collectively, these two studies suggest that CYP2B6 activity is decreased in patients with kidney disease.

CYP2C9

CYP2C9 is highly expressed in human liver and is responsible for the metabolism of approximately 13% of the most commonly prescribed drugs.[13] Warfarin is an anticoagulant drug used to prevent blood clot formation and migration. Warfarin is a widely used medication in CKD patients for treatment of atrial fibrillation, embolism, and thrombosis and acts by inhibiting vitamin K reduction. It is a racemic mixture of two active enantiomers. The two enantiomers are differentially metabolized by hepatic CYP enzymes. Although *R*-warfarin is metabolized by multiple CYPs including CYP1A1, CYP1A2, and CYP3A4, *S*-warfarin is primarily metabolized by CYP2C9 into multiple hydroxylated metabolites. The ratio of *S*-warfarin to *R*-warfarin is used as a probe of CYP2C9 activity in patients. The *S/R*-warfarin ratio is increased by 51% in ESRD patients compared to controls, suggesting that hepatic CYP2C9 activity is decreased in kidney disease.[51] This finding is consistent with decreased hepatic expression and activity of rat CYP2C11 (generally considered the rat ortholog of human CYP2C9) in CKD.[39–41,43]

CYP2C19

Mephenytoin is a hydantoin-derivative anticonvulsant agent that is typically used to treat partial seizures in patients resistant to less-toxic drugs. It is supplied as a racemic mixture of the enantiomers *R*-mephenytoin and *S*-mephenytoin. Similar to warfarin, mephenytoin is subject to stereoselective metabolism, with *S*-mephenytoin being hydroxylated to 4-hydroxymephenytoin by CYP2C19, whereas *R*-mephenytoin is slowly demethylated. Accordingly, mephenytoin has been used as an *in vivo* probe of CYP2C19 activity by measuring the formation clearance of the CYP2C19 specific metabolite 4-hydroxymephenytoin. Mephenytoin was administered as a single oral dose to patients with varying degrees of CKD and pharmacokinetic parameters assessed.[52]

No difference in the area under the curve of *S*-mephenytoin or the formation clearance of the 4-hydroxymephenytoin metabolite suggests that CYP2C19 activity is not different in patients with CKD.

CYP2D6

CYP2D6 is one of the most abundantly expressed hepatic cytochrome P450 enzymes. It metabolizes approximately 20% of the most commonly prescribed medications.[13] The *CYP2D6* gene is highly polymorphic, and many genetic variations (e.g. single nucleotide polymorphisms, gene insertions, gene deletions) are known to affect metabolism. However, discrepant findings pertaining to the effect of CKD on CYP2D6-mediated metabolism have been reported. Sparteine is a sodium-channel blocker and class 1a antiarrhythmic agent used as an *in vivo* probe of CYP2D6. It is metabolized by CYP2D6 into the metabolites 2-dehydrosparteine and 5-dehydrosparteine. Dextromethorphan is a widely used antitussive agent that has also been used as an *in vivo* probe of CYP2D6. It is metabolized by CYP2D6 into dextrorphan, an active metabolite. CYP2D6 activity was assessed in 12 CKD patients and 12 healthy controls by administering 100 mg of sparteine and 40 mg of dextromethorphan on separate days. The initial interpretation of the study suggested that CYP2D6 activity was not altered by kidney disease.[53] These data were subsequently reanalyzed using kinetic modeling, and the authors found that CYP2D6 activity was decreased in CKD.[54] There is other support for decreased CYP2D6 in kidney disease. Other studies evaluating the effect of kidney disease have assessed the pharmacokinetics of metoprolol and paroxetine, both drugs that are highly metabolized by CYP2D6.[55–57] These studies also show an increasing trend in plasma area under the curve, suggesting CYP2D6 activity is decreased. A more recent study investigated the effect of CKD and HD on nebivolol pharmacokinetics.[58] Nebivolol is a beta blocker supplied as a racemic mixture of the enantiomers d-nebivolol and l-nebivolol and is metabolized by CYP2D6-mediated hydroxylation and glucuronidation. The area under the curve of both nebivolol enantiomers is increased in CKD patients compared to controls, and this is accompanied by a decrease in the CL/F.[58] Interestingly, ESRD patients treated with HD have no change in AUC or CL/F compared to controls. Collectively, these data suggest that CYP2D6 activity is decreased in CKD and that HD restores CYP2D6 activity, potentially by removing uremic inhibitors of metabolism. The most convincing evidence of altered CYP2D6-mediated metabolism in CKD is from an FDA analysis that systematically and quantitatively evaluated the pharmacokinetics of numerous CYP2D6 substrates reported in CKD studies.[59] This work demonstrated a decrease in CYP2D6-mediated clearance and that drug clearance decreases as kidney disease progresses.

CYP2E1

CYP2E1 metabolizes less than 5% of the most highly prescribed drugs[13] but plays an important role in determining drug toxicity. Chlorzoxazone is a centrally acting muscle relaxant with sedative properties and is hydroxylated by CYP2E1 to form 6-hydroxychlorzoxazone. The formation clearance of 6-hydroxychlorzoxazone is commonly used as a marker of CYP2E1 metabolic activity. Chlorzoxazone was administered to patients with varying levels of kidney function to assess CYP2E1 activity.[60] There was no difference in 6-hydroxychlorzoxazone formation clearance between patients, indicating that CYP2E1 activity is not affected by CKD.

CYP3A4

CYP3A4, the most abundantly expressed human CYP, metabolizes between 30% and 50% of marketed drugs.[61] Similar to CYP2D6, the effect of CKD on CYP3A4 expression and activity is unclear. Although there are many preclinical studies that demonstrate CYP3A expression and activity are decreased in experimental models of CKD, the results of clinical pharmacokinetic studies in humans are less clear and highly variable.

The macrolide antibiotic drug erythromycin has been used extensively as a probe substrate to evaluate CYP3A4 activity *in vivo*. The erythromycin breath test was developed to facilitate a relatively noninvasive method to probe CYP3A4 activity in patients. In the erythromycin breath test, patients are given ^{14}C-erythromycin, which is demethylated by CYP3A4. The demethylated carbon then appears in the breath as $^{14}CO_2$, which was presumed to be a surrogate of CYP3A4 activity. Decreased $^{14}CO_2$ excretion in breath was interpreted as a decrease in CYP3A4 and conversely, increased breath $^{14}CO_2$ was interpreted as increased CYP3A4 activity. Multiple studies used this approach to study CYP3A4 activity in CKD patients.[62,63] $^{14}CO_2$ excretion was decreased by 28% in ESRD patients compared to controls, suggesting CYP3A4 activity is decreased in this population.[62] Interestingly, $^{14}CO_2$ excretion is increased by 27% immediately following HD, suggesting that HD acutely restores CYP3A4 activity.[63] Oral and intravenous pharmacokinetics of erythromycin was simultaneously assessed in control and ESRD patients. ESRD patients exhibited decreased hepatic clearance of erythromycin.[64] Collectively, findings of these studies were interpreted on the basis of

CYP3A4 alone, and all studies reported decreased CYP3A4 activity in kidney disease, based on the premise that erythromycin clearance is primarily mediated by CYP3A4.[62–64] It is now known that erythromycin is not a specific probe of CYP3A4. In fact, the drug exhibits overlapping substrate specificity, as it is a substrate of CYP3A4 as well as organic anion transporting polypeptides (OATPs) and P-glycoprotein (P-gp) transporters.[65,66] Therefore, although erythromycin pharmacokinetics is altered in CKD, it is unlikely to be due exclusively to altered CYP3A4-mediated metabolism.

Another widely used *in vivo* probe of CYP3A4 activity is the short-acting benzodiazepine midazolam. In contrast to erythromycin, midazolam is not a substrate for any uptake (e.g. OATP) or efflux (e.g. P-gp, BCRP) transporters. Plasma concentration time curves of midazolam and the CYP3A4-mediated metabolite 1-OH midazolam are nearly superimposable in ESRD and control patients after oral administration, with no differences in AUC or CL/F, suggesting that CYP3A4 is not altered in kidney disease.[67] However, in contrast to oral midazolam, ESRD patients treated with HD who received IV midazolam had a fivefold increase in AUC and a 65% decrease in clearance compared to control.[68] This difference was not observed in ESRD patients treated with peritoneal dialysis (PD). Although this study demonstrates decreased clearance of midazolam and suggests that hepatic CYP3A4 activity is decreased in CKD, it is surprising that midazolam half-life was not different between ESRD and control patients.

The complexity of the impact of CKD on nonrenal clearance has been highlighted by FDA investigators who assessed the impact of CKD on the systemic exposure of several new drugs.[69] Some CYP3A4 substrates required dosage adjustment in CKD while others did not.[69] For example, tadalafil is extensively metabolized by CYP3A4 and minimally eliminated by the kidney (fractional excretion <0.3%). ESRD patients taking tadalafil have a twofold increase in the maximal plasma concentration and a 2.7–4.1-fold increase in the AUC compared to controls. Accordingly, a reduction in dose is recommended for ESRD patients.[69] Solifenacin has a fractional excretion of 15% and is extensively metabolized by CYP3A4. In CKD, solifenacin maximal plasma concentration, AUC, and half-life are increased by 1.2-, 2.1-, and 1.6-fold, respectively, and dose reduction is recommended in CKD.[69] Conversely, alfuzosin and vardenafil are CYP3A4 substrates and are minimally excreted in the urine but demonstrate only modest increases in maximal plasma concentration and AUC. There are no recommendations for altered dosing for alfuzosin and vardenafil in CKD.[69] Further analysis of 18 different CYP3A4/5 model drugs in 24 different studies to evaluate the systemic and quantitative effect of CKD on CYP3A4/5 provided additional insight.[59] Although CYP2D6 model drugs demonstrate a consistent decrease in clearance in CKD patients, CYP3A4/5 model drugs exhibit variable responses, with no clear relationship between kidney function and changes in drug clearance. For the CYP3A4/5 model drugs that exhibited decreased clearance, the magnitude of change was modest.

Collectively, clinical pharmacokinetic studies in humans suggest that CYP3A4/5 may be modestly decreased or not changed in CKD patients. There does not appear to be consistency among model drug substrates, which likely points to some nonspecificity of probes (e.g. substrate of multiple CYPs or transporters) and the relatively minimal impact of CKD on hepatic CYP3A4.

Hepatic Reductases

Multiple drugs that undergo hepatic reduction exhibit altered pharmacokinetics in patients with kidney disease, suggesting that this pathway of nonrenal clearance involved. Two of the best-studied examples include the anthracyclines doxorubicin and idarubicin, which undergo hepatic reduction to doxorubicinol and idarubicinol, respectively. Following a 40–60 mg IV infusion of doxorubicin, HD patients had a 71% increase in AUC and a corresponding 41% decrease in total clearance compared to controls with normal kidney function.[70] The altered doxorubicin clearance was a result of decreased doxorubicinol formation. Doxorubicin is metabolized by the hepatic reductases CBR1 and AKR1C3, so the altered pharmacokinetics is likely a result of decreased activity of these hepatic reductases. Idarubicin pharmacokinetics was studied in patients with impaired kidney function following a single 12 mg/m^2 dose.[71] Patients with a creatinine clearance less than 60 mL/min had a 38% increase in idarubicin AUC and a 30% decrease in total clearance.

Ex vivo studies using cytosolic and microsomal fractions from cadaveric liver samples obtained from ESRD and control patients have investigated the effect of CKD on hepatic reductase expression and activity.[72] Western blotting demonstrated a 65% decreased protein expression of carbonyl reductase 1 in CKD livers, and a trend toward decreased mRNA expression was observed. These data may partially explain the altered pharmacokinetics of substrate drugs such as warfarin, doxorubicin, and idarubicin in CKD patients.

NAT2

Although less commonly studied, there is evidence for altered phase II drug-metabolizing enzymes such as NAT2 in patients with kidney disease. The

prototypical probe drug for NAT2 activity *in vivo* is isoniazid, an antibacterial agent used to treat tuberculosis. Isoniazid is most commonly used to classify patients as rapid or slow acetylators based on their NAT2 genotype. NAT2 activity was determined in rapid and slow acetylator ESRD patients prior to and following kidney transplantation.[73] The nonrenal clearance of isoniazid improved by over 50% in rapid acetylators and 225% in slow acetylators following kidney transplantation. This suggests that NAT2 activity is decreased in kidney disease and that restoration of kidney function by transplantation improves NAT2 activity. A similar finding of decreased NAT2-mediated activity was found in CKD patients using the NAT substrate procainamide.[74]

UGTs

Morphine and other opioid analgesics undergo extensive glucuronidation with some of the resultant glucuronide metabolites lacking pharmacological activity (e.g. morphine 3-glucuronide), whereas others are pharmacologically active (e.g. morphine 6-glucuronide). Morphine pharmacokinetics are substantially altered in patients with CKD, as they have a significantly increased AUC and decreased clearance following standard dosing, compared to control subjects with normal kidney function.[75] Morphine is metabolized by UGT1A3 and UGT2B7. The increased AUC and decreased clearance suggest the activity of these enzymes may be impaired in CKD. Other drugs that are extensively metabolized *via* glucuronidation such as the NSAID diacerein[76] and the nucleoside reverse transcriptase inhibitor zidovudine[77] exhibit decreased nonrenal clearance in patients with CKD, supporting a decrease in UGT-mediated metabolism in kidney disease.

DRUG TRANSPORT IN PRECLINICAL MODELS OF CKD

Although the impact of drug metabolism to overall drug disposition has been known for decades, it was only recently that the importance of drug transporters to drug disposition and pharmacokinetics has been appreciated. Accordingly, our understanding of the impact of CKD on drug transporters has lagged behind that of drug-metabolizing enzymes.

The subtotal 5/6 nephrectomy used to study the impact of CKD on drug metabolism has also been employed to study drug transporters. Starting in the late 2000s, Naud, Leblond, Pichette, and colleagues used the 5/6 nephrectomy model to study the impact of CKD on transporter expression and activity.[45,78–80] At the level of the intestine, transporters play an essential role in determining the oral bioavailability of substrate drugs, with uptake transporters enhancing oral bioavailability and efflux transporters restricting drug absorption (Figure 63.3). Rats with experimental CKD (5/6 nephrectomy) had 65%, 60%, and 35% reductions in the intestinal protein expression of the efflux transporters P-gp, multidrug resistance–associated protein 2 (MRP2), and MRP3, respectively.[79] Surprisingly, the mRNA expression of these transporters was not different between CKD and control animals. Transport activity of P-gp and MRP2 transporters were assessed using everted gut sacs and the probe substrates rhodamine 123 for P-gp and 5-(and 6-) carboxy 2′,7′dichlorofluorescein for MRP2. CKD rats had a 30% reduction in P-gp activity and a 23% reduction in MRP2 activity compared to control. There were no significant differences in the expression of the uptake transporters Oatp2 or Oatp3. An additional study evaluated the effect of CKD in rats subjected to 5/6 nephrectomy. The investigators found no change in the mRNA expression of intestinal efflux transporters, but they were unable to assess protein expression or activity.[81] The likely implications of downregulated protein expression of P-gp, MRP2, and MRP3 in the setting of CKD is an increased bioavailability of substrate drugs.

Hepatic uptake and efflux transporters have also been evaluated in rats with CKD and sham control animals.[80] Protein expression of the uptake transporter Oatp2 was downregulated by 35% in CKD animals compared to control with no change in the mRNA expression. In contrast to intestinal efflux transporters, hepatic P-gp protein and mRNA expression were upregulated by 25% and 50%, respectively. Injection of the P-gp probe rhodamine 123 revealed an approximately 50% increased biliary clearance, which supports a functional increase in hepatic P-gp activity in CKD. Although surprising that CKD appears to cause opposite effects in terms of P-gp activity in intestine compared to liver, a recent study has shed light on these seemingly contrasting findings. Using a human hepatoma cell line (HepG2) and both the adenine and 5/6 nephrectomy models of CKD in mice, Machado and colleagues demonstrated that the uremic toxin indoxyl sulfate upregulates P-gp in the liver by acting as a ligand for the aryl hydrocarbon receptor (AhR).[82] Indoxyl sulfate is a gut-derived uremic toxin made from indole synthesized from gut bacteria. Although indole is made in the gut, it is oxidized and sulfated in the liver, potentially explaining hepatic P-gp specific upregulation.

Further studies have evaluated the effect of 5/6 nephrectomy in rats on kidney and brain transporters. Transporters expressed on the apical and basolateral membranes of kidney tubule cells have a profound impact on the secretion and reabsorption of drugs

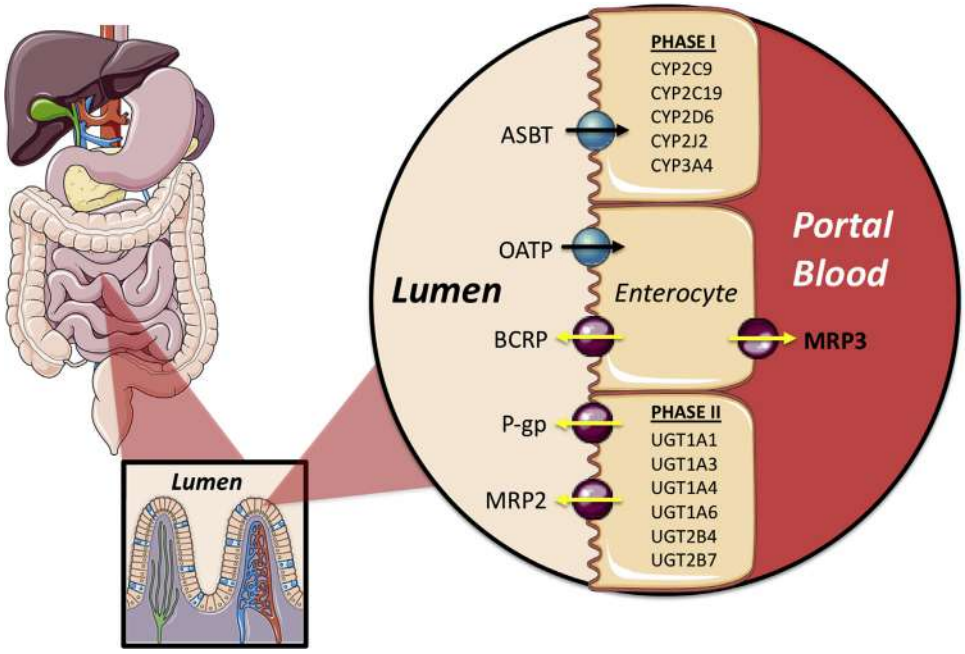

FIGURE 63.3 **Intestinal drug metabolism and transport pathways.** The majority of orally administered drugs are absorbed in the proximal intestine (duodenum and jejunum). These intestinal regions contain microvilli that increase the surface area for absorption. The apical membrane of intestinal enterocytes face the lumen of the intestine and have high expression of both uptake (*blue spheres*) and efflux (*purple spheres*) transporters. Enterocytes also express phase I and II drug-metabolizing enzymes and transporters on the basolateral membrane. Representative transporters and enzymes are shown for reference, note this is not a complete list. *Images used to generate this figure were modified from Servier Medical Art, licensed under Creative Commons Attribution 3.0 Generic License, http://smart.servier.com/.*

(Figure 63.4). In CKD rats the protein expression of several uptake transporters is downregulated, including organic anion transporter 1 (Oat1), Oat2, Oat3, organic anion transporting polypeptide (Oatp) 1, and Oatp4c1.[45] In contrast, Oatp2 and Oatp3 have increased protein expression in CKD. Efflux transporters Mrp2, Mrp3, and Mrp4 have increased protein expression in CKD. P-gp protein expression is downregulated in CKD kidneys. To assess the functional implication of CKD on transporter activity, ^{14}C-benzylpenicillin was used as a probe of Oat and Mrp transporters and ^{3}H-digoxin was used as a probe of Oatp4c1 and P-gp. The kidney/plasma ratio of ^{14}C-benzylpenicillin and ^{3}H-digoxin were increased nine-fold and four-fold, respectively, in CKD animals compared to control animals. These data suggest that CKD causes a reduction in transporter-mediated drug elimination and renal drug accumulation, which could further exacerbate kidney damage.

Endothelial cells at the blood–brain barrier help restrict drug entry into the brain. In CKD rats the protein expression of many blood–brain barrier transporters is reduced, including breast cancer resistance protein (Abcg2), Mrp2, Mrp4, P-gp, Oat3, Oatp2, and Oatp3.[78] ^{14}C-Benzylpenicillin, ^{3}H-digoxin, ^{14}C-doxorubicin, and ^{3}H-verapamil were used to assess the impact of CKD on transporter function. Surprisingly, the brain to plasma ratio was not different for ^{3}H-digoxin, ^{14}C-doxorubicin, and ^{3}H-verapamil, but it was decreased by 30% for ^{14}C-benzylpenicillin. These data suggest that a large fraction of blood–brain barrier integrity is preserved in CKD, despite significant reduction in the expression of many transporters.

DRUG TRANSPORT IN HUMANS WITH CKD

Drug transport in CKD is studied using similar approaches to drug metabolism. The pharmacokinetics of substrate drugs are evaluated, in particular the AUC and nonrenal clearance. Recent evidence suggests that several drug transporter substrates have altered pharmacokinetics in patients with kidney disease. Delineating the specific drug transporters that are affected in CKD has been difficult as many of the commonly used probe drugs are substrates of multiple transporters, and some are also metabolized.

The most consistent finding of altered drug transporter activity *in vivo* in CKD patients has been demonstrated using the transporter probe fexofenadine. Fexofenadine is useful for studying drug transporter activity in CKD because it is minimally metabolized and

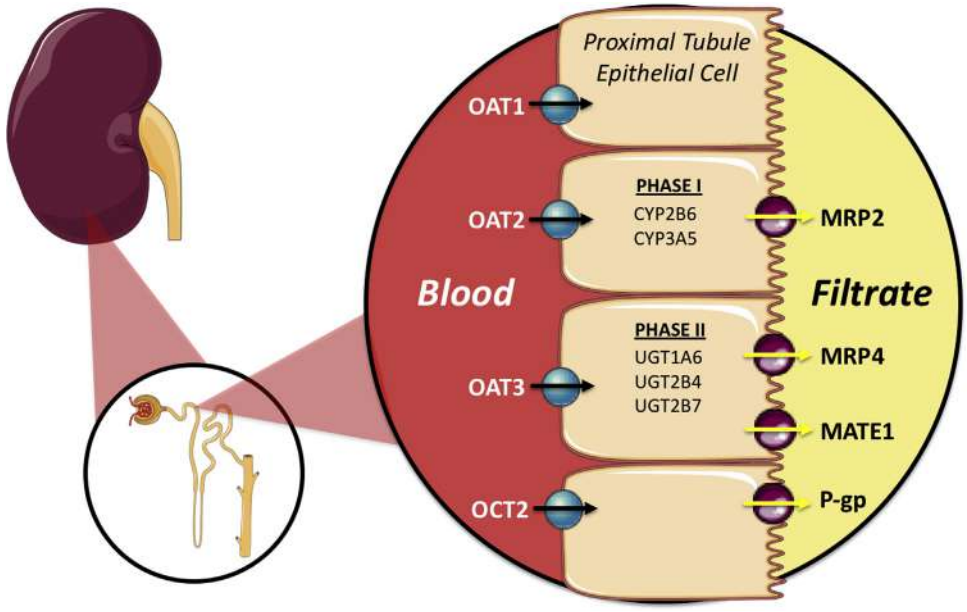

FIGURE 63.4 Kidney drug metabolism and transport pathways. The nephron is commonly thought of as the primary functional unit of the kidney. Although drug metabolism and transporter functions can be found at many regions of the nephron, the most commonly studied region are the proximal tubule cells. Uptake transporters (*blue spheres*) expressed on the basolateral membrane of proximal tubule cells carry drugs from the blood into the tubule cell. The tubule cells express several phase I (e.g. CYP) and phase II drug-metabolizing enzymes that may metabolize drugs. The apical membrane of proximal tubule cells expresses several efflux transporters (*purple spheres*) that move drugs from the tubule cell to the urinary filtrate in the lumen of the nephron to facilitate renal drug excretion. Although not shown here, there are also uptake transporters expressed at the apical membrane of proximal tubule cells that mediate drug uptake. Representative transporters and enzymes are shown for reference, note this is not a complete list. *Images used to generate this figure were modified from Servier Medical Art, licensed under Creative Commons Attribution 3.0 Generic License, http://smart.servier.com/.*

minimally excreted in the urine. Unfortunately, fexofenadine is transported by multiple uptake (e.g. OATP1B1, OATP1B3, OATP2B1) and efflux (P-gp, MRP2, MRP3) transporters, making the link between altered activity and an individual transporter very difficult to establish. Fexofenadine (120 mg oral dose) was administered to healthy controls and ESRD patients treated with maintenance HD.[67] The ESRD patients had a 2.8-fold increase in the AUC and a 63% reduction in clearance. In a similar study design, patients with biopsy-proven glomerulonephritis (systemic lupus erythematosus nephritis or small vessel vasculitis) were given 60 mg of fexofenadine.[83] The oral clearance of fexofenadine in glomerulonephritis patients was reduced by 40% compared to healthy controls. In a third study, patients with moderate to severe CKD (mean eGFR = 17 mL/min/1.73 m^2) and patients with ESRD treated by HD and PD were given 120 mg of fexofenadine.[68] The AUC in CKD, HD, and PD patients was increased by 2.9-, 2.3-, and 2.1-fold with a corresponding 61%, 56%, and 49% decrease in CL/F. Collectively, these three studies provide very strong evidence that transporter activity is altered in CKD.

Similar to fexofenadine, the HMG CoA reductase inhibitor rosuvastatin is minimally excreted in the urine (fractional excretion less than 6%) and has negligible hepatic metabolism. In addition, rosuvastatin is a substrate of multiple uptake (OATP1B1, OATP1B3, OATP2B1, OATP1A2, NTCP) and efflux (P-gp, BCRP, MRP2) transporters. Rosuvastatin plasma concentrations in patients with CKD (creatinine clearance less than 30 mL/min) are threefold higher than controls with normal kidney function, and steady state plasma concentrations are 50% higher in ESRD patients on maintenance HD.[69] Recommendations suggest that the dose of rosuvastatin in kidney disease patients should be decreased (start at 5 mg and not exceed 10 mg). Although it is difficult to delineate the pathway responsible for the altered rosuvastatin pharmacokinetics, it appears likely that OATP transporter activity is decreased in CKD, resulting in an increased accumulation of the drug in the plasma.

FDA investigators presented further evidence that OATP transporter function is impaired in humans with kidney disease[84] by evaluating 20 CKD studies of 12 different OATP substrate drugs with a fractional excretion less than 33%. The drugs included atorvastatin, bosentan, cerivastatin, erythromycin, fluvastatin, imatinib, pitavastatin, repaglinide, rosuvastatin, and torsemide. The ratio of clearance in CKD patients (mild, moderate, severe, and ESRD) to clearance in healthy controls for both total (free + protein bound) and free

drug demonstrated a clear trend of decreasing OATP substrate clearance as kidney disease progresses. Although none of the drugs are "pure" OATP substrates (they all are substrates of other transporters and/or drug-metabolizing enzymes), this clear relationship over a large number of drugs strongly suggests OATP mediated clearance is decreased in kidney disease.

MECHANISMS OF ALTERED DRUG METABOLISM AND TRANSPORT IN CKD

The mechanisms of altered drug metabolism and transport in CKD patients are somewhat controversial. Findings from preclinical models of CKD and human pharmacokinetic studies clearly indicate that kidney disease causes altered drug metabolism and transport in addition to the predictable decreases in renal excretion. The majority of reports suggest that molecules normally excreted by the functioning kidney, which are retained in CKD (uremic toxins), either 1) directly inhibit drug metabolizing enzymes and/or transporters or 2) cause up- or downregulation of expression through modification of transcriptional/translational processes. The uremic toxin hypothesis has been extensively reviewed.[14]

Direct Inhibition of Drug-Metabolizing Enzymes and Transporters

The first mechanism hypothesized for altered drug metabolism and transport in CKD is that uremic mediators directly inhibit drug metabolizing enzymes and/or transporters. For example, when microsomes from non-CKD subjects were incubated with plasma from ESRD patients, CYP2C9-mediated tolbutamide metabolism decreased by 37% and CYP3A4 midazolam metabolism decreased by 80%.[85]

Altered erythromycin pharmacokinetics have been observed in multiple human studies, and it is now well appreciated that erythromycin is a substrate of several transporters and the drug-metabolizing enzyme CYP3A4.[62,64,67] The effect of uremic toxins on erythromycin transport and metabolism was evaluated using rat hepatocytes and microsomes.[86] After incubation of multiple uremic toxins, 3-carboxy-4-methyl-5-propyl-2-furan-propanoic acid (CMPF) was demonstrated to inhibit the OATP-mediated uptake of erythromycin into hepatocytes, whereas indoxyl sulfate was shown to inhibit its CYP3A-mediated metabolism. Further evidence for the direct inhibition hypothesis comes from a human study evaluating erythromycin disposition before and after HD.[63] An improvement in erythromycin disposition (i.e. improved metabolism and/or transport) following HD was determined using the erythromycin breath test. As this was an acute study, it is likely that dialyzable uremic toxins removed during HD mediated this increase in metabolism and/or transport.

The effect of uremic toxins on OATP-mediated transport was further studied by transfecting human embryonic kidney cells (HEK293) with OATP1B1, OATP1B3, and OATP2B1.[87] The cells were then incubated with various uremic toxins and the cellular uptake of the OATP probe ^{3}H-estrone sulfate was evaluated. Uremic toxins had a profound effect on OATP-mediated transport. OATP1B1 was inhibited by indoxyl sulfate, CMPF, endothelin, quinolinic acid, indole-3-acetic acid, p-cresol, and homocysteine, whereas OATP1B3 was inhibited by indoxyl sulfate, CMPF, and p-cresol. Finally, OATP2B1 was inhibited only by CMPF. It should be noted that p-cresol is sometimes indirectly quantified as a by-product of p-cresyl sulfate, which is now known to be the circulating uremic toxin found in patients with kidney disease.

Altered Expression of Drug-Metabolizing Enzymes and Transporters

Although human pharmacokinetic studies make it difficult to determine altered expression of drug metabolism and transport in CKD, animal studies and experiments using *in vitro* cell culture techniques make it possible to interrogate mechanisms. Studies in animal models of CKD consistently demonstrate that CKD causes a decrease in enzyme and transporter mRNA and protein expression, which strongly suggests a transcriptional/translational mechanism. Several studies have taken these observations further in an attempt to delineate the mechanism. Using the 5/6 nephrectomy, chromatin immunoprecipitation (ChIP) was performed to evaluate transcription factor binding to the promoter region of the Cyp2c11 and Cyp3a2 genes in control and CKD rats.[88] Binding of RNA polymerase II to the Cyp2c11 and Cyp3a2 promoters was significantly decreased in CKD compared to controls, confirming that downregulation of these enzymes in preclinical models is mediated by decreased transcription. Further analysis demonstrated that the binding of transcription factors PXR and HNF4α to the promoter of Cyp2c11 (HNF4α) and Cyp3a2 (PXR and HNF4α) are decreased in CKD compared to controls. These nuclear receptors are primary determinants of CYP expression. The studies also indicated that CKD was associated with decreased histone acetylation, suggesting CKD induces epigenetic changes that may mediate altered expression.

Parathyroid hormone (PTH) has been proposed to be a uremic toxin that mediates the decreased expression of hepatic Cyp3a in rats with CKD. Studies that incubated

rat hepatocytes with human serum from CKD patients and healthy controls demonstrated that CKD serum downregulated the expression and activity of Cyp3a. When serum was fractionated, it was the fraction with a molecular weight between 10–15 kDa that mediated this decrease.[37] In a follow-up study, parathyroidectomy was shown to reverse the CKD-mediated decrease in Cyp3a expression and activity. Incubation with PTH dose dependently decreased Cyp3a expression in cultured rat hepatocytes.[36] Uremic mediators that downregulate CYP expression and activity appear to be dialyzable.[35] Rat hepatocytes incubated with serum obtained predialysis caused a 27% and 35% decrease in Cyp2c and Cyp3a protein expression, respectively. Serum obtained postdialysis had no effect on CYP expression.

OTHER CONSIDERATIONS IN KIDNEY DISEASE PATIENTS

Although alterations in drug metabolism and transport must be considered when prescribing drugs to patients with kidney disease, renal replacement therapy adds further complexity. The impact of dialytic clearance on plasma concentrations and, consequently, renal drug dosing must be considered. Dialytic clearance can be substantially different from renal clearance and is predominantly determined by the molecular weight, volume of distribution and protein binding of the drug, the type of dialysis membrane, and blood/dialysate flow rates.[21] There is a paucity of information currently, with data on drug dialyzability with measured clearance available for only about 10% of marketed drugs.[21] In addition, much of the information available is determined using the suboptimal arterial-venous (AV) difference method, which is known to overestimate clearance.[89]

Treating physicians can often select multiple drugs within the same class, and little information is available to determine which drug is most suitable in dialysis patients. Significant differences in drug dialyzability may exist, even among drugs within the same class.[12] For instance, atenolol and metoprolol are extensively cleared during HD, bisoprolol is moderately cleared, and the clearance of carvedilol is negligible.[12]

SUMMARY

Patients with kidney disease are prescribed numerous medications and commonly receive treatment with drugs that are predominantly cleared by nonrenal pathways. The nonrenal clearance of many drugs is altered in patients with impaired kidney function, often translating into clinically relevant changes in systemic exposure (see Table 63.1). This in turn may change the efficacy and adverse effect profile in patients if the drug dose is not adjusted. Although the precise mechanism of changes in nonrenal clearance pathways is unclear, selective modulation of activity and expression of drug-metabolizing enzymes and transport proteins has been implicated. Transcriptional, translational, and posttranslational modification, perhaps induced by uremic toxins, may play a role. Clinicians are encouraged to consider the impact of kidney disease on all aspects of safety and efficacy during the drug selection process. Although these data are limited currently, the US FDA now recommends that clinical studies be conducted for investigational compounds eliminated primarily *via* nonrenal pathways as well as those eliminated predominantly unchanged in the urine. Eventually this will generate improved data related to the impact of kidney disease on drug dosing requirements and will improve efficacy and safety in one of the most vulnerable patient populations.

QUESTIONS AND ANSWERS

Question 1

A new drug for the treatment of hypertension is being tested in patients with CKD. It is an OATP1B1 substrate and has a fractional excretion <5%. Which of the following pharmacokinetic changes are most likely to be observed in a CKD patient compared to a control?

A. An increase in the AUC and CL/F
B. A decrease in the AUC and CL/F
C. An increase in the AUC and a decrease in the CL/F
D. A decrease in the AUC and an increase in the CL/F
E. An increase in the AUC and a decrease in the half-life

Answer: C

Hepatic OATP function is decreased in CKD. The result of decreased OATP activity is a decrease uptake of the drug into the liver, which will result in an increase in the AUC. As the drug has a very low fractional excretion, its excretion is mediated by nonrenal clearance mechanisms. The decreased OATP function will in turn result in a decrease oral clearance (CL/F) as CL/F = dose*F/AUC.

Question 2

Morphine is administered to a patient with CKD with no consideration of the impact of the patient's decreased kidney function. Which of the following is the most likely outcome?

A. The patient may experience an increased analgesic response to morphine and may also experience respiratory depression
B. The patient may have a blunted analgesic response to morphine
C. The plasma levels and AUC for morphine may be decreased compared to a patient with normal kidney function
D. The patient may need more frequent administration of morphine for analgesia
E. Increased drug transporter expression at the blood–brain barrier may restrict the entry of morphine to the brain, decreasing the analgesic response.

Answer: A

Morphine is cleared primarily by glucuronidation with a small fraction cleared unchanged in the urine. Morphine pharmacokinetics are substantially altered in kidney disease with an increased AUC and decreased CL. In addition, some morphine metabolites (e.g. morphine 6-glucuronide) have activity at opioid receptors and are renally cleared. A CKD patient that receives morphine without careful consideration of disease stage may have increased therapeutic response (analgesia) but may also be susceptible to side effects such as respiratory depression.

Question 3

Which of following statements most accurately reflects CYP3A4 activity in CKD?

A. CYP3A4 activity is markedly reduced in CKD
B. CYP3A4 activity is significantly increased in CKD
C. Increased erythromycin AUC and decreased CL/F in CKD patients indicates decreased CYP3A4 activity
D. Only select CYP3A4 substrates exhibit decreased clearance in CKD and the magnitude of change is modest
E. Vardenafil AUC is substantially increased in CKD and dose adjustment is required

Answer: D

Although studies in preclinical animal models of CKD consistently demonstrate decreased activity, clinical pharmacokinetic studies are much more variable. Although CYP3A4 substrates such as erythromycin have an increased AUC and decreased CL/F, it is unclear what role changes in drug transporter activity have on mediating the decreased clearance. The best currently available evidence suggests that only some CYP3A4 substrates have decreased clearance in CKD and the magnitude of decrease for these substrates is only modest.

Question 4

Which of the following best describes the impact of CKD on P-gp expression and activity using preclinical models?

A. Intestinal and hepatic P-gp expression and activity are increased
B. Intestinal and hepatic P-gp expression and activity are decreased
C. Intestinal P-gp expression and activity are decreased whereas hepatic P-gp expression and activity are increased
D. Intestinal P-gp expression and activity are increased whereas hepatic P-gp expression and activity are decreased
E. There is no change of intestinal or hepatic P-gp expression and activity in CKD

Answer: C

Intestinal P-gp expression is decreased in preclinical models of CKD. Studies demonstrate that this decreased expression results in a decrease in substrate (rhodamine 123) transport. Conversely, hepatic P-gp expression is

increased in preclinical models of CKD. These animals have increased biliary clearance of the P-gp substrate rhodamine 123. The opposite effects in intestine and liver may be mediated by the uremic toxin and AhR ligand indoxyl sulfate. Indoxyl sulfate is generated in the liver from indole. Accordingly, intestinal exposure is expected to be minimal in relation to hepatic.

Question 5

Substrates of which CYP enzyme most consistently exhibit decreased clearance as kidney disease progresses?

A. CYP2C19
B. CYP2D6
C. CYP2E1
D. CYP3A4
E. CYP1A2

Answer: B

Clearance of CYP1A2, CYP2C19, and CYP2E1 substrates do not appear to be decreased in CKD. Although some CYP3A4 substrates exhibit decreased clearance, others do not. There is no clear relationship between clearance and kidney disease stage. The CYP enzyme that most consistently exhibits decreased clearance is CYP2D6. In addition, there is a clear relationship between kidney disease stage and clearance for multiple CYP2D6 substrate drugs.

Question 6

Which of the following best explains the increased AUC and decreased CL of doxorubicin in patients with CKD?

A. Decreased CYP2D6-mediated metabolism in CKD
B. Decreased NAT2 activity in CKD
C. Decreased UGT2B7 activity in CKD
D. Decreased CYP3A4 activity in CKD
E. Decreased CBR1 activity in CKD

Answer: E

Doxorubicin does not undergo substantial metabolism by any CYP enzymes. Hepatic reduction by CBR1 and AKR1C3 are the primary metabolic pathways responsible for reducing doxorubicin into doxorubicinol. CBR1 expression is decreased in CKD, and this most likely causes the increased AUC and decreased clearance observed in patients.

CHAPTER

64

Use of Diuretics in Chronic Kidney Disease Patients

Arthur Greenberg

Division of Nephrology, Department of Medicine, Duke University Medical Center, Durham, NC, United States

Abstract

Diuretics are commonly prescribed to treat the sodium retention, volume expansion, and hypertension characteristic of chronic kidney disease (CKD). With reduced renal function, delivery of the drugs to their renal tubular sites of action is impaired, potentially leading to diminished potency. In addition, reduced glomerular filtration rate and alterations in sodium transport at other tubular sites can reduce the natriuretic effect of delivered drug. To use diuretics effectively in CKD, clinicians must understand these changes in diuretic pharmacokinetics and pharmacodynamics. This chapter reviews the sites and mechanisms of action of diuretics, describes how diuretic pharmacologic characteristics are affected by CKD, and details how best to overcome diuretic resistance. Much of the focus is on the loop agents, which are the most potent class of diuretics and the mainstay of treatment in CKD patients. As increasing attention is being paid to the role of thiazides and mineralocorticoid antagonists, the use of other classes of diuretics is also covered, as is the use of diuretics to treat specific subsets of CKD patients.

INTRODUCTION

The natriuretic diuretics interfere with renal tubular reabsorption of sodium, leading to loss of sodium and other solutes. This effect is beneficial in circumstances characterized by sodium accumulation with an attendant increase in total body sodium and extracellular volume. Chronic kidney disease (CKD) is one such state, and diuretics are an important therapeutic tool in CKD for treatment of volume overload, edema, and hypertension.

The delivery of diuretics to the sites at which they work and their pharmacodynamics and pharmacokinetics, relative potency, and clinical effects and utility are markedly affected by changes in renal function. A detailed understanding of the mechanism of action of diuretics is necessary to anticipate the changes in their activity in CKD and employ them effectively.[1,2] Most of this discussion focuses on the potent loop diuretics, which are the mainstay of therapy for patients with reduced renal function.

SITE AND MECHANISM OF ACTION OF DIURETICS

Diuretics act from the luminal side of the renal tubule by binding to a solute transporter or, in the case of the carbonic anhydrase inhibitors, an enzyme that indirectly promotes sodium reabsorption. Exceptions to this rule are the mineralocorticoid receptor antagonists (MRAs), which reach the nuclear aldosterone receptor from the basolateral side of collecting duct cells. Glomerular filtration of diuretics is negligible because they are highly protein bound. Acetazolamide, the loop agents, and the thiazides are weak organic anions that are secreted into the proximal tubular lumen *via* the organic acid secretory pathway in the proximal tubule. Weak acids, amiloride, and triamterene, are secreted *via* the organic base pathway. Once they reach the proximal tubular lumen, diuretics move downstream in the glomerular filtrate to their specific site of action. On binding to their receptors, diuretics block transport of sodium and accompanying anions or cations at that site (Table 64.1).

Diuretics vary in potency, which depends on the fraction of filtered sodium reabsorbed at the site where the diuretic inhibits transport, sodium delivery to the inhibited site, and the potential for sodium reabsorption distal to the site. For example, the proximal tubule diuretics have limited ability to increase overall renal sodium excretion. Although treatment with acetazolamide may cause an increase of up to 8% in sodium delivered

TABLE 64.1 Sites of Action of Diuretic Drugs

Drug Class	Agents	Site of Action	Maximal FE Na	Transport Site	Other
Carbonic anhydrase inhibitors	Acetazolamide	Proximal tubule	5–8%	Carbonic anhydrase, lumen, and proximal tubular cell	
Loop agents	Furosemide Bumetanide Torsemide	Thick ascending limb loop of Henle	15–20%	NKCC2	
Thiazides	Hydrochlorothiazide Chlorthalidone Chlorothiazide Numerous others	Distal convoluted tubule	10–15%	NCCT NaCl cotransporter	
ENaC blockers	Amiloride Triamterene	Collecting duct	3–5%	ENaC	
Mineralocorticoid receptor antagonists	Spironolactone Eplerenone	Collecting duct	3–5%	ENaC	Also block effect of aldosterone to stimulate basolateral Na/K ATPase

ENaC, epithelial sodium channel; *FE Na*, fractional excretion of sodium; *NCCT*, sodium chloride cotransporter; *Na/K ATPase*, sodium-potassium adenosine triphosphatase; *NKCC2*, sodium-potassium-2-chloride cotransporter.

out of the proximal tubule, distal segments of the nephron, including especially the loop of Henle and the distal convoluted tubule, can easily reabsorb the increased sodium load with which they are presented. Little net increase in sodium excretion results. In contrast, the loop agents block the Na-K-2Cl (NKCC2) transporter responsible for the reabsorption of up to 20% of the filtered sodium load, an amount that cannot ordinarily be reabsorbed at more distal sites in its entirety. The operative word here is ordinarily.

PHARMACOKINETICS

The pharmacokinetics of diuretics in health and various disease states have been extensively reviewed.[3,4] The pharmacokinetics of the loop agents in patients with normal renal function and in individuals with reduced glomerular filtration rate (GFR) are shown in Tables 64.2 and 64.3.[5–8] The bioavailability of orally administered furosemide is approximately 50%, compared with 80% for bumetanide and torsemide. However, the reported values vary widely. When switching from intravenous (IV) to oral furosemide, a doubling of the dose is a reasonable starting point for achieving a similar effect. No change in initial dose and less expected variability apply to bumetanide and torsemide. Just as results of bioavailability studies vary, so do reported diuretic renal and nonrenal clearances, protein binding, volume of distribution, and overall pharmacokinetics.[3,4,9–15] Any dosing recommendations based on pharmacokinetics should be employed with circumspection, and clinicians should anticipate the need to follow the clinical response closely and titrate the dose accordingly.

The presence of reduced renal function alters the relative potency of the three commonly used loop agents. For each drug, absolute renal excretion and hence delivery to its site of action diminishes as renal function declines. Factors that may contribute to diminished delivery include reduced GFR, reduced renal blood flow, diminished protein binding with increased apparent volume of distribution, and competition with other organic acids for tubular secretion.[4,16,17] Changed metabolism of diuretics also contributes to diminished delivery. The kidney is not the sole route of excretion of diuretics. Nonrenal excretion of bumetanide and torsemide *via* the liver is unaffected by changes in renal function. Nonrenal excretion of furosemide, in contrast, occurs *via* glucuronidation, which is accomplished in the kidney and diminished when renal function is reduced. With relatively preserved nonrenal elimination, excretion of bumetanide and torsemide is in effect shunted away from the kidney. As shown in Table 64.2, with normal renal function, roughly equivalent fractions of administered furosemide or bumetanide are excreted *via* the kidney (~60%), the site of action of these drugs. With impaired renal function (Table 64.3), the absolute fraction of all three drugs excreted by the kidneys is reduced compared with normal, but the reduction for furosemide is less. The fraction of furosemide excreted by the kidneys (9%) is approximately twice that of bumetanide (5%). Thus, the relative potency of bumetanide especially and torsemide compared with furosemide is reduced in patients with impaired kidney function.

Diuretic binding to protein falls as renal function worsens, likely due to displacement by other accumulated anions. With hypoalbuminemia, as in nephrotic syndrome, protein binding is diminished and the volume of distribution of diuretics increases, further reducing delivery.[13,17,18] In animal studies, mixing albumin with furosemide before administration reverses some of the resistance.[19] Furosemide may bind to

luminal albumin present due to proteinuria. Inhibition of binding of furosemide to luminal albumin by a competitive inhibitor like warfarin augmented the diuretic effect observed during *in vivo* renal tubular perfusion.[20] Studies in humans with hypoalbuminemia or nephrotic syndrome have not shown a pharmacokinetic benefit of coadministration of furosemide and albumin. However, the favorable hemodynamic effect of albumin infusion can increase sodium excretion with submaximal but not maximal doses of furosemide.[21–23] Inhibition of intraluminal furosemide binding to albumin by warfarin does not result in a significant augmentation of natriuresis in the clinical setting.[24]

PHARMACODYNAMICS

The standard way to assess the ability of a diuretic to increase urinary sodium excretion is to relate sodium excretion to urinary diuretic excretion, because the latter is a direct measure of the amount of diuretic reaching its luminal site of action. As loop diuretics bind to the electroneutral NKCC2 Na-K-2Cl cotransporter in the thick ascending limb of the loop of Henle which cotransports a sodium ion, a potassium ion, and two chloride ions across the luminal membrane, one would predict that a plot of sodium excretion as a function of diuretic excretion (Figure 64.1) would be a sigmoid curve. At low excretion rates, few diuretic receptors are occupied by bound drug and inhibited, so sodium excretion is little increased. At high diuretic excretion rates, all receptors are already saturated and increasing diuretic excretion further has little additional effect. In between, the slope of the change in sodium excretion as a function of diuretic excretion or delivery is steep.

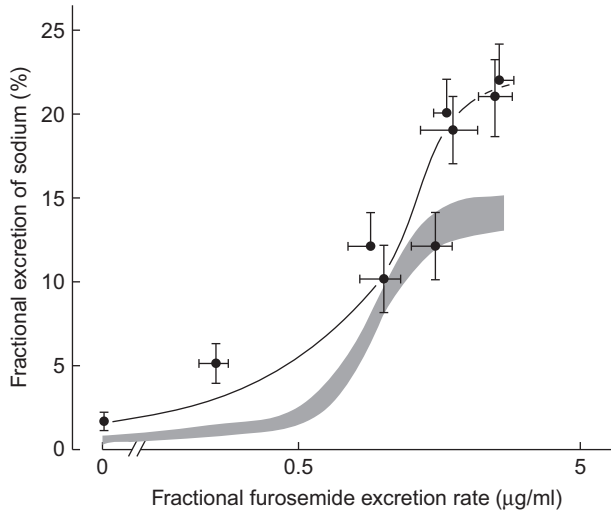

FIGURE 64.1 Relationship between fractional delivery of furosemide into urine and fractional excretion of sodium after a 2-hour furosemide infusion. Mean (±S.E.M.). Data are shown as *symbols with brackets* for patients with impaired kidney function and a *shaded curve* for normal individuals. *Reproduced with permission from reference 25.*

When expressed as fractional excretion of sodium, the response to furosemide in patients with impaired kidney function is augmented compared with normal individuals.[25] At any given rate of furosemide excretion, the fractional excretion of sodium is higher in patients with reduced GFR (Figure 64.1). This is likely a function of the adaptive mechanism for reduced GFR. To excrete the same daily load of ingested sodium, the fractional sodium excretion must be higher with reduced GFR. The curve in Figure 64.1 also provides a basis for the notion of a ceiling dose of loop diuretic. Administration of additional furosemide beyond the amount needed to reach the plateau of the sigmoid curve would not produce any additional benefit. In patients with normal renal function, the doses of loop agents required to reach maximal sodium excretion are furosemide 40 mg, bumetanide 1 mg, and torsemide 15–20 mg, hence the standard doses for these agents. With advanced renal functional impairment, only 9% of furosemide is excreted by the kidney, compared with 60% with normal renal function. The ceiling dose would therefore be expected to be five- or six-fold higher, i.e. approximately 200 mg.[25] The dose actually noted to reach saturation in the study shown in Figure 64.1 was 160 mg. Using a slightly higher value for clinical purposes leads to reasonable limits for ceiling doses of loop agents with reduced GFR in the range of 160–240 mg for furosemide, 6–10 mg for bumetanide, and 100–200 mg for torsemide.[2,6,7,26] No advantage would be expected from higher doses, although the risk of toxicity would be higher. Note the difference in equivalency ratio for impaired renal function for furosemide, bumetanide, and torsemide (20:1:20) compared with normal renal function (40:1:10–20)[6,7,27] Relative to furosemide, the potency of bumetanide especially and torsemide to some degree are diminished in patients with impaired kidney function.

DIURETIC BRAKING, TOLERANCE, AND RESISTANCE

The diuretic and natriuretic effect of a diuretic drug may decrease after the first dose and diminish further over time. Some authors reserve the term "braking" to describe the reduction in response to a diuretic that occurs after the first dose.[1,28] The principal cause is the acute reduction in intravascular volume with compensatory activation of a number of effectors including the renin–angiotensin–aldosterone system and the sympathetic nervous system, which together can reduce GFR

or alter the physical factors responsible for proximal tubular sodium and fluid reabsorption. As shown in a series of elegant studies by Wilcox et al., increased activity of these neurohumoral systems is not solely responsible for diuretic braking, because treatment with captopril and the α-adrenergic blocker prazosin does not abrogate its development.[29] A second cause of reduced diuretic efficacy is tolerance, a term used by many authors to refer to the reduction in diuretic effect seen with chronic use that develops in most patients.[1] Others employ the term tolerance to describe the first dose effect and braking to describe the subsequent effect.[30] Because these two effects predictably develop together in the setting of repeated diuretic dosing, making a precise distinction is not essential. The overall sequence is familiar to clinicians and patients alike. With first administration of an adequate dose, diuretics promote a conspicuous increase in urine output that is associated with net negative sodium balance, a reduction in weight, and lessening of edema. Over time, patients reach a steady state where the diuretic response to that same dosing regimen is less. Individual doses promote a smaller diuresis and natriuresis. Daily sodium balance may become neutral with no further weight loss occurring (Figure 64.2).

One important cause of diuretic tolerance is sequential reabsorption of solute at renal tubular sites more distal to the site of action of the administered diuretic. Loop agents are potent because they block the very large fraction of filtered sodium load reabsorbed in the loop. Under usual circumstances, transport sites

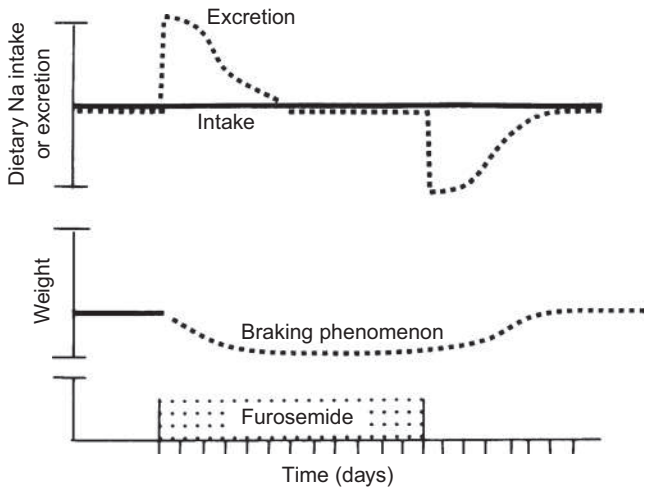

FIGURE 64.2 Diuretic tolerance or braking. Upper panel shows net sodium balance, and lower panel shows weight change in response to furosemide, which was given during the period indicated. *Reproduced with permission from reference 101 where it was redrawn with permission from Seely JF, Levy M.* Control of extracellular fluid volume. *In: Brenner BM, Rector FC, editors. The kidney. Philadelphia: WB Saunders; 1981.*

in the distal convoluted tubule and collecting duct reabsorb some but not all of the extra filtrate reaching these sites after administration of loop agents. The distal convoluted tubule can undergo structural changes that augment sodium reabsorptive capacity. Studies by Ellison et al. and by others have shown that in response to administration of furosemide, distal tubule cells undergo hypertrophy associated with increases in content of structural proteins, including the thiazide-inhibitable NaCl cotransporter (NCCT) and the Na/K ATPase that contribute to sodium transport and retention in this segment.[30–33] Over time, these adaptations increase.

Diuretic resistance is present if a dose significantly higher than the dose that produces maximal natriuresis under normal circumstances is required to produce a similar effect. Diuretic resistance can occur either on a pharmacokinetic basis due to reduced delivery of active drug to its site of action or on a pharmacodynamic basis with reduced responsiveness to drug that is delivered. The potential pharmacokinetic reasons for diuretic resistance in patients with impaired kidney function were previously discussed (see Pharmacokinetics).

The principal pharmacodynamic reason for diuretic resistance with impaired kidney function is self-evident. Despite the augmented fractional excretion of sodium that occurs with reduced kidney function (Figure 64.1), absolute sodium excretion is reduced in proportion to the reduction in filtered load and GFR.[34]

Diuretics are more effective when dietary sodium intake is restricted. A cause of apparent diuretic resistance in both patients with normal renal function and those with abnormal renal function is reabsorption of sodium at a time when the effect of a short-acting diuretic has worn off. In patients with normal renal function, the duration of action of furosemide is approximately 6 hours. Once the diuretic effect dissipates, the patient enters a compensatory sodium retentive state, i.e. diuretic braking occurs. If sodium intake is high enough, the sodium retained during that interval will reduce the net negative balance to a significant degree, leading to apparent diuretic resistance (Figure 64.3, panel A). It is clear from this figure that the administered furosemide works. It effectively increases sodium excretion during its period of activity. However, because net negative sodium balance has not been achieved, the clinically apparent effect is diuretic resistance. Imposition of a low-sodium diet (Figure 64.3, panel B) reduces the amount of sodium available for retention during the interval when the diuretic effect is absent. To some degree, this pharmacodynamic effect would be less significant with the longer acting torsemide.

Finally, augmented reabsorption of fluid due to persistence or augmentation of the factors that led to diuretic braking or tolerance can contribute to a need

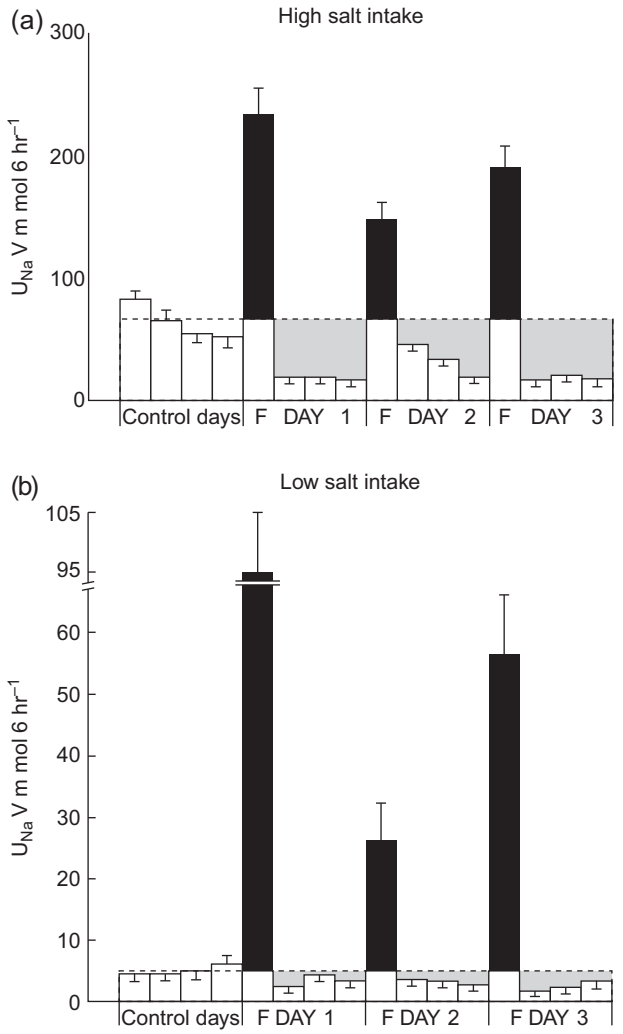

FIGURE 64.3 Apparent diuretic resistance. Effect of dietary sodium intake on overall sodium balance after administration of a single daily dose of furosemide to subjects with normal renal function. Height of bars indicates sodium excretion. *White portions* indicate excretion below ingestion rate, and *black bars* indicate excretion above ingestion rate. *Gray area* shows time period and magnitude of sodium retention during time periods when intake exceeds excretion. Note difference in scale on ordinate of each panel. In the study depicted in panel a, when subjects ingested a liberal sodium intake, the quantity of sodium retained during the intervals after the diuretic effect had dissipated (*gray areas*) was similar to the quantity of sodium excreted during the periods of diuretic action (*black bars*). The net natriuresis was thus very small. In the study depicted in panel b, dietary sodium was restricted. Little sodium was excreted during the comparable intervals after the diuretic effect dissipated. However, because there was little dietary sodium available for retention during ingestion of the restricted sodium diet, a significant net natriuresis occurred. *Reproduced with permission from reference 28.*

for higher diuretic doses. Strictly speaking, this is not diuretic resistance. The combination of mechanisms responsible for an inadequate diuretic response must be addressed simultaneously to ensure a clinically adequate diuresis (Table 64.4).

Strategies to Address Inadequate Diuretic Responsiveness due to Braking, Tolerance, or Resistance

Select an Appropriate Diuretic Dose

The dose of diuretic required to reach maximal efficacy is higher in patients with impaired kidney function than it is in individuals with normal kidney function. Using a standard 40 mg dose of furosemide in a patient with an estimated GFR (eGFR) of 20 mL/min/1.73 m^2 or a patient with hypoalbuminemia from nephrotic syndrome will predictably have limited effect. Start instead with 80 mg or 160 mg. Alternatively, start with a modest dose but plan to rapidly titrate the dose upward if no effect is observed. In the outpatient setting, patients can be counseled to observe the weight change that follows dosing and increase or decrease the dose to obtain the desired effect.

Furosemide is only 50% bioavailable, whereas the other loop agents have 80% bioavailability. Anticipate the need to double the dose of furosemide to achieve comparable activity when switching from IV to oral administration. This is especially important in patients who are discharged from the hospital coincident with the dosage and route change.

The fraction of diuretic excreted unchanged in the urine is a measure of the delivery of the diuretic to its site of action. Compared with normal renal function, with reduced kidney function, the fraction of furosemide excreted in the urine is better maintained than the comparable fractions for bumetanide and torsemide. Higher relative doses of bumetanide and torsemide will be required to treat CKD patients.

Assure that the Duration of Diuretic Effect is Adequate

As shown in Figure 64.3, reabsorption of sodium after the drug effect has dissipated may counterbalance any sodium excreted during the period of active natriuresis. Torsemide may have a longer period of action than the other loop agents, but the advantage is less in patients with reduced kidney function. Even so, a carefully conducted trial showed equivalent blood pressure lowering in CKD patients given a single daily dose of torsemide or a bioequivalent dose of furosemide in divided doses.[15] After establishing by titration a dose that is effective, repeat it on a BID or TID schedule to assure continuous inhibition of sodium reabsorption.

Limit Sodium Intake

CKD is no different than any other situation requiring diuretics. Limiting intake of sodium reduces the magnitude of natriuresis required. In addition, reducing the amount of dietary sodium available for

TABLE 64.4 Mechanisms and Possible Solutions for Diuretic Resistance in Patients with Impaired Renal Function

Observed Limitation	Possible Mechanism	Possible Solution
Overall and segmental fractional sodium excretion already increased	Limits effect of less potent diuretics	Start with a loop diuretic instead of a thiazide
Decreased proximal tubule secretion of diuretic	Competition with other organic acids for secretion	Avoid using with drugs that interfere with organic acid secretion such as cimetidine, methotrexate, sulfonamides, trimethoprim
Decreased renal elimination	Undiminished extrarenal clearance diverts drug from site of action	Note relative decrease in bumetanide and torsemide efficacy; increase dose
Enhanced sodium reabsorption in nephron segments downstream to site of action	Increased number of NCCT transporters in DCT cells, DCT hypertrophy	Use thiazide or metolazone for synergy; either effective despite reduced GFR
Diuretic is short acting	Delivery of diuretic below threshold toward the end of dosing interval	Follow diuretic response carefully and redose appropriately. Consider continuous IV infusion

Modified from reference 17.

retention during intervals between diuretic doses promotes the achievement of net negative balance (Figure 64.3). As patient compliance with prescribed sodium restriction is variable, measurement of 24-hour sodium excretion in the steady state can be useful to confirm adherence.

Block Reabsorption of Sodium in Sequential Nephron Segments

As discussed in diuretic braking, tolerance, and resistance, much of the tolerance seen with chronic dosing of the potent loop agents is due to augmented reabsorption in the distal convoluted tubule at the thiazide inhibitable NCCT NaCl cotransporter.[30–33] In patients with normal renal function, the addition of a thiazide or metolazone to a loop agent has a synergistic or at least additive effect on sodium excretion.[35–37] The addition of metolazone may in some circumstances produce a profound diuresis.[38] Because the effect of metolazone is protracted, it may take several days for the maximal effect to develop. Patients should be alerted to the possibility of development of an excessive response after a few days of treatment, and they should be advised to track weight loss and seek advice if urinary output exceeds the desired goal. It is often appropriate to prescribe metolazone, when used with furosemide, on an intermittent basis with dosing on alternate days or just two or three times a week. In patients limited to IV diuretics, chlorothiazide, 250 or 500 mg given intravenously twice daily, is a suitable dose for synergy. When given alone, the thiazides have reduced potency in CKD. However, several studies have documented their utility in augmenting the effect of loop agents even in patients with CKD stages 3 to 5[39,40] (Figure 64.4).

Administer the Drug via Continuous Intravenous Infusion

Continuous infusion of a loop agent may offer the advantage of maintaining a therapeutic level of diuretic over a more extended period than bolus administration. To some degree, bolus administration is inefficient. The very high blood level occurring soon after administration may be well above the plateau level of the sigmoid-shaped dose response curve. Toward the end of the dosing interval, the blood level may be below the threshold for efficacy. Although the fractional sodium excretion response to similar achieved rates of urinary furosemide excretion is the same for IV and bolus dosing, compared with bolus dosing, continuous infusion of bumetanide has been shown to produce greater sodium loss.[25,41] Furosemide bolus vs. continuous infusion was examined in a population of CKD patients given either a bolus dose or the same total dose of diuretic, with 25% given as a loading dose and 75% infused continuously over 4 hours. The continuous infusion protocol led to significantly greater absolute and fractional sodium excretion and a larger diuresis.[42] However, repeated bolus dosing can certainly be effective if urine output is monitored and the medication dose and frequency of administration is adjusted. One clinical advantage of continuous dosing is that it requires less attention compared with repeated bolus dosing on an as-needed basis. Having an effective continuous dose running "in the background" may be advantageous compared with a dosing scheme that requires active intervention and in which repeat bolus dosing may be delayed. In a different patient population, acute decompensated CHF, no efficacy difference was found with continuous compared

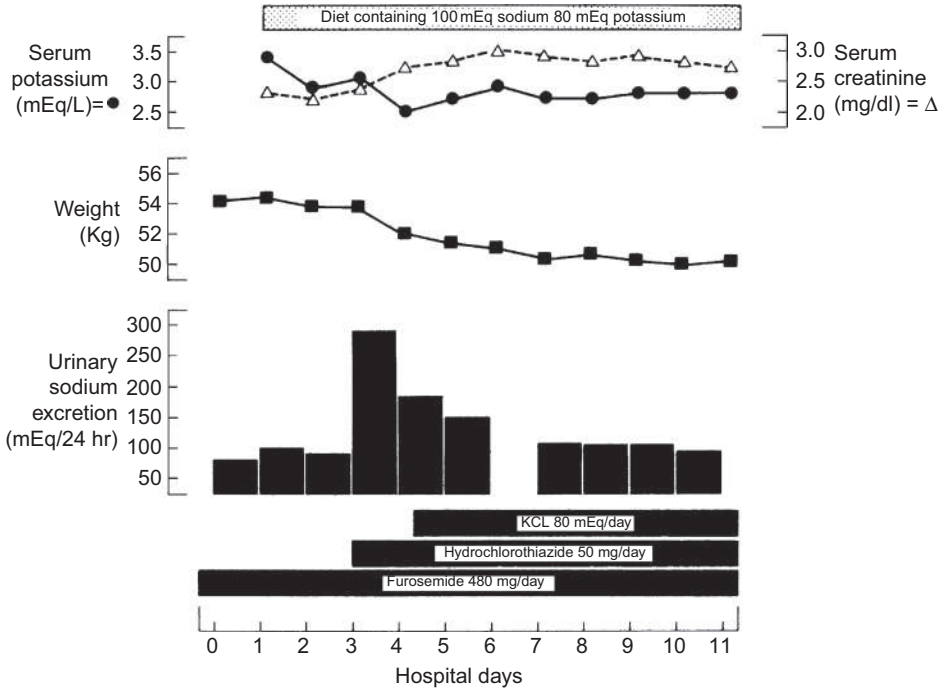

FIGURE 64.4 Additive natriuretic effect of hydrochlorothiazide to furosemide in a patient with CKD. Note that urine sodium excretion rose and weight fell coincident with addition of hydrochlorothiazide (HCTZ) to furosemide beginning on day 3. *Reproduced with permission from reference 39.*

with bolus dosing when both were given on a regular basis per protocol.[43]

The risk of diuretic ototoxicity is low with current doses of loop diuretics. Reversible ototoxicity may be noted when drug accumulates due to CKD. This is more likely with the higher peak levels achieved with bolus dosing. Continuous IV dosing may be safer in that respect.[44,45]

USE OF AGENTS OTHER THAN LOOP DIURETICS IN CKD

Carbonic Anhydrase Inhibitors

A brief course of acetazolamide may be particularly useful in patients with CKD who have developed metabolic alkalosis in clinical settings such as after receiving nasogastric suction or after a course of loop diuretics. Acetazolamide may be preferred to a thiazide when a second agent is needed to supplement a loop diuretic and metabolic alkalosis is present.

When metabolic alkalosis is absent, however, carbonic anhydrase inhibitors should be used only with great caution in CKD. Patients with impaired renal function are at increased risk for development of metabolic acidosis due to diminished ammonium production and diminished renal reserve, with an inability to compensate when acid production or bicarbonate loss is increased. Several studies have shown a high rate of development of hyperchloremic metabolic acidosis in elderly patients treated with conventional doses of acetazolamide for glaucoma.[46–48] In a study comparing 27 elderly glaucoma patients (mean age 69.1 ± 7.4 years) with age-matched controls, 4 patients (14.8%) developed mild acidosis ($7.29 < \text{pH} \leq 7.31$), 10 (37%) moderate acidosis ($7.20 < \text{pH} \leq 7.29$), and 1 (3.7%) severe acidosis (pH 7.15). Acidosis was not observed in the controls. In a second study, tCO_2 levels were inversely correlated with acetazolamide levels, which themselves correlated closely with drug dosage adjusted for creatinine clearance.

Thiazides

Conventional wisdom over many years has held that thiazides are not effective in patients with impaired kidney function. The pertinent KDIGO Guideline makes the observation that most clinicians switch from a thiazide to a loop agent in patients with CKD 4, and the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure advises adding a loop agent in patients with CKD 4[1,49–52] The role of thiazides is evolving as a result of accumulating evidence that thiazides do retain efficacy in patients with CKD.[53,54] Two early studies examined this question. The first included 17 individuals with creatinine clearances ranging from 5–133 mL/min. Half had creatinine

clearances at or below 53 mL/min. Bemetizide, 25 mg, resulted in an increase in absolute sodium excretion throughout the clearance range that was proportional to the clearance value. A second study by the same investigators, also in people with a wide range of creatinine clearances, noted an increase in fractional sodium excretion after a thiazide alone. The combination of low dose HCTZ (25 mg) and 40 mg furosemide produced a significant increase in absolute sodium excretion compared with baseline. However, the difference in absolute excretion of sodium with HCTZ alone was not significant compared with placebo.[55,56] The creatinine clearances in the subset of patients with CKD ranged from 4–75 mL/min, and the absolute increment in sodium excretion was reported for the group as a whole only. This makes assessment of the efficacy at the lower GFR range difficult. Two more recent studies using diuretics in CKD compared blood pressure, fractional sodium excretion, and weights in patients with stages 3–5 CKD. Using a double-blind, placebo-controlled, randomized crossover design, patients either received placebo, 25 mg HCTZ, 40 mg furosemide, or both. Fractional sodium excretion increased and weight fell in the combination diuretic group in both studies. In one study, but not the other, fractional sodium excretion rose with HCTZ. Furosemide alone at this low dose did not result in an increase in fractional sodium excretion, but it did lower weight in one of the two studies. HCTZ alone did not result in weight reduction. Despite the lack of consistent weight reduction, mean arterial pressure fell significantly in both studies in all three diuretic groups.[40,57] An open label, parallel treatment study compared the effect of chlorthalidone 25 mg in 60 patients with impaired kidney function (mean eGFR 39, range 15–59 mL/min/1.73 m^2) to its effect in 60 patients with normal kidney function (mean eGFR 76, range 60–104 mL/min/1.73 m^2). After 8 weeks of treatment, systolic blood pressure changes were similar, decreasing 20 mm Hg (95% confidence interval −22 to −18) and 23 mm Hg (−26 to −19), respectively. The blood pressure decrement was similar in the subgroups with CKD 3b, 4, and 5[58] (Figure 64.5).

Studies have examined the effect of add-on thiazide therapy to further reduce blood pressure, proteinuria, or albuminuria in patients with CKD already receiving ACEI or ARB treatment. Some compare a thiazide with a calcium channel blocker, noting a more favorable effect on albuminuria for the thiazide but a tendency for a larger short-term fall in eGFR. Most of these studies are small. They use heterogeneous submaximal doses of different thiazides in patients at varying stages of CKD who may or may not also be receiving maximal doses of loop diuretics, ACEIs, or ARBs. The studies provide evidence that thiazides can be beneficial in this setting. However, their design does not permit separating a specific antialbuminuric effect of the thiazide itself from the blood pressure lowering effect.[59,60] One such study, a randomized crossover trial, examined addition of spironolactone 25 mg or hydrochlorothiazide 50 mg to the regimen of 21 patients with CKD stages 1–3 who were already taking enalapril. After 4 weeks of treatment, systolic blood pressure fell from 130 ± 18 to 125 ± 20 mg Hg ($p < 0.05$) with spironolactone and from 129 ± 18 to 124 ± 19 mm Hg ($p = NS$)

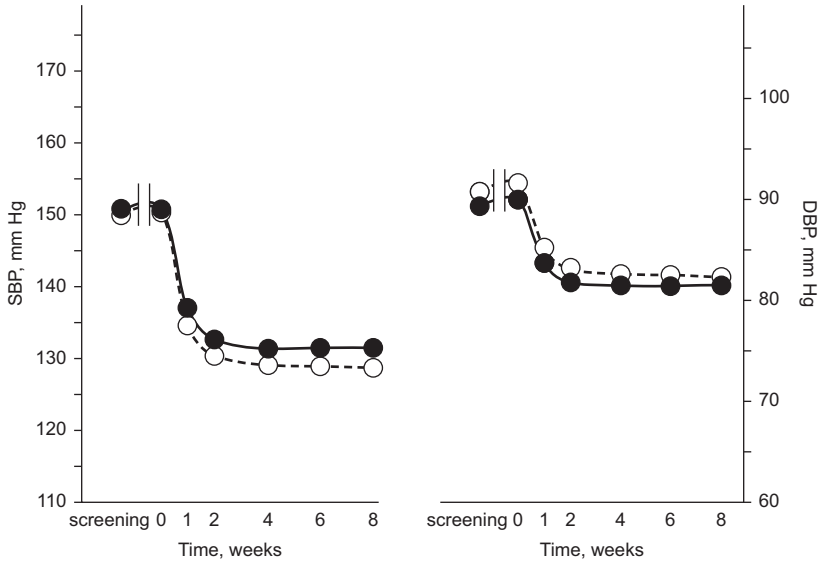

FIGURE 64.5 Means of systolic blood pressure (SBP, left) and diastolic blood pressure (DBP, right) in hypertensive individuals with eGFR<60 mL/min/1.73 m^2, *closed circles*, n = 60 and hypertensive individuals with 60 mL/min/1.73 $m^2 \leq$ eGFR $\leq$ 104 mL/min/1.73 m^2, *open circles*, n = 57 who received chlorthalidone, 25 mg daily, from week zero. with hydrochlorothiazide, as albumin excretion fell from 1600 (25–75% IQR 1047–2152) to 1125 mg/day (IQR 500–1750) ($p < 0.05$), with spironolactone and from 1417 (IQR 868–1965) to 935 mg/day (IQR 266–1603) ($p < 0.05$) with hydrochlorothiazide. In the spironolactone group, 12 patients (57%) experienced a >30% reduction in urinary albumin:creatinine ratio as did 17 (81%) of the hydrochlorothiazide-treated patients. Daily urine protein excretion fell from a mean of 1.7 (IQR 1.3–2.2) to 1.5 g (IQR 0.8–2.3) ($p < 0.05$) with spironolactone and from 1.7 (IQR 1.3–2.1) to 1.3 g (IQR 0.6–2) ($p < 0.05$) with hydrochlorothiazide. Weight fell with both regimens and the fall in albumin excretion correlated with the reduction in eGFR and blood pressure. Results were similar in a third group that received hydrochlorothiazide 50 mg plus amiloride 5 mg.[61] Taken together, these trials provide additional support for rejecting the notion that thiazides should be stopped when some arbitrary low threshold of GFR is reached, as they retain utility in lowering blood pressure and may reduce albuminuria or proteinuria.

The observed effects may be due to some other cause than a natriuresis. This is not a new observation.[62] Potential mechanisms, including diminished pressor response to catecholamines and angiotensin II, calcium desensitization of smooth muscle, nitric oxide release, and activation of potassium channels, have been reviewed.[53] Notably, intraarterial infusion of hydrochlorothiazide, but not the thiazide-like agent indapamide, causes a forearm vasodilator response both in normal individuals and those with Gitelman syndrome who lack the distal convoluted tubule NCC thiazide receptor.[63]

Results from large-scale trials also support the use of thiazides. In a *post hoc* analysis of the subgroup of patients in the ALLHAT trial with eGFR below 60 mL/min/1.73 m^2, chlorthalidone was noted to be more effective than amlodipine or lisinopril in preventing stroke and congestive heart failure, and noninferior in preventing coronary heart disease, cardiovascular disease events, or ESRD. These differences (except for a lower incidence of heart failure compared with amlodipine) did not persist at late follow-up, but patients were no longer being treated per protocol at that point. As such, this study provides evidence for efficacy of chlorthalidone in improving outcomes in CKD. Systolic blood pressure was slightly lower in the ALLHAT chlorthalidone group, although ALLHAT was not designed to assess patients with diminished renal function specifically, and patients with serum creatinine (S[Cr]) above 2.0 mg/dL or proteinuria were excluded.[64,65] Considerable support for the use of thiazide-type diuretics was provided by the SPRINT trial, which, in contrast to ALLHAT, was specifically designed to examine cardiovascular outcomes in patients with impaired kidney function. Its study protocol recommended that thiazide diuretics be chosen as initial antihypertensive therapy. Fully 46.8% of the 1330 intensively treated CKD patients and 30.1% of the 1316 CKD patients that received standard therapy were receiving a thiazide-type diuretic at last visit, although no breakdown between the two formulary agents, chlorthalidone and hydrochlorothiazide/amiloride, was provided. The study demonstrated reduced rates of major cardiovascular events and all-cause death in its intensive blood pressure control group, a large plurality of whom were receiving thiazides to achieve the blood pressure goal.[66]

A potential role of thiazide therapy compared with loop diuretic therapy to lessen the risk of development of secondary hyperparathyroidism in CKD has been suggested by an analysis of the Chronic Renal Insufficiency Cohort. In this patient population, eGFR ranged from 20 to 70 mL/min/1.73 m^2. In the subset of patients receiving diuretics, the adjusted daily calcium excretion was 39.6 mg/24 h (37.2–42.2, 95% CI). In the subset receiving loop diuretics alone, it was 55.0 mg/24 h (50.8–59.5, $p < 0.05$ vs. no diuretic). In the subset receiving thiazides alone, it was 25.5 mg/24 h (23.3–27.8, $p < 0.05$ vs. no diuretic). In the subset receiving both, it was 30.3 mg/24 h (26.6–34.5, $p < 0.05$).[67] PTH levels were higher in the loop diuretic-treated patients compared with patients who received no diuretics, but there was no difference between thiazide-treated patients and the controls. The adjusted odds ratio for secondary hyperparathyroidism, defined as a PTH≥65 pg/mL, was higher for participants treated with loop diuretics than for those with no diuretics. The odds of developing secondary hyperparathyroidism were not increased in patients receiving thiazides or in patients receiving both diuretics. The reduction in odds in the latter group was seen only in patients with stage 2 or 3 CKD. Thiazides were not protective in patients with stage 4 CKD. As the accompanying editorial pointed out, however, whether these biochemical differences mean that an improvement in clinical outcomes such as reduced cardiovascular morbidity or mortality or reduced fracture rate will result from addition or substitution of a thiazide is far from established.[68]

Little guidance is available on the choice of thiazide or thiazide-type diuretic to use in patients with CKD. Drug potency varies between agents. In normal individuals, the amount of drug estimated to produce a 10 mm Hg reduction in systolic BP is 1.4 mg for bendroflumethiazide, 8.6 mg for chlorthalidone, and 26.4 mg for hydrochlorothiazide.[69] Chlorthalidone is often recommended because of its longer duration of action, and the large-scale trials cited above used it exclusively or favored it over hydrochlorothiazide, but its longer

duration of action may predispose to a higher risk of complications.[64,66,70] Formal comparisons in patients with CKD are lacking.

Mineralocorticoid Receptor Antagonists

Two MRAs are currently approved for use by the US FDA, spironolactone and eplerenone. The former is nonspecific, with lesser but still significant affinity for progesterone and androgen receptors, a characteristic responsible for its endocrine side effects, including gynecomastia, diminished libido, and menstrual irregularities. Eplerenone is a more specific MRA. It has fewer off-target effects but is also less potent and more expensive. The pharmacokinetics of neither agent is significantly affected by renal functional impairment. Both these agents have steroid chemical structures. New, nonsteroidal agents, including finerenone, which has a dihydropyridine structure, are under development.[71–74] MRAs are highly effective in lowering blood pressure in patients with normal renal function and resistant hypertension. They have long been used as add on therapy in that setting.[75] However, any benefit of lowering blood pressure in CKD patients, particularly individuals already receiving an ACEI or ARB, has to be considered in the context of the risk of hyperkalemia.

Studies in patients with CKD document similar efficacy of MRAs for blood pressure control and provide reassurance that if used with care, the risk of hyperkalemia is not prohibitive. One such study retrospectively examined 88 patients with resistant hypertension who were begun on spironolactone. The baseline drug regimen included an ACEI or ARB in 90% of patients. Thirty-four patients had CKD, defined as an eGFR <60 mL/min/1.73 m^2. Mean systolic blood pressure fell from 153 ± 18 to 143 ± 20 mm Hg ($p = 0.006$), from baseline to first clinic visit after starting spironolactone in the CKD patients, and from 150 ± 17 to 135 ± 17 mm Hg ($p < 0.001$), in the patients without CKD. In both groups, about half of patients responded with a blood pressure drop, but half were nonresponders. Serum potassium (S[K]) increased by 0.5 ± 0.6 mEq/L in the CKD group vs. 0.3 ± 0.5 mEq/L in the patients without CKD, a difference that was not statistically significant. Hyperkalemia, defined as S[K] $>5.5\%$, occurred in 5.7% of CKD patients compared with none of the non-CKD patients ($p = 0.07$). In a multivariable model, only eGFR <45 mL/min/1.73 m^2 was associated with a higher risk of hyperkalemia. The dose of spironolactone was less than 25 mg in 93% of individuals. Length of follow-up beyond one return visit was not specified, and whether more patients would have responded with longer follow-up or developed hyperkalemia is unknown.[76] In a retrospective study of 36 patients with resistant hypertension, all with stage 3 CKD, in whom spironolactone (mean dose 23.6 ± 10.5 mg) or eplerenone (mean dose 60.4 ± 33.9 mg) was added to a preexisting drug regimen that included an ACEI or ARB, systolic blood pressure after a median of 312 days dropped from 162 ± 22 to 138 ± 14 mm Hg, $p < 0.0001$, and diastolic blood pressure from 87 ± 17 to 74 ± 12 mm Hg, $p < 0.0001$. The eGFR decreased from 48.6 ± 8.7 to 41.2 ± 11.5 mL/min/1.73 m^2 ($p = 0.002$). S[K] increased from 4.0 ± 0.5 to 4.4 ± 0.5 mEq/L ($p = 0.0001$), with 8 (22%) patients developing hyperkalemia (S[K] >5 mEq/L) at any time, including 3 (8%) with a value of S[K] above 5.5 mEq/L.[77] In a study of patients with mild to moderate CKD (eGFR 30–89 mL/min/1.73 m^2) spironolactone, 25 mg, or placebo was used as an add on to maximal ACEI or ARB therapy over a 40 week period. Patients who developed hyperkalemia during a one-month open label spironolactone run in period were dropped from the study before randomization. Of the 112 patients who went forward, fewer than 1% developed S[K] $\geq$6.0 mEq/L. Eleven patients (9 on spironolactone) developed hyperkalemia in the S[K] 5.5–5.9 mEq/L range. At 40 weeks, the drop in ambulatory systolic blood pressure was -6 mg Hg (95% CI -8 to -1) in the spironolactone treated group vs. 1 mm Hg (-3 to -1) in the placebo group ($p < 0.01$). In this group of patients who were already receiving maximal ACEI or ARB therapy, the only predictor of hyperkalemia was baseline S[K] > 5.0 mEq/L[78] Another study noted eGFR<45 mL/min/1.73 m^2 and treatment-induced drop in systolic blood pressure >15 mm Hg as risk factors for hyperkalemia.[79]

An influential population-based study showed an increased rate of hyperkalemia morbidity and mortality following publication of the RALES study, and the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure cautions against initiating aldosterone receptor antagonists in patients with a basal S[K] exceeding 5 mEq/L.[50,80] Even so, these small but granular studies provide reassurance that MRAs can be used safely in patients with mild to moderate reductions in GFR. Eplerenone has a shorter half-life than spironolactone. Its use has been suggested as an alternative to spironolactone in CKD because its effect will dissipate sooner if hyperkalemia develops. Conventional strategies to permit use of MRAs in CKD include restriction of potassium intake, supplementation with bicarbonate to provide a nonreabsorbable anion (excretion of which may enhance potassium excretion), and concomitant use of kaliuretic loop diuretics. Patiromer and sodium zirconium cyclosilicate have recently been approved as potassium lowering agents.[81,82] Published data specifically addressing hyperkalemia risk in patients with CKD stages 3b, 4, and 5 are lacking; no studies systematically address the effect of concurrently prescribed

kaliuretic loop or thiazide diuretics or bicarbonate on hyperkalemia risk.[83]

In summary, MRAs effectively lower blood pressure in patients with reduced GFR, including those receiving ACEIs or ARBs, but their safe use requires ongoing vigilance regarding the possible development of hyperkalemia.

Mineralocorticoid receptors are now known to be present not only in principal cells of the collecting duct but also in a variety of other cells or tissues, among them the heart, brain, vascular smooth muscle, and glomerular podocytes. At these sites, activation of the mineralocorticoid receptor has pleiotropic effects to increase the release or activation of vasoconstrictors and inflammatory or profibrotic cytokines, promote cardiac and kidney fibrosis, contribute to insulin insensitivity, and cause glomerular podocyte damage with worsened proteinuria. As a result, increasing attention has been drawn to the use of MRAs in patients with CKD to reduce proteinuria, reduce risk of ESRD, and improve cardiovascular outcomes.[84,85] As aldosterone levels increase in 30–50% of patients after initiation of ACEI or ARB therapy, a phenomenon called aldosterone escape or breakthrough, adding MRA therapy to the regimen of CKD patients already receiving ACEI or ARB therapy could be especially attractive.[72] Addition of spironolactone or eplerenone has been demonstrated to reduce proteinuria by 38–61% in such patients or to reduce albuminuria by 33–48%.[86–90] This practice has been the subject of several systematic reviews or meta-analyses. Although they confirm that added MRAs reduce blood pressure and proteinuria or albuminuria, increase the rate of development of hyperkalemia, and modestly lower GFR over the short term, none of the small studies that form the basis of this conclusion was designed or powered to assess hard, patient-centered outcomes such as cardiovascular events, mortality, or development of ESRD. Thus, neither individual studies nor the comprehensive reviews provide compelling evidence to date regarding whether MRAs have an indication in CKD beyond management of refractory hypertension.[84,91–93] Large-scale trials with the potential to provide more definitive data are underway[83] (https://clinicaltrials.gov/ct2/show/NCT02540993).

USE OF DIURETICS FOR TREATMENT OF HYPERTENSION IN CKD

Extracellular volume overload is an important contributor to hypertension in CKD patients, and correction of volume overload with diuretics is a key part of treatment. When appropriately dosed, loop diuretics are plainly effective in reducing extracellular volume and lowering blood pressure in CKD patients.[15,94] Although this principle is generally accepted, diuretics appear to be underutilized in CKD patients, perhaps because of prescriber concerns about the tendency of these agents to lower eGFR if clinical or subclinical volume depletion is induced. A large study evaluating treatment of hypertension in 26 Italian CKD clinics observed furosemide use (the loop diuretic prescribed virtually exclusively) in only 27% of stage 3, 42% of stage 4, and 51% of stage 5 patients. In more than half of the patients who were receiving a loop diuretic, the dose was deemed inadequate. A fixed dose combination of losartan 50 mg/hydrochlorothiazide 12.5 mg was found to be inferior to losartan 50 mg plus nifedipine 20–40 mg for lowering blood pressure in CKD patients, highlighting the need to choose an appropriate diuretic in an adequate dosage.

DIURETIC COMPLICATIONS

Diuretic complications have been extensively reviewed.[45,95] Metabolic derangements resulting from use of thiazide or loop diuretics include hyponatremia, hypokalemia, hypomagnesemia, hyperuricemia, hyperglycemia, and metabolic alkalosis. Hypokalemia and metabolic alkalosis become less of a problem as renal function worsens. In addition, concomitant use of ACEIs or ARBs as well as MRAs in this population may mitigate hypokalemia or result in frank hyperkalemia. Spironolactone may contribute to the development of metabolic acidosis.[96] When present, hypokalemia is readily managed with potassium supplementation or addition of a potassium-sparing agent. Hyponatremia carries an adverse prognosis in CKD patients, as it does in the general population.[97,98] Hyponatremia is much more common with the thiazides, which block sodium transport in the distal convoluted tubule diluting sites. Recently, a genetic risk factor for thiazide-induced hyponatremia related to altered prostaglandin transport and diminished water excretion has been identified.[99] In any event, thiazide diuretics should be stopped and a loop agent substituted if continued diuretic therapy is required in CKD patients with hyponatremia. Hyperuricemia can be a relative contraindication for diuretic use. Gout combined with the unsuitability of NSAID treatment in CKD patients may also be responsible for the reluctance of some clinicians to prescribe diuretics. However, hyperuricemia is amenable to therapy with allopurinol. Hypomagnesemia may be a particular problem in renal transplant patients with CKD who receive both diuretics and tacrolimus. Clinicians should be vigilant for this complication, supplement magnesium, and stop proton pump inhibitors, if coprescribed, as required. Finally, diuretics may exacerbate urinary incontinence. Reported diminished adherence to diuretics is 3–4 times more prevalent among patients with urinary incontinence, a factor that may contribute to apparent refractoriness to diuretics.[100]

CONCLUSION

As CKD is commonly associated with sodium retention, which contributes importantly to hypertension, diuretics are often prescribed to CKD patients. The potent loop agents remain the mainstay of diuretic therapy, but their proper use requires an understanding of their altered pharmacokinetics and pharmacodynamics in CKD. Repeating an inadequate dose is futile; it is essential to use upward dosage titration to identify an effective dose, which can then be repeated. Short-acting agents, such as furosemide and bumetanide, should be given more than once per day to assure that the antinatriuresis characteristic of the diuretic-free interval does not negate the natriuresis achieved while active drug is present. Recent data, confirmed by the SPRINT trial, suggest that thiazides have persistent benefit with improved outcomes even in advanced CKD. They need not be abandoned at some arbitrary level of GFR.[66] Mineralocorticoid antagonists are particularly useful add-on agents both for blood pressure control and to reduce proteinuria and slow disease progression in CKD, although clinicians should maintain vigilance for hyperkalemia when an agent of this class is used.

QUESTIONS AND ANSWERS

Question 1

A 63-year-old man with IgA nephropathy returns to CKD clinic for follow-up. He has no complaints and reports good compliance with his sodium and potassium restricted diet. Current medications include ramipril 10 mg, amlodipine 10 mg, and chlorthalidone 25 mg. Blood pressure is 128/78 mm Hg. Physical examination is unremarkable. No edema is present.

Laboratory values: BUN 17, S[Cr] 1.9, eGFR 36 mL/min/1.73 m^2, S[Na] 138 mmol/L, S[K] 5.2 mmol/L, S[Cl] 105 mmol/L, and tCO_2 23 mmol/L. Urine protein: creatinine ratio (UPCR) 1.1 g/g.

Which one of the following is the best course of action now?

A. Stop ramipril
B. Add sodium bicarbonate 650 mg BID
C. Stop chlorthalidone, substitute furosemide
D. Continue current regimen
E. Add sodium polystyrene sulfonate resin in sorbitol three times weekly

Answer: D

The patient is doing well, with excellent blood pressure control. Although renal function is worse than the level at which conventional wisdom holds that thiazides are effective, several recent papers suggest that thiazides do lower blood pressure at this level of renal function, perhaps through a mechanism other than diuresis. Thus, Answer C is incorrect. The potassium level is not high enough to warrant other measures (A, B, or E) to lower it.

Question 2

A 45-year-old woman with polycystic kidney disease presents for follow-up. She has noted difficulty focusing on intellectual tasks and mild memory impairment. Although she had significant difficulty with depression a year ago before sertraline was begun, in the interval, her insomnia and depressed mood have not recurred. Having read on a website that vasopressin may promote cyst growth, she has increased fluid intake to at least 3 L per day. She has smoked one pack of cigarettes per day since age 22. Medications include hydrochlorothiazide 25 mg, lisinopril 10 mg daily, sertraline 50 mg, and extended release metoprolol 25 mg daily. Physical examination discloses a well-appearing woman with blood pressure 131/82 mm Hg. The kidneys are not palpable. No edema is present.

Laboratory values: BUN 13 mg/dL, S[Cr] 1.6 mmol/L, eGFR 37 mL/min/1.73 m^2, S[Na] 128 mmol/L, S[K] 3.9 mmol/L, S[Cl] 103 mmol/L, tCO2 22 mmol/L, and glucose 98 mg/dL. Urine osmolality 205 mOsm/kg and urine sodium concentration 55 mmol/dL.

Which one of the following is the best approach now?

A. Urge the patient to drink only when thirsty
B. Stop hydrochlorothiazide, begin furosemide
C. Stop hydrochlorothiazide and sertraline
D. Obtain chest CT
E. Stop lisinopril

Answer: B

The patient's symptomatic hyponatremia may potentially be caused by several factors. Hydrochlorothiazide blocks sodium transport at the distal convoluted tubule diluting site and interferes with urinary dilution. Sertraline and other SSRIs are common causes of the syndrome of inappropriate anti-diuretic hormone secretion (SIADH). Ingestion of water in excess of thirst is unlikely to be a cause of hyponatremia on its own at this level of renal function, but it will lead to hyponatremia if renal diluting ability is impaired by hydrochlorothiazide or SIADH. ACEIs have rarely been reported to cause SIADH, but lisinopril is much less likely to contribute to the hyponatremia than sertraline or hydrochlorothiazide, so Answer E is wrong. It might be possible to correct the hyponatremia simply by urging the patient to reduce water intake, but she would still likely be at risk, so A is wrong. Furosemide blocks urinary concentration and is much less likely to cause hyponatremia; most cases of loop diuretic-induced hyponatremia occur in the setting of congestive heart failure, which itself may have been the cause. The patient benefitted significantly from the sertraline, so it would make sense to try to maintain her on this therapy by stopping the hydrochlorothiazide alone (B) rather than both drugs (C). As an initial step, one would observe the response to stopping hydrochlorothiazide before looking for a lung tumor as a cause of SIADH, so D is wrong.

Question 3

A 72-year-old man with ischemic cardiomyopathy (ejection fraction 35%) and presumed hypertensive nephrosclerosis returns for follow-up. He reports worsening dyspnea and edema despite following a low-salt diet. Specific questions about his dietary choices indicate that his salt intake is likely quite high. Current medications include furosemide 120 mg BID, carvedilol 25 mg BID, lisinopril 20 mg daily, ASA 81 mg daily, and diltiazem 240 mg daily. Pulse is 58 bpm with blood pressure 150/90 mm Hg. The jugular veins are seen 2 cm above the sternal angle and the chest is clear. No gallop is present. One plus edema is present bilaterally.

Laboratory values: BUN 33 mg/dL, S[Cr] 2.8 mg/dL, eGFR 31 mL/min/1.73 m^2, and S[K] 4.4 mg/dL.

In addition to recounseling the patient on a reduced sodium diet, which one of these changes in his therapeutic regimen is most appropriate now?

A. Add metolazone 2.5 mg three days per week
B. Stop furosemide, substitute torsemide
C. Increase diltiazem
D. Increase furosemide to 160 mg BID
E. Add spironolactone 25 mg

Answer: A

The patient demonstrates diuretic resistance. Despite being on a high dose of furosemide, volume overload and blood pressure are not controlled. There is no major advantage of torsemide over twice daily furosemide in this setting, and changing to a new loop agent would require dose finding, so B is incorrect. Simply increasing furosemide (D) is unlikely to be effective. Spironolactone is useful for refractory hypertension, but it is unlikely to provide enough diuretic effect in this case (E). Increasing diltiazem may be unwise at this pulse rate and will not improve sodium balance. Although it requires the addition of another medicine, adding metolazone is likely to have a pronounced additive or synergistic effect to furosemide on sodium excretion.

Question 4

A 53-year-old woman with long-standing type II diabetes mellitus is referred by her primary care physician for management of recent onset hypertension and edema. She is presently managed with insulin glargine 30 U HS and insulin aspart 5 U tid with meals, plus sliding scale, as well as losartan 100 mg. At presentation, her weight is 90 kg with height 61 inches, BMI 37.5 kg/m^2, and blood pressure 150/92 mm Hg. The balance of the physical examination is remarkable only for obesity and trace bilateral ankle edema.

Laboratory values: S[Cr] 1.8 mg/dL with eGFR 31 mL/min/1.73 m^2, serum albumin (S[Alb]) 3.2 g/dL. UPCR is 3.2 g/g.

You begin furosemide 40 mg daily, counsel her on a 4 g sodium diet, and arrange follow-up in a month.

On her return, the patient reports that the furosemide is working well. She has a brisk urine output right after she takes the drug. On examination, her weight is 90.3 kg, blood pressure 148/92 mm Hg, and trace bilateral ankle edema persists.

Which of the following is the best course of action now?

A. Counsel on 500 mg sodium diet
B. Add hydrochlorothiazide 25 mg
C. Add spironolactone 25 mg
D. Change furosemide to 40 mg BID
E. Switch to bumetanide 2 mg daily

Answer: D

From the patient's description, the furosemide is having its desired effect as a diuretic, but the patient has not lost weight or experienced an improvement in blood pressure or fluid overload. Reducing sodium intake would help (see Figure 64.3), but a 500 mg sodium diet (A) is unlikely to be achievable. Switching to another short-acting loop agent even at a higher dose (E) would not solve the problem of having diuretic activity of too brief a duration. The correct strategy is to add a second dose of furosemide to prolong its activity. Adding additional agents (B and C) would help, at the cost of more polypharmacy.

Question 5

A 26-year-old man with frequently relapsing minimal change nephropathy presents to the emergency room. He developed leg swelling over the several preceding days. Before that, he had been well. He was taking no medications and had normal renal function and no proteinuria. His last relapse was 18 months ago. His blood pressure was 105/68 mm Hg and the balance of the examination was remarkable only for 2+ bilateral leg edema.

Laboratory values: BUN 8 mg/dL, S[Cr] 0.9 mg/dL, and S[Alb] 2.4 g/dL.

The emergency room physician prescribes 40 mg furosemide IV to little effect.

The reason for this patient's poor response to furosemide is most likely which one of the following?

A. Diuretic braking
B. Diuretic tolerance
C. Reduced bioavailability
D. Diminished protein binding
E. Hypertrophy of distal convoluted tubule sodium reabsorptive sites

Answer: D

Diuretic braking refers to the reduced diuretic effect that occurs *after* the first or just a few doses of diuretic and tolerance to the reduced effect that occurs later and which is sometimes due to the hypertrophy of distal tubule sodium reabsorptive sites that occurs in response to the increased load of sodium passing that site after a loop agent is administered. This patient has not required diuretic therapy in some time and is thus diuretic naïve. So, the failure of the first dose of furosemide to act cannot be attributed to A, B, or E. Bioavailability of orally administered drugs may be reduced by gut edema, but the furosemide was given IV, bypassing the gut. Therefore, C is not relevant. Loop diuretics are highly protein bound in plasma. When hypoalbuminemia is present, the apparent volume of distribution increases, and delivery to the proximal tubule site where

furosemide is secreted into the lumen is diminished. Hence, D is the reason why a dose of furosemide that would have been expected to work at this level of renal function did not.

Question 6

A 63-year-old man with CKD due to diabetic nephropathy is admitted to the CCU after the sudden onset of chest pain and dyspnea. Home medications include aspirin, losartan, insulin, and furosemide 40 mg daily. Blood pressure is 140/95 mm Hg. Physical examination discloses rales midway up the chest and trace bilateral ankle edema is present. The chest radiograph shows mild pulmonary edema. Cardiac enzyme studies and ECG disclose a non-ST segment elevation myocardial infarction. Kidney function is at baseline.

Laboratory values: BUN 42 mg/dL, S[Cr]1.5 mg/dL, and eGFR 50 mL/min/1.73 m^2.

The patient is treated with supplemental oxygen, heparin, and a β-blocker, and aspirin and losartan are continued. You advise that furosemide be given with a goal of net negative fluid balance of 2 L over the course of the day. The CCU staff administers furosemide, 80 mg, intravenously.

The next morning, you note that in response to the furosemide, the urine output was 1200 mL over the ensuing 4 hours. However, overall fluid balance for the first 24 hours in the hospital was positive, with intake 2200 mL in and output 1800 mL (all urine). The patient continues to require supplemental oxygen. Renal function is unchanged.

At this point, you reiterate the goal of establishing net negative fluid balance and recommend which one of the following?

A. Furosemide 160 mg IV
B. Furosemide 80 mg followed by a continuous infusion
C. Stop losartan
D. Bumetanide 4 mg IV
E. Add chlorothiazide 250 mg IV BID

Answer: B

Furosemide 80 mg was effective in increasing urine output, but net negative fluid balance was not achieved because the diuretic effect was not sustained throughout the day. The patient could be managed effectively with repeated boluses of furosemide 80 mg if they are given. However, that option was available the day before but not utilized. It would thus make sense to switch to a continuous infusion titrated to a dose that will achieve negative balance. A single larger dose of furosemide or comparable dose of bumetanide would not solve the problem so A and D are incorrect. There is no evidence of diuretic tolerance as yet, so chlorothiazide is not indicated. Renal function is stable, so there is no reason to believe stopping losartan would improve the diuresis.

CHAPTER

Nonsteroidal Antiinflammatory Drugs and Opioids in Chronic Kidney Disease

David M. Clive[a], *Pia H. Clive*[b]

[a]University of Massachusetts Medical School, Department of Medicine, Division of Renal Medicine, Worcester, MA, United States; [b]UMass Memorial Medical Center, Worcester, MA, United States

Abstract

Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit the synthesis of prostaglandins, which comprise an important compensatory mechanism for maintaining renal blood flow, glomerular filtration, and water and electrolyte homeostasis in the setting of a number of pathophysiologic states including chronic kidney disease (CKD). CKD patients are, therefore, at risk for adverse renal side effects of NSAIDs, including acutely worsened renal function, hyperkalemia, hyponatremia, sodium retention, and exacerbation of hypertension. Although these effects are generally reversible on discontinuation of the drugs, patients with CKD must be monitored closely while taking NSAIDs.

Evidence suggests that heavy cumulative NSAID consumption is capable of causing chronic kidney injury with manifestations similar to those seen in classic analgesic nephropathy, including chronic interstitial nephritis and papillary necrosis. The pathogenesis of this disorder is probably renal medullary ischemia resulting from diversion of blood flow to the cortex that occurs with suppression of prostaglandin synthesis. CKD due to NSAIDs is probably rare.

Extra caution is indicated when (1) committing patients to high-dose, long-term NSAID therapy or (2) recommending NSAID therapy of any duration to patients with CKD or other risk factors for adverse renal side effects including advanced age, use of diuretics, congestive heart failure, cirrhosis, and hypertension.

As with NSAIDs, opioid analgesics must be considered from two standpoints: their ability to cause chronic kidney injury, which appears rare if it occurs at all, and the susceptibility of patients with chronically impaired renal function to the hemodynamic and neurotoxic effects of opioids, a problem commonly confronted in the clinic.

INTRODUCTION

Because pain is the most common symptom for which people consult their physicians, it is hardly surprising that the consumption of analgesic medications in the US is enormous. It is estimated that 19% of the population regularly use aspirin, albeit not exclusively for pain. Another 12.8% use nonaspirin NSAIDs regularly. These numbers appear to be on the rise.[1] Excessive use of opioids is now pervasive due to the prevalence of addiction, as well as profligate overprescription. At the time of this writing, opioid use represents one of the nation's greatest public health crises. Recent estimates of the prevalence of CKD in this country average around 15%. One may extrapolate from these numbers that the relationship between CKD and analgesic medications is a topic of potentially major clinical significance.

In examining this relationship, we will first explore the propensity of these agents to exert adverse effects on the kidney. Next, we will consider the extent to which CKD patients, by virtue of their reduced renal function, have a reduced tolerance for them. We will apply this approach to both the NSAIDs and opiates.

NSAIDS AND CKD

The potential for harmful interactions between nonsteroidal antiinflammatory drugs (NSAIDS) and the kidney has been known for 60 years. The earliest reports were of a fulminant form of acute kidney injury (AKI) known as "phenylbutazone anuria." Although phenylbutazone has virtually disappeared from clinical use in humans, the number of NSAID products available for administration to humans has exploded in the years since. Several different classes of NSAIDs have been marketed (Table 65.1), most recently the coxibs, or selective cyclooxygenase-2 antagonists. NSAIDs may be the

TABLE 65.1 Nonsteroidal Antiinflammatory Drugs

Class	Examples
Indoleacetic acid derivatives	Indomethacin, sulindac, ketorolac
Propionic acid derivatives	Ibuprofen, naproxen
Coxibs	Celecoxib, valdecoxib
Salicylates	Aspirin, salsalate
Fenamic acid derivatives	Meclofenamate
Oxicams	Meloxicam, piroxicam
Pyrazolidines	Phenylbutazone

most widely used of all drugs, with over 70 million prescriptions written annually in the US.[2] Aspirin, the first and most familiar NSAID, was developed in the late 19th century. In the decades since, newer and more potent agents have been introduced, some of which became available as over-the-counter formulations in the late 1980s. Two of these, ibuprofen and naproxen, can produce adverse renal effects. Both are widely advertised and consumed. The proliferation of NSAID products has not been confined to the introduction of new compounds. Newer formulations and delivery systems have also appeared. Adverse renal effects have recently been reported in association with topical NSAID formulations.[3,4]

The explosion in NSAID consumption in the US has occurred in parallel with a sharp increase in the prevalence of chronic kidney disease (CKD). Although the current epidemiologic trends of CKD doubtless reflect the influence of many factors, it is logical to ask whether NSAID use may be one of them. This is the first of two key issues to be examined in this chapter.

PHARMACOLOGY OF NSAIDS

The principal pharmacologic action of all NSAIDs is to alter the metabolism of arachidonic acid. This 20-carbon fatty acid, present in all cells, is the precursor of the eicosanoids, a family of physiologically active compounds comprising the prostaglandins and leukotrienes (Figure 65.1). These substances are *autocoids*, meaning their effects are exerted primarily on the tissue in which they are synthesized. Different cell types have differing proclivities for producing specific eicosanoid end-products. The paradigmatic illustration of this phenomenon is the abundant production by platelets of thromboxane A_2, a prostaglandin that induces platelet aggregation and vasoconstriction. In endothelial cells, the predominant eicosanoid product is prostaglandin I_2 (prostacyclin), a vasodilator and inhibitor of platelet aggregation. The opposing effects of these substances lend protective balance to the interaction between blood vessels and thrombocytes. Variability of eicosanoid production is seen among the renal cell types as well.

The primary step in the metabolism of arachidonic acid is catalyzed by cyclooxygenase (COX). It is this step that is inhibited by NSAIDs. Mammalian cells express two isoforms of cyclooxygenase, COX-1 and COX-2. COX-1 predominates in gastric mucosa, where prostaglandins confer protection against acid-peptic assault. For this reason, the specific COX-2 inhibiting NSAIDs are felt to be safer for patients at risk for gastric bleeding and ulceration. COX-2 is the predominant cyclooxygenase isoenzyme in the kidney. It is, therefore, not surprising that COX-2 inhibitors are reported to cause renal effects similar to those of the traditional, nonspecific NSAIDs.

PROSTAGLANDINS AND THE KIDNEY: AN OVERVIEW

Both COX-1 and COX-2 are present in kidney tissue. COX-1 is constitutively expressed in the distal nephron. Its chief product is prostaglandin E_2 (PGE_2). COX-2 is more widely distributed throughout the kidney. Like COX-1, it is constitutively expressed, but it is also inducible under conditions of physiologic stress. The inducible expression of COX-2 in the renal cortex and medulla appear to be under independent control.[5] The physiologic stresses that lead to enhanced cortical COX-2 activity are those associated with increased activity of the renin–angiotensin–aldosterone system (RAAS), such as sodium depletion and reduced renal perfusion. A bidirectional stimulatory relationship exists between the two hormonal systems: angiotensin II stimulates production of COX-2 eicosanoid products, and those products, in turn, stimulate renin release.

Several generalizations may be made regarding the actions of renal prostaglandins, which are listed in Table 65.2.

(1) As *autocoids*, prostaglandins synthesized in the kidney act on the kidney. Prostaglandins and prostaglandin metabolites excreted in the urine represent mostly those that were produced in the kidney.

(2) The importance of prostaglandins affecting compensatory mechanisms in pathophysiologic states exceeds that of their role in normal renal physiology. This assertion is based on two

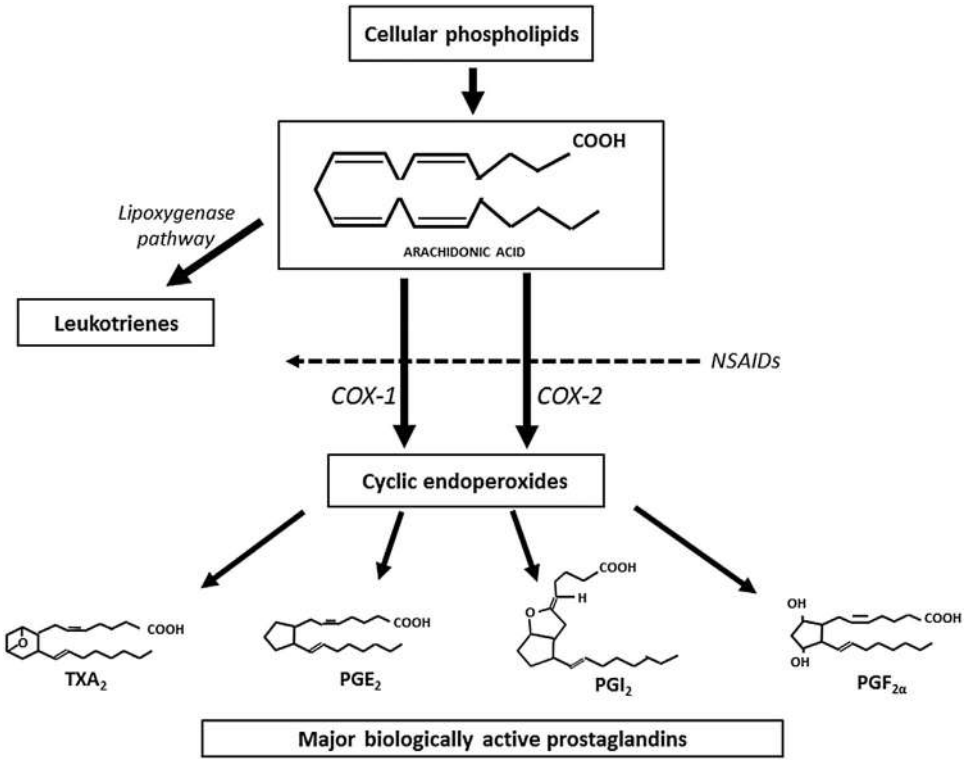

FIGURE 65.1 Biosynthetic pathway of eicosanoids. The eicosanoid precursor molecule is arachidonic acid, derived from substrate in the cell membrane phospholipid pool. Arachidonic acid may be metabolized by either of two enzymatic pathways. The lipoxygenase pathway produces a family of inflammatory mediators and cytokines known as leukotrienes. The cyclooxygenase (COX) system produces prostaglandins. Cyclooxygenase catalyzes the conversion of arachidonic acid to cyclic endoperoxides, which are short-lived prostaglandin precursors with no intrinsic biologic role other than as parent molecules for the biologically active prostaglandins. There are two isoforms of cyclooxygenase, COX-1 and COX-2; their relative importance varies among different tissues. NSAIDs inhibit cyclooxygenase activity. PGI_2 is prostacyclin. *PG*, prostaglandin; *Tx*, thromboxane.

TABLE 65.2 Major Roles of Prostaglandins in Renal Physiology and Clinical Consequences of Inhibition of Prostaglandin Synthesis

Role	Action	Consequences of Inhibition
Maintenance of renal blood flow	Counterregulate the action of vasoconstrictor hormones	Acute kidney injury (vasomotor nephropathy)
Potassium homeostasis	Promote potassium excretion through stimulation of renin secretion	**1)** Hyperkalemia **2)** Hyporeninemic hypoaldosteronism (type IV renal tubular acidosis)
Water balance	Counterregulate the action of antidiuretic hormone on medullary collecting tubule	Hyponatremia
Sodium homeostasis	Modulate sodium reabsorption at multiple nephron sites	**1)** Edema **2)** Exacerbation of congestive heart failure **3)** Exacerbation of cirrhotic ascites and edema **4)** Exacerbation of hypertension

observations. First, under normal physiologic conditions, people are rarely subject to adverse renal consequences of inhibition of prostaglandin synthesis by NSAIDS. Second, under many of the conditions associated with renal sensitivity to NSAIDs (Table 65.3), urinary excretion of prostaglandin metabolites is above normal, indicating a high level of renal cyclooxygenase activity.

(3) As already noted in relation to the RAAS, prostaglandins serve to counterregulate the actions of other hormones on the kidney. A similar check-and-balance relationship exists between antidiuretic hormone and prostaglandins.

TABLE 65.3 Predisposing Factors for Adverse Renal Effects of NSAIDs

Volume depletion
Congestive heart failure
Cirrhosis
Chronic kidney disease
Hypertension
Medications (triamterene, calcineurin inhibitors, ACE inhibitors, ARBs, diuretics)
Older age

Table 65.4 lists the various renal abnormalities that have been reported in patients taking drugs that inhibit prostaglandin synthesis. Most of these are predictable given the information in Table 65.2.

NSAIDS AS A CAUSE OF CHRONIC KIDNEY DISEASE

Mechanism

NSAID nephropathy is thought to be an ischemic, rather than toxic, process. In contrast to phenacetin, implicated in the pathogenesis of classic analgesic nephropathy, NSAIDs and their metabolites are not inherently nephrotoxic. In animal studies, suppression of prostaglandin synthesis by NSAIDs induces regional changes in intrarenal blood flow with marked reduction in medullary perfusion.[6] Prolonged medullary ischemia can lead to atrophy and fibrosis of deep nephron structures and ultimately papillary necrosis.

TABLE 65.4 Renal Syndromes Attributed to NSAIDs

• Hyponatremia
• Type IV renal tubular acidosis
Exacerbation of hypertension
Chronic kidney disease

Importance of NSAID Use as a Causative Factor in CKD

The collective evidence that NSAIDs are capable of causing irreversible renal damage is less robust than that supporting their role in AKI. In the past three decades, isolated reports have imputed such a relationship, but in none of these is the case for direct causality beyond question.[7–14]

Clinical investigators have attempted to solidify this case. Segasothy and coworkers evaluated renal function and morphology in 94 chronic arthritis patients with a history of relatively heavy NSAID exposure. Of 82 patients who completed the assessment, 12% had radiographic evidence of papillary necrosis and 24% higher than expected serum creatinine concentration (S[Cr]) levels. These findings were distributed among patients with several unrelated forms of arthritis, strengthening the authors' conclusion that heavy NSAID use, and not the disease process being treated, was culpable in the pathogenesis of their CKD.[15]

Sandler et al. conducted telephone interviews of 554 North Carolinians with newly diagnosed chronic renal disease to assess their prior intake of NSAIDs, and compared it with that of 516 control subjects. Heavy NSAID use was associated with a twofold risk of renal disease, although the effect was limited to male subjects over the age of 65.[16] In another survey, 716 end-stage renal disease (ESRD) patients and 316 control subjects were queried regarding their pattern of use of three types of analgesics: acetaminophen, aspirin, and nonaspirin NSAIDs. The ESRD patients were stratified into three groups according to the etiology of their renal disease: diabetes mellitus, hypertension, and all others. A very strong cumulative dose-dependent interaction was found between NSAID use and prevalence of ESRD. A weaker relationship was found for acetaminophen. It is interesting that no such risk enhancement was seen with aspirin.[17] A retrospective analysis of incident Taiwanese dialysis patients between 1998 and 2009 found that use of NSAIDs within the preceding 14 days raised the relative risk for initiation of chronic dialysis by a factor of 2 to 3.[18]

Renal function was followed over an 11-year period in a cohort of 1697 women enrolled in the national Nurses' Health Study. These women were asked about their use of aspirin, acetaminophen, and nonaspirin NSAIDs. Their change in renal function over time was

compared with that of non-NSAID users. The only significant interaction between analgesic intake and abnormally rapid decline in renal function was seen with acetaminophen.[19] Slightly different results emanated from a similar investigation looking at a healthy male cohort of participants in the national Physicians' Health Study. Here, a modestly increased risk of reduced renal function was demonstrated among especially heavy users of nonaspirin NSAIDs or acetaminophen, while a possibly protective, albeit minimal, effect was seen with aspirin.[20] More conventional usage patterns were not associated with risk enhancement.[21]

Further attempts have been made to identify an epidemiologic link between NSAID consumption and CKD.[22–27] As is often the case with retrospective, case-control, and cross-sectional studies, caution is warranted in interpreting these data. Many of these studies relied on estimates and recollections by patients of their pill consumption over many years. The variability of the collective data precludes any meaningful estimate of actual risk. In some studies, interactions of NSAIDs with renal failure were limited to small subsets of subjects. Even in those studies showing an association between NSAID use and CKD, the causal sequence remains unproven, because increased use of NSAIDs may occur as a consequence of musculoskeletal complications of CKD, such as metabolic bone disease and crystal arthropathies. Whether NSAID use is heavier among persons with CKD than in demographically comparable subjects with normal kidney function is unclear.[28]

One group has attempted to clarify the role of NSAIDs in the pathogenesis of CKD by prospectively examining the incidence of papillary necrosis among 259 people receiving long-term, high-dose NSAIDs for treatment of arthritis.[29] Over the 11-year study period, 69 new cases of papillary necrosis were diagnosed and confirmed radiographically. This study, while prospective, poses several impediments to interpretation. First, the population was demographically limited; the subjects were all Malaysian. Second, in addition to nonaspirin NSAIDs, some of the affected patients received other analgesics, including aspirin, phenacetin, paracetamol, and herbal supplements. Third, of the 29 patients who took nonaspirin NSAIDs alone, some received phenylbutazone. Fourth, no longitudinally studied control group of age-matched arthritis patients not receiving NSAIDs was available for comparison. These shortcomings notwithstanding, the incidence of papillary necrosis documented in this study is concerning, particularly in light of the fact that papillary necrosis is not a highly sensitive finding for diagnosing analgesic nephropathy radiographically.[30]

Relationship between NSAID-Induced CKD and Analgesic Nephropathy

The term *analgesic nephropathy* is traditionally reserved for a syndrome of progressive renal atrophy and failure resulting from long-term use of phenacetin or related compounds, alone or in combination with other drugs. Because NSAIDs have analgesic properties, NSAID-induced CKD is often classified under the same heading. Although classic analgesic nephropathy and chronic NSAID-induced interstitial disease are both characterized by chronic tubulointerstitial nephritis and papillary necrosis, it is unlikely that they share the same pathogenesis. The mechanism by which phenacetin injures kidneys involves accumulation in the medulla of nephrotoxic metabolites and generation of reactive oxygen species (its relative acetaminophen has similar, albeit milder, effects). NSAIDs have minimal cytotoxicity in renal tissue *per se*. Their damage appears mediated through the previously discussed ischemic mechanism. Despite these differences, the two drug etiologies are closely linked epidemiologically, because patients commonly use both forms of analgesics. It is likely that their respective mechanisms are synergistic in the pathogenesis of CKD in patients taking NSAIDs and acetaminophen or phenacetin in combination.[31] Although phenacetin-induced analgesic nephropathy predisposes to the development of renal and urologic neoplasms, this association has not been described with NSAIDs.[32,33]

Conclusions

Although the accrued evidence that NSAID use can induce chronic kidney injury is not ironclad, it is strong enough to support the following conclusions: (a) NSAIDs appear capable of causing a morphologic pattern of renal injury similar to that of classic analgesic nephropathy, with interstitial fibrosis and papillary necrosis; (b) this form of injury appears limited to patients with very high cumulative NSAID exposure; and (c) the toxicity of NSAIDs may be magnified when taken in combination, or in conjunction with other medications such as acetaminophen and caffeine. The possibility that men may be more susceptible than women to NSAID-related CKD, as suggested by two of the individual studies cited, bears further study. Clinicians should be mindful of the likelihood of a causal link between NSAIDs and CKD when committing patients to long-term NSAID therapy. Blood pressure, blood chemistries, and urinalysis should be monitored routinely during treatment. At the earliest sign of change in any of these

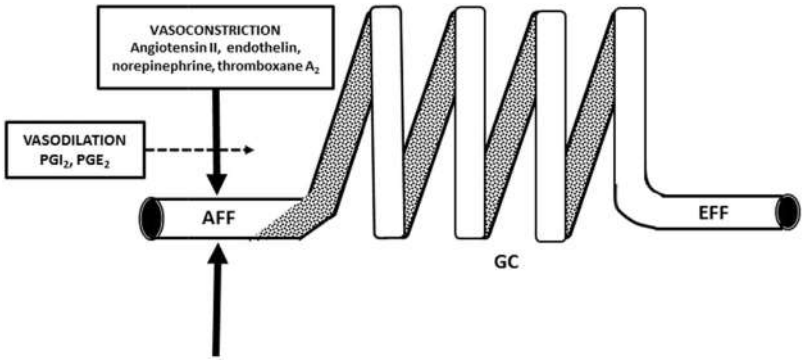

FIGURE 65.2 **Prostaglandin dependence of renal function.** Vasodilatory prostaglandins such as PGI_2 and PGE_2 offset the actions of circulating and locally produced vasoconstrictors at the afferent arteriole. This modulation of afferent resistance is particularly important in conditions of high vasoconstrictor activity. NSAID use under such conditions can lead to unopposed vasoconstriction and reduction of glomerular perfusion. *AFF*, afferent arteriole; *EFF*, efferent arteriole; *GC*, glomerular capillary.

parameters, alternatives to NSAID therapy should be considered, some of which may be found later in this chapter.

ADVERSE CONSEQUENCES OF NSAID THERAPY IN PATIENTS WITH CKD

Are patients with CKD at enhanced risk for adverse renal effects and, if so, which ones? What is known about the pathogenesis of such effects, and how can they be avoided in CKD patients for whom NSAID therapy is indicated?

Indeed, an array of renal abnormalities attributable to NSAIDs have been described. These have been reviewed extensively[34–41] and are shown in Table 65.4. In normal individuals, NSAIDs rarely evoke significant changes in blood pressure, renal function, water, or electrolyte balance. NSAID-related renal syndromes occur almost exclusively in pathophysiologic settings, an observation that is consistent with the primarily compensatory role of renal prostaglandins. Of these predisposing conditions, which are listed in Table 65.3, CKD was among the first to be reported.

Acute and Acute-On-Chronic Kidney Injury Due to NSAIDs

To maintain glomerular blood flow in the face of an activated renin–angiotensin system, as occurs in congestive heart failure, cirrhosis, and sodium deprivation, modulation of afferent arteriolar resistance by vasodilatory prostaglandins (PGs) is essential. The prostaglandin dependence of renal function in patients with these conditions is evidenced by their elevated urinary excretion of prostaglandin metabolites, and the observation that NSAIDs can cause AKI in these conditions. This form of AKI has been variously termed vasomotor nephropathy, autoregulatory failure, functional acute renal failure, or decompensated prerenal azotemia (Figure 65.2). As is characteristic of hemodynamically mediated forms of AKI, the syndrome will usually reverse readily when the offending agent is withdrawn, although if renal perfusion has been sufficiently compromised by the NSAID, frank acute tubular necrosis (ATN) may develop.[29]

Recent reports have suggested a particularly heightened risk for AKI when NSAIDs are added to the medication regimens of patients already receiving diuretics and ACE inhibitors or ARBs.[41–46] This would seem straightforward from a pathophysiologic perspective as this combination of agents could impair autoregulation of vascular tone in both the pre- and postglomerular arterioles.

The prevailing hemodynamic adaptations that occur in CKD kidneys are less predictable. Patients with CKD typically have chronic volume expansion and suppression of their renin–angiotensin system, yet are still prone to NSAID-induced vasomotor nephropathy. In 1978, Kimberly and Plotz reported several patients with systemic lupus erythematosus who developed reversible AKI while receiving aspirin.[47] They subsequently reported the same phenomenon in association with other NSAIDs.[48] The best explanation for these findings is that while these patients ostensibly had good baseline renal function, their glomerular filtration rate (GFR) was probably maintained by glomerular hyperfiltration, and that this process is prostaglandin-dependent. Evidence exists to support this hypothesis. It is known from micropuncture studies in rats that subnormal afferent arteriolar resistance permits hyperfiltration in remnant glomeruli.[49,50] In a rodent kidney ablation model, the renal functional changes associated with uninephrectomy were blunted in rats treated with either indomethacin or a selective COX-2 inhibitor.[51] In

humans, the hyperfiltration observed in a group of subjects with sickle cell nephropathy was blunted by both indomethacin and sulindac,[52] by celecoxib in euglycemic patients with early type 1 diabetic nephropathy,[53] and by aspirin in children with chronic obstructive uropathy.[54]

The observations of Kimberly and Plotz notwithstanding, review of the literature on NSAID-related AKI suggests that this phenomenon occurs much less frequently with salicylates than with other classes of NSAIDs. Early literature suggested that sulindac, too, was less often associated with such cases.[55,56] However, a recent meta-analysis of this literature suggests that the relative nephrotoxicity of different NSAIDs, including the selective COX-2 inhibitors, is still not well established.[57]

The exact risk of acute renal decompensation in a CKD patient at the outset of NSAID exposure is unknown because prospective data from randomized, controlled trials are lacking, and because this risk may be further influenced by multiple factors. In a general population survey among residents of Saskatchewan, current NSAID use was found to raise the risk of hospitalization for AKI fourfold. Age >65 years was likewise an independent risk factor with an associated hazard ratio of 3.5. Unfortunately, baseline level of renal function was not examined as a risk factor in this analysis.[58] However, other epidemiologic surveys as well as clinical investigation provide evidence that renal senescence is a risk factor (see below).

In patients with glomerular diseases, the sensitivity of renal function to cyclooxygenase-inhibiting drugs was noted by Patrono and colleagues to correlate with basal excretion of 6-keto-$PGF_{1\alpha}$, the chief metabolite of prostacyclin, suggesting dependence of renal function on prostacyclin. This group found that patients with active lupus nephritis excrete large amounts of not only 6-keto-$PGF_{1\alpha}$, but thromboxane B_2, the main metabolite of the vasoconstrictor prostanoid thromboxane A_2, as well. Their experience is that renal function in lupus nephritis is less severely affected by NSAIDs than in other glomerular diseases. They posit that, at baseline, lupus patients produce excessive thromboxane A_2 which causes chronic afferent vasoconstriction, thus limiting glomerular filtration. When these patients take NSAIDs, the decremental effect on GFR that would be expected from reduced prostacyclin production is offset by the concomitant reduction in thromboxane. Patrono has suggested that the clinical consequences of cyclooxygenase inhibition in the intrarenal microcirculation depend on the net change in the balance between prostaglandins that are vasodilatory and inhibitory of platelet function vs. those that are vasoconstrictive and prothrombotic.[59] Further support for this hypothesis comes from their finding that thromboxane-specific inhibitors raise GFR in SLE.[60]

In summary, the CKD patient's renal response to an NSAID may be influenced by several factors:

1) *The etiology of the underlying renal disease.*
2) *The change in the specific pattern of eicosanoid synthesis engendered by cyclooxygenase inhibition.*
3) *The nature of the NSAID, its pharmacokinetics, and COX-specificity.*

The pharmacologic effects of NSAIDs vary markedly among specific agents. Sulindac, despite its chemical kinship to indomethacin, is much less nephrotoxic, although probably not totally innocuous as originally thought.[50,51] NSAIDs in the salicylate class are the least frequently identified in reports of adverse renal effects, but tend to have lower antiinflammatory potency than other NSAIDs.

The interest in COX-2-specific inhibitors derives from the fact that COX-1-generated PGE_2 is integral to the protection of the gastric mucosa. The selective COX-2 inhibitors have been implicated in numerous reports of adverse renal side effects, as might be expected given the abundant expression of cyclooxygenase-2 in the kidney.[38,61–64] *They should be considered no less potentially nephrotoxic than traditional cyclooxygenase inhibitors*. This heterogeneity of effects between NSAIDs is well exemplified in the coronary circulation. Aspirin is a pure COX-1 antagonist that binds irreversibly to the membranes of platelets and blocks the synthesis of their principal eicosanoid product, thromboxane A_2. This specificity confers on aspirin its balance of antithrombotic and antiinflammatory potency that is unique among NSAIDs and has made aspirin the clinical mainstay in prophylaxis against coronary events.[65] A meta-analysis of the effects of other NSAIDs on the risk of atherothrombotic events (chiefly myocardial infarction and stroke) showed a substantially increased risk with rofecoxib, diclofenac, and ibuprofen, but not naproxen or celecoxib.[66] The association between rofecoxib and coronary events was sufficiently serious to force the withdrawal of this agent from the market.[67,68]

Pharmacokinetics may also influence risk. In a German study comparing renal function in NSAID users compared with nonusers undergoing elective orthopedic surgery, the prevalence of renal dysfunction was highest among patients using longer half-life (>4 hours) drugs. This study was a cross-sectional, interview-driven analysis looking at prevalence, not incidence, and thus limited in its ability to establish causality or to differentiate between CKD and AKI.[69] A randomized, prospective,

drug challenge study in an elderly cohort demonstrated that the negative effect on GFR of the longer acting NSAIDs sulindac and celecoxib is more sustained than that induced by ibuprofen.[70] Similar findings were reported by other investigators.[71]

4) *Timing of drug exposure.* The acute renal response to NSAIDs may differ from the chronic response. In the study referenced immediately above, which was designed to delineate the acute and chronic effects of various NSAIDs on renal function in an elderly cohort, while most subjects demonstrated a decline in GFR within an hour of drug challenge, no effects were seen following one-month of sustained exposure to the same agents.[72]
5) *"Host" factors, including patient age.* The response of renal function to NSAIDs has been studied extensively in the elderly population, because the prevalence of both CKD and age-related decline in renal function without evidence of discrete renal disease is high. The results have varied from study to study. Caution has been recommended in committing elderly patients to sustained courses of long-acting NSAIDs.[73,74] In another drug challenge study with a crossover design comparing the effects of celecoxib vs. naproxen in healthy elderly subjects over periods of up to 10 days, both agents engendered negative changes in GFR and sodium excretion, albeit of minimal magnitude.[62] Although the risk of AKI from NSAIDs in the truly healthy elderly is probably very small, the prevalence of comorbidities including unrecognized CKD among the aged warrants close monitoring when prescribing NSAIDs, especially in the very elderly (age >85 years).[74]

Nonhemodynamically Mediated Acute Kidney Injury Due to NSAIDs

A*cute interstitial nephritis* (AIN) due to NSAIDs is relatively unusual. It differs from typical drug-induced AIN in lacking hypersensitivity features such as eosinophilia, eosinophiluria, or rash and is often accompanied by nephrotic-range proteinuria. It is the most idiosyncratic of NSAID-related renal syndromes. Antecedent CKD is not, as far as is known, a risk factor. Tubulointerstitial nephritis was been reported in patients receiving aminosalicylates for inflammatory bowel disease.[75,76]

Medications with solubility characteristics conducive to intratubular crystallization can cause microobstructive AKI. This phenomenon is rare with NSAIDs, but has been reported with sulindac, and was partly responsible for the removal of zomepirac from the marketplace in the 1980s. As with AIN, there is no evidence that CKD places the patient at increased risk.

Effect of NSAIDs on the Progression of Established CKD

Concern has been expressed in the medical literature that long-term NSAID use may exacerbate the course, or accelerate the progression, of chronic renal parenchymal disease. Gooch et al. evaluated the effects of NSAIDs on kidney function in a large population of older (>66 years) patients with preexisting CKD. Patients in the highest decile of self-reported cumulative NSAID use had a 26% increase in risk of experiencing a mean decline in eGFR of >15 mL/min/1.73 m^2 over a two-year study period compared with nonusers.[77] A cross-sectional study of over 19,000 CKD patients in a random sampling of Taiwanese National Health Insurance enrollees found that use of aspirin, nonaspirin NSAIDs, and acetaminophen all were associated with markedly increased risk of ESRD in a cumulative dose-dependent manner. Again, the order of causality cannot be strictly established due to limitations inherent to this type of the study and the question raised by the observed interaction with acetaminophen.[78]

Exactly how serious a threat NSAIDs pose for accelerated progression of CKD, and whether certain etiologies of CKD may be more prone than others, are as yet unknown. From a mechanistic standpoint, it is entirely plausible that NSAIDs could accelerate CKD progression by superimposing an ischemic insult on that of the primary renal disease. However, this same reduction in perfusion might be expected to afford the glomeruli protection from hyperfiltration injury. These effects of NSAIDs on glomerular hemodynamics were the basis for their use years ago in patients with severe and refractory nephrotic syndrome for palliation of proteinuria. Despite sporadic reports of success, this approach has been largely abandoned due to the availability of more reliable alternatives. Consequently, little has been learned about the impact of prolonged, deliberate NSAID exposure on the course of CKD. NSAIDs have also been employed as antithrombotic therapeutic adjuncts in chronic glomerulonephritis, but this experience, too, has added little to our understanding of the net effect of long-term NSAID use on chronic renal disease outcomes. At this time, there is no solid evidence on which to base the use of NSAIDs as a nephroprotective measure in CKD. In fact, based on available data, the clinician is well advised to act on the assumption

that NSAIDs can speed the progression of renal injury and to minimize exposure of CKD patients to them. A recent meta-analysis of the global literature linking NSAIDs and CKD reached similar conclusions.[79]

Hyperkalemia

The overall risk of hyperkalemia among patients taking NSAIDs is unknown and is clearly subject to ancillary host susceptibility factors, many of them the same as those for other renal complications of NSAIDs. In a large, Veterans Administration case-control study, the effect of NSAIDs as a sole, independent risk factor for hyperkalemia was negligible.[80] A 1985 Israeli study analyzed changes in renal function and serum electrolytes in 50 elderly inpatients receiving indomethacin for a variety of indications. A minority (≈30%) of these patients had underlying renal insufficiency. In all patients, potassium concentration rose steadily until discontinuation of the drug. In 13 patients, the increment in serum potassium concentration (S[K]) exceeded 3.6 mMol/L, and in 23 the peak potassium concentration exceeded 5.0 mMol/L. Not surprisingly, older age and the presence of predrug azotemia correlated with the magnitude of rise in S[K] level. The authors did not report which other medications these patients might have received.[81]

Although the patients at greatest risk for hyperkalemia are those who sustain AKI from NSAIDs, hyperkalemia can occur even in the absence of a substantial fall in GFR. The pathogenesis of NSAID-related hyperkalemia is felt chiefly to reflect the suppressive effect on the renin–angiotensin–aldosterone axis of inhibiting prostaglandin synthesis and may present as type IV renal tubular acidosis. In one such case, the patient's underlying rheumatologic condition necessitated continuation of the NSAID, but the manifestations of type IV RTA were controlled with the addition of fludrocortisone to his therapeutic regimen.[82] An identical pattern of hyperkalemic acidosis occurs in congenital hypoprostaglandism.[83] Because, in normal subjects, indomethacin impairs neither the disposal of nor the aldosterone response to an acute potassium load,[84] one must assume that reduced availability of prostaglandins is somehow deleterious to adrenocortical function in those individuals who develop NSAID-induced hyporeninemic hypoaldosteronism.

Other pathogenetic mechanisms of hyperkalemia from NSAIDs have been posited. There is evidence suggesting that function of potassium secretory channels in the distal nephron may be dependent on prostaglandins.[85] It has also been speculated, albeit never proved, that prostaglandins may facilitate transcellular disposition of potassium.

NSAID therapy should be approached cautiously in patients with baseline renal insufficiency or other medical conditions that may reduce potassium tolerance. Extreme caution is warranted when adding NSAIDs to regimens that include other medications associated with hyperkalemia, notably ACE inhibitors, ARBs, aliskiren, spironolactone, trimethoprim, and potassium-sparing diuretics.

Hyponatremia

Prostaglandins oppose the effects of ADH on the collecting tubule epithelium, thus providing a counterregulatory balance to ADH-induced water reabsorption. It is not surprising that NSAIDs may render patients prone to hyponatremia. At highest risk are patients with preexisting conditions known to limit their water excretion, particularly those characterized by a reduction of effective circulating volume, such as congestive heart failure.[86] Even with normal systemic hemodynamics, however, CKD can predispose to NSAID-induced hyponatremia. Clinicians must exercise caution when considering persons with CKD for a course of NSAID therapy, particularly those patients with a prior history of hyponatremia. Blood chemistries should be monitored frequently (about every two weeks or until the stability of blood chemistries has been ascertained) with the expectation of determining the possible need for daily water restriction. Although a synergistic effect of NSAIDs and thiazide diuretics in promoting hyponatremia has not yet been demonstrated, it would seem prudent to avoid this drug combination.

Sodium Retention

Antinatriuresis is the most common renal side effect of NSAIDs. In large trials of nonspecific and COX-2-specific NSAIDs in patients with osteoarthritis, the incidence of edema, generally mild, ranged from approximately 2–6%.[87] Again, the most vulnerable patients are those with sodium retentive conditions such as cirrhosis and congestive heart failure, disorders in which optimization of renal hemodynamics is prostaglandin-dependent. Cyclooxygenase inhibition in these situations lessens glomerular perfusion and filtration, resulting in both a reduction of the filtered load and increased tubular reabsorption of sodium. In addition to altered hemodynamics, sodium retention also reflects the elimination of the natriuretic effects of prostaglandins, which inhibit tubular sodium transport in the normal kidney. This more direct antinatriuretic action of NSAIDs can occasionally have significant impact even in normal individuals. In one investigation in which 36 normal subjects were challenged with

indomethacin or a COX-2-selective NSAID, the antinatriuretic effects of each agent were shown to persist only through the first 72 hours of treatment.[88] How this escape natriuresis occurs is unknown nor is it known why it presumably fails to occur in those occasional seemingly normal individuals who develop edema on NSAIDs.

Studies have demonstrated NSAIDs are capable of mitigating the natriuretic effects of loop and thiazide diuretics.[89–94] Sodium retention, like most other renal side effects of NSAIDS, is reversible. Natriuresis generally occurs on discontinuation of the drug, with restoration of pretreatment sodium balance.

Exacerbation of Hypertension

The intimate relationship between hypertension and CKD is familiar to all clinicians and detailed elsewhere in this text. Hypertension is a common primary cause of CKD. Conversely, hypertension is the nearly inevitable result of declining GFR in patients with CKD of most etiologies. Regardless of whether hypertension represents a primary or secondary phenomenon in a given patient with CKD, it can accelerate the course of progressive renal injury. Besides blunting the action of diuretics, NSAIDs can reduce the efficacy of other antihypertensive agents including calcium channel blockers,[95] vasodilators,[87] and, possibly, beta blockers.[96,97] In a randomized controlled trial in which celecoxib was given to 178 participants already receiving an ACE inhibitor for hypertension, no effect of the NSAID on blood pressure was seen.[98] The ability of NSAIDs to mitigate action of some antihypertensive drugs is understandable, given the vasodilatory and natriuretic properties of the predominant renal eicosanoids. In the Success VI trial comparing the vascular effects of rofecoxib and celecoxib, the tendency to cause edema paralleled their tendency to cause increased systolic blood pressure, with rofecoxib exerting greater effects than celecoxib.[99] The significance of these observations is threefold. First, they strengthen the contention that antinatriuresis plays a role in NSAID-related exacerbation of hypertension. Second, they illustrate that cyclooxygenase-2 specificity may actually enhance the harmfulness of NSAIDs to the kidneys. Third, they underscore the disproportionate morbidity of rofecoxib compared with the closely related compound, celecoxib. This last point was upheld in another similar study comparing the vascular actions of several NSAIDs in type 2 diabetic hypertensive patients receiving NSAIDs for osteoarthritis, which found rofecoxib more apt to exacerbate hypertension than either naproxen or celecoxib.[100]

Because CKD is so prevalent and so likely to go unrecognized in our population, and because antiinflammatory self-medication use is so abundant, physicians should alert their patients to the potential for untoward interactions.[26] The significance of NSAIDs in clinical hypertension resides in their ability to exacerbate preexisting hypertension or to vitiate the actions of antihypertensive drugs. However, evidence from several sources, including the national Nurses Health Study, raises concern about an increased risk of incident hypertension among otherwise healthy persons who use NSAIDs heavily.[101–103] In any event, blood pressure, like other parameters of renal function, should be monitored closely throughout the course of NSAID therapy in patients with known hypertension or CKD or both, and appropriate adjustments in antihypertensive regimens made when necessary.

NONRENAL SIDE EFFECTS OF NSAID USE IN PATIENTS WITH CKD

NSAIDs can increase the risk of cardiovascular events in patients with atherosclerosis. Given the enormous prevalence of atherosclerosis at all stages of CKD, such patients should be considered at particularly high risk for cardiovascular morbidity when taking NSAIDs. It is important to inform patients of this risk and advise them to seek immediate medical attention if any symptoms suggestive of coronary or cerebrovascular ischemia should arise. The risk of atherothrombotic complications in these patients is another reason why stringent attention must be paid to blood pressure control.

Of all NSAID side effects, the most familiar to physicians and patients alike, and the most concerning epidemiologically, are those involving the gastrointestinal tract: dyspepsia, gastritis, peptic ulceration, and upper gastrointestinal hemorrhage. Gastritis and peptic ulcer disease were formerly thought to be more prevalent in CKD patients than in the population at large. Although current consensus challenges this contention, recent evidence suggests that CKD patients with peptic ulcer disease are more prone to complications such as recurrent bleeding.[104] Given this, and the clinical observation that peptic ulcer disease tends to be less symptomatic in CKD patients than in others, it is prudent to consider these patients at increased risk of gastrointestinal morbidity from NSAIDs. Although COX-2 inhibitors are safer from the gastrointestinal standpoint, they are no safer for the kidneys than traditional NSAIDs and may pose a higher risk of cardiovascular complications. It is thus impossible to specify a particular NSAID of choice for CKD patients. Agents of either group should be used with extreme caution, and patients should be monitored for the appearance of gastrointestinal

complications. CKD patients receiving NSAIDs should receive proton-pump inhibitors concomitantly for gastrointestinal prophylaxis.

NSAIDS AND CKD: RECOMMENDATIONS FOR THE CLINICIAN

The combined prevalence of NSAID use and CKD throughout the modern world represents a substantial hazard for untoward interactions. Fortunately, most adverse renal effects of NSAIDs are reversible, and patients at highest risk are readily identifiable. The presence of risk factors does not categorically preclude the use of NSAIDs when indications arise, as long as careful physician oversight of NSAID therapy is provided. An algorithm illustrating an approach we recommend is shown in Figure 65.3. When NSAID therapy is indicated for a patient with renal risk factors, it may be worth starting with one of the better tolerated agents such as a nonacetylated salicylate. While less often associated with renal side effects, these agents lack the antiinflammatory potency of most other NSAIDs. They are unlikely to be of benefit in a highly active inflammatory state such as acute gouty arthritis or a flare of systemic lupus. If they are tried, and fail to engender the desired therapeutic response, a trial of a more potent NSAID such as naproxen, indomethacin, or ibuprofen may be considered, provided the patient is closely monitored.

NSAIDs are extremely effective in the treatment of a wide variety of inflammatory conditions and have an established role in the palliation of pain. What alternatives are available for patients who cannot tolerate them? The answer to this question clearly depends on the indication for treatment. Corticosteroids offer an alternative option for treating inflammatory disorders. The risks associated with systemic steroid therapy must be weighed if this option is under consideration. A localized inflammatory condition, such as a monoarthritis or bursitis, may respond to direct injection, which lessens systemic exposure. CKD patients with gout or pseudogout can be safely treated with colchicine provided the clinician titrates the dose carefully to minimize gastrointestinal symptoms. If colchicine therapy is to last longer than a week, the white blood cell count should be monitored.

Acetaminophen is a good alternative to NSAIDs for management of mild to moderate pain. Although

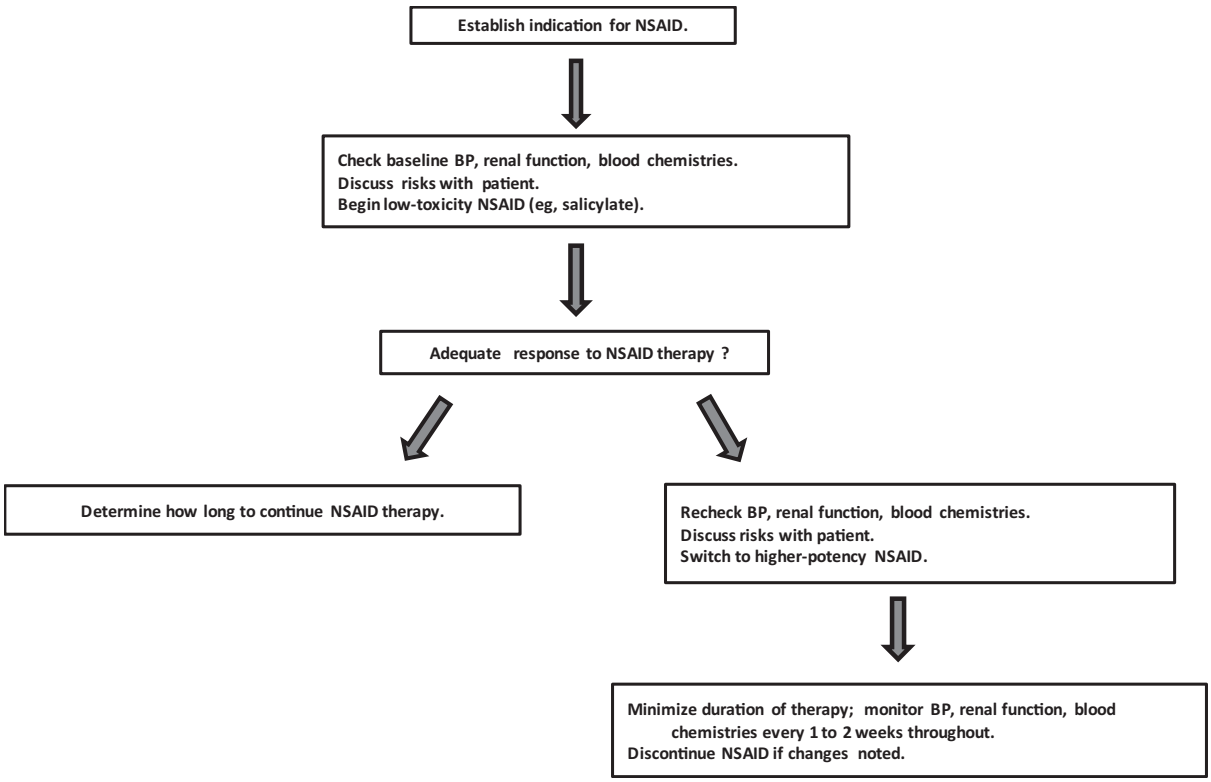

FIGURE 65.3 **Suggested algorithm for safe treatment with NSAIDs in patients with CKD.** Patients with known risk factors should be monitored for renal complications throughout course of therapy. Low-toxicity NSAIDs, specifically nonacetylated salicylates, are less apt to cause renal side effects, but often have less therapeutic efficacy. When higher potency nonsteroidals are used in patients at risk, vigilance must be intensified. Alternatives to NSAIDs for the management of pain and inflammation are discussed in text.

acetaminophen does have slight nephrotoxic potential, this does not pose a significant risk until a very high cumulative dose exposure is reached. Opioids represent another option.

OPIOIDS AND CKD

Narcotic analgesics can be used as NSAID alternatives in patients with moderate to severe pain provided the clinician and patient are mindful of their risks. Clinical safety of these agents from the renal standpoint will be considered in the following section.

OPIOID-INDUCED NEPHROPATHIES

Although the direct nephrotoxicity of opioids is questionable, they have the ability to engender acute effects on prerenal, intrarenal, and postrenal physiology. Understanding these effects is essential to predicting the acute and long-term effects of opioids on kidney function.

Acute Renal Effects of Opioids

Prerenal renal azotemia due to opioids occurs as a result of opioid-induced hypotension, which arises through several mu opioid receptor (MOR)-mediated mechanisms. These include suppression of CNS sympathetic outflow, histamine-induced vasodilation, and blunting of reflex vasoconstriction in response to fluctuations in arterial blood gases.[105] Recent *in vivo* studies suggest this effect may also be mediated by nitric oxide[106,107], or by indirect activation of the apelin receptor.[108] Because of their hypotensive effect, opioids should be used with caution in CKD patients to avoid worsening of intradialytic hypotension and further decrease in renal perfusion in the setting of already compromised renal blood flow. Fentanyl, which has multiple pharmacokinetic properties favorable for use in renal impairment, appears to exert the least hemodynamic impact among opioids.

Acute intrarenal effects of opioids. Kidney injury due to rhabdomyolysis is commonly seen with opioid overdoses that result in prolonged immobilization. Animal studies suggest that opioid exposure itself also has the potential to exert physiological damage on the kidney at the cellular level. Morphine has been shown to compromise podocyte integrity, inducing microalbuminuria[109] and to induce mesangial cell proliferation and superoxide formation resulting in glomerular injury *in vitro*.[110–112] Perhaps related to these observations, Yatsynovich et al. described a case of a 61-year-old man with stage IIIa CKD attributed to chronic NSAID use for back pain. After two years of abstention from NSAIDs, during which time the patient had been using oxymorphone for analgesia, he developed proteinuria and acute-on-chronic renal failure. Renal biopsy revealed lamellated, phospholipid-like deposits in podocytes similar to those seen in Fabry's disease as well as in renal injury from other medications. The patient's kidneys recovered to baseline following abstinence from oxymorphone.[113] Therapeutic doses of tramadol and tapentadol have also been shown to produce histological changes in rat renal tissue mediated by oxidative stress[114] although we are unaware of any reports of human renal injury due to these agents.

Postrenal effects of opioids. Opioid-induced urinary retention results from MOR-mediated inhibition of the volume-evoked micturition reflex[115] and from decreased detrusor contractility *via* the inhibition of acetylcholine release by parasympathetic sacral neurons.[116,117] The anticholinergic activity of opioids does not correlate directly with their narcotic potency. Despite being among the weaker opioids, tramadol tends to exert the most potent anticholinergic effect among drugs in this class.[118]

Heroin Nephropathy and Other Renal Syndromes Associated with Opioid Abuse

"Heroin nephropathy" was widely reported in the 1970s and 1980s, although such reports have become rare in recent years. Whether this syndrome was attributable to the pharmacological properties of the active drug *per se*, to bulking agents and contaminants within the drug product, or to comorbidities and social factors associated with intravenous drug use (IVDU), has been debated. The preponderance of evidence favors the latter two explanations. Most cases were reported in users of "brown heroin," a variety originating predominantly in southwest Asia. Its brownish color reflects the specific chemical process by which it is formulated.[119] Phenacetin, a commonly used heroin additive, was banned by the FDA in 1983 because of its nephrotoxicity. The withdrawal of phenacetin may have contributed to the waning of the heroin nephropathy phenomenon.[120] A patient has been reported who developed acute renal injury due to crystallization of heroin in the renal tubules. Although this mechanism of renal injury is well known in relation to other pharmacologic agents, including NSAIDs, we know of only one such report of tubular injury due to heroin dissolubility.[121] Indeed, renal biopsies of patients with "heroin nephropathy" most commonly revealed the lesions of focal segmental glomerulosclerosis and membranoproliferative glomerulonephritis. These are also the lesions seen in the glomerulopathies associated with HIV and HCV infection,

also highly prevalent among IV drug users. It is speculated that advances in the diagnosis and treatment of these diseases have resulted in the reduced frequency with which heroin nephropathy is documented.[122–124] Infections associated with IVDU may have additional, indirect renal implications as they often result in exposure to nephrotoxic antiinfective agents. For example, tenofovir, a widely used antiretroviral agent for the treatment of both HIV and HBV infection, is known to cause ATN and Fanconi syndrome.[125–127] IVDU-associated bacterial infections such as infective endocarditis may also result in prolonged exposure to highly nephrotoxic antibiotics such as vancomycin and/or aminoglycosides, which may cause AIN and ATN, respectively.[128]

USE OF OPIOIDS IN PATIENTS WITH CKD

Recent evidence suggests that therapeutic use of opioids is widespread among patients with CKD and may even increase in patients with more advanced stages of CKD.[129] It behooves the nephrologist to have at least passing familiarity with the clinical pharmacology of these agents.

Agent-specific Considerations

As a family, the opioids vary widely in terms of their individual pharmacokinetics and routes of metabolism. This variability markedly influences the safety and proper prescription of each agent for use in patients with CKD. The following paragraphs, and Table 65.5, summarize the key considerations.

Morphine[130]: Morphine's kinetic and dynamic profiles make it unfavorable for use in patients with kidney disease. Symptoms of neurotoxicity such as cognitive impairment, tremors, and myoclonus can result from the glucuronidated morphine metabolite M3G, which tends to accumulate in patients with impaired renal function.[131] Morphine is also especially histaminergic[132] and therefore more likely to produce untoward hemodynamic effects than other drugs in this class.

Hydromorphone[133]: Hydromorphone's active metabolite HM3G has been shown to have neurotoxic effects similar to those produced by toxic morphine metabolites.[134,135] However, it is considered safer and possibly more effective than morphine.[136,137]

Codeine[138]: Codeine's metabolism and excretion are quite variable and subject to the influence of factors besides renal function, particularly CYP2D6 activity.[139,140] Codeine is converted into multiple metabolites, including morphine, *via* the CYP2D6 pathway. Given its unpredictable kinetics, and the likelihood of accumulation of downstream toxic metabolites, codeine is not recommended in kidney disease.

Hydrocodone[141,142]: As hydrocodone is eliminated primarily *via* the kidneys, patients with renal disease are at increased risk of sedation and respiratory depression. Dosage adjustment and careful titration are warranted.

Oxycodone[143]: Oxycodone is extensively renally eliminated and minimally dialyzable.[144] Renal dosing adjustments and careful titration are warranted with its use.

Meperidine[145]: The antinociceptive properties of meperidine have been shown to be minimal relative to the toxicity of its primary metabolite, normeperidine. Its place in pain management is, therefore, limited.[146] Because meperidine and normeperidine are extensively renally eliminated, its use is discouraged in renal failure. However, both meperidine and normeperidine are effectively removed by dialysis.[147]

Tramadol[148]: Tramadol exerts a weak narcotic effect and was only recently added to the DEA list of controlled substances. Approximately 30% of tramadol is eliminated by the kidney, resulting in its prolonged duration of effect with renal impairment. Because of its structural similarity to meperidine, tramadol shares many of its off-target anticholinergic and serotonergic effects and a propensity to cause seizures. Reduced dosing frequency in patients with renal failure and avoidance of use all together in patients with seizure history are therefore recommended.

Fentanyl[149,150]: Because less than 10% of active drug is excreted in the urine, fentanyl is unlikely to accumulate in patients with mild to moderate renal disease or when given in appropriately adjusted doses to patients with

TABLE 65.5 Suggested Dosing of Opioids as a Function of GFR[153–155]

GFR (mL/min)	Methadone	Oxycodone	Hydromorphone	Hydrocodone	Oxymorphone	Fentanyl	Tramadol	Morphine
>60	5 mg PO 2.5 mg IV	5–10 mg PO	1–2 mg PO 0.25–0.5 mg IV	5–10 mg PO	5 mg PO	25–50 mcg IV	50 mg PO	10 mg PO 2.5–5 mg IV
30–60	100*	50*	50*	75*	75*	100*	100*	50*
<30	75*	25*	25*	50*	50*	75*	Dose q12 hours	25*

Note: Further dose reduction should be considered for patients with eGFR <10 mL/min/1.73 m^2. Use of codeine, morphine, or meperidine is not recommended in CKD. Dosing recommendations are for immediate release dosage forms only.

** Percent of starting dose for GFR >60 mL/min.*

severe renal disease. The most commonly used nonparenteral formulation is the transdermal patch. Unfortunately, transdermal delivery delays the onset and duration of action by up to 12 hours from the time the patch is applied or removed, making it somewhat more difficult to monitor and titrate. As such, the patch is not recommended in patients who are opioid naïve, and further caution must be exercised when initiating its use in patients with kidney disease.

Methadone[151]: Methadone is notoriously difficult to titrate for several reasons including its tendency to accumulate in tissues, its long elimination half-life relative to duration of analgesia, and its somewhat idiosyncratic dose–response relationship. However, like fentanyl, less than 10% of active methadone is excreted in the urine, resulting in pharmacokinetics that are only minimally altered in the setting of renal impairment. Unlike other opioids, methadone can cause cardiac arrhythmias when combined with other QT-interval-prolonging agents. Patients with renal failure may be more susceptible to such drug–drug interactions.[152]

Dialytic Considerations

Because the narcotic effects of opioids, with few exceptions, are readily reversible with naloxone, the safety implications of nondialyzability are generally minimal. As dialyzability is inversely proportional to molecular weight, volume of distribution, protein binding, and water solubility, it is not surprising that pharmacokinetic studies have found methadone and fentanyl concentrations least affected by hemodialysis,[156–159] whereas drugs like morphine may be so readily dialyzed that a rebound effect may be observed as the elimination from the plasma during dialysis may exceed the rate of drug transfer to and from the CNS.[160] The chemical properties of each opioid agent that may affect its dialyzability are listed in Table 65.6.

Conclusions

The combined prevalence of NSAID use and CKD throughout the modern world represents a substantial hazard for untoward interactions. Fortunately, most adverse renal effects of NSAIDs are reversible, and patients at highest risk are readily identifiable. The presence of risk factors does not categorically preclude the use of NSAIDs when indications arise, as long as careful physician oversight of NSAID therapy is provided. An algorithm illustrating an approach we recommend is shown in Figure 65.3. When NSAID therapy is indicated for a patient with renal risk factors, it may be worth starting with one of the better tolerated agents such as a nonacetylated salicylate. While less often associated with renal side effects, these agents lack the antiinflammatory potency of most other NSAIDs. They are unlikely to be of benefit in a highly active inflammatory state such as acute gouty arthritis or a flare of systemic lupus. If they are tried, and fail to engender the desired therapeutic response, a trial of a more potent NSAID such as naproxen, indomethacin, or ibuprofen may be considered, provided the patient is closely monitored.

NSAIDs are extremely effective in the treatment of a wide variety of inflammatory conditions and have an established role in the palliation of pain. What alternatives are available for patients who cannot tolerate them? The answer to this question clearly depends on the indication for treatment. Corticosteroids are an option for treating inflammatory disorders. The risks

TABLE 65.6 Drug-specific Factors Affecting the Dialyzability of Opioids[161]

Agent	Molecular Weight	Volume of Distribution (L)	Protein Binding	Water Solubility
Methadone	309.4	1–8	85–90%	–
Oxycodone	315.4	2.6	38–45%	+
Hydromorphone	285.3	4	8–19%	+
Hydrocodone	299.8	Not reported	36%	–
Oxymorphone	301.3	2–4	10–12%	++
Fentanyl	336.5	4–6	79–87%	–
Tramadol	263.3	2.6–2.9	20%	–
Morphine	285.3	1–6	20–35%	++
Codeine	299.4	3–6	7–25%	–
Meperidine	247.3	3–4	65–75%	+

associated with systemic steroid therapy must be weighed against the use of other approaches if this option is under consideration. If the inflammatory condition is localized (such as a monoarthritis or bursitis), it may respond to direct injection, which lessens systemic exposure. CKD patients with gout or pseudogout can be safely treated with colchicine, provided the clinician titrates the dose carefully so as to minimize gastrointestinal symptoms. If colchicine therapy is to last longer than a week, the white blood cell count should be monitored.

Acetaminophen is a good alternative to NSAIDs for management of mild to moderate pain. Although, as noted, acetaminophen does have mild nephrotoxic potential, this does not represent a significant risk until a very high cumulative dose exposure is reached. Narcotic analgesics can be used as NSAID alternatives in patients with moderate to severe pain, provided the clinician and patient are mindful of the well-known risks associated with these agents.

Serious problems are associated with the widespread use of opioids, including misuse, abuse, overprescription, and diversion. Nevertheless, these drugs remain a valuable therapeutic tool in the treatment of pain refractory to nonnarcotic analgesics. Pharmacokinetics of many opioids are altered in CKD, and they vary in their dialyzability. For these reasons, dosing modifications are often necessary.

QUESTIONS AND ANSWERS

Question 1

A 64-year-old man is hospitalized for worsening shortness of breath. Ten days ago, he saw his physician for pain due to osteoarthritis of the knees and was given a prescription for naproxen (750 mg twice a day). He has a history of dilated cardiomyopathy felt to be of ischemic etiology, type 2 diabetes mellitus, and hypertension. He has remained on his other medications, which include lisinopril (20 mg a day), furosemide (20 mg twice a day), and glyburide (10 mg a day). On examination, BP = 150/95 mm Hg, heart rate = 98 bpm, respirations = 20/min. His O_2 saturation is 88% on room air. He appears short of breath. Crackles are heard over both lung fields, and 2+ pitting edema is present in the ankles and feet. Blood chemistries are as follows:

Sodium 133 mEq/L, potassium 6.0 mEq/L, chloride 109 mEq/L, bicarbonate 22 mEq/L, BUN 24 mg/dL, S[Cr] 1.1 mg/dL (baseline = 0.9 mg/dL), and glucose = 140 mg/dL.

A urinalysis is unremarkable.

ECG reveals no changes from his baseline. Chest X-ray reveals incipient pulmonary edema and blunting of the costophrenic recesses bilaterally.

Discontinuing his naproxen is unlikely to improve which of the following?

A. His ventricular function
B. His peripheral edema
C. His blood pressure
D. His hyperkalemia
E. His pulmonary edema

Answer: A

This 64-year-old man presents with signs and symptoms of decompensated heart failure. This is a well-known phenomenon associated with NSAID use in patients with precarious hemodynamics and chronic prerenal azotemia ("cardiorenal syndrome"). Because of their antinatriuretic effects, NSAIDs may cause peripheral and pulmonary edema. They can also worsen the degree of azotemia by causing autoregulatory failure in the intrarenal circulation. In addition to his worsened renal function, suppression of the renin–angiotensin–aldosterone axis leads to hyperkalemia. All these effects are mediated by abrogation of the compensatory physiologic effects of prostaglandins. NSAIDs have no direct or indirect effect on ventricular performance.

Question 2

A 35-year-old woman with stage 3 CKD due to reflux nephropathy decides to try ibuprofen in an over-the-counter formulation to relieve her dysmenorrhea. She has no other medical problems. Her only prescription medications include fosinopril (40 mg a day) and a prenatal-type multivitamin. She gets rapid improvement in her dysmenorrhea, but on the third day of taking it, she develops epigastric pain and nausea. She sees her physician who notes some localized epigastric tenderness on exam. She orders blood tests, recommends discontinuing the ibuprofen, and tells her to return tomorrow for follow-up.

Which of the following statements is TRUE?

A. Over-the-counter NSAID preparations are too mild to affect her renal function
B. The patient's symptoms probably reflect uremic gastritis
C. Stopping ibuprofen will likely resolve her epigastric pain and tenderness
D. Substituting a COX-2-specific NSAID is less likely to affect her kidney function
E. Substituting a COX-2-specific NSAID is likely to worsen her abdominal complaints

Answer: C

Gastric upset is one of the most common side effects of NSAIDs and, in contrast to most of the renal complications, may occur in otherwise normal individuals. Gastric symptoms may occur even with low-dose formulations such as those sold over-the-counter. Although this woman has underlying CKD, three days is much too rapid a time course for her to have developed uremic gastritis. There is no reason why she could not have cholelithiasis, but the time course points to the NSAID as the source of her abdominal discomfort. COX-2-specific NSAIDs are better tolerated by the GI tract, but just as risky from the renal standpoint.

Question 3

A 42-year-old man has been referred to you for evaluation of stage 4 CKD of unknown etiology. He recently emigrated from east Africa where he did not receive regular healthcare and can provide little information about his personal health history. He does not consume tobacco or alcohol and uses only one medication for aches, pains, and headaches. He shows you a bottle of this drug, but the label is written in his native language, and you cannot read it. The patient appears somewhat malnourished in appearance, but otherwise his examination, including his blood pressure, is unremarkable.

Blood chemistries are as follows: sodium 140 mEq/L, potassium 5.4 mEq/L, chloride 100 mEq/L, bicarbonate 24 mEq/L, BUN 30 mg/dL, S[Cr] 1.8 mg/dL, glucose 110 mg/dL, calcium 8.0 mg/dL, and albumin 3.4 g/dL. Urinalysis reveals 1+ proteinuria and no other notable findings.

A sonogram of his kidneys reveals them to be 8 and 9 cm in length with increased echogenicity, irregular contours, and findings consistent with papillary necrosis.

Which of the following possible etiologies for his renal disease is the LEAST likely?

A. Tuberculosis
B. Schistosomal nephropathy
C. NSAID-induced nephropathy
D. Non-NSAID analgesic nephropathy
E. Sickle cell nephropathy

Answer: B

All of the answer options represent diseases a patient with this geographic background could have, and all but one of them can cause papillary necrosis: schistosomal nephropathy, which is a glomerular disease. Renal tuberculosis would be an important "rule-out" in a patient of third-world origin presenting in this fashion. Sickle cell nephropathy must be considered in an African patient. Both of these diseases could account for his cachectic appearance. Lastly, until we have discerned the identity of the medication he takes for chronic aches and headaches, we must consider the possibility that it contains phenacetin or a nonsteroidal drug, either of which (especially the former) might cause papillary necrosis.

Question 4

A 77-year-old woman has a history of hypertension which has been very well controlled on atenolol (25 mg a day) and hydrochlorothiazide (25 mg a day). 5 days ago, she developed a painful monoarthritis of her right food diagnosed as gout. She was given a prescription for indomethacin (75 mg twice a day). Her foot pain improved dramatically, but over the past day-and-a-half she has been feeling "spacey" and a little nauseated. Other than a BP of 160/85 mm Hg, some residual right foot warmth and tenderness, and some subtle signs of confusion, her physical examination is unremarkable. Routine blood chemistries and a CBC are sent. Her serum sodium concentration is found to be 120 mEq/dL.

Which of the following statements is FALSE?

A. Indomethacin can potentiate the actions of antidiuretic hormone in the distal nephron
B. Indomethacin tends to increase urinary sodium excretion
C. Indomethacin can exacerbate hypertension even in previously well-controlled patients
D. Indomethacin is effective for treating gouty arthritis
E. Her indomethacin should be stopped and her hydrochlorothiazide put on hold

Answer: B

Indomethacin is effective in treating gouty arthritis and is a satisfactory alternative to steroids and colchicine. It is also a potent NSAID and has been implicated in more reports of renal side effects than any other drug in that family. Because prostaglandins counteract the effects of ADH on the collecting tubule, NSAIDs potentiate the activity of that hormone and can cause hyponatremia. For this reason, medications that can impair urinary dilution, like thiazides, should be avoided by patients taking NSAIDs. Prostaglandins inhibit tubular sodium reabsorption; they are natural natriuretic hormones. For this reason, NSAIDs can cause sodium retention and this can exacerbate hypertension.

Question 5

An 88-year-old woman complains of back pain and is found to have a compression fracture of her thoracic spine. She had tried taking acetaminophen without relief. Because she does not tolerate opiates well, her physician wishes to prescribe ketorolac for analgesia. The patient's medical history is remarkable for osteoporosis, congestive heart failure, and stage 2 CKD (baseline S[Cr] = 1.1 mg/dL). Her medications include enalapril (10 mg twice a day), furosemide (20 mg twice a day), alendronate (35 mg once every a week), and aspirin (81 mg a day).

How many risk factors does she have for untoward renal effects due to the ketorolac and what are they?

A. One
B. Two
C. Four
D. Five
E. Seven

Answer: C

She has four risk factors for untoward renal effects from the ketorolac: her (1) advanced age, (2) underlying renal insufficiency, (3) history of congestive heart failure, and (4) medications (ACE inhibitor and diuretic).

Question 6

A 29-year-old competitive distance runner collapses at the end of half-marathon and is transported to the emergency room of a local hospital. On arrival, she suffers a generalized seizure, following which she remains unresponsive for several hours. Her medical history is entirely unremarkable; her only medication is diclofenac 75 mg twice a day.

On physical examination, BP = 150/100 mm Hg, HR = 110/bpm, regular, and respirations = 14/min. She is afebrile and has a room air oxygen saturation of

99%. She is moving all extremities but is unresponsive. She is diaphoretic but does not appear noticeably volume depleted.

A cranial CT scan shows no evidence of trauma or hemorrhage, but there is a suggestion of cerebral edema.

A complete blood count, blood chemistry panel, and arterial blood gases are sent. The only abnormality is a serum sodium concentration of 119 mEq/L.

Which of the following statements about her presentation is TRUE?

A. She has acute hyponatremic encephalopathy
B. Diclofenac causes salt wasting by the kidney
C. Based on her high blood pressure, it is unlikely she is truly volume depleted
D. Diclofenac does not interact with ADH
E. Diclofenac probably triggered inappropriate ADH release

Answer: A

This patient has acute hyponatremic encephalopathy, an emergent and sometimes fatal condition that can occur in distance runners who drink water faster than they can metabolize it. As a result, osmotic dysequilibrium develops between the CNS and the bloodstream, leading to cerebral edema. Although diclofenac does not cause inappropriate ADH release, it, like other NSAIDs, potentiates the action of ADH on the renal collecting duct and can thus exacerbate hyponatremia of any etiology. Diclofenac, like all NSAIDs, is antinatriuretic. Many of the reports of acute hyponatremic encephalopathy in runners involved those who were taking NSAIDs.[162–164]

Question 7

A 31-year-old man with a longstanding history of intravenous heroin abuse is referred for evaluation of hematuria and proteinuria. Physical examination is remarkable for BP 140/95 mm Hg, diffuse lymphadenopathy, and scattered maculopapular, purplish lesions over his lower legs. BUN is 30 mg/dL, S[Cr] 1.8 mg/dL. Urinalysis reveals 2 to 3+ proteinuria and 1+ occult blood. Sediment contains 5–10 dysmorphic red blood cells per hpf and occasional finely granular casts.

In addition to renal biopsy, which of the following tests is/are indicated?

A. HIV serology
B. Cryoglobulins
C. Viral hepatitis panel
D. Urine toxicology
E. Antinuclear antibody

Answer: A, B, and C

This patient's history of intravenous heroin abuse places him at risk for HIV and chronic viral hepatitis infection. Both of these infections are associated with glomerulopathic syndromes. Hepatitis C is associated with membranoproliferative glomerulonephritis and cryoglobulinemic vasculitis, which could account for the lesions on lower extremities as well as the renal abnormalities. HIV-associated nephropathy (HIVAN) could also present in this fashion. The syndrome known as heroin nephropathy presents with FSGS-like histopathology and a similar presentation to this patient's and is of unclear pathogenesis, possibly representing one of the above viral-associated glomerulopathies or a reaction to impurities in the heroin. Various glomerulonephridites have also been associated with HIV infection. Even if his urine were to test positive for opioids, this would not refine the differential diagnosis at all, nor would it add anything to what we already know about his history. The patient's presentation makes lupus nephritis unlikely.[123,124]

CHAPTER

Dyslipidemia and Chronic Kidney Disease

Scott Reule[a], *Areef Ishani*[a], *David Goldsmith*[b]

[a]Minneapolis VA Health Care System, University of Minnesota, Minneapolis, MN, United States;
[b]Guy's and St Thomas' Hospital, London, United Kingdom

Abstract

Dyslipidemia in patients with chronic kidney disease (CKD) is common, characterized by high triglyceride levels and low HDL concentrations, while total and LDL cholesterol (LDL-C) are normal or low. Most CKD patients are at very high risk of cardiovascular events. CKD patients with low as well as high levels of total and LDL-C are at the highest risk of developing adverse outcomes. Thus, elevated cholesterol seems unsuitable as the sole criterion for prescription of statins in CKD patients. The decision to treat patients should be based on pretreatment risk of cardiovascular events and not solely pretreatment LDL-C.

The new Kidney Disease: Improving Global Outcomes clinical practice guidelines on lipid management recommend fixed statin or statin/ezetimibe treatment in adults aged ≥50 years with eGFR <60 mL/min/1.73 m^2 but not treated with chronic dialysis or kidney transplantation. In dialysis patients, the magnitude of any relative reduction in risk appears to be substantially smaller than in earlier stages of CKD. Initiation of statin treatment is not recommended for most prevalent hemodialysis patients. Treatment escalation with higher doses of statins is not recommended because higher doses of statins have not been proven to be safe in the setting of CKD. Because LDL-C levels do not necessarily suggest the need to increase statin doses, follow-up measurement of lipid levels is not recommended.

THE TYPICAL LIPID PROFILE IN CKD PATIENTS

Disturbance in serum lipid constituents is a common and well-recognized feature of chronic kidney diseases (CKDs). However, as so many body systems adapt, change, or fail in the context of CKD, it is imperative to understand whether these lipid disturbances are etiopathogenically relevant to patient outcomes, which are, as is widely known, dire regarding cardiovascular disease. With trials reported over the last two decades, some new insights have been made regarding this important matter. Hyperlipidemia or dyslipidemia in patients with CKD is typically characterized by high triglyceride (TG) levels and low high-density lipoprotein (HDL) concentrations, while total and low-density lipoprotein concentrations (LDL-C) are normal or low.[1,2] Patients with proteinuria and patients treated with peritoneal dialysis (PD) have higher levels of LDL-C than nonproteinuric CKD or hemodialysis (HD) patients. The distribution of lipid profile can vary with respect to stage of CKD, the presence of the nephrotic syndrome, and type of renal replacement therapy (RRT) employed. The typical distribution of lipid among patients with various stages of CKD and end-stage renal disease (ESRD) is shown in Table 66.1.[3] Although the lipid abnormalities delineated by routine laboratory measurements may not seem to be numerically impressive, more sophisticated research analyses reveal profound underlying disturbances in lipid metabolism. One example is a shift in the composition and size distribution of all lipoproteins. The best example is the shift in the composition and size distribution of LDL to increased content of small dense LDL, which is then susceptible to undergoing oxidation during prolonged circulation.

PATHOPHYSIOLOGY OF DYSLIPIDEMIA IN CKD AND END-STAGE RENAL DISEASE

The concentration of TG-rich lipoproteins (very low–density lipoprotein (VLDL), intermediate-density lipoprotein (IDL)) is increased in CKD and ESRD patients, mainly as a result of decreased catabolism, particularly in the postprandial phase. Lipolysis of the highly atherogenic VLDL and chylomicron remnants is impaired, partly due to decreased lipoprotein lipase (LPL) on the vascular endothelium and partly due to increased levels of the major LPL inhibitory

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00066-8

TABLE 66.1 The Typical Lipid Profile of Patients With CKD

	CKD 1–5	Nephrotic Syndrome	Hemodialysis	Peritoneal Dialysis
Total Cholesterol	↗	↑↑	↔↓	↑
LDL-C	↔↓	↑↑	↔↓	↑
HDL-C	↓	↓	↓	↓
Non-HDL-C	↗	↑↑	↑	↑
TG	↗	↑↑	↑	↑
Lp(a)	↗	↑↑	↑	↑↑

Non-HDL cholesterol includes cholesterol in LDL, VLDL, IDL, and chylomicron and its remnant. Explanation of arrows: normal (↔), increased (↑), significantly increased (↑↑), and decreased (↓) plasma levels compared with nonuremic individuals; increasing (↗) and decreasing (↘) plasma levels with decreasing GFR.

apolipoprotein, apo CIII. Increased levels of small dense LDL result from increased TG concentration, which, by the action of cholesterol ester transfer protein and hepatic lipase, are involved in the formation of small dense LDL.

Functional deficiencies in lecithin:cholesterol acyltransferase (LCAT) and LPL activity affect HDL maturation and disorders. Processes favoring HDL maturation are associated with a greater abundance of large mature HDL, affecting serum levels. The formation of HDL particles is mediated by LCAT, resulting in the esterification of cholesterol—as well as by LPL. In addition, elevated levels of lipoprotein(a) (Lp(a)) have been found in CKD patients.[4–8] Lp(a) is an LDL-like particle which has an additional protein, apolipoprotein(a). Lp(a) constitutes an important independent risk factor for the development of atherosclerosis.

IMPACT OF PROTEINURIA ON DYSLIPIDEMIA

Patients with nephrotic syndrome have the most prominent abnormalities in lipid metabolism. About half of the patients have total cholesterol concentrations above 300 mg/dL, and 80% of the patients had LDL-C levels above 130 mg/dL.[7,9] Many patients also have elevated levels of TGs. Additionally, HDL-C levels are distributed abnormally (increased HDL_3 fraction and decreased HDL_2 fraction). Dyslipidemia in the nephrotic syndrome results from increased hepatic synthesis and decreased catabolism of lipoproteins. Increased TG-rich lipoprotein concentration, VLDL, and IDL primarily result from decreased clearance, partly due to reduced LPL activity. LPL is necessary for normal lipolysis. In addition, both LDL and Lp(a) synthesis are increased, due to decreased activity of LCAT, and the number of spherical HDL particles is decreased. These particles are important carriers for apo CII, a cofactor determining LPL activity and VLDL levels.[10,11]

IMPACT OF DIALYSIS ON DYSLIPIDEMIA

Dyslipidemia becomes more pronounced as decrements in glomerular filtration rate (GFR) advance to CKD Stage 5 requiring dialysis. An increase in plasma TGs, VLDL, and IDL, along with a reduction in HDL-C, is typical. HD and PD appear to have different effects on uremic dyslipidemia.[12,13] Patients treated with PD have higher cholesterol, TG, LDL, and Lp(a) levels than patients treated with HD, where total cholesterol and LDL-C can be normal or low. Possible reasons may be a considerable loss of protein (7–14 g/day) into the peritoneal dialysate, and the absorption of glucose (150–200 g/day) from the dialysis fluid. This leads to an increase in the pool size of TGs and apoB100 in the VLDL fraction of PD patients.

WHY SHOULD PATIENTS WITH CKD STAGES 3–5 BE TREATED WITH A STATIN?

Recently, KDIGO (Kidney Disease: Improving Global Outcomes) released the Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease. Stratified analyses of CKD patients included in randomized controlled trials and the SHARP study suggest CKD patients should be treated with statins. The SHARP trial included 9270 participants with CKD who received simvastatin 20 mg plus ezetimibe 10 mg daily or placebo and followed them for a mean of 4.9 years. 67% of participants (n = 6247) had CKD not treated with dialysis at randomization, and 23% (n = 2094) had diabetes. In the overall study, statin plus ezetimibe therapy led to a significant 17% reduction (HR 0.83; 95% CI 0.74–0.94) in the relative hazard of the primary outcome of major atherosclerotic events (coronary death, MI, nonhemorrhagic stroke, or any revascularization) compared with placebo, driven by significant reductions in nonhemorrhagic stroke and coronary revascularization. SHARP

indicated that risk for the primary outcome of major atherosclerotic events other than death was reduced by simvastatin/ezetimibe among a wide range of patients with CKD; however, there was no demonstrable effect on mortality in this trial.

In the nondialysis CKD subgroup (mean estimated GFR (eGFR) of 26.6 mL/min/1.73 m^2), treatment with simvastatin plus ezetimibe led to a 22% reduction in major atherosclerotic events (HR 0.78; 95% CI 0.67−0.91). These results were similar in all CKD subgroups defined by eGFR category (eGFR 30−60 mL/min/1.73 m^2 HR 0.75, 95% CI 0.57−1.00, eGFR 15−30 mL/min/1.73 m^2 HR 0.78 95% CI 0.62−0.98; eGFR <15 mL/min/1.73 m^2 HR 0.82, 95% CI 0.59−1.13; p for difference between groups 0.73). Treatment did not reduce the risk in any of the prespecified renal outcomes of CKD progression or incident RRT, however. The risk of serious adverse events was similar in participants assigned to treatment or control. These data are supported by *post hoc* analyses of randomized trials of statin vs. placebo that focus on the subset of participants with CKD at baseline. In general, these analyses suggest that statins reduce the relative risk of cardiovascular events to a similar extent among patients with and without CKD, but that the absolute benefit of treatment is larger in patients with CKD due to their higher baseline risk (>10 events per 1000 patient years among patients >50 years of age and eGFR <60 mL/min/1.73 m^2, for example). Most of the participants with CKD in these analyses had eGFR 45−59 mL/min/1.73 m^2 and very few had eGFR less than 30 mL/min/1.73 m^2. However, treatment with a statin plus ezetimibe reduced the risk of major atherosclerotic events in the subgroup of participants (n = 2565) in SHARP with eGFR of 15−30 mL/min/1.73 m^2 (HR 0.78; 95% CI 0.62−0.98). Based on the results of the SHARP trial, treatment with a statin or statin/ezetimibe therapy is indicated across a broad range of CKD stages.

WHY NOT PERFORM FREQUENT FOLLOW-UP MEASUREMENTS OF SERUM LIPIDS?

Previous guidelines have emphasized treatment escalation to achieve specific LDL-C targets by increasing the dose of statin and/or combination therapy. Given the lack of data to support this approach, the substantial variability in LDL-C measurements and the potential for comedication-related toxicity, this approach is not recommended for people with CKD by KDIGO. Because higher risk of future coronary events, rather than elevated LDL-C, is the primary indication for initiating lipid-lowering treatment in CKD patients, follow-up monitoring of LDL-C is not required for many patients given within person variability of LDL-C over time, reducing the utility of follow-up measurements.[14,15] It is also unnecessary to measure LDL-C in many situations where the results likely would not change management, for example, patients already receiving a statin. However, in patients with nondiabetic, stable CKD 3b, reassessment of lipid status in follow-up may result in significant cardiac risk stratification increases, such that prescription of a statin should be considered.

As the link between LDL-C and adverse clinical outcomes is less robust in people with CKD than among those without CKD, the value of measuring LDL-C to assess prognosis is unclear. This care algorithm has never been subjected to clinical trial testing, though clearly it should be part of ongoing research efforts.

There is no direct evidence that following lipid levels during treatment will improve clinical outcomes or encourage adherence to statin therapy. However, some patients may prefer to know their lipid levels during follow-up or may increase their adherence to statin treatment in response to feedback about these levels. This KDIGO guideline is not graded, meaning it is used to provide guidance based on common sense or when the topic does not allow adequate application of evidence.

INCIDENT DIALYSIS PATIENTS

Current guidelines recommend withholding initiation of statin therapy among patients with dialysis-dependent CKD (KDIGO level 2A). However, 2141 (34%) of SHARP patients without kidney failure at baseline initiated dialysis during the trial and were included as "nondialysis" patients. Overall benefit was observed in this subgroup. As incident dialysis patients may be systematically different from those who are already prevalent dialysis patients (such as those included in the major trials of lipid-lowering treatment in dialysis patients), it is reasonable to continue statins in patients already receiving them at the time of dialysis initiation. It is important for the clinician to recognize that this may lead to less clinical benefit than in patients without CKD, possibly exposing these patients to the risks of drug−drug interactions, increased pill burden, and the inherent low risk of liver and muscle damage caused by statin exposure. Discontinuing statin or statin/ezetimibe treatment may be reasonable through value-based shared decision-making, placing a higher value on the risk of drug−drug interactions, polypharmacy, and drug toxicity compared with the relatively small potential relative risk reduction in vascular events.

STATIN TREATMENT IN PREVALENT DIALYSIS PATIENTS

The 4D Study (Die Deutsche Diabetes Dialyze Studie)

The 4D, a multicenter, double-blind, randomized trial assigned 1255 HD patients with type 2 diabetes to receive placebo or 20 mg of atorvastatin daily. After 4 weeks of treatment, atorvastatin reduced the median LDL-C level by 42%, while those in the placebo group had a 1.3% reduction in LDL-C. At least 1 mmol/L (39 mg/dL) difference in LDL-C level was maintained throughout the treatment period. During a median follow-up of 4 years, 469 patients (37%) reached the primary endpoint (a composite of cardiac death, nonfatal MI, and fatal and nonfatal stroke). 226 had been assigned to atorvastatin and 243 assigned to placebo (RR 0.92; 95% CI 0.77−1.10; $p = 0.37$). Atorvastatin had no effect on the individual components of the primary endpoint with the exception of fatal stroke, in which atorvastatin was associated with an increased relative risk (RR 2.03; 95% CI 1.05−3.93; $p = 0.04$). The secondary endpoint of combined cardiac events (RR 0.82; 95% CI 0.68−0.99; $p = 0.03$) was significantly reduced, but not all combined cerebrovascular events (RR 1.12; 95% CI 0.81−1.55; $p = 0.49$) or total mortality (RR 0.93; 95% CI 0.79−1.08; $p = 0.33$).

Aurora Study

In this international double-blind randomized trial, 2776 HD patients were assigned to receive rosuvastatin 10 mg daily or placebo, and followed for a median of 3.8 years. Despite the mean reduction in LDL-C of 43% (42 mg/dL) in the intervention group, the combined primary endpoint of death from cardiovascular causes, nonfatal MI, or nonfatal stroke was not reduced (HR 0.96; 95% CI 0.84−1.11; $p = 0.59$). In addition, rosuvastatin did not significantly reduce the risk of individual components of the primary endpoint, nor of all-cause mortality (all $p > 0.05$).

SHARP (STUDY OF HEART AND RENAL PROTECTION)

This international double-blind randomized trial assigned 9270 participants older than 40 years with CKD to receive simvastatin 20 mg plus ezetimibe 10 mg daily or placebo, and followed them for a mean of 4.9 years. 33% of the patients ($n = 3023$) were treated with maintenance dialysis at randomization. Mean reduction in LDL-C among the treatment group was 0.83 mmol/L (32 mg/dL), compared with placebo. While there was an overall reduction in the combined primary outcome, combination treatment did not significantly reduce the risk of the primary outcome in the subgroup of over 3000 patients treated with dialysis at baseline (HR 0.90; 95% CI 0.75−1.08). SHARP, however, was not powered to assess difference in major atherosclerotic events in dialysis vs. CKD subgroups. The study was powered for an overall effect and not to examine subgroups. The p for interaction (an underpowered test) was not significant comparing those on dialysis vs. nondialysis CKD ($p = 0.21$).

A systematic review pooling data from all available randomized trials done in CKD populations reported significant heterogeneity between dialysis and nondialysis patients for the benefit of statins on major cardiovascular events (HR for dialysis 0.96; 95% CI 0.88−1.03; HR for nondialysis 0.76; 95% CI 0.72−0.79; p for heterogeneity <0.001).[16] When findings from SHARP, 4D, and AURORA are considered together, the clinical benefit of statins or statin/ezetimibe therapy in prevalent dialysis patients is uncertain. Another meta-analysis confirmed these results, although the data were analyzed in a different manner.[17,18]

Even if statins truly do prevent cardiovascular events in prevalent dialysis patients, it is clear that the magnitude of any relative reduction in risk is substantially smaller than in earlier stages of CKD. However, if this speculative benefit among dialysis patients is confirmed in future studies, the absolute benefit might be comparable to that in people with less severe CKD, due to the higher event rate among dialysis patients. It is possible that the smaller relative risk reduction noted in SHARP may be explained by lower baseline LDL-C levels as well as less use of LDL lowering therapy in the subgroup of dialysis patients. The findings of SHARP suggest that every 1 mmol/L reduction in LDL-C led to a risk reduction of 19% in major atherosclerotic events overall; however, risk reduction among those treated with dialysis was lower at 16% per 1 mmol/L reduction. These findings are likely due to the finding of approximately one-third less reduction in LDL concentration among dialysis patients in comparison with the nondialysis CKD group (0.60 mmol/L (23 mg/dL) reduction in dialysis subjects vs. 0.96 mmol/L (37 mg/dL) reduction in nondialysis subjects).

In total, these trials failed to show a conclusive benefit of statin treatment (alone or in combination) among prevalent dialysis patients.[19−21] Therefore, initiation of statin treatment is not recommended for most prevalent HD patients (KDIGO level 2A). KDIGO stated that patients and their medical teams might decide to deploy statin-based treatment if they are still interested in a relatively uncertain and small reduction in cardiovascular events. Because the presence of a high LDL-C might increase the likelihood of benefit from statin therapy in a

dialysis patient, patients who meet this criterion may be more accepting of receiving statin treatment, recognizing that any potential benefit remains entirely speculative in 2019, while the small risks are certain. Other factors that might influence a patient's decision to ask for statin treatment could include a recent cardiovascular event (myocardial infarction or stroke) or longer anticipated life expectancy (both of which would favor treatment), and more severe comorbidity or higher current medication burden (both of which would favor lack of treatment). It would certainly be troubling to find a patient with a strong atherosclerotic risk and history being denied access to statin-based therapy by rote application of weak guidelines.

RESULTS FROM TRIALS IN THE GENERAL POPULATION

Trials and comorbidity had an impact on a strong recommendation in younger patients and those with earlier CKD stages. Most patients with CKD and eGFR $\geq$60 mL/min/1.73 m^2 have albuminuria and slightly reduced or normal eGFR. Most such patients would have been included but not recognized in trials of statins done in the general population. The benefit of statin monotherapy in reduction of incident cardiovascular disease (defined as incident MI, stroke, or need for coronary revascularization) appears similar in people with and without albuminuria (HR for albuminuric patients 0.59; 95 % CI 0.35−0.98 for albuminuric patients; HR for nonalbuminuric patients 0.64; 95% CI 0.46−0.89; p for interaction = 0.7).[22,23] Given the high cardiovascular risk among people with CKD and eGFR categories G1−G2, the large body of evidence supporting the efficacy of statins in the general population, and the lack of justification for a new trial done specifically in people with CKD and eGFR categories G1 or G2, high priority should be given to treatment in these patients.

PROMISING NEW THERAPIES IN THE TREATMENT OF DYSLIPIDEMIA AND CKD

Proprotein convertase subtilisin/kexin 9 (PSCK9) is an enzyme encoded on chromosome 1 that is part of the subtilisin-like proprotein convertase family. PSCK9 plays a role in cholesterol and fatty acid metabolism. It is expressed on various tissues including the liver, intestine, and kidney. PCSK9 may be involved in kidney development.[24] It is secreted as an inactive protein that undergoes proteolytic cleavage, leading to activation and subsequent binding to LDL receptors expressed on various tissues. Blockage of PCSK9 leads to increased expression of LDL receptors, resulting in significant reductions in LDL concentration. Development and subsequent approval of two monoclonal antibodies (alirocumab and evolocumab) targeting PSCK9 have been shown to significantly reduce LDL-C concentrations.[25] A *post hoc* review of eight studies pooled compared LDL-C lowering efficacy among subgroups with an eGFR 30−59 mL/min/1.73 m^2 vs. those with eGFR $\geq$60 mL/min/1.73 m^2. Treatment consisted of alirlocumab vs. placebo or ezetimibe plus statin. Baseline LDL-C concentrations were comparable and reductions in concentration ranged from 40% to 68% after 24 weeks of treatment regardless of eGFR.[26] Recent American College of Cardiology recommendations have suggested that PSCK9 be among the nonstatin options to consider as add-on therapy among those with high cardiovascular risk, not achieving a target LDL-C or <50% reduction in LDL concentration.[27] Once again, however, any utilization of this novel therapy in CKD patients has been hindered by the systematic exclusion of such patients in regulatory registration trials, a trend that has held back therapeutic progress in CKD by decades.

CONCLUSION

Dyslipidemia in patients with CKD is common, characterized by high TG levels and low HDL concentrations, while total and LDL cholesterol (LDL-C) levels are normal or low. Most CKD patients are at very high risk of cardiovascular events. CKD patients with low as well as high levels of total cholesterol and LDL-C are at the highest risk of adverse outcomes, due to a variety of reasons, including the long lag between risk factor development and outcome. This may cloud the interpretation of association with causality, as the patient's own phenotype and comorbidity may change as well.

Recent large clinical trials and guidelines have better informed treatment of patients with CKD and dyslipidemia. Elevated cholesterol concentrations *per se* as the sole criterion for prescription of statins in patients with CKD are unsuitable. The decision to treat such patients should be based on pretreatment risk of cardiovascular events and not on LDL-C, even though the vast bulk of that potential cardiovascular disease may be refractory to the use of statin-based therapies. One of the most concerning and frequent causes of death in maintenance dialysis patients is "sudden cardiac death" which is unaffected by ambient serum cholesterol (and subfraction) concentrations. Shared information-delivery and decision-making between physicians and CKD patients regarding potential treatment of lipid disorders

("individualization") in light of recent findings and guidelines is imperative, and vastly preferable to the application of weak guidelines to a complex patient population by rote.

QUESTIONS AND ANSWERS

Question 1

A 64-year-old man with ESRD treated with maintenance HD, controlled hypertension, hyperlipidemia, gastroesophageal reflux, and gout undergoes routine lipid screening. Current medications are carvedilol 25 mg twice daily, amlodipine 10 mg daily, simvastatin 20 mg daily, ranitidine 150 mg daily, and calcium acetate 667 mg three times daily with meals. He follows a sodium restricted diet and tries to limit his daily fluid intake as instructed. He has not had problems with hypotension on HD. His laboratory values return with LDL-C 105 mg/dL, total cholesterol 260 mg/dL, TGs 220 mg/dL, and HDL 30 mg/dL. You review the results with the patient.

What is the next step in treatment?

A. Switch to rosuvastatin 10 mg daily, his LDL is not at goal
B. Add fenofibrate and recheck TGs
C. Use of statin therapy confers substantial mortality risk benefit compared with those not on statins
D. Increase simvastatin to 80 mg daily
E. No change in medication therapy

Answer: E

Routine surveillance of lipid profile in prevalent dialysis patients has not been recommended by KDIGO (*not graded*), although it may be considered if it may influence adherence to therapy in a patient centered approach (A incorrect). Targeting TG levels and routine TG surveillance is not recommended (B incorrect). The patient is currently receiving treatment with statin therapy. Neither existing treatment nor dose escalation of statin therapy has been shown to be effective in reduction of mortality in patients receiving HD (C and D incorrect). No evidence links routine surveillance of lipid profile with improved outcomes.

Question 2

A nonsmoking 58-year-old administrative assistant is referred to the outpatient clinic with S[Cr] 1.8 mg/dL for treatment of potential hyperlipidemia. The history, classification, and prognosis evaluation confirmed CKD CGA category G3bA3 (cause, eGFR, albuminuria). Renal biopsy 10 years ago showed IgA nephropathy. The CKD-EPI equation revealed Stage 3b with eGFR 43 mL/min/1.73 m^2. 24-hour urinary protein excretion was 2.45 g and albuminuria was 1.8 g.

Which ONE of the following is recommended as part of the management of this patient?

A. Evaluation with a lipid profile (TC, LDL-C, HDL-C, TGs)
B. Measuring a lipid profile is not recommended because treatment is ineffective
C. Measurement of Lp(a) should guide treatment decisions
D. Measurement of LCAT should guide treatment decisions
E. Treatments should target an LDL-C goal as this patient is at substantial cardiovascular risk

Answer: A

Evaluation of a lipid profile is recommended by KDIGO and is the correct answer. Initial evaluation of the lipid profile is intended to diagnose severe hypertriglyceridemia and/or hypercholesterolemia while ruling out any underlying secondary causes. No direct evidence indicates that measuring lipid status will lead to better clinical outcomes. However, measuring lipid status is noninvasive, inexpensive, and might improve the health of people with secondary dyslipidemia. A relatively strong recommendation is notable, given the low quality of the reporting evidence (*Grading 1C*). The true effect may be substantially different from the estimate of the effect. The SHARP trial demonstrated a benefit of treating Stage 3−5 CKD patients with a statin and ezetimibe (B is incorrect). Although Lp(a) is increased in CKD and is an independent risk factor for atherosclerosis, it is not routinely measured or used as a guide to treatment decisions (C is incorrect). LCAT activity is decreased in CKD but is not routinely measured and does not guide treatment decisions (D incorrect). Treat to target LDL-C levels is not recommended (E incorrect).

Question 3

The results of the lipid profile for this patient were as follows: total cholesterol 236 mg/dL, HDL-C 39 mg/dL, TG 165 mg/dL, LDL-C 142 mg/dL calculated using the Friedewald formula (Friedewald formula is applicable when TGs are <400 mg/dL).

Which ONE of the following is NOT TRUE regarding the management of this patient?

A. Start simvastatin 20 mg po qd and ezetimibe 10 mg po qd
B. Therapeutic lifestyle changes are advised
C. No lipid treatment is indicated
D. Treat other cardiovascular risk factors such as hypertension
E. Start fish oil therapy given his elevated TG level

Answer: C

Serum LDL-C concentrations were 142 mg/dL with otherwise "unremarkable" serum lipid concentrations (TGs and HDL cholesterol). Overall, the lipid profile was typical for CKD patients, similar to type 2 diabetes

mellitus, with slightly elevated TG concentrations (>150 mg/dL) and low HDL cholesterol (<45 mg/dL). Answer A, starting statin and ezetimibe treatment, is reasonable based on the results of the SHARP trial. During the visit, other actions were taken, such as advising lifestyle changes such as weight loss and a low fat diet (Answer B), and treating other cardiovascular risk factors such as hypertension (Answer D). The patient confirmed being able to take the number of pills prescribed. Answer C would be incorrect as the patient will receive a multitargeted approach to lipid care as outlined in the other answers. Fish oil therapy has been studied in the context of IgA nephropathy; however, targeting TG levels in isolation has not demonstrated benefit in CKD patients (E incorrect).

Question 4

Six months later, the patient returns to the outpatient renal clinic. He complains that his primary physician has forgotten to measure his cholesterol. He wants to know his cholesterol level. The patient denies any side effects. A lipid profile is repeated with the following results: total cholesterol 155 mg/dL, HDL-C 35 mg/dL, TG 189 mg/dL, and LDL-C 82 mg/dL.

Which ONE of the following is the best treatment decision for this patient?

A. Increase the simvastatin to lower total cholesterol to <130 mg/dL
B. Continue same dosages of the statin and ezetimibe
C. No change in treatment but repeat lipid levels in 3 months
D. Add gemfibrozil to lower TG levels
E. Switch to rosuvastatin therapy

Answer: B

Answer B is correct, as simvastatin and ezetimibe treatment were effective. The effect most likely is a combination of true drug effects and reduction of residual albuminuria. Current guidelines do not recommend treatment to target; therefore, it is not necessary to repeat lipid levels (C incorrect). KDIGO guidelines provide potential reasons to remeasure serum lipids in people with CKD, including assessment of adherence to statin treatment, change in dialytic modality or concern about the presence of a new secondary cause of dyslipidemia, or to assess 10-year cardiovascular risk in patients aged <50 years and not currently receiving a statin. Gemfibrozil can reduce TG levels but would not be indicated at the borderline high levels seen in this patient (D incorrect). There is no evidence to support changing to alternative agents such as rosuvastin or change of current therapy with a treat to target goal (A and D incorrect).

Question 5

You review the results of his lipid profile and make recommendations to the patient. You counsel the patient regarding cardiovascular risk and benefits of your approach to care, with an individualized approach given comorbidities and pill burden.

Which of the following is true about this patient?

A. Cardiovascular risk among those with CKD is lower than in the general population
B. Benefit of statin therapy among those with albuminuric CKD and preserved eGFR is similar to those without CKD
C. There appears to be benefit of rosuvastatin over other agents for treatment of hyperlipidemia
D. There is no increased risk of cardiovascular event
E. Among patients with late-stage CKD, particularly among those treated with dialysis, a reduction in cardiovascular risk is commensurate with absolute reduction in LDL-C value

Answer: B

Current literature suggests that statins reduce the relative risk of cardiovascular events to a similar extent among patients with and without CKD, but that the absolute benefit of treatment is larger in patients with CKD due to their higher baseline risk (>10 events per 1000 patient years among patients >50 years of age and eGFR <60 mL/min/1.73 m^2). Choices A and D are incorrect. The benefit of statin monotherapy in reduction of incident cardiovascular disease (defined as incident myocardial infarction, stroke, or need for coronary revascularization) appears similar in people with and without albuminuria (HR for albuminuric patients 0.59 for albuminuric patients; HR for nonalbuminuric patients 0.64; p for interaction = 0.7). B is correct. There is a paucity of evidence to suggest benefit of one statin over other agents (C incorrect). The findings of SHARP suggested that a decrease of 1 mmol/L in LDL-C was associated with a 19% RR reduction in major cardiovascular events; however, these observations where lower among those receiving maintenance dialysis (16% reduction). Although these findings may have been explained by baseline differences in LDL-C values, conclusive evidence is yet to be demonstrated (E incorrect).

Question 6

One year later, the eGFR has fallen to 35 mL/min/1.73 m^2. The annual loss of eGFR is approximately 4 mL/min/1.73 m^2. The patient asks about continuation of treatment because the pill burden is high.

Which ONE of the following is TRUE regarding best management of this patient?

A. Stop lipid therapy when patient starts dialysis
B. Stop lipid therapy if patient receives a kidney transplant
C. Decrease lipid therapy because the LDL-C is too low
D. Continue lifelong lipid-lowering treatment even after initiation of dialysis
E. Continue therapy and consider intensification given worsening eGFR

Answer: D

Lipid-lowering treatment should be continued even when RRT will become necessary (KDIGO, *grading 2C*). Answer A is therefore incorrect, although individualized treatment decisions are needed. Each patient needs help arriving at a management decision consistent with her or his values and preferences. The risk of future coronary events in kidney transplant recipients is markedly elevated. Data from the placebo arm of the ALERT trial (Assessment of Lescol in Renal Transplantation trial) suggest that the rate of cardiovascular death or nonfatal MI is approximately 21.5 per 1000 patient years. Current KDIGO guidelines recommend adult kidney transplant recipients be treated with a statin (*grading 2B*) making Answer B incorrect. There is no target for LDL-C levels and no evidence that low values have adverse effects (C incorrect). There is no evidence to suggest that intensification of therapy is needed with decreasing eGFR (E incorrect).

CHAPTER

67

Nephrolithiasis, Nephrocalcinosis, and Hypercalciuria

Anirban Bose, David A. Bushinsky

Division of Nephrology, Department of Medicine, University of Rochester School of Medicine and Dentistry, Rochester, NY, United States

Abstract

The incidence of kidney stones is rising worldwide. Kidney stones cause significant morbidity and are associated with chronic kidney disease (CKD). Because the incidence of recurrent stones decreases with progressive CKD, it may be underrecognized as the cause of end-stage renal disease. Kidney stones form when urine becomes supersaturated with respect to the specific components of the stone's constituents. A metabolic evaluation for the underlying causes of kidney stones is recommended after the initial episode. Urinary supersaturation studies and analysis of any passed stones help guide treatment. General measures to prevent recurrence of calcium-based stones include dietary modifications to increase fluid intake, reduce intake of salt and animal protein, and encourage consumption of age- and gender-appropriate amounts of calcium. Measures to reduce urinary supersaturation are highly effective in lowering recurrent stone formation. Thiazide diuretics are a cornerstone of therapy in hypercalciuric patients, whereas potassium citrate is also highly effective in reducing recurrent stone formation.

INTRODUCTION

Kidney stones have a propensity to afflict people in industrialized nations but also cause significant morbidity worldwide.[1] Their annual incidence is more than 1 per 1000 persons[2] resulting in nearly two million physician-office visits in the year 2000, with estimated annual costs totaling $2 to 5.5 billion.[1,3] The incidence of nephrolithiasis in the US has increased from approximately 3% in the late 1970s to about 5% in the 1990s, paralleling the rising rates of obesity, type-2 diabetes, and insulin resistance.[4] Kidney stones affect men more frequently than women. The incidence peaks among patients in their 30s and 40s before declining in frequency in the sixth to seventh decade of life.[5–7] In addition to age and sex, race and geographic location influence the prevalence of stones. Caucasians are more likely to develop stones compared to African Americans, Hispanics, and Asian Americans, and the disease affects more people in hotter climates.[8] In the Middle East, more than 70% of kidney stones are composed of uric acid, whereas a similar percentage of patients in the US have calcium-based stones.[8] In 2008 melamine-adulterated milk in China led to a large number of Chinese babies developing kidney stones and, in some cases, renal failure due to obstructive nephropathy.[9]

Kidney stones result in substantial morbidity. The severe pain of renal colic can lead to frequent hospitalizations, shock wave lithotripsy, or invasive surgical procedures. Though rarely a cause of end-stage renal disease (ESRD), nephrolithiasis has been associated with chronic kidney disease (CKD) in various populations.[10,11] Patients with kidney stones have an increase in aortic calcification, and kidney stones are associated with adverse cardiovascular events,[12,13] especially in men and an increase in stroke, especially in women.[14] There is a significant decrease in bone mineral density leading to fracture in patients with nephrolithiasis.[15,16]

TYPES OF STONES

In the US, calcium-based stones account for more than 75% of all stones passed. As shown in Figure 67.1, uric acid and struvite stones account for approximately 10–20% of cases, whereas cystine stones are seen in 1–2% of all stone formers. The recurrence rate of calcium oxalate nephrolithiasis is about 50% at 5–10 years. Recurrence rates are higher for cystine, uric acid, and struvite stones.[12,13]

Chronic Renal Disease, Second Edition

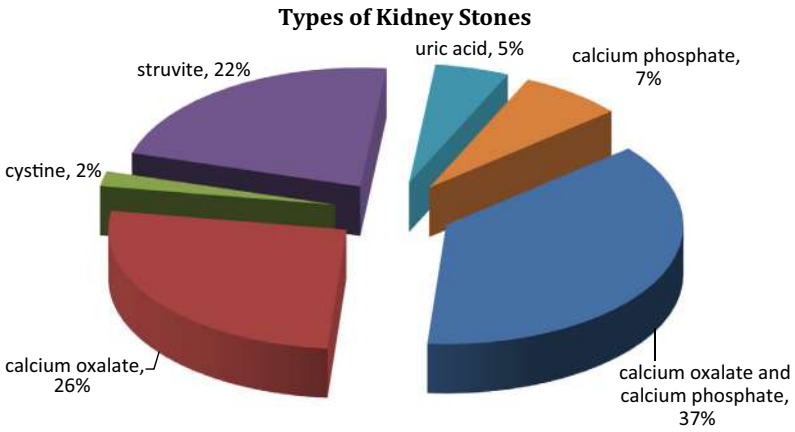

FIGURE 67.1 Stone types.

Pathogenesis of Kidney Stone Formation

The final common pathway of stone formation is the supersaturation of urine with the ionic constituents of the specific stone. Saturation refers to the driving force for formation of the solid phase and takes into account the ambient conditions, concentrations, and free-ion activities of stone components that influence their solubility. Thus, saturation is not just a simple function of ionic molar concentrations. Using calcium oxalate as an example, even if the concentration of these free ions is increased in urine, other substances such as citrate, potassium, and magnesium act as inhibitors and prevent crystallization. The interaction with these other solutes decreases the free ion activity and allows the lithogenic constituents to increase in concentration to levels that would otherwise cause crystal formation in water. Thus lithogenicity could result from increased excretion of poorly soluble substances or decreased excretion of inhibitors of stone formation. Other factors such as urine pH influence supersaturation by affecting the solubility of these ions.

When urine becomes supersaturated, free ions have a greater propensity to combine to form the more stable, solid phase.[17] This process is called nucleation. Nucleation can happen from similar ions (homogeneous nucleation) or around dissimilar crystals or sloughed epithelial cells (heterogeneous nucleation). If several small crystals bond together and grow in size (aggregation), this crystal complex can cause obstruction in the urinary tract.

Calcium oxalate crystals often initially adhere to calcium phosphate deposits, so called Randall's plaques, which are located on the renal papillae (Figure 67.2). This adherence and subsequent growth occurs only in urine that is supersaturated with respect to calcium oxalate. With continued urinary supersaturation the stone increases in size and, if it breaks off from the Randall's plaque, it may be large enough to obstruct the ureter causing clinically significant stone disease.[18]

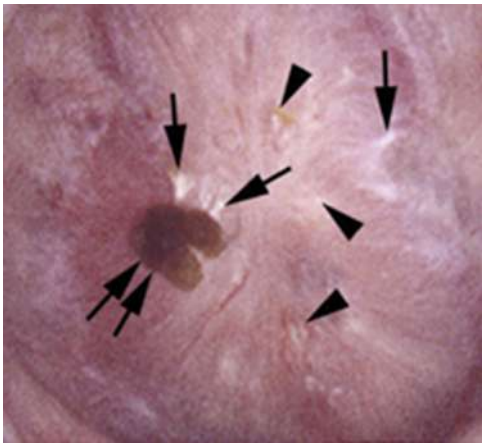

FIGURE 67.2 An attached stone (*double arrow*) is seen resting on a region of white plaque (*single arrows*) and intermixed with small areas of white (*single arrow*) and yellow plaques (*arrowheads*). *From Evan AP, Lingeman JE, Worcester EM, Bledsoe SB, Sommer AJ, Williams Jr JC, Krambeck AE, Philips CL, Coe FL. Renal histopathology and crystal deposits in patients with small bowel resection and calcium oxalate stone disease.* Kidney Int *2010;78:310–7.*

Risk Factors for Stone Formation

Various clinical conditions and dietary habits increase the risk of nephrolithiasis. Diets high in sodium and animal protein increase urinary calcium excretion and increase the risk of stone formation.[19–21] High-oxalate or high-purine diets also lead to increased risk of stone formation by increasing urinary supersaturation with respect to calcium oxalate and uric acid respectively.[19,20,22–24] Low fluid intake is a crucial risk factor for stone formation because a low urine volume increases urinary supersaturation of all stone types.[25–29] These factors are discussed in more detail under dietary interventions for the treatment of kidney stones. Prior history of nephrolithiasis,[30] family history of nephrolithiasis,[31] recent gastric bypass procedures, bariatric

surgery, or short bowel syndrome are all associated with increased risk of stone formation.[32,33] Recurrent urinary tract infections with urease-producing organism such as Proteus or Klebsiella predispose to the formation of struvite stones. Medications such as indinavir, acyclovir, sulfadiazine, ceftriaxone, and triamterene can crystallize and form stones in urine.[34–36] The risk of nephrolithiasis is higher in patients with hypertension, diabetes, obesity, metabolic syndrome, and gout.[4,37,38] Fructose, a ubiquitous sweetener in processed American foods, is associated with significant risk of developing nephrolithiasis. Although the mechanism is unknown, fructose is the only known carbohydrate that increases uric acid production.[39]

GENETIC CAUSES OF STONE FORMATION

X-Linked Hypercalciuric Nephrolithiasis (Dent's Disease and Others)

This X-linked disorder of proximal renal tubular dysfunction manifests as hypercalciuria, low–molecular weight proteinuria, nephrocalcinosis, hypophosphatemic rickets, and renal failure.[40–44] Dent's disease has been linked to mutations affecting the genes encoding the Cl^-/H^+ exchanger ClCN5 in the majority of patients, and/or inositol polyphosphate 5-phosphatase (OCRL1). Both genes are on the X chromosome.[40–42] How defects in these genes lead to the array of these proximal tubular disorders is not yet understood. Parathyroid hormone (PTH) tends to be quite low and $1,25(OH)_2D_3$ high in the majority of patients.

Bartter Syndrome

Bartter syndrome is caused by at least five genetic mutations, predominantly autosomal recessive, which lead to sodium chloride wasting at the thick ascending limb (TAL) of the loop of Henle.[20,45,46] These genes, all expressed in the TAL, cause a defect in sodium transport that leads to a reduction in the transtubular potential difference, resulting in a decrease in paracellular calcium reabsorption in the TAL leading to hypercalciuria, nephrocalcinosis, and nephrolithiasis.

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is an autosomal recessive disorder genetic disorder resulting from the defective production of either of the tight junction proteins, claudin 16, and claudin 19. FHHNC results in hypomagnesemia, hypercalciuria, nephrolithiasis, and distal renal tubular acidosis. Polyuria and severe nephrocalcinosis also ensue, and progressive kidney failure is common by late childhood.[45,47–49]

Distal Renal Tubular Acidosis

Distal RTA (dRTA) is caused by dysfunctional α-intercalated cells, resulting in defective acid excretion and the inability to maximally acidify the urine.[45,46,50–54] The ensuing metabolic acidosis, hypocitraturia, hypokalemia, and hypercalciuria cause nephrocalcinosis, and primarily calcium phosphate stones. dRTA can be inherited or be secondary to Sjögren's syndrome or induced transiently with carbonic anhydrase inhibitors such as acetazolamide.[55,56]

Hereditary Hypophosphatemic Rickets with Hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria is an autosomal form of hypophosphatemic rickets, caused by mutations in solute carrier family 34, member 3 (SLC34A3), the gene that encodes the sodium Na^+-dependent phosphate cotransporter 2c (NPT2c). Hereditary hypophosphatemic rickets with hypercalciuria manifests clinically as hypophosphatemia secondary to renal phosphate wasting.[57–60] Hypophosphatemia directly increases $1,25(OH)_2D_3$, which leads to increased intestinal calcium absorption and hypercalciuria. The bone pain, muscle weakness, limb deformities, and rickets resolve with administration of oral phosphate.

Primary Hyperoxaluria and Cystinuria

Primary hyperoxaluria (PHO) and cystinuria are each discussed in their respective sections in Specific Therapy below.

Others Causes

Numerous other monogenic disorders cause hypercalciuria, either by augmenting bone resorption (osteogenesis imperfecta type 1, multiple endocrine neoplasia type 1 with hyperparathyroidism, McCune-Albright syndrome, infantile hypophosphatemia) or by increasing intestinal absorption of calcium (hypophosphatemia, Down syndrome, congenital lactate deficiency) and can also lead to nephrolithiasis or nephrocalcinosis.[17,61–64] Pseudoxanthoma elasticum is caused by mutations of the *ABCC6* gene that results in low urinary pyrophosphate levels and development of Randall's plaques in both mice and humans beings.[65]

CLINICAL PRESENTATION

The clinical presentation depends on the size, type, and location of the stone. Commonly, stones present with pain or hematuria but can vary from asymptomatic small stones discovered on incidental imaging to large calculi that cause obstruction and renal failure. Large obstructing staghorn calculi may be asymptomatic. Therefore nephrolithiasis should be in the differential diagnosis of unexplained CKD.[66]

Pain

The passage of stones often results in ureteric colic that is abrupt in onset, excruciating, and frequently accompanied by hematuria, nausea, and vomiting. The pain generally migrates from the flank toward the abdomen and into the groin as the stone moves toward the uretero-vesicle junction. Nephrolithiasis can also produce a dull, poorly localizing pain or be an incidentally discovered radiologic finding unrelated to the actual cause of flank pain.

Hematuria

Hematuria occurs in 90–95% of patients with acute unilateral flank pain caused by stones. It may be microscopic or macroscopic.[67,68] Large calculi generally cause macroscopic hematuria and, expectedly, are often associated with bouts of colic. In patients with hematuria, it is always important to consider diagnoses other than kidney stones, including tumors and infection throughout the kidney and genitourinary tract, glomerular and interstitial diseases, and hypercalciuria in children.[69]

Rarer Presentations

Less common presentations of nephrolithiasis include urinary tract infections and acute kidney injury (AKI) if the stone is obstructing a single functioning kidney, or if both kidneys are obstructed simultaneously. Staghorn calculi often do not produce symptoms unless the stone results in obstruction, leading to renal failure that may occur in more than a quarter of these patients.[70]

THE BASIC EVALUATION

History

Stone History

A chronology of stone events should be generated. Age at first stone, size and number of stones formed, frequency of passage, and stone type are all useful, to judge not only the severity of the stone disease but also to provide clues regarding the origin of the patient's nephrolithiasis. Presentation characteristics of each stone type are discussed subsequently under their individual descriptions.

Medical History

Systemic disorders that can cause nephrolithiasis are sought in the medical history. Clues to diseases that cause hypercalcemia (such as sarcoidosis, hyperparathyroidism), hyperoxaluria (such as sprue, Crohn's disease), or hyperuricemia in patients with and without gout are often uncovered with direct questioning or after examination of the medical record.

Family History

A number of stone disorders are inherited, making the family history an important component of the basic evaluation. Stones arising in childhood or young adulthood can be related to autosomal recessive disorders such as cystinuria and primary oxaluria.

Medications

Calcium-containing supplements can result in hypercalciuria from the increased absorption of calcium, increasing its filtered load and, ultimately, the excretion of calcium.[71] Loop diuretics promote renal tubular excretion of calcium and are associated with nephrocalcinosis in neonates who have received the drug.[72,73] Acetazolamide induces a mild metabolic acidosis and alkaline urine, favorable conditions for the development of calcium phosphate stones. Uricosuric medications, such as salicylates and probenecid, have been implicated in uric acid lithiasis.[74] Triamterene, indinavir, sulfadiazine, and intravenous (IV) acyclovir can precipitate as crystals in the urine. The end product of Vitamin C metabolism generates oxalate, and, when taken in large doses, Vitamin C may predispose to stone formation.[75,76]

Diet

A thorough review of the patient's diet and fluid intake may illuminate relevant risk factors, such as ingestion of foods high in sodium, animal protein, oxalate, or purine. Low water intake to avoid frequent trips to the restroom, as often practiced by surgeons and traveling salesmen, also predisposes to nephrolithiasis. Many patients are erroneously counseled by physicians to avoid calcium-containing foods, a suggestion that is not only associated with increased risk of stone formation; low-calcium diets may also result in bone demineralization, a serious concern in women with kidney stones.[77–79]

DIFFERENTIAL DIAGNOSIS

Pyelonephritis

Fever is an uncommon finding in patients with simple stones without concurrent infection. Thus, fever should trigger an evaluation for pyelonephritis that can complicate stones. Struvite stones are often associated with infections by urease-producing organisms. Xanthogranulomatous pyelonephritis is a form of chronic pyelonephritis often associated with kidney stones that can produce significant destruction of the renal parenchyma. Xanthogranulomatous pyelonephritis may mimic a tumor radiologically.[80]

Ectopic Pregnancy, Rupture or Torsion of Ovarian Cysts, Dysmenorrhea

Flank pain associated with these conditions can closely mimic the pain caused by stones. Hematuria is frequently misdiagnosed to have been caused by stone disease if the urine is contaminated with vaginal blood.[81]

Acute Appendicitis, Diverticulitis, Intestinal Obstruction, Mesenteric Ischemia, and Biliary Colic

These conditions can mimic the pain seen with kidney stones and the accompanying nausea and vomiting. However hematuria is unusual in these cases, and abdominal signs on physical examination are more prominent than with renal colic.[82]

Loin Pain Hematuria Syndrome

Typically a disease of young or middle-aged women, this poorly understood condition can cause hematuria, both microscopic and macroscopic, and must be in the differential diagnosis of all conditions that cause flank pain and hematuria.[83] This diagnosis is made by excluding other conditions such as small stones, tumors, urinary infections, and glomerular disease.[84]

Clot-Colic, Debris-Colic

Bleeding into the renal pelvis from tumors or after kidney biopsy can produce clots that obstruct the ureter and cause pain.[85] Papillary necrosis secondary to diabetes, analgesic abuse, or infections can also present similarly.[86,87]

DIAGNOSIS

Suspicion for nephrolithiasis, or workup of other causes of abdominal pain with or without hematuria, typically involves radiological evaluation to help differentiate the disorders. The tests that can be performed in such a situation include a Kidney Ureter Bladder (KUB) radiograph, an ultrasound, a computed tomographic (CT) scan, an intravenous pyelogram (IVP), or a magnetic resonance image (MRI). We do not recommend routine radiographic procedures. They should only be performed when the outcome is likely to alter therapy.

Abdominal X-Ray/KUB

Although 90% of urinary calculi (calcium, struvite, and cystine) are radio-opaque, the sensitivity of a KUB is 45–59% and specificity is 71–77%.[88] In addition to uric acid stones being radiolucent, such a low diagnostic yield is likely because of problems with stones being obscured by stool, bowel gas, or overlying vertebrae.

Intravenous Pyelography

IVP is more sensitive (64–87%) and specific (92–94%) than a KUB for the detection of renal calculi.[89] IVP can also identify structural abnormalities of the urinary tract that predispose to stone formation. During acute colic an IVP may even help move the stone along the ureter by creating a strong osmotic diuretic effect. However, IVPs can miss nonobstructing radiolucent stones that do not generate a "filling defect," carry the risk of contrast exposure in patients with compromised renal function, carry the risk of radiation exposure, and sometimes need reimaging at 12–24 hours in patients with high-grade obstruction because of inadequate concentration of the contrast medium.[89] With the current availability of other radiographic tests, an IVP is rarely indicated in contemporary practice.

Renal Ultrasonography

Ultrasonography is easily performed and very sensitive at detecting the presence of stones and of obstruction.[90] Ultrasound is the imaging modality of choice when radiation exposure must be minimized, such as in young women, especially if they are pregnant. Emergency department patients with suspected nephrolithiasis who initially have ultrasonography have lower total radiation exposure than those initially evaluated with CT, without any difference in serious adverse events, missed important diagnoses, pain scores, or subsequent emergency department visits or hospitalizations.[91,92]

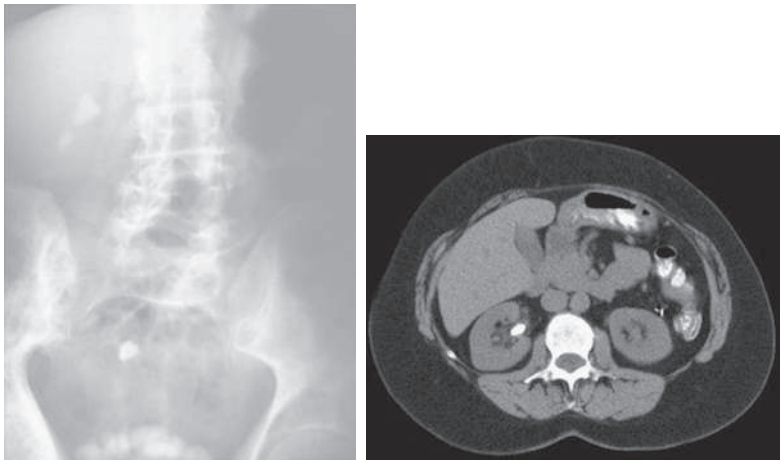

FIGURE 67.3 Renal stones on abdominal X-ray and CT scan. A radiolucent kidney stone can be seen on the KUB at the uretero–vescial junction. A large stone is seen in the renal pelvis of the right kidney. *From www.gehealthcare.com/usen/ct/products/urologyimagegallery.html.*

Noncontrast Helical CT

Noncontrast helical CT can detect most stones with a sensitivity of 95–98% and specificity of 98%.[90,93] Noncontrast helical CT has been shown to be superior to IVP as a diagnostic modality.[94] Based on the Hounsfield density of the identified stone, cystine and uric acid stones can be differentiated from calcium-bearing stones using this technique.[95] A helical CT is also useful to detect other causes of abdominal pain and thus is the imaging modality of choice for most cases.[96] However, a CT is more expensive than other tests and has the added disadvantage of increased exposure to radiation. Often a noncontrast helical CT is followed by a contrast study. This practice should be avoided unless absolutely necessary, as the radiation exposure is doubled and the patient is exposed to the risks of the contrast medium.

MRI

Although quite sensitive (82%) and specific (98%) for detecting kidney stones, this modality is rarely used as a diagnostic test except in situations where it is important to avoid radiation.[90]

Although most stones are detected using one or a combination of the above radiological techniques, HIV protease inhibitor–induced stones are not radiopaque and often do not manifest signs of obstruction, leading to the diagnosis being missed on IVP, ultrasound, and noncontrast CT scan.[34,35] In such patients, contrast-enhanced CT scanning may be required to establish the diagnosis[97] (Figure 67.3).

NEPHROLITHIASIS AND CHRONIC KIDNEY DISEASE

Nephrolithiasis is associated with a twofold increase in CKD that is independent of other risk factors such as diabetes and hypertension found in stone formers.[98–100] A French study estimated the incidence rate of ESRD because of nephrolithiasis to be about 3.1 cases per million population per year.[101] A Canadian study demonstrated that although only 0.8% of patients with ESRD had nephrolithiasis, any previous stone episode was associated with an increased risk of ESRD (hazard ratio 2.16).[10] This risk was greater in women than in men. Approximately 40% of stone formers who develop ESRD had a solitary functioning kidney.[102] The most common reasons for loss of a single kidney in stone formers were staghorn calculi, high stone burden, infection, and ureteral obstruction.[103]

The mechanism of development of renal damage with stone disease probably arises from ureteral obstruction causing parenchymal damage.[98] Animal models suggest that unilateral ureteral obstruction causes intense renal vasoconstriction and reduces renal blood flow and glomerular filtration rate (GFR).[104] Other injury-producing events induced by obstruction include increased interstitial volume, matrix deposition, monocyte infiltration, and fibroblast differentiation, leading to upregulation of TGF-β and TNF-α, and progression to tubule-interstitial inflammation and fibrosis.[105,106] Brushite (CaHP) stone formers have an increased risk of cortical fibrosis.[107]

The formation of Randall's plaques in brushite stone formers is associated with duct plugging, collecting

duct cell death, and inflammation.[18] In patients with staghorn calculi, a renal biopsy often demonstrates extensive inflammation and macrophage infiltration.[108] Other stone-forming diseases such as PHO, cystinuria, and Dent's disease have all been associated with crystal formation in the renal parenchyma that presumably triggers subsequent inflammation and CKD.[109]

With declining GFR, urinary calcium excretion decreases.[110] Evidence suggests that stone recurrence rates are lower in stone formers with reduced GFR.[111] Thus there may be significant underrecognition of the contribution of kidney stones to the development of CKD.

MANAGEMENT

Management of Acute Renal Colic

Management of acute renal colic is centered on pain control with adequate analgesia, assessment of the stone size/location to determine its likelihood of passing, and evaluation of coexistent conditions or complications that might necessitate urgent urologic intervention.

Analgesia is achieved by use of either nonsteroidal antiinflammatory drugs (NSAIDs) or opiates. A systematic review found both were equally effective in achieving analgesia.[112] A combination may be superior to either one alone.[113,114]

NSAID administration avoids the nausea and vomiting common to opiates but carries the risk of worsening AKI in an obstructed kidney. Also, NSAIDs must be stopped 3 days before planned lithotripsy to avoid excessive bleeding.[115]

The more distal the stone in the ureter, the more likely it is to pass spontaneously. In the kidney, stones in the lower pole are associated with poor clearance after lithotripsy and may need percutaneous lithotomy for removal if they are more than 10 mm in size.[116] Stones 2–4 mm in diameter have a 76% chance of passing spontaneously, 5–7 mm a 60% chance, 7–9 mm a 48% chance, and greater than 9 mm a 24% chance of passing spontanuously.[117–119] If the decision is made to allow a stone to pass spontaneously, patients must have repeat radiographic examinations to document the stone's passage. Patients should be followed weekly for any signs of sepsis or worsening renal function.

Medical expulsive therapy has been utilized to speed stone passage. A general consensus is that this form of therapy may be used for ureteral stones less than 10 mm in diameter in patients with normal renal function, controllable pain, no evidence of infection, or significant ureteral obstruction for up to 4 weeks. Although the results of individual studies have varied, a recent meta-analysis of 67 trials including over ten thousand patients demonstrated that an alpha-adrenergic blocker, such as tamsulosin (0.4 mg/day), was effective in improving stone clearance, reducing the time to stone passage by 3.4 days with a slight increase in major adverse events.[120] There were fewer hospitalizations in the treated patients with no change in the rate of surgical intervention. Two other smaller meta-analyses confirmed that therapy with tamsulosin also leads to a greater likelihood of stone passage.[121] Other agents such as the selective alpha-1A adrenoreceptor receptor antagonist silodosin (8 mg/day) appear to speed stone passage as well.[122]

For patients presenting with acute renal colic and signs of sepsis, anuria, acute renal failure, intractable vomiting, or intractable pain or with a stone larger than 10 mm, an urgent urologic consultation is essential to relieve the obstruction.[123,124]

Metabolic Evaluation of Kidney Stone Formers

Most patients need a metabolic evaluation to identify lithogenic risk. It is recommended that this be performed 4–6 weeks after an acute episode, when the patient is eating a usual diet.[125] After the initial episode of nephrolithiasis, observational studies estimate that the likelihood of recurrence, in the absence of specific treatment to prevent recurrence, is quite variable, ranging from about 5% per year for the first 5 years[29] to 50% at 5 years.[126,127]

Given the success of the general measures to prevent recurrent stone formation, such as ample fluid intake, sodium reduction, age- and gender-appropriate calcium intake, and reduction of dietary protein, some have recommended that a comprehensive evaluation be reserved for patients with multiple stones, a strong family history of stones, those passing gravel, those with metabolically active stones (stones that grow in size or number on follow up), in children, in demographic groups not prone to forming stones and in those in whom the stones are not made of calcium. However, studies have shown that first-time stone formers have the same underlying metabolic risk factors and severity of stone disease as recurrent stone formers.[127] We recommend at least a basic metabolic evaluation on all stone formers.

The basic metabolic evaluation includes measurement of S[Na], serum potassium concentration (S[K]), S[Cl], bicarbonate, serum creatinine concentration (S[Cr]), serum calcium concentration (S[Ca]), serum phosphate concentration (S[P]), and serum uric acid concentration, urine analysis, and urine culture. A PTH level should be measured if the S[Ca] is elevated or even at the upper limit of normal, and if the S[P] is decreased or even at the lower limit of normal. The presence of hypokalemia and metabolic acidosis may suggest a renal tubular acidosis. Urine analysis might reveal crystals of uric acid, cystine,

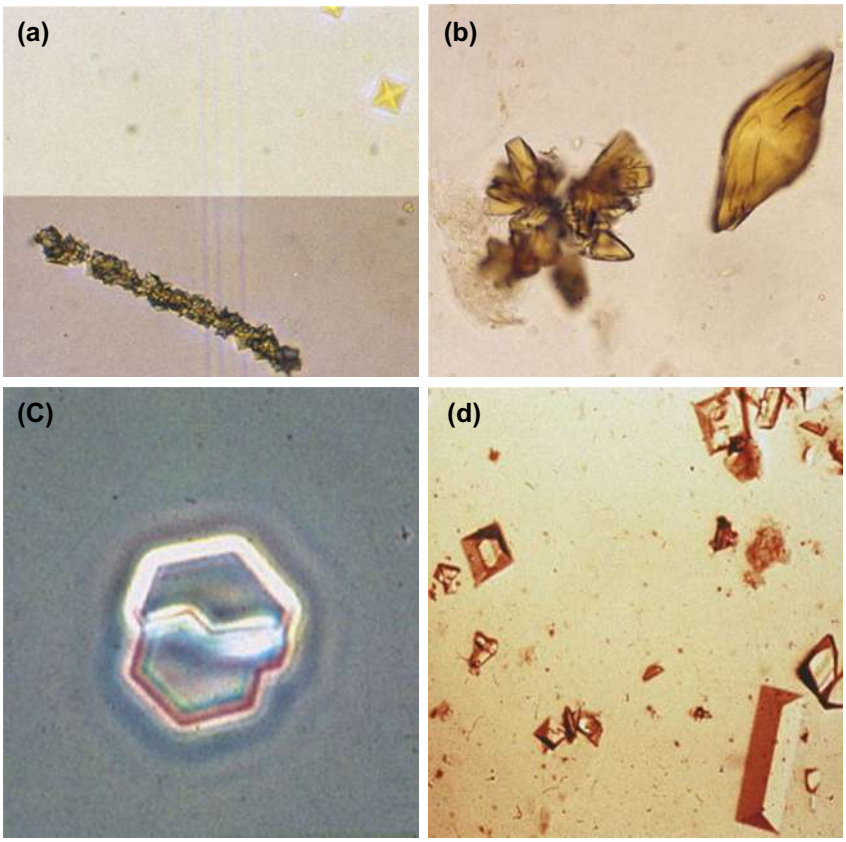

FIGURE 67.4 Crystals seen in urine of stone formers. (a) Calcium oxalate; (b) Urate; (c) Cystine; (d) Struvite. *From Monk RD, Bushinsky DA. Nephrolithiasis and nephrocalcinosis. In:* Comprehensive clinical nephrology. *London: Mosby; 2010.*

calcium oxalate, calcium phosphate, or magnesium ammonium phosphate (Figure 67.4) (Table 67.1).

The comprehensive evaluation includes all of the above, as well as a 24-hour urine collection for assessment of urinary volume and ion excretion, with the supersaturation calculated for the calcium oxalate, calcium phosphate, and uric acid solid phases. Supersaturation of urine correlates well with stone composition[128] and involves the measurement of urinary volume, pH, calcium, oxalate, citrate, uric acid, creatinine, sodium, potassium, magnesium, sulfate, phosphate, chloride, and urine urea nitrogen. Patients should collect their urine on a typical day while eating a typical diet and should be instructed appropriately to obtain an accurate urine collection (Table 67.2).

GENERAL MEASURES TO PREVENT STONE RECURRENCE

The goal of treatment is to lower urinary supersaturation, as an undersaturated urine reliably predicts freedom from recurrence.[2,5]

Fluid Intake

Fluid intake resulting in a urine volume of more than 2−2.5 L a day has been shown to reduce the incidence of stone formation[29,129] and is a mainstay of therapy for nephrolithiasis. Because the risk of stone formation is maximal at night when urine concentration is increased, patients should be encouraged to drink enough water to provoke nocturia and drink more fluid before returning to bed.[2]

Dietary Salt Intake

As illustrated in Figure 67.5, urine calcium excretion parallels urinary sodium excretion.[20] Therefore limiting dietary salt intake (<2 g/day) will reduce urinary supersaturation for calcium-containing stones.[130]

Dietary Protein Intake

Consumption of animal protein is a risk factor for calcium as well as uric acid stone formation.[131] The acid generated from this diet causes efflux of calcium from bone[132] and increases filtered load of calcium. An acidic

tubular fluid decreases renal tubular calcium reabsorption leading to increased calcium excretion. Reduced urinary citrate excretion[133] and lowered calcium solubility because of the presence of sulfates from the acidic amino acids are other lithogenic effects of such a diet.[132] Reducing the animal protein content of diet to 0.8–1.0 g/kg/day can help reduce the risk of stone formation.[78]

Dietary Calcium

In the intestine dietary calcium binds dietary oxalate, which leads to decreased oxalate absorption and a reduction in oxaluria.[77,134] Thus, patients on a low-calcium diet have a significantly increased incidence of stone formation compared to patients on a normal calcium diet.[77,78] The beneficial effect of dietary calcium is abrogated in women taking calcium supplements, likely because the supplement is often taken between meals. The supplement generally rapidly dissolves, resulting in a bolus of calcium that is quickly absorbed, leading to increased urinary supersaturation.[134–136] Although a low-calcium, low-oxalate diet can also reduce urine supersaturation with respect to calcium oxalate,[19] given the risk of bone demineralization with this approach it should be avoided. It is currently

recommended that most patients consume an age-appropriate calcium diet.[79,135] The current recommendations regarding daily elemental calcium intake are 1000 mg for men aged 19–70 and 1200 mg from age 71. For women it is 1000 mg from ages 19 to 50 and 1200 mg after age 51.[137]

TREATMENT OF SPECIFIC STONE TYPES

Calcium Stones and Hypercalciuria

Most calcium-based kidney stones are composed of calcium oxalate but can also contain calcium phosphate or uric acid. In addition to the increased risk associated with low-fluid consumption, high- or low-calcium intake, high-sodium and high–animal protein intake, the specific metabolic risk factors for development of calcium stones include hypercalciuria, hyperoxaluria, hyperuricosuria, and renal tubular acidosis. Most causes of hypercalcemia (hyperparathyroidism, vitamin D intoxication, for example) can cause hypercalciuria because of the increased filtered load of calcium, which is incompletely reabsorbed. Hypercalciuria is defined as daily urinary calcium excretion exceeding 250 mg in women and 275–300 mg in men.[17] Although we set arbitrary levels for defining hypercalciuria, it is clear that stone formation is a continuous function of urine calcium excretion—the higher the urinary calcium, the greater the supersaturation of the urine and the greater the risk for stone formation.

Idiopathic Hypercalciuria

Idiopathic hypercalciuria (IH) is defined as excessive urinary calcium excretion in the setting of normocalcemia and the absence of secondary causes of hypercalciuria. IH is the most common cause of calcium-containing kidney stones.[20,61] The mechanism by which IH leads to hypercalciuria is not known. It had been postulated that IH comprises three distinct disorders: excessive intestinal calcium absorption, decreased renal tubular calcium reabsorption, and enhanced bone demineralization. In a genetic strain of hypercalciuric stone-forming rats, hypercalciuria appears to be due to an excessive number of enteric Vitamin D receptors, leading to a generalized disorder of calcium transport at all sites of calcium transport, including the kidneys, intestine, and bone.[138,139] In humans, intestinal calcium absorption is significantly higher in subjects with IH.[140] Urinary excretion of calcium is also increased, thus placing many of these patients in net negative calcium balance if they consume a low-calcium diet.[17]

It was previously considered important to determine whether a patient with IH tended to have excessive GI calcium absorption (absorptive hypercalciuria) or excessive renal calcium excretion (renal leak).[19,141] Patients with excessive renal calcium excretion were prescribed thiazide diuretics, and those thought to have a predominantly absorptive defect were prescribed a low-calcium diet. However, many patients with IH had urinary calcium excretion that exceeded their intake,[142] and a low-calcium diet can result in a dangerous reduction in bone mineral density, especially in women.[15,143–145] Additionally, a low-calcium diet increases the risk of recurrent stone formation, presumably due to enhanced oxalate absorption and excretion.[77–79] There is no benefit, and a number of well-documented risks, to advising a low-calcium diet to prevent recurrent stone formation in patients with IH. We do not advise trying to determine the cause of the IH and never recommend a low-calcium diet to any stone patient.

Thiazide diuretics such as hydrochlorothiazide, chlorthalidone, and indapamide can significantly decrease urinary calcium excretion and reduce the incidence of stone formation.[28,146,147] Thiazides also may improve bone mineralization and reduce the risk of fractures.[28,148,149] A S[K] should be checked within 7–10 days of starting a thiazide diuretic and hypokalemia supplemented with potassium citrate. Alternatively, a potassium sparing diuretic such as amiloride can be added to further reduce hypercalciuria.[150] The potassium sparing diuretic, triamterene, should be avoided as it can itself form a stone.

Hyperoxaluria

Hyperoxaluria results from excessive dietary intake (dietary oxaluria), gastrointestinal disorders or surgery that lead to excess oxalate absorption (enteric oxaluria), or rarely an enzyme deficiency that results in excessive production of oxalate (PHO). Dietary oxaluria from oxalate-rich foods (Table 67.3) generally does not raise urinary oxalate above 60–80 mg/day.[151] Although most dietary oxalate is of plant origin, a high-protein diet stimulates endogenous oxalate production. Dietary oxalate becomes even more important in patients on a low-calcium diet, where the unbound oxalate is absorbed instead of precipitating with calcium in the intestine. Complex formation of intestinal oxalate with calcium supports the recommendation that patients with oxalate stones consume a normal calcium diet in addition to restricting high-oxalate foods. Enteric oxaluria is a feature of patients with gastrointestinal disorders such as celiac disease, Crohn's colitis, chronic pancreatitis, short bowel syndrome, and following some types of bariatric surgery, where the shortened bowel length allows for excessive oxalate absorption. The urinary oxalate excretion in enteric hyperoxaluria is often greater

than 60 mg/day (often more than 100 mg/day), which imparts a higher risk of nephrolithiasis.[152] Enteric oxaluria is persistent and needs aggressive and lifelong therapy for the hyperoxaluria, acidosis, hypokalemia, and hypocitraturia to not only prevent nephrolithiasis but also CKD.[153,154]

PHO, results in excessive oxalate production that deposits in different tissues and causes cardiomyopathy, bone marrow suppression, and renal failure at an early age.[155] PHO arises from various genetic mutations of oxalate production by the liver. PHO type 1 (80% of the cases) is due to a defect in the gene encoding the hepatic enzyme alanine glyoxylate aminotransferase involved in the conversion of glyoxylate to glycine. PHO type 2 (10% of cases) is due to a defect in the gene that encodes for the hepatic enzyme glyoxylate reductase/hydroxypyruvate reductase, involved in the conversion of glyoxylate to glycolate. PHO type 3 represents a defect in the HOGA1 gene that encodes for the mitochondrial 4-hydroxy-2-oxoglutarate aldolase enzyme, accounting for the remaining cases of PHO. In all of these, urinary oxalate excretion is increased, often to more than 300 mg/day[156] and patients can present in childhood with nephrocalcinosis. Systemic deposition of oxalate in organs leads to renal failure, cardiac defects, joint immobility, gangrene, and bone marrow suppression.[155,156]

Treatment of dietary hyperoxaluria consists of restricting dietary oxalate intake and using calcium carbonate with meals to bind oxalate in the intestine. To prevent the sequestration of calcium by fatty acids, the diet should also be low in fat. Cholestyramine is effective in binding oxalate, but its unpleasant taste limits its use.[2] In patients with enteric oxaluria, treatment of the underlying malabsorption syndrome leads to reduced urinary oxalate secretion. The chronic diarrhea often associated with such colonic conditions leads to bicarbonate loss, hypokalemia, hypocitraturia, hypomagnesmia, and low urine volumes, increasing the risk of nephrolithiasis. In such situations, treatment should also include increased fluid intake, potassium citrate and magnesium supplementation. The treatment of PHO is best managed by specialists in this disorder. Treatment involves administration of high doses of pyridoxine and orthophosphate to reduce oxalate levels and inhibit urinary calcium oxalate precipitation.[155,157] Treatment with both pyridoxine and orthophosphate improved renal survival from 20% to 74% at 20 years in patients with PHO type I and II.[157] Liver transplantation to treat the enzyme deficiency is the definitive therapy for this condition,[158] but a combined kidney–liver transplant may be necessary if nephrocalcinosis has developed.[159]

Hypocitraturia

Citrate is an important inhibitor of calcium crystallization in the urine.[160] Conditions that acidify the proximal tubule cell (renal tubular acidosis, chronic diarrhea, hypokalemia) cause hypocitraturia. Other causes of hypocitraturia include high protein diets, exercise, infections, androgens, starvation, and acetazolamide therapy. Although a level below 320 mg/day/1 L of urine is defined as hypocitraturia, the risk of nephrolithiasis is a continuous function of urinary citrate concentration.[161]

Therapy involves dietary modification in the case of excessive protein intake and treatment with potassium citrate[162] or potassium–magnesium citrate.[163] Both citrate formulations have proven to be efficacious in prevention of calcium stone formation, even in patients who do not have hypocitraturia.[163] Patients with CKD should have S[K] monitored while on therapy.

Oxalobacter formigenes

Oxalobacter formingenes is an enteric bacterium that uses oxalate for energy. Studies have shown that patients colonized with the bacterium have lower urinary oxalate compared to those not colonized.[164,165] However data to show that probiotic supplementation to increase colonization with *Oxalobacte formingenes* would lead to reduction in urinary oxalate excretion are lacking.[166] An interesting study suggests that the increased incidence of stones in industrialized nations may be explained by the reduced enteric *Oxalobacte formingenes* colonization from substantial antibiotic use.[167]

Uric Acid Stones and Hyperuricosuria

Hyperuricosuria refers to the increased excretion of both uric acid as well as sodium urate. Like calcium, oxalate, and citrate excretion in urine, hyperuricosuria may be considered a continuous variable. In addition to excess uric acid/urate production, the key factors influencing solubility of these substances in urine are urine pH and urine volume. Most patients with uric acid kidney stones do not excrete excessive amounts of uric acid; rather they have a low urinary pH.[17] Of those with hyperuricosuria the most common cause is excessive intake of dietary purine from animal proteins.[168,169] Other causes of hyperuricosuria include gout, uricosuric medications such as atorvastatin, amlodipine, and losartan, and, less commonly, disorders of excess production such as myeloproliferative disorders, tumor lysis syndrome, hypoxanthine-guanine phosphoribosyl transferase deficiency or phosphoribosyl pyrophosphate excess.

Urine pH is the major determinant of uric acid nephropathy (Figure 67.6). The solubility of uric acid rises sixfold with an increase in urine pH from 5.3 to 6.5.[170] In a compilation of four studies, every patient with uric acid stones had a urine pH less than 6.[171–174] Even when the total amount of uric acid being excreted is not above normal, a low urinary pH leads to the formation of uric acid, which is poorly soluble as opposed to the urate anion that is more soluble.[170] A similar mechanism, where decreased ammoniagenesis leads to a lowered urine pH, is postulated to be the cause of uric acid stones in patients with type 2 diabetes, metabolic syndrome, and chronic diarrhea.[37,175]

Uric acid stones are not radio-opaque and an ultrasound, or CT with contrast may be needed to diagnose their presence. Treatment of uric acid stones involves alkalizing the urine, switching to a low animal protein diet, avoiding high-purine foods (Table 67.4), increasing urine volume, and lowering uric acid production.[17] Sufficient alkali should be prescribed to raise the urine pH to above 6.5.[176] Because there is no added benefit to raising the urine pH beyond 7.0, and there is a potential risk of forming calcium phosphate stones in alkaline urine, patients should be instructed to check their urine pH once a day and titrate their consumption of alkali to aim for a urine pH between 6.3 and 7.[177] Increasing urine pH with potassium citrate or potassium bicarbonate can dissolve uric acid stones.[178] In patients at risk for hyperkalemia, acetazolamide can be used instead of potassium citrate therapy to increase urinary bicarbonate excretion and urine pH and reduce the risk of uric acid stones.[179] If patients continue to form uric acid stones, or excrete uric acid in excess of 1000 mg/day, allopurinol is recommended to decrease uric acid stone formation.[180] Allopurinol has been shown to reduce the incidence of calcium stones in hyperuricosuric patients,[181] but must be used with caution in patients of Han Chinese descent who carry the HLA-B*5801 gene and have a high risk of cutaneous drug reactions.[182,183]

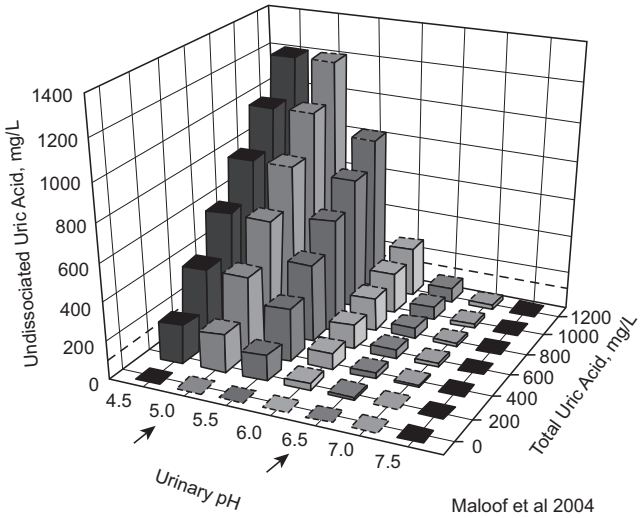

FIGURE 67.6 pH and solubility of uric acid. The solubility of Uric acid changes markedly with urine pH. At a urine pH of 5.5 slight increases in uric acid, even within the normal clinical range, lead to marked increase in undissolved uric acid. *From Maalouf N, Gaska MA, Abate N, Sakhaae K, Moe OW. New insights in the pathogenesis of uric acid nephrolithiasis.* Curr Opin Nephrol Hypertens *2004;**13**:181–9.*

TABLE 67.4 Foods High in Purine

Organ meats: Sweetbreads, Liver, Kidney, Brains, Heart
Shellfish
Meat: Beef, pork, lamb, poultry
Fish: Anchovies, sardines, herring, mackerel, cod, halibut, tuna, carp
Meat extracts: Bouillon, broth, consommé, stock
Gravies
Vegetables: asparagus, cauliflower, peas, spinach, mushrooms, lima beans, lentils

Calcium Phosphate Stones and Nephrocalcinosis

Some calcium stones are predominantly composed of calcium phosphate. Typically these patients are hypercalciuric and their urine volumes and urine pH are higher than observed in calcium oxalate stone formers.[184] The precise pathogenesis of such calcium phosphate stones is unclear, but the inciting event is thought to be a renal tubular acidosis that can be incomplete (no evidence of acidemia on serum chemistry but patients cannot properly acidify urine if challenged with an oral acid precursor such as ammonium chloride). In such cases, the urine pH stays above 6.1 and supersaturation of calcium phosphate is increased. Type 1 RTA is a dramatic example of this clinical scenario and can manifest as nephrocalcinosis where there is extensive deposition of calcium phosphate within the renal parenchyma. Drugs such as acetazolamide or topiramate also produce a similar urinary chemical milieu that is conducive to calcium phosphate stone formation.

Hyperphosphaturia is another risk factor that can lead to the development of calcium phosphate stones or nephrocalcinosis. Hyperphosphaturia contributes to stone formation in patients with hyperparathyroidism, vitamin D intoxication, tumor lysis syndrome, acute phosphate nephropathy after oral sodium phosphate bowel preparation, and inherited phosphate-wasting disorders. Treatment consists of general measures outlined above and therapy to lower urinary calcium excretion with thiazides. Alkali supplementation may be beneficial if there is acidemia. However, care must be taken to ensure that the urine pH does not increase to beyond 7, as that may worsen the supersaturation for calcium phosphate.

Struvite Stones

Also referred to as triple phosphate stones, struvite stones are seen in urine colonized with urea splitting organisms and are composed of magnesium ammonium phosphate (struvite) and hydrated calcium carbonate (apatite). Struvite stones are formed when urease-producing bacteria (Table 67.5) split urea and generate ammonia and an alkaline urine. Under these conditions phosphate combines with ammonium, magnesium, and calcium and leads to the formation of struvite. Untreated, they can grow rapidly and fill the renal-collecting system forming staghorn calculi. Women are more prone to forming such stones because of their increased risk of urinary tract infections.[185] Patients with urinary catheters, neurogenic bladders, spinal cord lesions, and anatomical abnormalities of the genitourinary tract are also predisposed to the development of struvite stones. Infection with urease-producing bacteria, alkaline urine, and large stones are very suggestive of struvite nephrolithiasis. Colony counts can be low, but speciation and sensitivities are necessary for diagnosis and treatment. If cultures are negative, a specific request should be made for *Ureaplasma urealyticum* that exhibits fastidious growth on regular culture medium.

TABLE 67.5 Infections Associated With Struvite Stone Formation (Urease-Producing Bacteria)

Proteus
Haemophilus
Yersinia
Staphylococcus epidermidis
Pseudomonas
Klebsiella
Serratia
Citrobacter
Ureaplasma

Left untreated, struvite stones can cause sepsis or lead to ESRD. Struvite stones therefore require aggressive medical and surgical therapy.[102] Early urological intervention is necessary for stone removal. Stones less than 2 cm may respond well to extracorporeal shock wave lithotripsy (ESWL). For larger stones, percutaneous lithotomy, with or without ESWL, is the preferred surgical intervention.[186] Stone fragments should be cultured and bacteria-specific antibiotics used until urine cultures remain sterile for 3 consecutive months. Surveillance cultures should be continued for a year.[187] Adjunctive medical therapies include urease inhibitors and chemolysis. Urease inhibitors such as acetohydroxamic acid are effective in inhibiting urease and can retard the growth of struvite stones and prevent new stone formation[188,189] but are limited by their side effects and use in patients with renal failure. Chemolysis—the irrigation of the kidney through a nephrostomy tube or ureter with a solution used to dissolve the stones—is currently rarely used because of the significant severe side effects[190,191] and might only be useful in patients with residual disease that cannot be cleared surgically.

Cystine Stones

About 1−2% of all kidney stones are composed of cystine. This genetic disorder of amino acid transport across the tubular membrane leads to reduced proximal tubular reabsorption of cystine from the filtrate and excess urine excretion of this sparingly soluble amino acid.[192,193] Normally, the daily volume of urine is adequate to keep the typical urinary cystine excretion of about 50 mg/day in solution. Patients with cystinuria

produce 250–1000 mg of cystine, which is exceedingly difficult to keep in solution, resulting in crystal and stone formation.[194] Cystine solubility rises markedly when urine pH is greater than 6.5. Because of their sulfur content, these stones are radio-opaque. Cystine stones should be suspected in patients with staghorn calculi. Visualization of the pathognomonic hexagonal crystals in urine (Figure 67.4) supports this diagnosis. Treatment is directed at increasing urine volume to 4 L/day, lowering urine sodium[195] and dietary protein intake,[196] and urinary alkalinization with potassium bicarbonate or acetazolamide.[179] d-Penicillamine[197,198] or tiopronin,[199,200] which form soluble heterodimers with cysteine and thereby reduce the cystine available for crystallization, may also be utilized. However, both these medications can produce similar side effects of loss of taste, fever, proteinuria, serum sickness reactions, and even nephrotic syndrome. Thus these drugs are added if stone formation continues despite conservative measures such as increasing fluids, dietary changes, and alkalinization.

CONCLUSIONS

Kidney stones are a cause of significant morbidity worldwide. After the initial episode a metabolic evaluation to search for the underlying causes is recommended in most patients, and especially in those with risk factors such as a family history of kidney stones, history of bowel surgery, or laboratory abnormalities that suggest other diagnoses. Most stones in patients in the US are calcium based. Kidney stones may lead to CKD, but because the incidence of recurrent stone formation decreases with progressive CKD, they may be underrecognized as a cause. Dietary modifications to increase fluid intake, reduce salt and animal protein intake, and encourage consumption of an age- and gender-appropriate amount of calcium, preferably from dairy, and not supplements may be recommended therapies. Restriction of oxalate rich foods is also utilized to reduce recurrence rates. Determination of urinary supersaturation and analysis of any passed stones guide treatment. Measures to reduce urinary supersaturation are highly effective in lowering recurrent stone formation. Reduced urinary pH is found in most patients with uric acid stones, and patients benefit from an increase in urinary pH. Targeted medical therapy can be initiated once a metabolic abnormality is found. Medications used to prevent stone recurrence are well tolerated and highly effective. Thiazide diuretics are a cornerstone of therapy in patients who form calcium-containing kidney stones. Potassium citrate is also highly effective in reducing recurrent stone formation.

QUESTIONS AND ANSWERS

Question 1

Which of the following diets is associated with an increased risk of nephrolithiasis?

A. Low-sodium diet
B. Low-calcium diet
C. Low-oxalate diet
D. Low-protein diet
E. Low-purine diet

Answer: B

All other diets reduce the risk of stone formation except a low-calcium diet, which has been associated with increased risk of stone formation. Dietary calcium binds dietary oxalate in the intestine, which decreases oxalate absorption and excretion. Eating a low-calcium diet results in unbound oxalate in the intestine leading to increased absorption and hyperoxaluria.

Question 2

A 32-year-old female presents to the emergency department with a 3-hour history of right flank pain radiating to her groin. She has profound nausea, but denies dysuria, gross hematuria, diarrhea, or fever. She is not on any medications. On examination, she is restless from pain.

Her blood pressure is 146/79 mm Hg, heart rate is 98/min, and temperature is 37°C (98.6°F). She has some right costo-vertebral angle tenderness on exam but no abdominal guarding or rigidity. Bowel sounds are heard.

Labs reveal S[Na] 142 mEq/L, potassium 3.9 mEq/L, chloride 114 mEq/L, bicarbonate 26 mEq/L, blood urea 23 mg/dL, and S[Cr] of 0.9 mg/dL. Urinalysis shows a specific gravity of 1.025, 3+ blood, and no protein are noted on dipstick. Urine microscopy shows greater than 50 erythrocytes/hpf, 3–5 leukocytes/hpf, and occasional calcium oxalate crystals.

What is the optimal radiologic procedure at this time to assist in diagnosis?

A. Plain radiography of the abdomen
B. Intravenous pyelography
C. Abdominal Ultrasonography
D. Noncontrast spiral computed tomography

Answer: C

Abdominal ultrasound is a safe test for initial assessment of abdominal pain in young women of childbearing age. Although her presentation is suspicious for nephrolithiasis, gynecological conditions such as ectopic pregnancy, ovarian torsion, and abdominal conditions such as acute appendicitis are included in the differential. Ultrasound has a low sensitivity but a high specificity for nephrolithiasis. All other tests include some form of radiation that is best avoided until she has had a negative pregnancy test. The most sensitive and specific test, once pregnancy has been ruled out, is a noncontrast computed tomography.

Question 3

A 37-year-old man presents for evaluation of recurrent kidney stones. He has passed six stones during the past 2 years. He is currently asymptomatic. He was diagnosed with ulcerative colitis 12 years ago and underwent a partial bowel resection 6 years ago. Since then he has not had any flares and has not noticed blood or mucus in his stool. He is not on any medications at this time. There is no family history of renal stone disease.

On examination, the patient is comfortable and without distress. His blood pressure is 115/74 mm Hg, pulse is 72/min, and he is afebrile. The rest of his exam is unremarkable.

Laboratory results demonstrate: hemoglobin, 13.2 g/dL; hematocrit, 39%; leukocyte count, 7.4×10^9 cells/μL; blood urea nitrogen 18 mg/dL; S[Cr] 1.9 mg/dL; S[Na], 138 mEq/L; S[K], 3.7 mEq/L; serum chloride, 109 mEq/L; serum bicarbonate, 24 mEq/L; S[Ca], 9.8 mg/dL; serum phosphorus, 3.2 mg/dL; urinalysis: pH, 6.0, specific gravity, 1.020, trace hematuria, no proteinuria; arterial blood: pH, 7.42.

His 24-hour urine studies show urine volume 1.8 L, urine Ca 205 mg, urine Na 2300 mg, urine oxalate 98 mg, urine citrate 300, urine phosphorus 800 mg, and urine uric acid 600 mg. Plain abdominal radiography reveals a 6-mm stone in the left kidney and a 2-mm stone in the right renal pelvis.

What is the most likely cause of this patient's renal stone disease?

A. IH
B. Primary hyperparathyroidism
C. Distal renal tubular acidosis
D. Enteric hyperoxaluria

Answer: D

The patient has enteric hyperoxaluria. With a history of ulcerative colitis and partial bowel resection, his risk of hyperoxaluria is very high because of the shortened bowel loop. He is not hypercalciuric (urine Ca less than 250 mg) and hyperparathyroidism is not likely to be the cause because most patients with hyperparathyroidism are hypercalciuric. dRTA is again unlikely because of the absence of acidosis and hypokalemia.

Question 4

A 40-year-old woman presents to the ED complaining of acute abdominal pain. She "knows" it is a kidney stone because she had a similar episode of 6 months ago when she passed a stone. At that time she was treated with narcotics and, following passage of the stone, was told that she did not need any intervention because in the absence of a family history and a normal laboratory workup her risk of recurrence was low. She was advised to increase her fluid intake. Other than a history of back pain for which she takes an occasional Ibuprofen she is otherwise healthy. In the ED, her vital signs are stable, and examination is unrevealing except for a young woman in mild distress.

Her laboratory results show: hemoglobin, 12 g/dL; leukocyte count, 11.4×10^9 cells/μL; S[Cr] 0.7 mg/dL; S[Na], 144 mmol/L; S[K], 3.9 mmol/L; serum chloride, 106 mmol/L; serum bicarbonate, 23 mmol/L; S[Ca] 10.8 mg/dL; serum phosphorus, 2.2 mg/dL; urinalysis: pH, 6.0, specific gravity, 1.020, lots of blood, and 1+ protein on dip.

Her renal ultrasound reveals right-sided hydronephrosis and a 4 mm-stone in her left renal pelvis.

Which of the following tests is likely to reveal the cause of her recurrent stone formation?

A. Review of her adherence to dietary and fluid recommendations
B. Spiral CT of the abdomen after a pregnancy test
C. Intact PTH and urinary calcium excretion
D. Urine examination for crystals

Answer: C

Recurrent stone formation in a patient should raise the suspicion for metabolic abnormalities that predispose patients to multiple stones. In this patient, the mild hypercalcemia and hypophosphatemia are clues that she has primary hyperparathyroidism. Although dietary and fluid recommendations should be reviewed and reinforced, that by itself, is not likely to prevent recurrence of stones. The renal ultrasound reveals a stone and hydronephrosis, and hence a urine examination for crystals or a spiral CT is not likely to add to the diagnosis or therapy.

Question 5

A 74-year-old patient, a resident of a nursing home, is sent to the renal clinic for evaluation of an elevated S[Cr]. She had a stroke 3 years ago and since then has been mostly bed bound. The nursing home reports that she had many urine infections in the past that were treated with antibiotics.

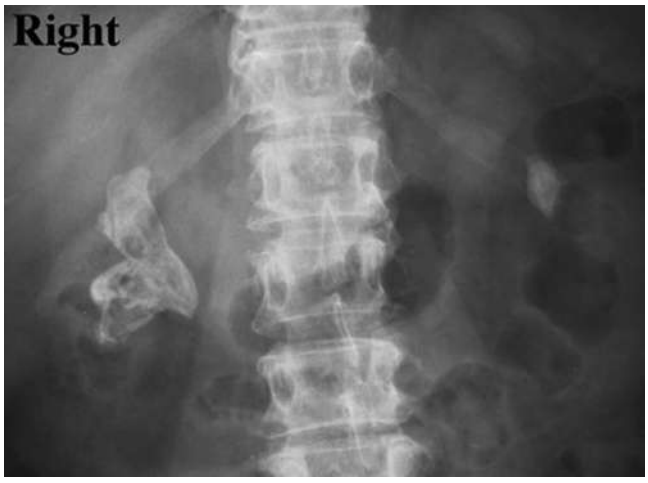
Further history is limited because the patient is nonverbal. Vital signs are stable except for a temperature of 38°C, and examination elicits some tenderness on deep palpation over the right flank. Labs are within normal limits except for a S[Cr] of 2.0 g/dL. Her urine analysis in the clinic shows specific gravity of 1028, pH of 8.4, blood ++, leukocyte esterase ++, nitrite +. Her urine microscopy shows many coffin lid−shaped crystals. X-ray KUB is shown below. She is started on antibiotics and her urine is sent for culture.

Which of the following organism is least likely to grow in her urine?

A. Proteus
B. E coli
C. Klebsiella
D. Serratia
E. Pseudomonas

Answer B

With a history of recurrent infections, high urine pH, struvite crystals in urine, and the appearance of a staghorn calculus on KUB, the patient has struvite stones. These are composed of magnesium ammonium phosphate and form when urease-producing bacterial infections split urea and generate ammonia in alkaline urine. Of all the bacteria *E. coli* does not produce urease.



KUB X-ray.

Treatment of Psychiatric Disorders in Chronic Kidney Disease Patients

L. Parker Gregg[a], *S. Susan Hedayati*[b]

[a]University of Texas Southwestern and Veterans Affairs North Texas Health Care System, Dallas, TX, United States; [b]University of Texas Southwestern, Dallas, TX, United States

Abstract

Patients with chronic kidney disease (CKD) have a high rate of comorbid psychiatric conditions, including mood and anxiety disorders, substance use disorders, and eating disorders. Treatment of psychiatric disorders in CKD patients can be complicated by altered pharmacokinetics, unclear safety and efficacy of treatments, and lack of supporting evidence to guide treatment decisions. Furthermore, some psychiatric interventions may lead to renal complications, such as fluid and electrolyte disorders or worsening CKD. We review the evidence base regarding treatment of psychiatric disorders in CKD patients. We also present practical considerations regarding the management of psychiatric disorders in patients with CKD, including identifying candidates for therapy or mental health referral, the evidence for pharmacologic and nonpharmacologic therapy in CKD patients, the effects of CKD on psychiatric treatment, and consequences of these interventions that may prompt nephrology consultation.

INTRODUCTION

Increasing evidence shows a high rate of comorbid psychiatric disorders in patients with chronic kidney disease (CKD). Patients with CKD and psychiatric disorders are at risk for poor outcomes, including progression of CKD, hospitalization, cardiovascular events, and death. Unfortunately, symptoms of uremia often overlap with psychiatric symptom profiles (Table 68.1), which can complicate identification of appropriate candidates for psychiatric therapies. Furthermore, recent studies call into question the effectiveness and safety of some standard treatments for psychiatric disorders in CKD patients, or whether treatment affects long-term outcomes such as death. We review the literature and discuss practical concerns important to the nephrologist regarding the treatment of psychiatric disorders in patients with kidney disease.

GENERAL CONSIDERATIONS IN THERAPY

Pharmacologic and Nonpharmacologic Options

CKD patients are medically complex, often with multiple comorbid illnesses, receive polypharmacy, and have frequent healthcare contacts. Therapies for psychiatric disorders frequently include pharmacologic and nonpharmacologic interventions, either alone or in combination. Individual patients may have different preferences in seeking treatment. Some may prioritize avoiding additional pill burden, while others may find frequent healthcare appointments onerous. There is limited available evidence to compare the safety and efficacy of pharmacologic and nonpharmacologic interventions to placebo or to each other in CKD patients. In general, treatment should be guided by individual patient preference and available resources where evidence is lacking.

Drug–Drug Interactions

CKD patients often have a high pill burden due to the illness, its multiple sequelae, and comorbid medical conditions such as hypertension, diabetes, and cardiovascular disease. Psychotropic medications such as certain antidepressant medication classes and lithium carbonate can lead to harmful drug–drug interactions, increased risk of bleeding, cardiovascular toxicity, and central nervous system effects (Table 68.2).[1]

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00068-1

TABLE 68.1 Symptoms Associated with DSM-5 Disorders Common in Chronic Kidney Disease Patients

Disorder	Symptoms
Major depressive disorder	Depressed mood, decreased pleasure, weight changes, sleep disturbance, psychomotor agitation or retardation, fatigue, feelings of worthlessness or guilt, decreased concentration, recurrent thoughts of death or suicide.
Generalized anxiety disorder	Excessive, difficult to control worry associated with restlessness, fatigue, difficulty concentrating, irritability, muscle tension, or sleep disturbance.
Panic disorder	Recurrent, unexpected panic attacks associated with persistent worry about or maladaptive response to the attacks.
Posttraumatic stress disorder	Reexperiencing a trauma through flashbacks, intrusive thoughts, or nightmares; avoidance of stimuli associated with the trauma; irritability, anger, or hypervigilance.
Bipolar affective disorder I	At least one lifetime manic episode, defined as $\geq$1 week of elevated or irritable mood associated with grandiosity, decreased sleep, talkativeness, flight of ideas, distractibility, increased goal-directed activity, or activities with high potential for adverse consequences. Patients often also have intermittent depressive symptoms.
Substance use disorder	Problematic substance use involving greater intake than intended, difficulty decreasing use, large time commitment to obtaining/using/recovering, craving, failure to fulfill obligations, interpersonal problems, use in hazardous situations, tolerance, or withdrawal.
Anorexia nervosa	Caloric restriction leading to low body weight, associated with intense fear of weight gain. May be associated with purging.
Bulimia nervosa	Recurrent episodic binge eating associated with inappropriate compensatory behaviors (i.e. purging).

Consequently, treatment individualization and adjustments in nonpsychotropic medications when initiating or adjusting pharmacotherapy for a psychiatric condition is required. In addition, dose adjustment in the setting of reduced estimated glomerular filtration rate (eGFR) is needed for drugs that are cleared by the kidneys to avoid increased risk of toxicity.

Pharmacokinetics in CKD

The kidneys play a key role in drug metabolism. CKD can significantly affect pharmacokinetics by altering absorption, volume of distribution, and excretion of medications and their metabolites (Table 68.2). For example, urea is secreted into the gut, where it is hydrolyzed to ammonia. This may increase gastric pH and alter the oral bioavailability of medications.[2] Nausea and vomiting or increased gastric emptying time due to gastroparesis may also alter enteral medication absorption. Once absorbed, a drug's volume of distribution can be altered by fluid overload, hypoalbuminemia, or malnutrition in CKD patients.[2] Protein binding of drugs can be affected by nephrotic-range proteinuria and hypoalbuminemia. Accumulated organic acids and uremic toxins can compete with drugs for binding sites on albumin and other proteins.[3] Decreased protein binding increases the concentration of unbound circulating drug, leaving more drug available for activity at its receptor and decreasing the dose necessary for both therapeutic and adverse effects.[3] Drugs and their metabolites may also have decreased renal excretion, due to abnormalities of glomerular filtration, tubular secretion, and passive tubular reabsorption. Altered hepatic drug metabolism may occur due to downregulation of the cytochrome P450 enzymes in CKD.[4,5] In patients with end-stage renal disease (ESRD), consideration must be given to the intermittent removal of some medications by dialysis.

CKD clearly has far-reaching effects on multiple aspects of pharmacokinetics, extending beyond decreased renal clearance in the setting of low glomerular filtration rate (GFR). Because of these varied effects, drug pharmacokinetics can be difficult to predict in individuals with CKD. Few studies have investigated the pharmacokinetics of psychotropic medications in CKD patients. Generally, in the absence of specific recommendations to guide dosing, it is advisable to start at a low dose and gradually uptitrate, with careful, frequent monitoring for adverse effects in patients with CKD. Use the lowest effective but tolerable dose of psychotropic medications in CKD patients.

Treatment Nonadherence

Between 34% and 60% of patients with CKD demonstrate poor adherence to prescribed pharmacologic therapy.[6,7] Total pill burden, regimen complexity, lack of social support, side effects, and concern about drug interactions have been identified as primary factors associated with poor adherence, whereas studies vary as to whether older or younger age is more strongly associated with nonadherence.[8,9] Nephrologists and mental health providers should consider polypharmacy and the patient's likelihood of adherence when initiating treatment for psychiatric disorders, and routinely reassess adherence.

TABLE 68.2 General Considerations for the Prescription of Psychotropic Medications in CKD Patients

Drug–Drug Interactions
Bleeding risk with SSRIs, antiplatelet agents, and anticoagulants
Prolonged QTc and arrhythmias with SSRIs, TCAs, and antipsychotics exacerbated by hypomagnesemia due to diuretics
Hyponatremia with SSRIs and thiazide diuretics
Thiazide and loop diuretics can increase lithium carbonate levels
Pharmacokinetic Derangements in CKD
Medication absorption
Increased gastric pH due to uremia
Nausea and vomiting
Chelation due to concurrent medications such as phosphate binders
Gastroparesis
Decreased protein binding
Hypoalbuminemia
Competitive protein binding by uremic toxins
Volume of distribution
Volume overload leading to increased volume of distribution
Muscle wasting leading to decreased volume of distribution
Metabolism and excretion
Decreased renal clearance of drugs and metabolites
Decreased hepatic drug clearance by cytochrome P450 enzymes
Other than lithium carbonate, most psychotropic medications are protein bound and not significantly dialyzable
Medication Nonadherence
High total pill burden due to CKD and its sequelae
Lack of social support
Significant adverse effects of psychotropic medications

Abbreviations: *CKD*, chronic kidney disease; *SSRIs*, selective serotonin reuptake inhibitors; *TCAs*, tricyclic antidepressants.

MOOD AND ANXIETY DISORDERS

Major Depressive Disorder

Identifying Candidates for Treatment

Major depressive disorder (MDD), prevalent in approximately 7% of the general population, is disproportionately common in patients with kidney disease, with up to 20–25% of both nondialysis- and dialysis-dependent CKD patients meeting *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) criteria.[10–15] Diagnostic criteria for MDD include the presence, for at least 2 weeks, of at least 5 of 9 symptoms of depression (Table 68.1, Figure 68.1), one of which has to be sadness or anhedonia. Some of the physical symptoms (fatigue, weight or appetite changes, and insomnia) can also be attributed to uremia (Figure 68.1).[16] CKD patients may experience psychosocial stressors associated with their disease process, such as pain and fear or dislike of dialysis.[17,18] The symptom overlap between CKD and MDD can present a challenge to the clinician in identifying patients who may benefit from treatment for depression.

Identifying candidates for treatment requires initial screening and subsequent evaluation to confirm the diagnosis of MDD or other psychiatric disorders such as psychosis or bipolar disorder. Recognizing important symptoms such as suicidal ideation that may require urgent intervention is also critical (Figure 68.2). There is currently no consensus about which measurement tool is the best to screen for and diagnose MDD. In CKD patients, cutoffs of the Beck Depression Inventory (BDI) $\geq$11 and the Quick Inventory of Depressive Symptomatology Self-Reported Questionnaire (QIDS-SR) $\geq$10 have been validated as sensitive and specific screening tools for MDD.[19,20] In dialysis patients, cutoffs of BDI $\geq$14–16, Center for Epidemiologic Studies Depression Scale (CESD) $\geq$18, and Patient Health Questionnaire (PHQ) $\geq$10 are associated with MDD.[14,15,21,22] However, in addition to the significant symptom overlap between CKD and MDD, self-report measures may lack scoring criteria for the inclusion of depressed mood or anhedonia to diagnose depression. Consequently, the prevalence of MDD is generally higher when estimated by self-report screening tools than by interview-based DSM-5 criteria.[14,23] Although the use of structured psychiatric interview tools, such as the Mini International Neuropsychiatric Interview (MINI),[24] can verify the diagnosis of MDD, these tools are generally not widely available for clinical use by a nephrologist and require special training for administration. Therefore, a diagnosis of MDD can be more feasibly confirmed by inquiring whether the patient endorses depressed mood or anhedonia after identifying a patient with a positive self-report screening measure.[20] Finally, clinical suspicion for other complex psychiatric conditions such as psychosis or bipolar disorder may require different management and referral to mental health specialists. Clinicians can then consider initiation of treatment for patients with uncomplicated MDD.[20]

Traditional Pharmacologic Therapy

Treatment of MDD can involve both pharmacologic and nonpharmacologic interventions (Figure 68.2). Although several classes of antidepressant medications have been developed and proven effective for MDD in the general population, clinicians must prescribe these medications cautiously for CKD patients, due to decreased drug clearance, drug–drug interactions, and higher potential for adverse side effects (Table 68.3). Most studies of these drugs excluded patients with CKD and ESRD, so dose recommendations and pharmacokinetic information are often based on little evidence. Because of the lack of data supporting safe and effective

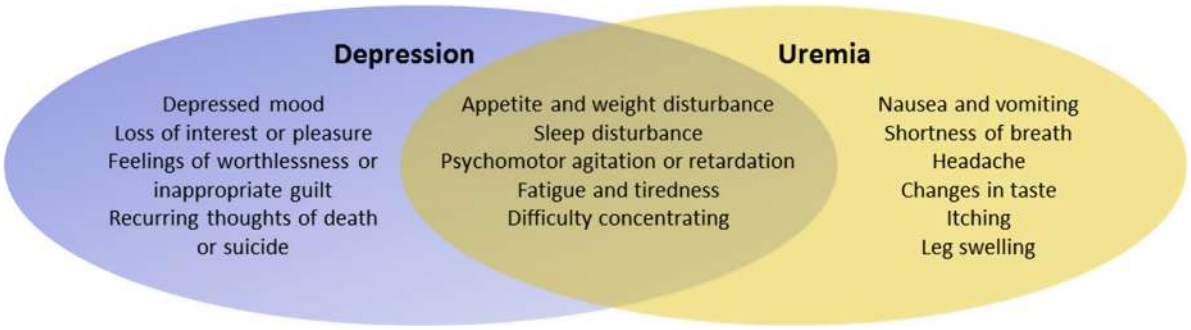

FIGURE 68.1 Similarities and differences in symptoms of depression and uremia.

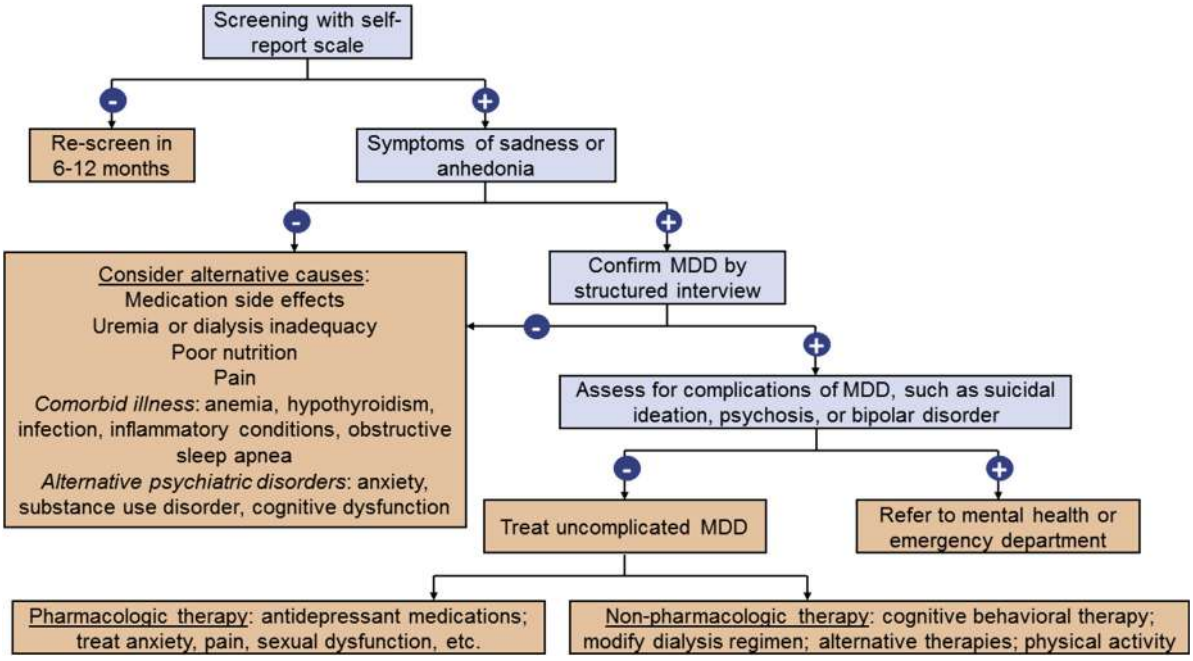

FIGURE 68.2 Identification of chronic kidney disease patients who may benefit from treatment of major depressive disorder (MDD).

dosing in these populations, underdosing of antidepressant medications is a major concern in both clinical care and existing studies of these medications in CKD patients.

In addition to the safety concerns regarding traditional antidepressant medications in CKD patients, several studies indicate that they may be less effective for treating MDD associated with chronic medical comorbidities, such as CKD or heart failure, than in the treatment of primary MDD in the general population. Most prior trials of antidepressant medications in CKD or ESRD patients were limited by small sample sizes,[25–30] nonstandard diagnostic criteria for MDD,[26,30,31] absence of a placebo control group,[27–32] or possible inadequate exposure to the drug by either low dose or short treatment duration.[25–27,30,31] The Chronic Kidney Disease Antidepressant Sertraline Trial (CAST) is the only adequately powered double-blind, randomized, placebo-controlled clinical trial that evaluated the effectiveness of a commonly prescribed antidepressant, sertraline, compared with placebo for the short-term treatment of depression in CKD patients.[33] In this trial, there was some improvement in depressive symptoms from baseline to study exit in both groups after 12 weeks of treatment, but there was no benefit of sertraline over placebo.[33] These results were similar to other trials showing no benefit of selective serotonin reuptake inhibitors (SSRIs) compared with placebo for the treatment of depression in patients with other chronic diseases such as heart failure, coronary artery disease, or asthma.[34–37] In addition, sertraline resulted in a higher incidence of gastrointestinal side effects (nausea and diarrhea) compared with placebo in CKD patients.[33]

Clinicians must consider the lack of efficacy data for traditional antidepressant medications in CKD patients, unclear dosing, and increased risk of side effects when

TABLE 68.3 Antidepressant Medication Dosing and Toxicities in CKD and ESRD

Medication	Non-CKD Dose	Manufacturer-Recommended Dose in CKD and ESRD	Potential Class and Individual Toxicities
SSRIs			Increased bleeding risk; GI symptoms such as nausea and diarrhea; CNS effects; sexual dysfunction; hyponatremia
Citalopram	20–40 mg once daily	Initial dose: 10 mg once daily Not recommended for eGFR <20 mL/min/1.73 m^2	Higher doses associated with QTc prolongation, torsades de pointes
Escitalopram	10–20 mg once daily	Use with caution in severe renal impairment	
Fluoxetine	20–80 mg once daily	No dose adjustment recommended; use with caution due to long half-life	
Paroxetine immediate release	20–50 mg once daily	Initial dose: 10 mg once daily Max dose: 40 mg once daily	
Paroxetine controlled release	25–62.5 mg once daily	Initial dose: 12.5 mg once daily Max dose: 50 mg once daily	
Sertraline	50–200 mg once daily	No dose adjustment recommended, but active metabolite is renally excreted	
TCAs		Generally avoid TCAs given cardiac side effects	QTc prolongation, arrhythmias, orthostatic hypotension; CNS and anticholinergic effects
Amitriptyline	75–150 mg per day in 1–3 divided doses	No dose adjustment recommended	
Desipramine	100–300 mg once daily or in divided doses	Caution advised in eGFR <15 mL/min/1.73m^2	
Doxepin	25–300 mg once daily or in divided doses	No dose adjustment recommended	
Nortriptyline	25 mg in 3–4 divided doses; max 150 mg daily	No dose adjustment recommended	
MAOIs		Avoid MAOIs in CKD due to drug–drug interactions	Significant drug–drug interactions, risk of hypertensive emergency with tyramine-rich foods, orthostatic hypotension
Phenelzine	45–90 mg daily in 3–5 divided doses	No dose adjustment advised for mild to moderate renal impairment	
Selegiline	6 mg per 24 hours *via* transdermal patch		
Serotonin Modulators			
Nefazodone	100–600 mg/day in 2 divided doses	Generally avoid in cardiovascular or liver disease, increase dose carefully	Cardiac dysrhythmias, Stevens Johnson syndrome, liver failure, serotonin syndrome, priapism
Trazodone immediate-release	150–400 mg/day, divided	Increase dose carefully, use divided dose in the elderly	
Trazodone extended-release	150–375 mg once daily at night		
Other			
Bupropion	100 mg twice daily; max 450 mg per day in 3–4 divided doses	Active metabolite; reduce frequency and/or dose	Accumulation of toxic metabolites; cardiac dysrhythmia; wide QRS complex; nausea; insomnia; dizziness

Continued

TABLE 68.3 Antidepressant Medication Dosing and Toxicities in CKD and ESRD—cont'd

Medication	Non-CKD Dose	Manufacturer-Recommended Dose in CKD and ESRD	Potential Class and Individual Toxicities
Mirtazapine	15–45 mg daily at bedtime	Reduce dose; clearance reduced by 30% if CrCl 11–39 mL/min, and by 50% if CrCl <10 mL/min	CNS effects including somnolence, weight gain
Venlafaxine immediate release	75–225 mg/day in 2–3 divided doses	Reduce dose by 25–50% in patients with mild to moderate renal impairment	Hypertension, sexual dysfunction, neuroleptic malignant syndrome, serotonin syndrome, accumulation of toxic metabolite O-desmethylvenlafaxine
Venlafaxine extended release	37.5–225 mg once daily		

Abbreviations: *CNS*, central nervous system; *CrCl*, creatinine clearance; *eGFR*, estimated glomerular filtration rate; *GI*, gastrointestinal; *MAOIs*, monoamine oxidase inhibitors; *SSRIs*, selective serotonin reuptake inhibitors; *TCAs*, tricyclic antidepressants.

prescribing pharmacologic therapies to treat MDD. If pharmacologic treatment is being considered, an SSRI such as sertraline, which currently has the best safety profile in CKD patients, may be initiated at a low dose while monitoring the patient closely for side effects during gradual dose uptitration every 1–2 weeks. Finally, consideration should be given to early withdrawal of the SSRI if the patient develops intolerable side effects or the drug proves to be ineffective. Adequately powered placebo-controlled clinical trials of alternative SSRIs and other classes of antidepressant medications in CKD patients are needed to guide pharmacologic treatment of MDD.

Nontraditional Pharmacologic Therapy

St. John's Wort is a popular herbal supplement advertised for the treatment of depression, but this approach is fraught with drug–drug interactions important in patients with CKD.[38] St. John's Wort is known to alter hepatic metabolism by inducing the cytochrome P450 system and gastrointestinal P-glycoprotein.[39,40] This becomes particularly important in patients who require immunosuppressive therapy with calcineurin inhibitors for diseases such as focal segmental glomerulosclerosis, or who go on to receive a kidney transplant, as St. John's Wort can decrease cyclosporine and tacrolimus levels.[41] When given in combination with SSRIs, St. John's Wort can also cause serotonin syndrome.[42] There are no data to suggest safety or efficacy of this supplement in CKD patients.

Limited evidence also suggests possible utility of antiinflammatory therapies to treat depressive symptoms. In the general population, inflammatory biomarkers including interleukin-6 (IL-6), high sensitivity C-reactive protein (hsCRP), and tumor necrosis factor-α (TNF-α) are elevated in people with depressive symptoms.[43–47] Given the connection between MDD and immune activation, it is thought that elevated baseline inflammation associated with chronic medical illnesses may account for the high prevalence of MDD in patients with comorbidities such as CKD,[12,13] heart failure,[48,49] and diabetes.[50] Some studies demonstrated improvement in depressive symptoms in patients with other chronic diseases such as rheumatoid arthritis, psoriasis, or Crohn's disease treated with anticytokine or anti-TNF-α therapies.[51,52] No trials have studied these interventions in CKD or ESRD patients, who are at high risk of side effects from such treatments. Despite this potentially promising preliminary data, further studies are needed to determine whether antiinflammatory therapies may be useful in the treatment of depressive symptoms in CKD patients.

Nonpharmacologic Therapy

Nonpharmacologic therapies avoid the risks and toxicities associated with antidepressant medications. However, other barriers may limit access to these treatments, particularly in resource-limited settings, or they may be undesirable due to increased patient time spent on disease management. Cognitive behavioral therapy (CBT) is an evidence-based treatment targeting a patient's "automatic thoughts" in response to negative emotions, to improve distorted thinking, behavior, and communication.[53] Four small randomized trials in hemodialysis patients showed significantly greater improvement of depressive symptoms in the CBT group compared with controls.[54–57] However, no studies have investigated the effectiveness of CBT in nondialysis-dependent CKD patients. Nonetheless, CBT may be a promising nonpharmacologic intervention to treat MDD in individuals with CKD.

A recent randomized trial, A Trial of Sertraline vs. CBT for End-Stage Renal Disease Patients with Depression (ASCEND), compared nonpharmacologic to pharmacologic therapy. This multicenter trial randomized 120 hemodialysis patients with MDD to sertraline or CBT.[58] Depressive symptoms ascertained by the QIDS-Clinician Rated scale improved from baseline with both treatments, with a modestly greater improvement with sertraline than with CBT, effect estimate (95% CI), −1.84 (−3.54, −0.13).[59] Because an active control arm was not included, conclusions regarding the efficacy of either treatment compared with no active treatment were not possible. In addition, there was a greater frequency of mild to moderate nonserious adverse events with sertraline than with CBT.

Physical activity also improves mental health in various populations.[60,61] Low physical activity is associated with depression in CKD and ESRD patients.[62,63] Several studies have demonstrated a benefit of aerobic activity on depressive symptoms in dialysis patients.[64–69] Although these studies were limited by sample size[65–69] or absence of a control group,[64,67] nephrologists should recommend an exercise regimen to their patients due to other potential benefits such as improved cardiovascular health, with the assumption that it may also improve their depressive symptoms.

Recommendations

In summary, little is known about the safest and most effective way to treat MDD in CKD patients, and whether treatment impacts long-term outcomes such as cardiovascular events and survival. Existing data do not support the indiscriminate use of sertraline or other medications to treat MDD in CKD patients, due to lack of efficacy and increased side effects, but sertraline can still be considered in select individuals who tolerate the medication and show a treatment response. Studies of other antidepressant medications are needed. Limited data suggest that nonpharmacologic therapies, such as CBT, may be effective for and better tolerated by motivated individuals.

Anxiety

Identifying Candidates for Treatment

Most studies of dialysis patients measured anxiety symptoms such as uncertainty, fear, restlessness, disordered sleep, shortness of breath, and palpitations, rather than specific DSM-5-based anxiety disorders.[70] Anxiety was reported in 12−52% of patients with CKD or ESRD.[71,72] As with MDD, overlap between symptoms of anxiety, depression, and CKD can thwart clinicians in recognizing candidates for treatment. In dialysis patients, these symptoms can manifest as the patient shortening dialysis treatments, dizziness, palpitations, nausea, sweating, chest pain, shortness of breath, numbness, tremors, or disruptive behaviors.[71] Similar to MDD, there is no consensus about which screening tools should be used to identify anxiety disorders in CKD and ESRD patients. Studies have used the Structured Clinical Interview for DSM-IV,[72–74] Hospital Anxiety and Depression score,[64,73] Beck Anxiety Inventory,[56] State-Trait Anxiety Inventory,[65,75,76] and the Hemodialysis Stressor Scale.[75] The 7-item Generalized Anxiety Disorder Scale (GADS-7) is a short and simple self-report tool that can be easily administered that is being used in ongoing trials in ESRD patients.[58]

Pharmacologic Therapy

SSRIs are now considered first line for chronic outpatient therapy of anxiety disorders. Unfortunately, no randomized trials have investigated their effectiveness compared with placebo for the treatment of anxiety in CKD or ESRD patients. The CAST study showed sertraline had an increased risk of gastrointestinal side effects compared with placebo in CKD patients.[33] Therefore, treatment should be individualized based on response and tolerability (Table 68.2).

Benzodiazepines are prescribed in the general population for use on an as-needed basis for acute anxiety symptoms. The addictive potential of these medications, as well as the accumulation of active metabolites,[3] limits their use in the CKD population.

Nonpharmacologic Therapy

CBT has the largest evidence base supporting its effectiveness for the treatment of anxiety disorders in the general population and has been demonstrated to be effective in hemodialysis patients.[55,56] In dialysis patients, physical activity[65] and music therapy[75–78] may also decrease anxiety symptoms. Although not systematically studied, individualization of dialysis therapy such as switching dialysis modality, short frequent dialysis treatments, or consistent assignment to the same dialysis nurses, technicians, and physicians may also alleviate anxiety for selected patients. There are no studies of nonpharmacologic interventions for anxiety in nondialysis CKD patients.

Recommendations

Although symptoms of anxiety are common in CKD patients, evidence-based screening, diagnosis, and treatment options for anxiety disorders are lacking in this population.[71] Limited existing evidence favors a nonpharmacologic approach, although a trial of SSRI therapy while monitoring for efficacy is reasonable. CBT, physical activity, and individualization of dialysis therapy may alleviate anxiety.

Bipolar Affective Disorder

Bipolar affective disorder appears to have a strong connection with CKD, which may be largely driven by nephrotoxic effects of chronic lithium therapy.[79,80] Close communication between nephrology and psychiatry specialists is critical to ensure safe and effective treatment of this serious psychiatric condition.

Pharmacologic Therapy

Maintenance pharmacologic therapy is the mainstay of treatment of bipolar disorder (Table 68.4). Lithium carbonate, one of the first-line therapies for bipolar affective disorder, has multiple known nephrotoxic adverse effects such as nephrotic syndrome resulting from minimal change or membranous nephropathy, as well as tubulointerstitial disease and nephrogenic diabetes insipidus with chronic use. In individuals with CKD stage 3 (eGFR 30–59 mL/min/1.73 m^2), it is recommended to measure eGFR every 3 months and urine albumin:creatinine ratio annually.[81] Because lithium is 89–98% renally cleared, lithium should be avoided in patients with eGFR <30 mL/min/1.73 m^2.[81] Medications commonly prescribed to CKD patients may affect lithium pharmacokinetics. Thiazide and loop diuretics can raise lithium concentrations by inducing reabsorption of lithium along with sodium in the proximal tubule.[82] Initiation or dose increase of angiotensin-converting enzyme inhibitors may lead to a decline in GFR that can raise lithium levels.[81] Because lithium is a small molecule that is not protein bound, it is easily removed by hemodialysis. Therefore, lithium can be safely prescribed in hemodialysis patients with dosing after dialysis sessions.[3]

Other first-line agents for bipolar affective disorder include anticonvulsants such as divalproex and lamotrigine, and atypical antipsychotics such as quetiapine. Manufacturers do not recommend dose adjustment of

TABLE 68.4 Commonly Used Mood Stabilizer Medication Dosing and Toxicities in CKD and ESRD

Medication	Non-CKD Dose	Manufacturer-Recommended Dose in CKD and ESRD	Potential Toxicities
Lithium carbonate immediate release	900–1200 mg daily in 3–4 divided doses (goal serum lithium level 0.6–1.2 mmol/L)	No dose adjustment for GFR >50 mL/min; give 50–75% of dose for GFR 10–50 mL/min; give 25–50% of the dose at the usual dosing interval for GFR <10 mL/min. For dialysis patients, give 600–900 mg maintenance dose three times weekly after HD	Nephrotoxicity including nephrogenic diabetes insipidus, progressive CKD; nausea; weight gain; cardiovascular effects including bradycardia and sinus node dysfunction
Lithium carbonate extended release	900–1200 mg daily in 2–3 divided doses (goal serum lithium level 0.6–1.2 mmol/L)		
Divalproex	Maximum 60 mg/kg/day in divided doses	No dose adjustment recommended in CKD or ESRD. Monitoring total concentrations can be misleading due to decreased protein binding	Nausea, diarrhea, and other GI side effects; increased bleeding risk; CNS effects; cardiovascular effects including chest pain, hypertension or hypotension, tachycardia, and edema
Lamotrigine	200 mg once daily, with adjustment based on drug–drug interactions	No dose adjustment in CKD, but reduced dose may be effective. Unknown if removed by dialysis	Nausea, diarrhea, and other GI side effects; DRESS; CNS effects; rarely can cause hematuria and AKI
Quetiapine regular release	400–800 mg daily in two divided doses, generally used in combination with lithium or divalproex	No dose adjustment recommended. For geriatric patients initiate at 50 mg daily and increase slowly based on response and tolerance	Increased appetite and other GI side effects; anemia; tachycardia; rare but serious cardiovascular effects such as prolonged QTc, syncope, and bradycardia; CNS effects are common
Quetiapine extended release	400–800 mg once daily, generally used in combination with lithium or divalproex		

Abbreviations: *AKI*, acute kidney injury; *CKD*, chronic kidney disease; *CNS*, central nervous system; *DRESS*, drug reaction with eosinophilia and systemic symptoms; *ESRD*, end-stage renal disease; *GFR*, glomerular filtration rate; *GI*, gastrointestinal; *HD*, hemodialysis.

divalproex in CKD or ESRD patients. Similarly, manufacturers do not recommend decreased lamotrigine dose for those with CKD, but they note that a lower dose may be effective in those with low eGFR. Although there are no dose adjustments for quetiapine in CKD patients, it is recommended starting at a dose of 50 mg daily, and increasing the dose carefully in the elderly. Because of significant treatment heterogeneity, in general, the best therapy for bipolar disorder is the one that works for the patient. However, given the nephrotoxicity of lithium carbonate, other agents should be used preferentially in individuals with CKD and ESRD, if possible.

Nonpharmacologic Therapy

Therapy for bipolar affective disorder is primarily pharmacologic, as few nonpharmacologic therapies have been proven effective in bipolar disorder in the general population. Despite this, many psychiatrists recommend concurrent psychotherapy and pharmacologic therapy to prevent relapse. The only nonpharmacologic therapy substantiated by evidence is electroconvulsive therapy, an intervention reserved for those who fail medical therapy.[83] Electroconvulsive therapy has been successfully administered to individuals with CKD and ESRD, but possible complications include hyperkalemia due to succinylcholine, altered pharmacokinetics of anesthetic agents, fractures during the procedure due to secondary hyperparathyroidism and poor bone mineralization, and alteration of the seizure threshold due to hypocalcemia and acidosis.[84,85]

Recommendations

Nephrologists should carefully monitor CKD patients treated with lithium, particularly when adjusting their dose of diuretics or renin–angiotensin–aldosterone system blocking agents. In patients with advanced CKD, nephrologists may recommend changing to alternative pharmacologic therapies due to the nephrotoxicity of lithium. In cases of severe bipolar affective disorder, electroconvulsive therapy has been safely conducted in CKD and ESRD patients, but nephrologists should be aware of the potential complications of this treatment.

SUBSTANCE USE DISORDERS

Substance use disorders are serious psychiatric conditions requiring involvement of a mental health or addiction specialist to manage pharmacologic and nonpharmacologic therapies. Existing data are inconsistent regarding the association of substance abuse with CKD.[86,87] Such a potential association may be in part due to direct relationships between various substances of abuse and causes of kidney disease. For example, intravenous drug use is associated with hepatitis B and C and human immunodeficiency virus infections, cocaine and methamphetamines are associated with hypertension, levamisole-adulterated cocaine is associated with pauci-immune vasculitis, and alcohol abuse is linked to the development of cirrhosis. There are nearly no data regarding treatment of substance use disorders in individuals with CKD, so treatment decisions must be guided by studies done in the general population. For the nephrologist, appropriate management of substance use disorders is particularly important, as they are associated with nonadherence with medical therapy, which becomes problematic in patients' adherence to pharmacologic and dialytic therapies.

Alcohol Use Disorder

Pharmacologic Therapy

Naltrexone is an opioid antagonist used to treat alcohol and opioid use disorders and is sometimes used off-label to treat generalized pruritus in hemodialysis patients. Naltrexone is thought to act by blocking the mu-opioid receptor, thus decreasing expression of the reinforcing effects of alcohol.[88] According to the manufacturer's label, there is no recommended dose adjustment for those with creatinine clearance of 50–80 mL/min, but naltrexone has not been studied in those with more advanced CKD. Only one study of naltrexone used to treat pruritus in hemodialysis patients reported that there is no need to modify the starting dose, but blood levels were higher in dialysis patients than in healthy controls.[89] Importantly, prescription of opioids for pain is a contraindication to therapy with naltrexone for substance use disorder.

Acamprosate is another first-line pharmacologic option to treat alcohol use disorder, thought to work by normalizing neurotransmitter activity that can be altered in the setting of frequent alcohol use.[90] Almost half of acamprosate is excreted in the urine, and in individuals with CKD the total and renal clearance of acamprosate are decreased.[90,91] Thus, acamprosate requires a dose decrease in those with a creatinine clearance of 30–50 mL/min and is contraindicated for those with a creatinine clearance less than 30 mL/min.

Nonpharmacologic Therapy

There are no specific data or recommendations about the effectiveness of nonpharmacologic therapies for addiction, such as 12-step programs or inpatient rehabilitation, in patients with CKD. Referral for psychiatric evaluation to determine the timing and duration of these interventions is key. As with other nonpharmacologic psychiatric treatments, the time commitment may be a

barrier for patients burdened by frequent medical visits and physical symptoms such as fatigue.

Opioid Use Disorder

The alarming epidemic of opioid use, and consequent rise in deaths due to opioid overdose, has prompted nationwide interest in increasing access to treatment of this serious condition.[92] As chronic pain is common in patients with CKD, as many as 31.8% of CKD patients are prescribed opioids, with higher rates of prescription in those with more advanced CKD stages.[93] Nephrologists should be aware of available treatments for opioid use disorder and have a low threshold to refer such patients to mental health or addiction specialists.

Pharmacologic Therapy

Supervised treatment with opioid receptor antagonists has remained the cornerstone of treatment of opioid use disorder for decades.[92] Methadone, a long-acting opioid receptor agonist, is often prescribed to opioid users to decrease both the highs and withdrawal symptoms of shorter-acting opioids such as heroin. Methadone is primarily hepatically metabolized and excreted in the stool, but up to 20% of the active drug and metabolites are also excreted in the urine.[94] When used in anuric dialysis patients, it is excreted entirely in the stool and does not accumulate systemically despite being poorly removed by hemodialysis.[95,96] Manufacturers recommend lower initial dose, longer dosing intervals, and slower titration in patients with CKD.

Buprenorphine is another partial opioid receptor antagonist, most commonly prescribed in combination with naloxone to treat opioid use disorder. Although few data exist to guide the use of buprenorphine/naloxone in patients with CKD, some studies show that the pharmacokinetics of buprenorphine are unaltered in hemodialysis patients, likely due to its primarily hepatic metabolism.[97,98] There are no manufacturer recommendations for dose adjustment in patients with decreased renal clearance.

EATING DISORDERS

Eating disorders are underdiagnosed, and such patients may present to nephrologists with acute kidney injury, CKD, nephrolithiasis, or electrolyte disturbances.[99] It is important for nephrologists to recognize patients with eating disorders and refer them for appropriate management. Serious electrolyte disturbances are common in patients undergoing therapy for eating disorders, so nephrologists should understand the implications of eating disorders on the management of CKD and fluid and electrolyte disorders.

Anorexia Nervosa

Patients with anorexia nervosa, characterized by pathologic dieting, exercise, or purging, have a high rate of kidney complications. Severe caloric restriction and purging behaviors such as vomiting and diuretic or laxative abuse in patients with anorexia nervosa can lead to the development of hypokalemia, kidney stones, and chronic volume depletion, which are thought to contribute to an increased risk of developing CKD.[99,100] The prevalence of hypokalemic CKD in patients with anorexia nervosa is 15–20%.[99,101] One study showed that 5.2% of individuals with anorexia nervosa developed ESRD over 21 years of follow-up.[102] Diagnosis of anorexia nervosa can be challenging in patients with CKD due to the loss of appetite that occurs with uremia. Prevalence of low appetite using self-report measures is as high as 47% in hemodialysis patients and correlates with poor quality of life and depression.[103,104] There are no specific recommendations for the screening and diagnosis of anorexia nervosa in CKD patients. A clinician who suspects this diagnosis can screen using tools validated in the general population, such as the SCOFF or Screen for Disordered Eating questionnaires (Table 68.5).[105,106] These screening questions distinguish uremic anorexia from anorexia nervosa by focusing on the patient's psychologic relationship to food.

Pharmacologic Therapy

No pharmacologic therapies have been proven effective for anorexia nervosa in adults, although open-label nonrandomized preliminary data suggest that olanzapine may be useful to help patients gain weight.[107] Mental health providers will frequently treat comorbid anxiety and depression with pharmacologic therapy,[108] but these interventions have serious limitations in CKD patients as detailed above.

Nonpharmacologic Therapy

Anorexia nervosa is a psychiatric illness notoriously difficult to treat. Patients with suspected eating disorders should be referred to psychiatry for management. The cornerstone of therapy is weight gain *via* restoration of normal nutrition by focusing on eating behaviors, including high-protein intake and regular meals.[109] Dietary restrictions in CKD can complicate this treatment by limiting intake of protein, phosphate, and potassium. Importantly, patients undergoing nutritional rehabilitation after prolonged malnutrition are at risk for refeeding syndrome, which is a potentially fatal complication associated with severe electrolyte disturbances.

TABLE 68.5 Screening for Eating Disorders

Item	SCOFF Screening Questionnaire	Screen for Disordered Eating
1	Do you make yourself sick because you feel uncomfortably full?	Do you often feel the desire to eat when you are emotionally upset or stressed?
2	Do you worry that you have lost control over how much you eat?	Do you often feel that you cannot control what or how much you eat?
3	Have you recently lost more than one stone (14 lb) in a 3-month period?	Do you sometimes make yourself throw up (vomit) to control your weight?
4	Do you believe yourself to be fat when others say you are too thin?	Are you often preoccupied with a desire to be thinner?
5	Would you say that food dominates your life?	Do you believe yourself to be fat when others say you are thin?
Scoring	1 point for each yes answer; a score of ≥2 points total should increase suspicion for anorexia nervosa	1 point for each yes answer; a score of ≥2 points total should increase suspicion for any eating disorder

Refeeding syndrome can be prevented in these patients by repleting electrolytes before the gradual reintroduction of caloric intake.[110] Management of refeeding syndrome includes limiting caloric intake and close monitoring and correction of hypophosphatemia, hypomagnesemia, and hypokalemia.[110,111] CBT, with the goal to affect attitudes and behaviors related to food, in conjunction with nutritional rehabilitation has been shown to prevent relapse of anorexia nervosa.[112]

Bulimia Nervosa

Like anorexia nervosa, this disorder is also characterized by unhealthy compensatory behaviors such as vomiting, diuretic or laxative abuse, or enema abuse to avoid weight gain. Such patients may present to nephrologists with acute kidney injury, CKD, or electrolyte abnormalities resulting from these behaviors. Bulimia nervosa can be distinguished from anorexia nervosa by the presence of binge eating and generally a normal or high total body weight. The Screen for Disordered Eating can be used to identify patients with bulimia nervosa, with a sensitivity of 100% and a specificity of 51%.[106]

Pharmacologic Therapy

Pharmacologic therapy with fluoxetine or other SSRIs in conjunction with nonpharmacologic interventions is more effective for the treatment of bulimia nervosa than psychotherapy or pharmacologic therapy alone.[113,114] However, no studies have examined the efficacy of these treatment modalities in individuals with CKD, particularly regarding safe and effective dosing of SSRIs, leaving clinicians with only vague recommendations to start at a low dose and gradually uptitrate while monitoring for adverse effects.

Nonpharmacologic Therapy

Treatment hinges on nutritional rehabilitation focused on addressing binge eating and purging behaviors. Psychiatry involvement is critical to manage CBT, which has been demonstrated as an effective treatment modality for this disorder.[115]

Management of Pseudo-Bartter Syndrome

Purging cessation can lead to Pseudo-Bartter syndrome. Purging behaviors lead to chronic volume depletion, which stimulates the secretion of renin. The consequent secondary hyperaldosteronism causes hypokalemia, hypochloremia, and metabolic alkalosis, and plasma aldosterone does not normalize for up to 3 weeks after cessation of purging behaviors.[116] Patients who abruptly cease chronic purging, often in a medical setting, will maintain an ongoing aldosterone-induced sodium avidity. Administering intravenous fluid boluses to such patients can cause net positive fluid balance, third spacing of fluid, and edema that can be remarkably severe.[117,118] Intravenous fluids should be administered at a slow continuous rate for a total administration no greater than 1−2 L over 24−48 hours, with the goal to normalize metabolic alkialosis.[116] Hypokalemia should be corrected.[119] Aldosterone antagonists such as spironolactone (25−200 mg once daily) can be used to prevent or manage edema and hypokalemia for 2−3 weeks after cessation of purging, but this should be done cautiously in those with CKD to avoid the development of hyperkalemia.[116]

CONCLUSIONS

Psychiatric disorders are common in CKD patients, likely due to concomitant burden of chronic medical illnesses, renal complications of psychiatric disorders or

treatments, and inflammation or other risk factors in CKD patients that may lead to psychiatric disorders. Despite this, few data exist to guide safe and effective treatment of these disorders in this large group of patients at risk for significant adverse effects, unpredictable pharmacokinetics, and unclear efficacy for some standard first-line therapies. Studies are needed to determine the most appropriate therapies for psychiatric disorders in CKD patients, with a focus on safety and dosing of pharmacologic interventions, as well as the efficacy and feasibility of nonpharmacologic interventions.

QUESTIONS AND ANSWERS

Question 1

In addition to decreased renal clearance of drugs in the setting of reduced GFR, which of the following consequences of CKD can affect medication pharmacokinetics?

A. Increased gastric pH
B. Nausea and vomiting
C. Hypoalbuminemia
D. Fluid overload
E. All of the above

Answer: E

The correct answer is E. CKD has multiple effects on drug pharmacokinetics beyond decreased renal clearance, such that anticipating the net effect of CKD on the clinical properties of medications can be challenging. Elevated blood urea nitrogen levels lead to increased secretion of urea into the stomach, where it is hydrolyzed to ammonia. Ammonia can pick up a proton and increase gastric pH, which can either increase or decrease oral medication bioavailability, depending on the properties of the medication in question. Nausea and vomiting are common symptoms in advanced CKD and can decrease oral bioavailability for those unable to retain medications in the stomach. Urinary protein loss in patients with nephrotic syndrome leads to hypoalbuminemia. Decreased available sites for medication protein binding can increase the fraction of unbound drug, which alters the amount of drug available for action at receptor sites. Fluid overload, even in the absence of overt peripheral edema, can alter medication pharmacokinetics by increasing volume of distribution, leading to lower than expected drug concentrations.

Question 2

A 56-year-old woman with CKD stage 4 due to diabetes mellitus and hypertension presents for a follow-up visit. She has lost 5 pounds since her last visit 3 months ago. She also mentions that she has been sleeping much less than usual lately. On further questioning, she notes that she has felt fatigued and has had a difficult time concentrating. She denies itching and metallic taste. On physical examination, blood pressure is 135/72 mm Hg, heart rate is 84 beats per minute, and oxygen saturation is 99% on room air. Auscultation of the chest reveals a regular heart rhythm with no pericardial friction rub. She has trace lower extremity pitting edema. Laboratory tests reveal a hemoglobin of 9 g/dL. Which of the following is the most appropriate next step?

A. Have the patient complete a screening questionnaire for MDD
B. Refer to psychiatry for CBT
C. Begin treatment with an erythropoiesis-stimulating agent
D. Start sertraline 50 mg daily
E. Initiate dialysis for uremic symptoms

Answer: A

The correct answer is A. This patient presents with several symptoms that could be consistent with either MDD or uremia, including changes in weight, sleep disturbance, fatigue, and difficulty concentrating. To distinguish between uremia and MDD, clinicians should first screen patients with a self-report questionnaire and confirm the presence of anhedonia or sadness. If the patient's screening questionnaire is positive, clinicians should then confirm the diagnosis by a structured clinical interview. Answers B and D are incorrect because the diagnosis of uncomplicated MDD must be established before considering the patient's preference for treatment with either pharmacologic or nonpharmacologic therapy. Distinguishing between uremic symptoms and MDD is critical, because dialysis initiation would not address the underlying problem if the patient's symptoms are caused by MDD, so Answer E is incorrect. Answer C is incorrect because although anemia can result in fatigue symptoms, beginning treatment for anemia with an erythropoiesis-stimulating agent is not the next best step.

Question 3

A 48-year-old man with CKD stage 3b presents for follow-up. He notes loss of interest in going for walks in his neighborhood, which he previously enjoyed. He also states that he has been having a difficult time sleeping and feels tired all the time. You suspect that he may have MDD. Screening questionnaire with the Quick Inventory of Depressive Symptomatology revealed a score of 14. Structured clinical interview confirms MDD. He denies any episodes of psychosis or mania. He asks about initiating pharmacologic treatment.

Compared with placebo, sertraline has been shown to have which of the following effects in patients with nondialysis CKD stages 3–5 and MDD?

A. Improvement in depressive symptoms and no increased side effects
B. Improvement in depressive symptoms and increase in neurologic side effects such as somnolence
C. No improvement in depressive symptoms and greater gastrointestinal side effects such as nausea and diarrhea

D. Improvement in depressive symptoms and increased gastrointestinal side effects
E. No improvement in depressive symptoms and neurologic side effects

Answer: C

The correct answer is C. Only one clinical trial has compared a SSRI to placebo for the treatment of MDD in patients with nondialysis CKD. The Chronic Kidney Disease Antidepressant Sertraline Trial (CAST) was a double-blind, randomized, placebo-controlled trial evaluating the efficacy and tolerability of sertraline for the treatment of MDD. In this trial, participants in both the placebo and sertraline groups demonstrated some improvement in depressive symptoms from baseline to study exit, but there was no benefit of sertraline over placebo. Furthermore, participants randomized to sertraline experienced greater side effects of nausea and diarrhea compared with the placebo group. Given the lack of data to support efficacy of treatments for MDD in patients with CKD, it is reasonable to initiate a cautious trial of sertraline in patients who are interested in pharmacologic therapy, with close monitoring of depressive symptoms and side effects.[33]

Question 4

A 42-year-old woman with bipolar affective disorder I and hypertension is referred to you for management of CKD stage 3a. She takes lithium and amlodipine. On physical examination, blood pressure is 152/94 mm Hg, heart rate is 74 beats per minute, and oxygen saturation is 98% on room air. Cardiopulmonary and abdominal examinations are unremarkable. She has trace lower extremity edema. You start chlorthalidone 25 mg once daily to treat her hypertension. She returns two weeks later for follow-up. Laboratory values from her initial and follow-up visit are as follows:

Laboratory Value	Initial Visit	Follow-Up Visit
S[Na]	142 mEq/L	139 mEq/L
S[K]	4.2 mEq/L	4.1 mEq/L
tCO2	23 mEq/L	25 mEq/L
S[Cr]	1.41 mg/dL	1.38 mg/dL
eGFR	52 mL/min/1.73 m^2	53 mL/min/1.73 m^2
Lithium level	1.1 mEq/L	1.5 mEq/L (target range 0.6−1.2 mmol/L)

Which of the following is the most likely mechanism of the elevated lithium level?

A. Intentional lithium overdose
B. Increased lithium reabsorption in the proximal tubule
C. Prerenal acute kidney injury due to starting a diuretic
D. Alteration in lithium protein binding due to inhibition by the thiazide diuretic
E. Development of lithium-induced tubulointerstitial kidney disease

Answer: B

The correct answer is B. Lithium is filtered at the glomerulus and reabsorbed in a manner similar to sodium in the proximal tubule, so states associated with increased proximal tubular sodium reabsorption also increase lithium reabsorption. Thiazide and loop diuretics augment natriuresis, generating a state of mild volume depletion that increases sodium and lithium reabsorption in the proximal tubule. Answer A is incorrect because known medication interactions should be considered before making a diagnosis of intentional lithium overdose. Answer C is incorrect because her eGFR was unchanged from the initial visit to her follow-up visit 2 weeks later. Answer D is incorrect because thiazide diuretics are not known to alter protein binding. Answer E is incorrect because tubulointerstitial disease is a potential chronic complication of lithium therapy and would not develop as an acute complication.

Question 5

You are called to evaluate a 19-year-old woman admitted to the hospital for the management of anorexia nervosa. On physical examination, blood pressure is 106/72 mm Hg, heart rate is 90 beats per minute, respiratory rate is 16 per minute, and oxygen saturation is 100% on room air. Her body mass index is 16 kg/m^2. She has increased risk of which of the following?

A. Kidney stones
B. Chronic kidney disease
C. Refeeding syndrome
D. Metabolic alkalosis
E. All of the above

Answer: E

The correct answer is E. Kidney stone risk is thought to be increased in patients with anorexia nervosa due to chronic volume depletion and low urinary output, as well as renal homeostatic alterations in response to hypophosphatemia and chronic hypochloremic alkalosis that can develop in the setting of chronic purging behaviors. Patients with anorexia nervosa have a high rate of CKD, thought to be related to chronic volume depletion, hypokalemia, and nephrolithiasis. Refeeding syndrome is an important complication of nutritional therapy and weight gain for patients with anorexia

nervosa. Patients admitted to the hospital for weight gain require careful monitoring and correction of electrolyte disturbances, and gradual reintroduction of caloric intake. Metabolic alkalosis can develop in the setting of chronic purging behaviors, such as laxative or diuretic abuse.

Question 6

During hemodialysis rounds, you are called to evaluate a 50-year old woman with ESRD secondary to lupus nephritis. She is trying to sign off early again. She also has a history of chronic back pain, migraine headaches, and irritable bowel syndrome. Today she complains of left arm tingling and cramps and states that "Maxine was not here to cannulate me. The rest don't know what they're doing." The dialysis staff have voiced frustration about this patient's hemodialysis shortening and skipping behavior.

Which of the following is the next best step in management?

A. Prescribe temazepam to take orally 2 hours before dialysis treatments
B. Start treatment with sertraline 100 mg once daily
C. Assign the same dialysis nurse to the patient during hemodialysis treatments
D. Change dialysis prescription to frequent daily hemodialysis
E. Refer to psychiatry for further management

Answer: C

The correct answer is C. The patient manifests symptoms of a generalized anxiety disorder often encountered in hemodialysis patients, such as somatic symptoms, hemodialysis shortening and skipping behavior, and fear of losing control by asking for the same caretaker. One approach, therefore, is to assign the same hemodialysis nursing staff to take care of the patient, which could lessen or alleviate anxiety symptoms during the hemodialysis procedure. Options B, D, and E could be considered if conservative measures do not address the patient's anxiety symptoms but are not the next best options. Benzodiazepines should be avoided in dialysis patients due to adverse effects such as psychomotor retardation and cognitive dysfunction, so option A is incorrect.

CHAPTER

69

Preparing for Transplantation

Alexander C. Wiseman, Scott Davis, Erik Stites, James E. Cooper

Division of Nephrology, University of Colorado Anschutz Medical Campus, Aurora, CO, United States

Abstract

Individuals with progressive advanced chronic kidney disease (CKD) have a number of treatment modalities to consider before reaching end-stage renal disease. As CKD reaches stage 4, and particularly as glomerular filtration rate approaches 20 mL/min, patients should be informed of kidney transplantation as a treatment option, provided education regarding the transplant process, and be referred to a transplant center unless there are clear contraindications or comorbidities that preclude consideration. There is an unfortunate and dramatic disparity between those who are eligible for transplantation and those who receive a transplant, due in part to referral biases, the comparative shortage of deceased donors, and a lack of acceptance or awareness of living kidney donation as an option. This chapter reviews the transplant landscape, discusses the procedural and pathophysiological considerations for kidney transplantation, and outlines the transplant evaluation process, including inclusion and exclusion criteria.

KIDNEY TRANSPLANTATION VERSUS DIALYSIS: SCOPE OF THE PROBLEM AND PUBLIC HEALTH IMPLICATIONS

After over a century in development, kidney transplantation is well established as the preferred treatment modality for patients with severe chronic kidney disease (CKD). As Alexis Carrel, a pioneering figure who developed vascular suturing techniques and contributed to the invention of the first perfusion pump, wrote in 1914, "The surgical side of transplantation of organs is now completed, as we are now able to perform transplantation of organs with perfect ease and with excellent results from an anatomical standpoint…all our efforts must now be directed toward the biological methods which will prevent the reaction of the body against foreign tissue and allow the adapting of homoplastic organs to their hosts."[1] Our evolving understanding of the immunologic barriers has resulted in critical discoveries involving the major histocompatibility complex (MHC), tissue typing, and immunosuppressive drugs and advanced transplantation as the standard of care. Although dialysis has developed alongside kidney transplantation as an important alternative for patients with end-stage renal disease (ESRD), transplantation can now offer more years of life that are of higher quality and often at less cost to society when performed in appropriately selected individuals.

Patients undergoing kidney transplantation have higher mortality shortly after surgery compared with patients still awaiting transplant on dialysis, related to the surgical procedure and the associated induction immunosuppression. In a landmark study performed in 1999, Wolfe et al. reported an early risk of death that was 2.8-fold higher 2 weeks after surgery, which importantly became equal at 106 days after transplantation, with improved survival by 244 days. Similar analyses have been performed in many different subgroups and in contemporary cohorts of patients.[2,3] In a low cardiovascular risk elderly patient, living donor transplantation confers an immediate survival advantage, while even a high cardiovascular risk elderly patient undergoing transplantation with a deceased donor kidney with comorbidities (termed expanded criteria donor, ECD) enjoys a survival benefit of transplantation over dialysis after 528 days (Figure 69.1).[2] This survival benefit can represent many more years of life, particularly for younger patients. A 37-year-old woman might be expected to gain 21.2 more years of life through kidney transplantation compared with dialysis, although this is still several years less than the expected lifetime of a person who is of the same age and sex in the general population.[4] Longer duration of pretransplant dialysis exposure decreases posttransplant survival, emphasizing the critical importance of early referral to transplant, identification of living donors, and performing preemptive kidney transplantation.[5–7]

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00069-3

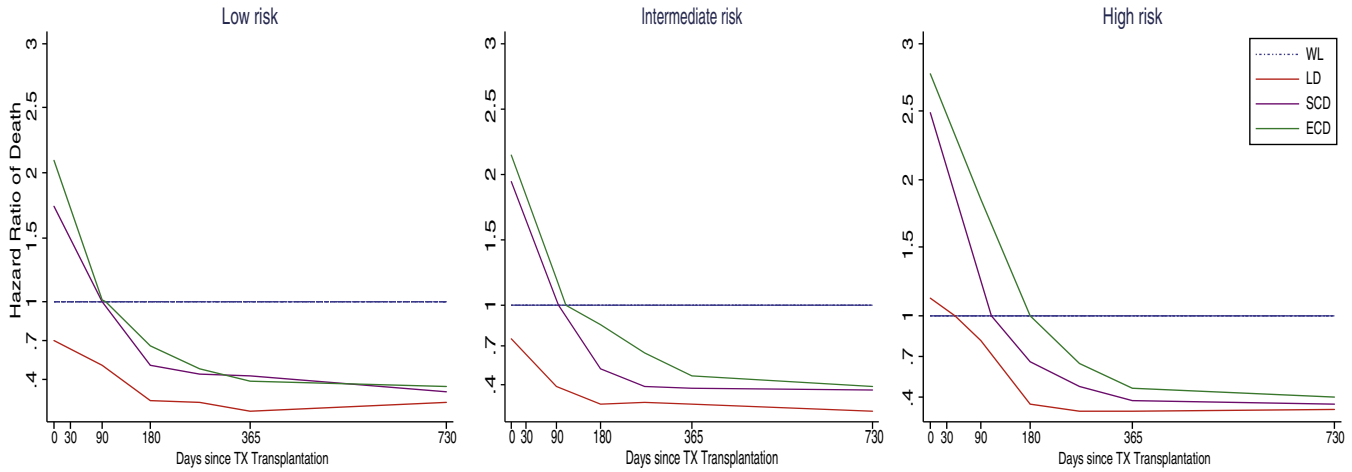

FIGURE 69.1 Quantification of the Early Risk of Death in Elderly Kidney Transplant Recipients. The multivariate adjusted relative risk of death in low (first panel), intermediate (second panel), and high (third panel) cardiovascular risk patients. In each panel, the multivariate adjusted risk of death in living donor (LD, shown in red), standard criteria deceased donor (SCD, shown in purple), or expanded criteria deceased donor (ECD, shown in green) transplant recipients is compared with that in waitlisted patients of similar cardiovascular risk (shown in blue) who had been on dialysis for equal lengths of time but who had not yet received a kidney transplant. In all cardiovascular risk groups, the risk of death immediately after SCD and ECD transplantation was higher than that among waitlisted patients of similar cardiovascular risk. In contrast, the risk of death in low and intermediate cardiovascular risk recipients was immediately lower than that in similar risk patients who remained on the waiting list. The long-term risk of death was lower with transplantation in all risk groups and with all donor types. *J. S. Gill, E. Schaeffner, S. Chadban, et al, Quantification of the Early Risk of Death in Elderly Kidney Transplant Recipients, American Journal of Transplantation, John Wiley and Sons, November 21, 2012.*

In addition to improved survival, patients undergoing transplantation enjoy improvements in quality of life. ESRD is commonly marked by physical symptoms and impairments, an increasing burden of lifestyle restrictions, medications, and procedures, as well as psychological distress and depression, all of which can impose stress on personal and professional relationships. Several different instruments have been used to measure health-related quality of life in kidney transplant recipients. The vast majority demonstrate significant improvements in physical, emotional, and social well-being compared with responses in those treated with multiple different renal replacement modalities and throughout many different healthcare systems.[8,9] Many of these benefits extend to several different subgroups of patients, including the elderly, the morbidly obese, and patients with significant comorbid medical conditions.[10,11]

Kidney transplantation can also be cost-saving or more cost-effective compared with dialysis therapy. In 2015, the US spent $88,195 per patient per year for hemodialysis care, compared with $34,084 per patient per year for transplant care.[4] A study in 2003 found that living donor kidney transplantation saved $94,579 and with the added value of 3.5 quality-adjusted life years gained per recipient, a total savings of $269,319 compared with remaining on dialysis was achieved.[12] A more recent study estimated the monetary savings of improved survival and health of the recipient at $1.3 million.[13] Even practices designed to increase access to transplantation that are often associated with more resource utilization, including the use of kidneys from deceased donors with increased comorbidities and transplantation across ABO- or human leukocyte antigen (HLA)-incompatibility with enhanced immunosuppressive strategies, may be cost-effective compared with continued dialysis therapy.[13]

Despite these striking clinical and social benefits of kidney transplantation, transplant rates have only incrementally increased relative to those in need.[14–16] There are myriad factors that limit transplantation rates, with organ availability often paramount. Although preemptive living donor kidney transplantation currently represents the optimal treatment for ESRD, living donor rates have decreased over the past decade in the US, with 6436 in 2006 and 5630 in 2016. Barriers to living donation include cultural or religious beliefs, help in identifying donors, and lack of effective education, costs, and transplant center processes, much of which can be manifestations of socioeconomic, racial, and geographic differences.[17,18]

Although approximately 2.4 million people die every year in the US, only a fraction of these deaths occur in absence of comorbid conditions and in a manner that allows effective procurement and subsequent kidney utilization, excluding them from donation. In 2016, the potential deceased donor pool was estimated to be around 38,500 donors, much larger than the 14,229 deceased donor kidneys actually transplanted, yet still dwarfed by the 95,456 patients on the transplant waitlist that same year.[14,19] As a result, 20% of patients on the kidney transplantation waiting list in 2016 had been on dialysis for at least 6 years, placing them at continued

risk of developing health complications that ultimately exclude them from transplantation.[14,20] 50% of patients listed in 2013 were still waiting for transplantation by 2016, whereas only 20% and 15% had undergone deceased or living donor transplant. 11% were removed from the list, and 8% died while awaiting transplantation.[14]

Long waiting times make it imperative to maximize the utilization of the potential deceased donor pool, yet barriers exist for organ procurement organizations in obtaining donor consent and procuring organs. Many countries have enacted "opt-out" laws for donor consent to expand the donor pool.[21] Additionally, many kidney offers are turned down by transplant centers or patients because of perceptions of poorer organ quality. Various categories have been designed to capture the variables of a given organ to estimate graft survival and aid appropriate allocation, including standard criteria donor (SCD) vs. ECD, the latter encompassing donors >60 years of age or donors age 50–59 years who have at least two of the following: hypertension, terminal S[Cr] > 1.5 mg/dL, or death from a cerebrovascular accident. Recently, the US adopted the Kidney Donor Profile Index (KDPI), which combines ten variables to predict the likelihood of graft failure relative to all donor kidneys recovered the prior year to aid in organ allocation. There have been several efforts to increase use of marginal organs and reduce discard rates, including ECD or high KDPI kidneys, those with acute kidney injury, and kidneys with hepatitis C, human immunodeficiency virus (HIV), or increased risk for infectious disease transmission. Importantly, all of these practices have shown better outcomes for patients who receive these organs compared with the competing risk of continued dialysis while waiting for a better organ offer.[22–25]

There are also several factors associated with the recipient that limit access to transplantation. A number of barriers other than medical conditions include appropriate insurance coverage and financial means, a social support system to help patients through the posttransplant period, and the ability to stay in the area of the transplant center the first several weeks after surgery. All these factors can introduce socioeconomic, racial, and geographic disparities in patient access to transplantation.[26,27]

KIDNEY TRANSPLANTATION: PATHOPHYSIOLOGY AND IMMUNOBIOLOGY

Kidney transplantation is now highly successful, due to advances in understanding the immunological response to transplanted tissue and in the development of pharmaceutical agents that inhibit this response. The discovery of the HLA gene complex on chromosome 6 that encodes a highly polymorphic group of MHC proteins responsible for antigen presentation to T cells was critical in identifying the major factors in host recognition of donor tissue. Transplantation between two non-HLA identical individuals results in a recipient alloimmune response to donor HLA proteins (or "antigens"), necessitating the use of posttransplantation immunosuppression to minimize the risk of allograft rejection. The following section provides an overview of the mechanisms underlying alloimmune responses to kidney grafts and the immunosuppressive therapies used to prevent these processes from occurring.

The HLA antigens most relevant to transplant immunobiology are organized into two classes. Each class has a common function of antigen presentation to lymphocytes. Class I HLA molecules are present on all nucleated cells, consist of a polymorphic α-chain and a nonvariable β2 microglobulin molecule, and include HLA-A, B, and C peptides. Class II HLA molecules are found on antigen-presenting cells (APCs), consist of two polymorphic α and β chains, and include HLA DR, DQ, and DP peptides. Both HLA antigen classes are codominantly expressed, such that individuals express two copies of each protein, one from each parent.

Because these highly polymorphic HLA proteins represent the major antigenic stimuli in host recognition of donor tissue, it stands to reason that improved HLA matching between donor and recipient would equate to less alloimmune response following transplantation, with improved longer-term allograft outcomes. This is indeed the case, with better HLA-matched transplant recipients experiencing longer average graft survival[28]; however, the relative importance of HLA matching has been lessened over time with the development of more effective "modern day" immunosuppression.[29] Traditional HLA matching between kidney donors and recipients takes into consideration antigen alleles at the A, B, and DR loci. Accounting for two codominant antigens at each of these loci on each copy of chromosome 6, a total of six HLA loci are considered for each transplant pair (2 A, 2 B, and 2 DR HLA). Although not historically factored into traditional match/mismatch calculations, the degree of matching at other HLA loci, namely DQ, has also been shown to correlate with graft outcomes.[30] The decision to proceed with kidney transplantation between a particular donor/recipient pair is not typically contingent on the degree of HLA match/mismatch. However, this information does influence deceased donor organ allocation, may be used if multiple potential living kidney donors are available for a particular recipient, and may influence posttransplant immunosuppression goals (e.g. less aggressive immunosuppression for better HLA-matched donor/recipient pairs).

Preexisting antibodies directed against HLA antigens represent a significant barrier to transplantation for many individuals. These anti-HLA antibodies develop as a result of exposure to another individual's HLA antigens, usually by way of blood transfusions, pregnancies, or prior organ transplants. A landmark study in the 1960s by Paul Terasaki demonstrated transplantation in the presence of high levels of donor-specific anti-HLA antibodies (DSAs) often leads to catastrophic hyperacute graft rejection.[31] His subsequent development of pretransplant cross-match assays revolutionized transplantation by allowing clinicians to identify and avoid dangerous levels of donor-specific anti-HLA antibody (DSA) between a particular donor–recipient pair.

The total burden of an individual's anti-HLA antibodies is quantified as a panel reactive antibody, or PRA, and represents the population frequency to which an individual will be incompatible due to their current level of circulating anti-HLA antibodies. PRA is calculated as a percent ranging from 0 to 100, such that an individual with a PRA of 50% would be expected to have transplant-limiting anti-HLA antibodies directed toward approximately 50% of the population. Higher degrees of PRA increasingly limit the available population of kidney donors for a particular individual, resulting in increased average waiting times for patients with high PRA values (Figure 69.2). Given this disadvantage, allocation policies attempt to prioritize organs to highly sensitized patients regardless of region of donor origin.[32]

Following transplantation, immunosuppression is used to prevent allorecognition of the donor organ and subsequent graft rejection; however, insufficient immunosuppression may allow an alloimmune response to occur. This begins with recipient T-cell recognition of donor HLA antigens, presented either intact on donor-derived APCs (direct pathway) or as allopeptides presented by recipient APCs (indirect pathway). T-cell activation proceeds *via* several overlapping pathways that can be organized into three separate signals.

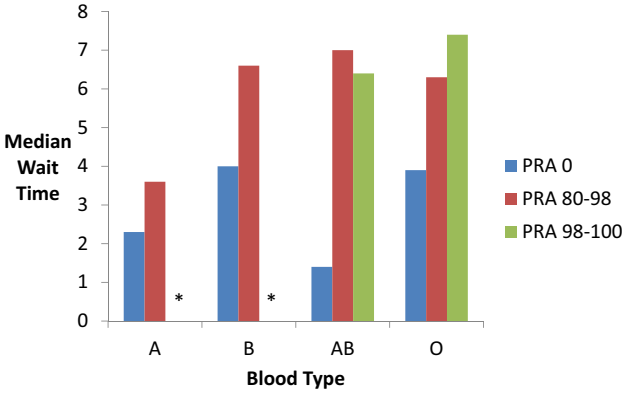

FIGURE 69.2 Median wait times for patients with 0%, 80–98%, and 98–100% PRA by blood type. *Median wait time cannot be calculated due to estimated time to transplant probability has not reached 50%. *Adapted from the* USRDS 2017 annual data report, *vol. 2, Chapter 6.*

Signal 1 follows T-cell receptor recognition of antigen. It includes calmodulin activation of calcineurin, subsequent dephosphorylation of the nuclear factor of activated T cells and its translocation to the nucleus, eventually leading to transcription of growth signals.

Signal 2 is a costimulatory event that, together with signal 1, is required for T-cell activation to occur. In one of the better-characterized pathways, the CD80/86 complex on APCs binds to CD28 on T cells, providing a costimulatory signal resulting in T-cell cytokine production, including IL-2, inducing further T-cell development. This signaling pathway is inhibited by the T-cell surface protein CTLA-4, which competitively binds to CD80/86, effectively acting as an "off" switch. CTLA-4 expression is upregulated when foreign antigen is less abundant.

Signal 3 is initiated with IL-2 binding to its receptor on T cells, leading to activation of proliferative signals, such as the mammalian target of rapamycin (mTOR) pathway, and subsequent cell cycle progression, resulting in lymphocyte proliferation.

The more commonly prescribed immunosuppressive agents used to prevent and treat allograft rejection in transplant recipients can be described in terms of their mechanisms of action (Figure 69.3). Induction therapy given in the perioperative phase includes T-cell depleting rabbit-derived anti-thymocyte globulin (rATG) or the IL-2 receptor antagonist basiliximab. rATG is more effective at preventing acute rejection compared with basiliximab, especially in higher immunologic risk transplant recipients,[33,34] and is used in the majority of US transplants.[14]

Maintenance immunosuppression regimens most commonly include a combination of a calcineurin inhibitor (CNI) with an antiproliferative agent, with or without prednisone. The CNIs cyclosporine (CsA) and tacrolimus inhibit calcineurin activity (signal 1), and the purine analogues azathioprine and mycophenolate mofetil (MMF) inhibit lymphocyte cell cycle progression (signal 3), preventing subsequent T-cell proliferation. Tacrolimus and MMF have largely replaced CsA and azathioprine, respectively, due to their increased efficacy in preventing acute allograft rejection.[14,35–38] Indeed, over 93% of all US transplant recipients are prescribed tacrolimus and MMF, with or without prednisone, at the time of transplantation.[14]

Despite the well-documented superior efficacy of CNIs in preventing acute allograft rejection, considerable effort has focused on minimizing posttransplant CNI exposure due to concerns over potential long-term nephrotoxicity. Inhibitors of the signal 3

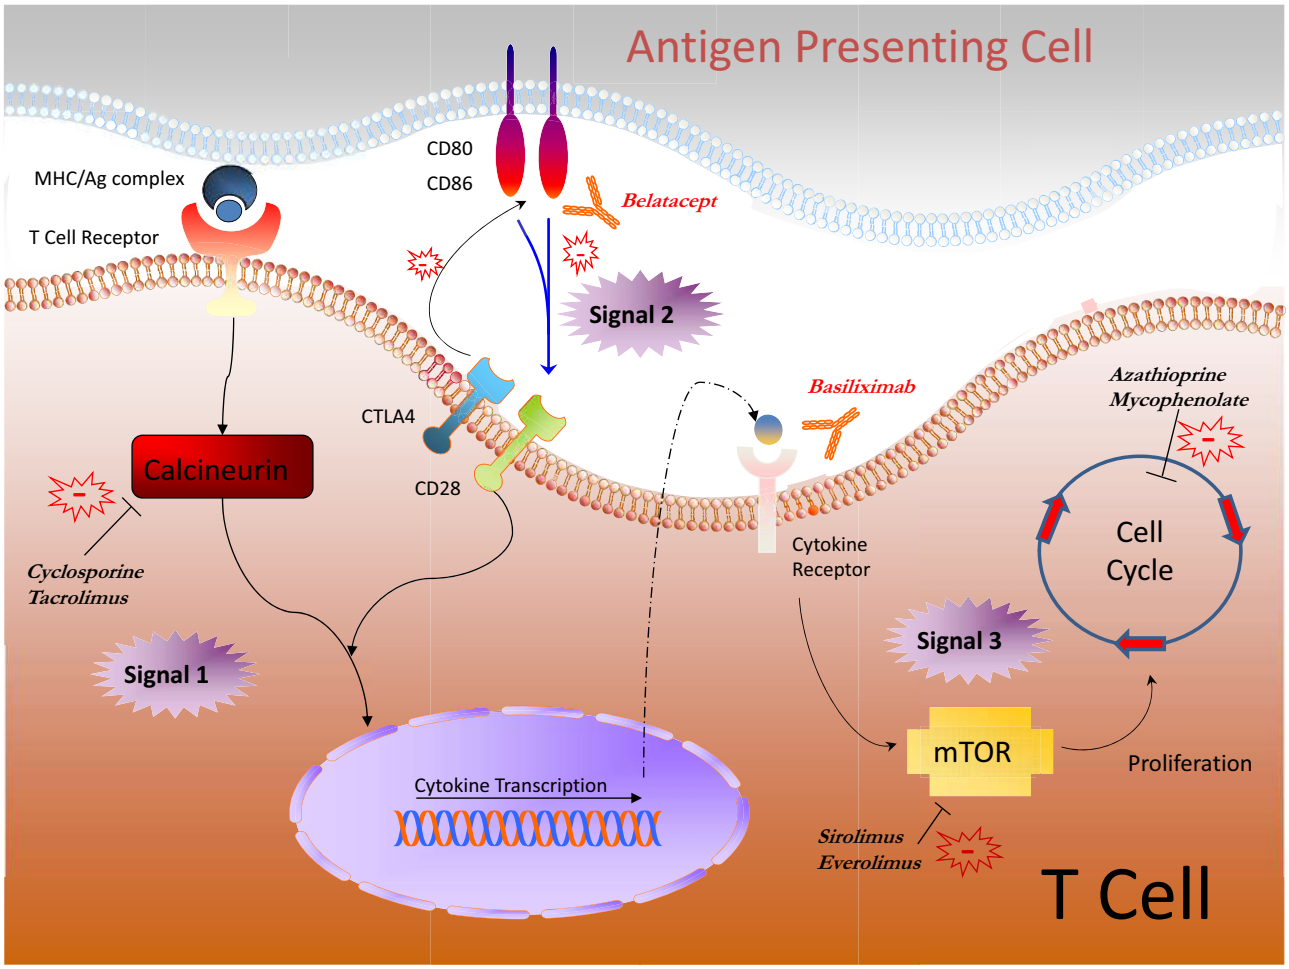

FIGURE 69.3 Schematic cartoon depicting a simplified schematic of T-cell activation with sites of action for common immunosuppressive agents.

proliferative mTOR pathway (mTORis) sirolimus and everolimus have been used in several CNI-minimization strategies, including CNI withdrawal, CNI conversion, reduced CNI exposure, and complete CNI avoidance.[37–41] Higher rates of acute rejection, unfavorable side effect profiles, and a lack of data showing improvement in longer-term outcomes such as graft or patient survival compared with CNI-containing regimens has tempered enthusiasm for these agents. The costimulation inhibitor belatacept has been studied as an alternative to CNI-based therapy with more promising results. Belatacept is a humanized monoclonal antibody containing the extracellular portion of human CTLA-4, which inhibits signal 2 costimulation by providing a negative signal to the CD80/86 complex on APCs. When compared with CsA and combined with MMF and prednisone, improved graft and patient survival was reported in those receiving belatacept despite higher early acute rejection rates.[42] Recent data suggest introducing belatacept while tapering CNI for several months after transplantation may reduce the higher rejection rates seen when used in complete CNI-avoidance regimens.[43]

The evolution of posttransplant immunosuppression protocols over the last 5 decades has resulted in a significant reduction in allograft rejection rates. Nevertheless, allograft rejection continues to occur in approximately 10–15% of transplant recipients during the first year following transplantation, conveying inferior graft outcomes.[44] Following T-cell activation events, the surrounding cytokine milieu further influences T-cell differentiation into various effector subtypes, each with the ability to damage allograft tissue *via* distinct mechanisms. These patterns of immune-mediated allograft damage, or graft rejection, are broadly characterized as "cell-mediated" (T-cell) and "antibody-mediated" (B-cell, or AMR) rejection. Cell-mediated rejection is driven mainly by CD8+ and CD4+ T-cell activity. Cytotoxic CD8+ T cells can cause direct tissue toxicity by way of the fas-fas ligand complex and perforin/granzyme B

mechanism. Proliferative signals from CD4+ helper T cells can augment further CD8+ T-cell activation, macrophage activation, and subsequent delayed-type hypersensitivity reaction within the graft, as well as B-cell activation. Activated B cells, in turn, when differentiated into antibody-producing plasma cells, produce antibodies directed against donor HLA-antigens (DSA). Antibody–antigen binding can then lead to complement-dependent graft damage, or AMR.

Allograft rejection is diagnosed histologically using allograft biopsy samples. Rejection is characterized by the Banff criteria,[45] and this information is used to direct appropriate treatment. Milder forms of T cell–mediated rejection include lymphocytic infiltration of tubules and the interstitium and are usually treated with 3–5 days of intravenous (IV) steroids. More severe forms of T-cell mediated rejection involve lymphocytic infiltration of large vessel endothelium, requiring treatment with lymphocyte depleting therapies such as rATG. In contrast, AMR is characterized by microvascular (capillary) inflammation with or without complement split-product C4d deposition in the presence of circulating DSA. Treatment of AMR is directed at removal of DSA with methods such as plasma exchange or immune absorption, and various combinations of therapies to suppress further antibody development, such as the immunomodulatory agent intravenous immunoglobulin (IVIG), the anti-B-cell CD20 monoclonal antibody rituximab, and the anti-plasma cell proteasome inhibitor bortezomib.[46] Recently, several groups have studied terminal complement inhibition with the anti-C5 humanized monoclonal antibody eculizumab in the treatment of more severe forms of AMR.[47]

DIAGNOSIS: DETERMINING ELIGIBILITY FOR KIDNEY TRANSPLANTATION

While kidney transplantation is the optimal mode of treatment for patients with severe CKD, the surgical procedure and the attendant risks of chronic immunosuppressive therapy require that screening processes are in place to ensure successful posttransplant outcomes. There are few absolute contraindications for kidney transplantation (Table 69.1).

Beyond these considerations, there are a number of medical conditions that may represent relative contraindications, including hypotension, pulmonary hypertension, morbid obesity, frailty, asymptomatic cardiovascular disease, and moderate-severe pulmonary disease.[3,48–50] While these factors may not be exclusionary in isolation, a combination of these factors may lead to the consideration of risk/reward of transplantation favoring risk rather than reward. These conditions may have treatment options or rehabilitation potential that may mitigate these risks. Many patients therefore should be referred and evaluated for transplantation despite these potentially hazardous conditions.

TABLE 69.1 Contraindications to Kidney Transplantation

Recent or metastatic malignancy
Severe, irreversible vascular disease
Active/uncontrolled infection
Severe, irreversible organ disease such as severe chronic obstructive or restrictive lung disease, cirrhosis, or heart failure (although in certain cases combined lung–kidney, liver–kidney, or heart–kidney transplant could be considered)
Severe debilitation
Persistent nonadherence
Uncontrolled psychiatric disease
Persistent substance abuse

The evaluation is a multidisciplinary process that takes into consideration the potential candidate's medical, surgical, and psychosocial circumstances, ultimately leading to a determination by both the candidate and the transplant center of the potential advantages and disadvantages of transplantation compared with other treatment options. Highlights of this process include specific considerations and resulting assessments.

Medical

Mortality after transplantation is driven by infections, malignancy, and cardiovascular disease. Effort to mitigate these risks is a goal of the evaluation process. Patients with a history of coronary artery disease (CAD) or congestive heart failure (CHF) and patients with risk factors for CAD/CHF are typically screened for the presence of ongoing disease by an echocardiogram and cardiac stress testing. Recent guidelines suggest that screening for CAD may be considered for asymptomatic patients without prior history of CAD if greater than three or more of the following risk factors are present: (a) diabetes mellitus, (b) prior cardiovascular disease, (c) more than 1 year on dialysis, (d) left ventricular hypertrophy, (e) age greater than 60 years, (f) smoking, (g) hypertension, and (h) dyslipidemia (Class IIb; Level of Evidence C).[51] Positive findings often lead to evaluation by coronary angiography. Intervention once disease is characterized remains a topic of controversy. In general, critical lesions (e.g. proximal left main CAD) should be revascularized. Noncritical disease should not arbitrarily lead to revascularization. The physician and patient should balance the risk of revascularization and the potential (but perhaps unproven) benefits.

The prognosis and the response to immunosuppressive therapy of patients with a history of malignancy influence the candidacy for and the timing of transplantation. In general, those with a history of treated malignancy with >95% 5-year estimated disease progression-free survival (DPFS) may proceed with transplantation. Those with 85–95% DPFS may be best served by a 2-year waiting period before transplantation. Those with <85% DPFS may be asked to wait 5 years before transplantation, to avoid the risk of recurrence and accelerated progression once receiving immunosuppression.[52] Oncology consultation is necessary to assist in predicting expected disease remission and risk of recurrence, as well as the likelihood of progression and the potential response to additional treatments following transplantation.

Routine screening for infections before transplantation includes a chest radiograph, dental assessment, urinalysis, screening for mycobacterium tuberculosis, and serologic testing for cytomegalovirus (CMV), Epstein–Barr virus, hepatitis B and C virus, HIV, and syphilis. Additional screening based on regional risk factors (e.g. coccidioides, histoplasma) may also be considered. These tests assist in guiding pretransplant treatment, assessing for risk of reactivation of disease, and planning for appropriate antibiotic prophylaxis and monitoring following transplantation. Patients with controlled HIV infection and those with chronic hepatitis C virus infection in the absence of cirrhosis may still successfully undergo transplantation with appropriate monitoring and treatment following transplant.[53,54] Active bacterial infections must be treated successfully before transplantation. Vaccinations should be up to date and should include vaccination for hepatitis A and B virus, influenza, varicella zoster, and pneumococcus. Live vaccines and live attenuated vaccines are contraindicated in immunosuppressed candidates, candidates within one month of transplantation, and in recipients following transplantation.

Surgical

Urologic evaluation entails assessment of adequate bladder structure and function. Patients with known neurologic or structural concerns including congenital anomalies, neurologic diseases, and bladder or ureteral obstruction will typically require evaluation of bladder integrity *via* urodynamic studies and cystoscopy.

Vascular issues pertinent to transplantation include identification of healthy vasculature to facilitate vascular anastomosis. Imaging of the aortoiliac system typically entails computed tomography to evaluate for vascular calcification, with IV contrast as needed if significant concern is raised on initial imaging.

Psychosocial

A key component in determining transplant candidacy is the assessment of potential barriers to success either from a psychological or social perspective. Nonadherence is a primary cause of chronic rejection and graft loss following transplantation. Efforts to identify potential barriers to adherence (whether physical, emotional, financial, or educational) are important at an early stage of referral. Screening for untreated/undertreated mental health disorders, a history of nonadherence, substance abuse, and financial or physical/geographic barriers to appropriate medical care, is performed as part of the transplant evaluation process, typically by a social worker. These may include referral for psychological, psychiatric, or neurocognitive testing.

Risk Factor-Specific Considerations

Elderly Patients

There is no defined age at which one is deemed no longer a transplant candidate, but age does serve as a framework for discussing associated risks as well as a more broad understanding of the relative benefits of transplantation compared with dialysis, which diminish with increasing age and comorbidities. Elderly patients with a history of cardiovascular disease may still derive benefit from transplantation. They may particularly benefit from the lower-risk procedure of living donor transplantation rather than deceased donor transplant (Figure 69.1).[2] Given the lack of an absolute "age cutoff" for transplant eligibility, measures of frailty are more commonly employed to assist in determining differences in "biological age" vs. "chronological age."[50,55,56]

Obesity

Similar to age, there is not a clear body mass index (BMI) cutoff at which point transplant is demonstrably inferior to remaining on dialysis; however, obesity contributes to posttransplant recovery/morbidity including wound healing, infections, delayed graft function (DGF), increased risk of posttransplant diabetes, and cardiovascular disease.[57] Given these concerns most transplant centers request weight loss interventions pretransplant to minimize complications and untoward outcomes following transplant.

Risk for Recurrent Renal Disease

A number of renal diseases leading to CKD will recur in the allograft but are variable in their presentation and

TABLE 69.2 Estimated Risks for Recurrent Disease Following Transplant and Risk for Graft Loss Related to Recurrence

Disease	Approximate Recurrence Rate (%)	Graft Loss due to Recurrence
FSGS	30–60	Common
Atypical HUS	20–50	Common
Immune complex–mediated MPGN	30–50	Common
Complement-mediated MPGN	60–100	Common
ANCA-associated Vasculitis	10–20	Common
Membranous	10–30	Uncommon
Henoch Schonlein Purpura (HSP)	15–50	Uncommon
IgA nephropathy	30–50	Uncommon
Anti-glomerular basement membrane (GBM)	Rare	Uncommon

severity following transplant.[58–60] In general, there is no primary renal disease that recurs with such frequency or severity that poses a contraindication for transplantation. If disease recurrence does occur and leads to early or rapid graft loss, future retransplantation may be deferred until a different therapeutic intervention emerges. Table 69.2 delineates a number of diseases that recur in the transplanted kidney, and the risk of subsequent graft loss related to disease recurrence.

TREATMENT: THE KIDNEY TRANSPLANTATION PROCEDURE

Organ Procurement

Deceased Donor Organ Procurement

Procurement of organs from deceased donors occurs following declaration of patient death (either brain death or cardiac death). The kidneys are typically removed *en bloc* to ensure preservation of the vasculature. Special attention is given to avoid stripping the adventitial tissue surrounding the ureters and potentially compromising their blood supply. The kidneys are prepared on the back table with further dissection and isolation of vessels, flushed with cold preservation fluid, and then placed in cold storage for transportation and preservation until the transplantation procedure.

A number of preservation solutions are available. There is no consensus evidence to support the use of one solution over another. Use patterns therefore vary by region.[61] Cold storage can either be static or with machine-driven pulsatile perfusion ("pumped"). Prolonged cold storage (cold ischemia time) is one of several factors that has a strong association with the risk for developing DGF, commonly defined as the need for renal replacement therapy within seven days after transplantation. DGF results in higher posttransplantation costs due to the cost of dialysis and higher rates of readmission.[62] DGF is associated with decreased 1- and 5-year graft survival.[63] Machine perfusion has been associated with reduced rates of DGF[64] and has become increasingly prevalent, but its widespread use continues to be controversial due to increased procurement costs and unclear impact on long-term patient and graft outcomes.[65]

Living Donor Surgical Procedure and Kidney Procurement

Open surgery for living donor nephrectomy has largely been replaced by less-invasive laparoscopic approaches, due to several advantages including reduced morbidity, shorter length of stay, and better cosmetic results. Laparoscopic nephrectomy accounts for greater than 97% of living donor nephrectomies in the US.[14] There are multiple technical variations of laparoscopic donor nephrectomy. Hand-assisted laparoscopic nephrectomy in which one of the laparoscopic ports is large enough for the surgeon to manually manipulate intraabdominal structures is twice as common in the US compared with unassisted methods. Newer approaches on the horizon include single-site laparoendoscopic nephrectomy and robotic nephrectomy.

The Transplantation Procedure

The kidney graft is typically placed extraperitoneally in the recipient right or left iliac fossa, with venous and arterial anastomoses to the ipsilateral external iliac vein and artery, respectively. The ureter is preferably anastamosed to the bladder, but can also be connected to the

ipsilateral native ureter if needed. A double-J ureteral stent is commonly placed at the time of transplant to reduce the risk of major urologic complications, such as urine leak and ureteral obstruction, but at the cost of an increased risk of urinary tract infection and BK virus activation (see below, complications).[66] The ureteral stent is typically retrieved by cystoscopy 2–6 weeks after transplantation.

Surgical complications of transplantation typically manifest with graft dysfunction within the first few days to months after transplantation. They can be generally divided into vascular complications, urologic complications, and extrinsic compression by fluid collections.[67] Prompt imaging of the graft with duplex ultrasound is crucial to diagnosis and management. Arterial or venous thromboses are rare, but can be catastrophic, and often require urgent surgical reexploration. Dilation of the ureter or collecting system may suggest ureteral obstruction or bladder dysfunction that must be relieved with placement of a ureteral stent, percutaneous nephrostomy, or bladder catheter. Fluid collections due to hematomas, seromas, and lymphocoeles are common after transplantation and are often benign and need only be monitored. However, collections may lead to graft dysfunction *via* compression of vascular structures, renal parenchyma, or urine outflow and require intervention. Urinary leak, commonly from the ureteral anastomosis, manifests as a fluid collection and is diagnosed by measuring the fluid creatinine concentration, which will be higher than the S[Cr] in the setting of a urine leak, but will be similar/equivalent to S[Cr] in the setting of a lymphocoele.

Short-Term and Long-Term Outcomes

Unadjusted patient and graft survival for both living donor and deceased donor kidney transplantation has steadily improved over the past several decades. In the US, 1- and 5-year patient survival is 97% and 87% for deceased donor kidney transplantation and 98% and 92% for living donor kidney transplantation, respectively. Graft survival at 1 and 5 years is 93% and 75% for deceased donor kidney transplantation and 98% and 85% for living donor kidney transplantation, respectively.[14] Reported registry outcomes from other regions of the world such as Europe, the United Kingdom, Australia, and New Zealand are very similar to US outcomes.

Among the most important donor factors predicting outcomes is whether the donor is a living donor or a deceased donor. Many risk factors for deceased donor transplantation are captured by a Kidney Donor Risk Index,[68] that is then translated to a KDPI that stratifies and estimates expected graft longevity on a percentile scale. A higher score on a scale of 1–100% is associated with an increased risk of graft failure. For example, the predicted median graft survival of a deceased donor kidney with a KDPI >85% is 5.6 years, compared with a median graft survival of over 11 years for a deceased donor kidney with a KDPI <20%. Despite the associated increased risk of graft failure, patients with higher predicted waitlist mortality (i.e. older, diabetic, or on renal replacement therapy) still derive benefit from accepting higher risk transplants rather than remaining on dialysis.[24]

Preemptive Transplantation

Early access to transplantation is important to optimize posttransplant outcomes. Receiving a transplant before initiating dialysis, termed preemptive transplantation, is associated with a substantial improvement in patient and graft survival. Recipients of preemptive deceased donor transplants experience an 18% reduced risk of death and a 25% reduced risk of graft failure. Preemptive living donor recipients experience a 31% reduced risk of death and a 27% reduced risk of graft failure compared with those treated with dialysis before transplantation.[69] This only encapsulates posttransplant advantages and neglects the additional morbidity and mortality benefits of avoiding initiation of and maintenance on dialysis.

Common Complications Following Transplantation

Immunologic injury due to graft rejection is a primary focus when considering potential complications after transplantation leading to early and late graft loss. Other complications, often related to immunosuppression, also have important implications for patient morbidity and mortality and graft loss. Over 40% of renal graft failures are due to patient death with a functioning graft (DWFG). Rates of DWFG have remained constant over the past 20 years.[14,70] Recurrent or *de novo* glomerular disease leads to graft loss in 18% to 22% of renal transplants, with particularly high rates of recurrence for patients with focal segmental glomerulosclerosis and some complement-mediated diseases such as dense deposit disease (Table 69.2).[70,71]

Cardiovascular disease is the leading cause of death in renal transplant recipients, accounting for about 25% of graft loss due to DWFG.[70,72] This is due to the high burden of preexisting disease in the advanced

CKD/ESRD population and traditional risk factors such as hypertension, dyslipidemia, diabetes, and obesity. Other contributing factors include the increased risk of development of diabetes after transplantation due to adverse effects of immunosuppression medications, particularly attributed to CNIs and corticosteroids. Patients developing diabetes after transplantation have a threefold increased risk of major cardiac events compared with patients without diabetes.[73]

The second leading cause of death after transplantation is infection, accounting for about 15% of graft loss from DWFG.[70,72] The source and type of infection is influenced by recipient characteristics, immunosuppression regimen, and time since transplantation.[74] Donor-derived and nosocomial infections must be considered within the first few weeks after transplantation. Reactivation of latent infections occurs within the first few months after transplantation. Beyond six months after transplantation, community-acquired infections are the most prevalent. Infections of particular importance after kidney transplant include CMV and BK virus infection.

CMV is a member of the human herpesvirus family, with 60–70% seroprevalence in adults. CMV infection after transplantation is associated with increased mortality and death-censored graft failure after transplant, and is common in high-risk recipients (CMV-seropositive donor to CMV-seronegative recipient).[75,76] Prophylactic antiviral therapy is often prescribed for 3–6 months following transplantation, but after discontinuation of prophylaxis, a high index of suspicion must be maintained because late-onset infection is not uncommon.[77]

BK virus is a polyomavirus with 80–90% seroprevalence in the population. It remains dormant in the uroepithelium. The virus may reactivate after transplantation in the setting of immunosuppression, leading to allograft nephropathy, characterized by tubulointerstitial inflammation. BK viruria and viremia typically precede nephropathy by 2–3 months and 2–6 weeks, respectively, offering an opportunity to screen for BK virus during periods of increased risk (e.g. the first 1–2 years following transplantation). Most BK viremia occurs in the first 3–6 months after transplantation. While not a life-threatening infection, nephropathy can result in graft loss in 15–40% of cases.[78]

Malignancy accounts for 12–14% of DWFG and is the third leading cause of death after kidney transplantation.[70,72] Several cancers have higher incidence in renal transplant recipients compared with the general population, particularly nonmelanoma skin cancer, lymphoma, kidney cancer, melanoma, leukemia, and cervical and vulvovaginal cancers.[79] Posttransplant lymphoproliferative disorder (PTLD) is a spectrum of disorders ranging from localized polymorphic B-cell proliferation to B-cell and rarely T-cell lymphomas. It is relatively rare, with an incidence of 0.1–0.2% per year overall, but EBV-seronegative transplant recipients (approximately 5% of the US population) have a significantly higher risk of early PTLD than EBV-seropositive recipients.[80]

TABLE 69.3 Important Drug–Drug Interactions with Immunosuppressive Agents and Commonly Used Medications

Drug Class (Examples)	Causes of Increased Blood Levels	Causes of Decreased Blood Levels
Calcineurin inhibitors* (tacrolimus, cyclosporine)	Azole antifungals (i.e. fluconazole) Protease inhibitors (i.e. atazanavir, nelfinavir) Calcium channel blockers (nondihydropyridine > dihydropyridine) Macrolide antibiotics Antiretroviral-boosting agent (i.e. ritonavir) Amiodarone Grapefruit Other CYP3A4 inhibitors	Antiepileptics (i.e. carbamazepine, phenytoin) Rifampin Efavirenz St. John's Wort Other CYP3A4 inducers
mTOR inhibitors (sirolimus, everolimus)	Azole antifungals (i.e. fluconazole)	Antiepileptics (i.e. carbamazepine, phenytoin)
	Macrolide antibiotics	Rifampin
	Grapefruit	St. John's Wort
	Other CYP3A4 and P-glycoprotein/ABCB1 inhibitors	Other CYP3A4 and P-glycoprotein/ABCB1 inducers
Antimetabolites (azathioprine, mycophenolate)	Allopurinol or febuxostat (only for azathioprine)	Antacids (mycophenolate)

** Calcineurin inhibitors (cyclosporine > tacrolimus) inhibit metabolism of statins and increase risk of myopathy.*

Treatment depends on the morphology, location, and EBV status of the lesion but involves immunosuppression reduction and potentially chemotherapy, radiation, and surgical resection.

Drug Interactions

Immunosuppression medications have narrow therapeutic windows to achieve the desired effect of reducing the risk of graft rejection while minimizing the risk of toxicities. Therefore, it is important to understand the impact that other medications and substances can have on their metabolism that may perturb this balance, particularly by affecting the cytochrome P450 (CYP3A4) metabolism of CNIs.[81] Table 69.3 provides a list of interactions with the most common immunosuppression therapies in kidney transplant patients.

CONCLUSIONS

Early consideration of transplantation and referral for transplant evaluation for appropriate candidates with stage 4 CKD is essential. This priority is necessary to determine candidacy and begin the discussion of the waitlist process and living kidney donation options. Education regarding the surgical procedure and immunosuppressive agents is important to balance the potential risks vs. the rewards of transplantation. With few exceptions, transplantation is the treatment of choice for eligible individuals. When proactively considered (particularly in the context of potential living kidney donation) transplantation can be performed preemptively and dialysis treatment can be avoided.

QUESTIONS AND ANSWERS

Question 1

What factors contribute most to the variability in expected wait time among patients waiting for a deceased donor kidney transplant in the US?

A. Blood type, prior transplantation
B. Age, PRAs
C. PRAs, blood type
D. PRAs, insurance type
E. Blood type, age

Answer: C

Blood type and tissue matching play roles in the allocation of kidneys for transplantation. A patient's "sensitization" or burden of preformed antibodies to human tissue, often generated through prior exposures such as pregnancy, blood transfusions, or past transplants, is measured by a PRA test, representing the estimated percentage of people in the general population against whom a recipient might have HLA antibodies. It can often be very difficult to find an acceptable match for patients with very high PRAs. Priority is given to blood type matching between donor and recipient, with patients with blood type AB and A having the shortest time until transplantation, and those with blood types B and O with longer wait times. Recipient age and insurance type do not influence matching but could be relative barriers in gaining access to the waiting list.

Question 2

A 53-year-old woman with stage 4 CKD due to diabetic nephropathy presents to a transplant center for transplant evaluation. She has a history of three pregnancies and two blood transfusions. HLA testing reveals a calculated PRA of 73%. Which of the following statements pertaining to her PRA is accurate?

A. The patient carries a 73% risk of antibody-mediated graft rejection following transplant due to circulating anti-HLA antibodies
B. The patient would be expected to have a positive cross-match against 73% of the population due to circulating anti-HLA antibodies
C. 73% of the patient's circulating anti-HLA antibodies would be expected to react with a particular kidney donor organ
D. The patient is expected to have 0 of 6 HLA matches (six mismatches) with 73% of the population

Answer: B

The PRA test is a quantitative assessment of anti-HLA antibody burden in terms of likelihood of a positive cross-match with any other individual within the population. In this example, this patient has developed anti-HLA antibodies throughout her lifetime that, when taken as a whole, would be expected to cross-react with the tissue of another individual within the population approximately 73% of the time. The PRA is calculated using known frequencies of individual HLA alleles throughout a given population. Antibodies against common HLA antigens will add significantly to an individual's PRA, whereas antibodies against rare HLA antigens may not add to the PRA at all. The PRA is calculated using the sum of all anti-HLA antibodies detected by screening methods.

Because the pool of available kidney donors for a given patient in need of transplantation becomes increasingly restricted as the PRA level rises, patients with high PRA levels suffer from longer wait times for donor kidneys.

Answer A is incorrect because PRA does not necessarily correlate with risk of acute rejection. Rejection risk stems from DSA as opposed to the overall PRA level. Answer C is incorrect as PRA is a measure of total anti-HLA antibodies, not a percentage of antibody burden. Answer D is incorrect as PRA level does not necessarily correlate with the degree of HLA-antigen matching between a recipient and a particular donor. Rather it is a measurement of the likelihood that an individual's total antibody load may react with another individual within the population.

Question 3

A 69-year-old man with CKD stage 4 due to type 2 diabetes undergoes kidney transplant evaluation. His past medical history is significant for stable CAD, status-post a drug-eluting stent to his left circumflex artery 3 years ago. A stress echocardiogram demonstrates no wall motion defects. Ejection fraction is 40%. His BMI is 35.5 kg/m^2. During evaluation, he is noted to be frail due to slow walk speed, weakness as assessed by grip strength, self-reported exhaustion, and low physical activity. Which risk factor will be of greatest concern regarding his posttransplant graft loss and death?

A. His age
B. His cardiovascular history
C. His obesity
D. His risk of recurrent disease
E. His functional status

Answer: E

Chronological age is not a contraindication to kidney transplantation. While increasing age may lead to increase in associated morbidities that influence successful transplantation, age alone is not a risk factor. Similarly, patients with appropriately treated cardiovascular

disease are transplant candidates and demonstrate significant survival benefit particularly when receiving a living donor kidney transplant. Diabetic nephropathy commonly occurs following transplantation but is typically indolent and not clinically significant until late (~10 years) into the posttransplant period. Diabetic nephropathy is not a contraindication for transplant. Obesity is a risk factor for DGF and graft loss but not increased mortality following transplantation. However, this patient's functional status (assessed by objective measures of frailty) is associated with DGF, early hospital readmission, graft loss, and mortality and is the primary risk factor from the above choices that would deserve attention. Dedicated physical therapy with longitudinal assessments may improve outcomes after transplantation.

Question 4

A 61-year-old male with a history of CKD due to lupus nephritis, status-post deceased donor kidney transplant 15 months ago presents for routine follow-up. His graft function has been stable with S[Cr] 1.5 mg/dL. His immunosuppression regimen consists of tacrolimus, mycophenolate, and prednisone. He has had no rejection, *de novo* DSA, BK virus reactivation, or infection. He denies any complaints other than having gained 15 pounds since transplantation. He now has a BMI of 34. His blood pressure is 142/89 mm Hg. Physical examination is otherwise unremarkable. Relevant laboratory values are below:

S[Cr] 1.6 mg/dL
Fasting glucose 150 mg/dL
Tacrolimus trough 9.8 ng/mL
Urine protein:creatinine ratio 0.5 g/g

Which of the following steps will address the most likely cause of his eventual graft failure?

A. Stop tacrolimus and replace with an mTOR inhibitor
B. Check serum ANA titer, anti-dsDNA titer, and complement levels
C. Kidney biopsy to assess for acute rejection
D. Check hemoglobin A1c, encourage weight loss, and optimize blood pressure control
E. Check BK virus PCR

Answer: D

Forty percent of renal graft failures are due to DWFG. Cardiovascular disease is the leading cause of death. The patient has multiple risk factors for cardiovascular disease including obesity, hypertension, and now likely posttransplant diabetes based on an elevated fasting glucose. He needs aggressive management of his cardiovascular risk factors. Isolated CNI toxicity is now thought to be a rare cause of graft failure. Lupus nephritis can recur after transplantation, but this is relatively rare. Stable graft function would be inconsistent with lupus recurrence or acute rejection. BK nephropathy is more commonly diagnosed within 3–6 months after transplantation.

Question 5

A 62-year-old man with chronic glomerulonephritis due to hepatitis C virus infection is referred for kidney transplant evaluation. His estimated glomerular filtration rate is 19 mL/min/1.73 m^2. During the evaluation, he is noted to have anti-HCV antibodies. HCV RNA is 680,000 copies/mL. The detected HCV is genotype 1a. He has no stigmata of liver disease on physical examination. His liver function panel, prothrombin time, serum albumin concentration, and platelet count are all within normal range. A liver ultrasound is normal. With respect to his transplant candidacy and renal replacement therapy planning, which of the following is true?

A. He is not eligible for transplantation due to chronic HCV infection
B. He should be treated to clear HCV before transplantation because the direct-acting antiviral agents are ineffective following transplantation
C. If approved for transplant, he should undergo combined liver–kidney transplantation
D. His waiting time for transplant will be shorter because he can be transplanted with organs from HCV positive donors without increased risk
E. He should undergo transplantation with a kidney from an HCV Ab-negative donor to prevent potential complications related to HCV coinfection and reactivation.

Answer: D

Chronic HCV infection is not an exclusion to kidney transplantation. The survival benefit of transplantation over dialysis still prevails, despite the potential for HCV-related complications such as worsening liver disease and recurrence of glomerulonephritis. Understanding the degree of liver injury before transplantation is important, as advanced cirrhosis is a contraindication to kidney transplantation. Patients should be considered for combined liver–kidney transplantation under these circumstances. The direct-acting antivirals are effective in both the pre- and posttransplant settings, despite the theoretical impact of immunosuppression on viral clearance, and drug–drug interactions that exist with some DAA and CNIs. Patients with chronic viremic HCV infection can receive organs from HCV-positive kidney donors. Because the pool of HCV positive donors is much larger than the pool of HCV positive candidates,

waiting time for transplantation is dramatically shorter for HCV positive candidates. (Transplantation with less than 6 months waiting time is not unusual in the US.) This should be taken into consideration when caring for the HCV-positive patient with stage 4–5 CKD. DAA therapy should be withheld in many circumstances if the patient is determined to be transplant-eligible due to this tremendous advantage.

Question 6

A 26-year-old patient is admitted with acute kidney injury of his kidney transplant, now 4 years after transplantation. He has missed a number of clinic appointments recently. His most recent visit to the transplant center the month prior had identified fluctuating and downtrending tacrolimus trough concentrations, as well as the presence of new-onset donor-specific antibody to DR7 (class II HLA). S[Cr] is 2.4 mg/dL, increased from a baseline of 1.5 mg/dL with no explanation after initial evaluation. You obtain a kidney transplant biopsy that demonstrates microvascular inflammation in the peritubular capillaries without tubulitis. Immunohistochemical stain for C4d staining is positive. In addition to high-dose corticosteroids, initial therapy should include which of the following?

A. Belatacept
B. Thymoglobulin
C. High-dose IVIG
D. Plasmapheresis/low-dose IVIG
E. Basiliximab

Answer: D

The biopsy and accompanying circulating donor-specific antibody results are consistent with AMR. Antibody-directed therapy should be used. Basiliximab, belatacept, and thymoglobulin act on T cells, not B cells or plasma cells. Belatacept acts by inhibiting activation of T cells, thymoglobulin by binding to and depleting T cells, and basiliximab binds to IL-2 receptors and inhibits T-cell proliferation. Therefore, A, B, and C are incorrect. IVIG is a useful therapy for inhibiting antibodies and antibody production but has not been shown to be adequate alone in treating AMR. Plasmapheresis together with IVIG is more effective than IVIG alone in inhibiting alloantibody responses, albeit proven in small, uncontrolled studies. Answer D is correct.

CHAPTER

70

Preparing for Hemodialysis

Robert T. Isom, Glenn M. Chertow

Stanford University School of Medicine, Division of Nephrology, Palo Alto, CA, United States

Abstract

Decisions regarding the initiation of renal replacement therapy (RRT)—whether hemodialysis (HD), peritoneal dialysis, kidney transplantation, or palliative care is chosen—are critical when considering combined efforts among nephrologists, patients, family members, and nonphysician health care personnel. The transition from management of progressive chronic kidney disease (CKD) to that of end-stage renal disease (ESRD) requires the nephrologist to have a clear understanding of the disease trajectory in the individual patient and to function as a teacher for the patient and members of the patient's family, as well as for their professional and social networks. These functions involve an understanding of the patient both as an individual and as a member of a social milieu and require an appreciation of the patient's culture, spirit, and belief systems. Although all therapeutic choices facing patients with advanced CKD have advantages and disadvantages, many of the steps in the transition to ESRD care are common to all the choices. In particular, recent advances in clinical science (based on evidence derived from observational studies and clinical trials) allow the nephrologist to advise patients regarding appropriate timing of initiation of RRT and factors related to successful creation of vascular access, which will promote the best health outcomes. The nephrologist, while delivering complex care at the time of a crucial transition, plays a key role in determining whether the start of RRT with HD will be characterized by a "smooth landing" or a "crash landing," ultimately by serving as a coordinator of education and multidisciplinary consultation.

INTRODUCTION

Patients with all forms of progressive chronic kidney disease (CKD) whose glomerular filtration rate (GFR) is expected to decline within their lifetime, to the point where life-threatening manifestations of advanced uremia are expected to develop, have a number of treatment and management options to consider. The different forms of renal replacement therapy (RRT) include hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation (KTx). The choice of RRT modality should be tailored to the individual patient. The choice is generally based on a combination of medical and surgical comorbidities, anticipated life expectancy, psychosocial factors, and patient preference. KTx, when possible, remains the preferred treatment modality for almost all patients with end-stage renal disease (ESRD). Kidney transplant recipients, in aggregate, enjoy prolonged life expectancy and enhanced quality of life relative to patients undergoing either HD or PD.[1] However, when transplantation is not an option for an individual patient, or if not available preemptively (before the initiation of dialysis), the patient and his or her nephrologist must decide between planning for PD, HD, or, in selected circumstances, emphasizing a more conservative, nondialytic approach. Palliative nephrology implies nonprovision of RRT in situations where, because of a patient's cumulative comorbidities (or less commonly due to patient choice), dialysis of any type tends to provide only limited prolongation of life or functional rehabilitation, such that symptom-based, comfort-directed measures may be more appropriate.[2,3] For most younger (and healthier) patients with ESRD, goals of dialysis include prolongation of life expectancy and service as a bridge to KTx. For many older patients, however, dialysis itself is palliative care, in that its principal objective is to relieve symptoms rather than to necessarily prolong life.

Planning for dialysis requires convincing a patient that he or she will derive meaningful quality and prolongation of life by submitting him or herself to an intrusive, mechanical form of support for a failing organ system, without which uremic symptoms and eventually death would ensue. The first step in this process involves educating the patient about the role of the kidneys in maintaining health and the anticipated effects on the patient's health and survival associated with different degrees of impaired kidney function. The nephrologist cannot assume that the patient understands the roles of the kidneys in maintaining health or

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00070-X

what signs and symptoms might develop in an individual patient as kidney function declines. (Indeed, even an experienced nephrologist may be fooled by patient-to-patient variation in the expression and timing of symptoms.) The nephrologist must tailor his or her information delivery based on the patient's intellectual capacity, educational background, culture, hopes for and fears about the future, and fixed beliefs, to integrate complex medical concepts. Not all patients, for example, can grasp the concept of estimated glomerular filtration rate (eGFR), although this parameter is increasingly noted on laboratory reports, and many patients will present for nephrology consultation with the chief complaint of having been told of a "low eGFR" by their referring internal medicine or family medicine physician, physician assistant, or nurse practitioner. Confusion surrounding parameters of kidney function, whether eGFR or serum creatinine concentration (S[Cr]), can place the nephrologist in an awkward position because the terms "glomerular" and "filtration" are foreign to most laypersons, and addressing the concern of a "low eGFR" to a patient's full satisfaction may compel the nephrologist into a discussion of renal microanatomy, including details on the structure and function of the glomerulus. How else might a patient be able to understand what "eGFR" means? Understandably, without even a cursory discussion of this concept, patients may leave the consultation room still wondering, "What does my low eGFR actually mean?" Or, they may question "What is a glomerulus?" Some patients may be able to integrate this degree of physiologic discussion, if communicated skillfully by the nephrologist. For others, it may be more helpful to tell them to disregard the term "eGFR" and focus instead on something more tangible, such as "the kidneys' percent ability to filter waste products" (conveniently, because an eGFR of 100 mL/min is not far off an expected, "normal" value for a young to middle-aged person). Ultimately, in terms that he or she can understand, the patient needs to learn that progressive CKD is associated with substantial morbidity and symptomatology, and if untreated in its most advanced form, is a lethal condition.

Bearing in mind the patient's cognitive function, capacity to understand, attention, cultural background, and ability to integrate medical terminology, the nephrologist must explain the different forms of RRT, emphasizing that these are treatments, not cures, for ESRD. Indeed, it is not unusual for a patient with ESRD to arrive for his or her first HD session and ask how long it will take for his or her kidneys to get better. Or he or she may ask, understandably, "Is there anything I can do to make my creatinine go down?"

Many patients are understandably reluctant to go along with the recommended planning phases in preparation for dialysis initiation. Patients may repeatedly delay or outright refuse dialysis planning. The idea of being tethered to a machine several times a week for necessary life support may seem painful, unnatural, overly time-consuming, and unacceptable. Although they may already have advanced CKD, patients are often free of the typical signs and symptoms of uremia, such that the stated benefits of dialysis (prolonging life and relieving symptoms), when viewed against the perspective of the hardships of the planned dialysis modality, remain abstract and difficult for a layperson to embrace.

The first step in planning for HD, therefore, involves educating the patient and his or her sources of social support regarding the role of the kidneys in maintaining health and the anticipated impact of a progressive decline in kidney function on the patient's health status and life expectancy. If the patient's CKD is expected to progress to end-stage, he or she must be educated regarding the potential health benefits that would realistically be expected from dialysis. Patients should also have a good understanding of the trade-offs that would be encountered after they have started dialysis, in terms of dietary restriction, time commitment to the procedure, and subsequent impact on the lifestyle and occupation they may currently enjoy, as well as the physiologic limitations of what dialysis is and is not able to correct. The concept of "RRT" must be carefully explained to the patient, because HD and PD, strictly speaking, do not replace kidney function in its entirety. Although dialysis may diminish high serum levels of potassium, acid and by-products of nitrogenous (ingested protein) and muscle metabolism, it fails to correct a variety of reabsorptive, excretory, secretory, endocrine, metabolic, anti-inflammatory, and other functions of the kidneys. As a result, even when patients are fully adherent with their prescribed dialysis regimen, they typically do not experience the comprehensive physiologic and lifestyle rehabilitation that only transplantation affords. In other words, although dialysis sustains life, it typically fails to restore health.

When caregiver and patient agree on eventual provision of dialysis, a choice must be made between HD and PD. Although long-term survival among patients receiving HD and PD are generally similar, the argument has been made that when possible from the technical and psychosocial points of view, the initial modality of choice for most patients should be PD.[4,5] This view is based on the observation that PD is associated with improved quality of life and patient independence, is less costly on an annual basis than HD, and is associated with longer preservation of residual kidney function. This is important because as is well known to nephrologists, maintenance of residual kidney function is associated with improved fluid and blood pressure control, phosphate and middle molecule clearance,

nutritional status, left ventricular hypertrophy and cardiovascular (CV) risk, decreased inflammatory markers, and prolonged survival.[6–8]

When the nephrologist and patient do agree on future implementation of HD as the optimal and preferred RRT modality, many factors must be addressed during the course of the patient's declining kidney function, to allow optimization of outcomes at the time of initiation of HD, as well as during the ensuing months and years of maintenance therapy. We make the distinction to patients between a "smooth landing" and a "crash landing," where crash landing may involve emergency hospitalization of the patient with decompensated uremic symptoms, severe metabolic disarray, pulmonary edema, possibly uremic pericarditis, and without preexisting vascular access, necessitating placement of a temporary vascular catheter, often in a critical care setting by less-experienced personnel. Outcomes under these circumstances are generally poor—hospitalizations may be lengthy and costly, infection rates from emergency catheter placement are high, and long-term patient rehabilitation from having started dialysis *in extremis*, with globally decompensated signs and symptoms of uremia, may be suboptimal. Causes of a crash landing may include (a) lack of primary medical care and/or the patient being unaware of his or her disease until it becomes symptomatic, (b) late referral to nephrology services from the patient's primary care provider, (c) the patient's inability to come to terms with the progressive nature of his or her disease, leading to failure to follow the nephrologist's recommendations, or (d) failure by the nephrologist and his or her treatment team to have a structured, guideline-based approach to management of the pre-ESRD patient.

Ideally, preparation of the patient for HD should result in meeting several conditions.

From the educational point of view, patients and families should have a reasonable understanding of the functional and symptomatic consequences of progressive kidney failure. They should also have a good understanding of the various modalities of RRT, with the eventual modality choice being tailored to the individual circumstances, taking into account medical and surgical comorbidities, age and projected life expectancy, lifestyle and occupation, social support system, and personal choice. Patients should have a reasonable set of expectations regarding what HD can and cannot replace for the failing kidneys. Patients should have a clear understanding of the scheduling and logistic requirements that will be expected of them and how new dietary restrictions will be imposed on them. For selected patients, because of either advanced age or other significant comorbid conditions, there should be an understanding that a palliative, conservative, symptom-based, and comfort-based approach may be reasonable.

Appropriate measures to slow the progression of the patient's CKD should be in place, targeting the underlying etiology of the patient's CKD, potential implementation of a protein-restricted diet, and ongoing use (or *de novo* implementation) of inhibitors of the renin–angiotensin–aldosterone system (RAAS), even in late stage CKD. Importantly, with the newer generation potassium-binding agents now available, nephrologists should feel more emboldened to continue RAAS blockade further into the trajectory of a given patient's CKD, without the fear of encountering critically significant hyperkalemia.[9–12]

The patient's nutritional and functional status should be optimized.

Guidelines regarding treatment of the anemia of CKD should be adhered to, with the goal of avoiding blood product administration before or at the time of dialysis initiation, particularly if patients are deemed to be (or will likely be considered) acceptable kidney transplant recipients.

Because of the heightened risk of CV morbidity and mortality associated with moderate to advanced CKD and ESRD, modifiable risk factors for CV disease should be optimized, including coronary revascularization if significant, reversible ischemic heart disease is present.

For those patients deemed to be medically and otherwise suitable for transplantation, they should, ideally, be seen and evaluated by a local transplant center and listed for eventual transplantation as soon as feasible. This should occur well before the actual time of dialysis initiation because an eGFR of 20 mL/min/1.73 m^2 or less qualifies a patient for transplant listing with the United Network for Organ Sharing (UNOS). Waiting to refer for transplantation until dialysis is initiated, when eGFR is much lower than 20 mL/min/1.73 m^2, essentially "robs" the patient of valuable waiting time (sometimes on the order of years, for those with more slowly progressive forms of nephropathy) that they could otherwise accrue on the deceased donor waiting list. Waiting to refer patients for transplantation until dialysis has been initiated will therefore produce the unintended effect of prolonging the waiting time for eventual transplantation, and potentially exposing patients to the interval development of dialysis-associated morbid events, not uncommonly rendering them subsequently unsuitable for transplantation. We recommend referral for transplantation when the eGFR is between 20–25 mL/min/1.73 m^2 so that medical and psychosocial evaluations can be completed, the patient tentatively approved, and subsequently listed as soon as the referring nephrologist documents an eGFR consistently below 20 mL/min/1.73 m^2 during serial monitoring.

Perhaps most importantly, the patient should have a functional, permanent vascular access in place when HD is initiated. This requires early referral to a vascular

surgeon, usually at least 4–6 months in advance of the anticipated time of starting HD. This provides sufficient time to allow maturation of a newly placed native arteriovenous fistula (AVF) (usually 3–6 months). Early vascular surgery referral also allows for the relatively high rate of primary failure of newly placed AV fistulae, leading to the need for repeated interventional procedures and/or revision surgeries to facilitate maturation of the fistula. If the first fistula created fails to develop in spite of optimal interventional support, the surgeon will need to place a new fistula at another site or place an arteriovenous graft (AVG) instead. Although fistulae are clearly preferable to grafts in terms of infectious risk and durability, both are vastly preferable to catheters, which are associated with the highest risks of infection, venous stenosis, and subclinical and clinically overt venous thromboembolic disease, including superior vena cava syndrome.

As the steps outlined above are being followed, the nephrologist needs to formulate an ever-refined estimate of the time when HD will need to be initiated for the patient. This requires an appropriate schedule for laboratory monitoring, with attention focused most importantly on the patient's evolving S[Cr] and eGFR, but with careful attention also being paid to serum potassium concentration, acid–base balance, serum phosphate concentration, and hemoglobin/hematocrit concentrations. From the clinical point of view, the patient should be seen at appropriate intervals by either the nephrologist or an advanced practice provider, so that a focused, renal-specific review of systems and physical examination can assess potential development of incipient signs or symptoms of uremia, which would prompt initiation of dialysis.

If the above approach is followed, the patient should be able to initiate HD on an elective, outpatient basis. If eligible, patients should already be listed for KTx. The hemoglobin concentration should be at targets set by Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, without blood transfusions. Patients should have a functional permanent vascular access, preferably an AVF. Patients should be free of severe, decompensated signs or symptoms of advanced kidney failure that would prompt emergent hospitalization for dialysis initiation—such as refractory hyperkalemia, encephalopathy, severe hypertension, congestive heart failure, or serositis (especially pericarditis).

The considerations outlined, when properly adhered to, increase the likelihood of safe and successful initiation of HD, when the nephrologist has reached the conclusion that for the individual patient, benefits of dialysis have begun to outweigh the risks associated with the procedure, and that from the patient's point of view, the lifestyle burden that maintenance dialysis will place on him or her and the family, when viewed against the perspective of worsening symptoms and/or death without provision of dialysis, now becomes acceptable.

Patient education, CV risk factor management, anemia management, vascular access placement, and timing of the initiation of HD are all critical to patient care. Some of the issues touched on above, though relevant to the management and planning stages of dialysis preparation (such as delaying the progression of disease and the details of kidney transplant planning), are outside the scope of this chapter.

PATIENT EDUCATION

A distressing and repeated observation is that the majority of patients starting HD have not been through a formal pre-ESRD teaching program designed to prepare them for transition to initiation of dialysis. Many patients report not having been made aware of modality choices other than thrice weekly in-center HD, including self-care in-center HD, home HD, nocturnal HD, PD, or KTx. The information gap regarding CKD and its treatment modalities appears more pronounced among African Americans.[13,14] The majority of patients starting HD in the US continue to begin treatment with a central venous (tunneled) catheter, as opposed to a permanent arteriovenous vascular access, whether native vein or synthetic graft.

Nevertheless, it has been repeatedly observed in multiple studies that formal pre-ESRD educational programs for patients and families result in a higher percentage of patients opting for home-based therapies; a higher percentage of patients beginning treatment with a mature, functioning vascular access, and more favorable nutritional status (assessed by S[Alb] or other parameters) at the time of dialysis start; and decreased need for emergent, hospital-based initiation of treatment, fewer hospitalizations at one year, and overall cost savings per patient during the first year of dialysis.[15–21]

Several studies have also demonstrated improved survival among patients managed before the initiation of dialysis by multidisciplinary approaches aimed at educating the patient regarding modality choice, dietary interventions, blood pressure control, and emphasis on timely vascular access placement.[20,22,23] Devins et al. reported 20-year follow-up of a cohort of patients who had been randomized in the mid-1980s to predialysis psychoeducational interventions aimed at increasing patients' knowledge of CKD and its treatment vs. usual care. These investigators found that patients who received predialysis CKD education survived a median of over 2 years longer than those assigned to usual care. Following initiation of dialysis, survival was 8 months

longer in those having received CKD education, compared to the usual care group.[24] Barriers to implementation of such predialysis educational programs are not clear, but probably include a combination of physician and institutional inertia, and the perception that implementation of such programs may prove prohibitively costly. Nevertheless, because of the evidence supporting implementation of such programs on patient outcomes and ESRD program-wide costs, the Centers for Medicare and Medicaid Services (CMS) has implemented financial incentives to foster growth of such programs. It is hoped that with ongoing, cumulative evidence demonstrating enhanced patient outcomes and cost savings, comprehensive predialysis patient education programs will become increasingly prevalent and become standard of care.

Comprehensive education regarding treatment options in ESRD should not neglect a discussion of possible conservative, nondialytic management, such as nonprovision of RRT. However, when given a choice between prolongation of life with maintenance dialysis and nonprovision or RRT (which in nearly all patients with progressive CKD would temporally hasten their demise) most patients opt for dialysis, even bearing in mind the hardships associated with the procedure. For example, for the very elderly patient with advanced CKD or persons with multiple, significant comorbidities (e.g. active, metastatic cancer), especially when functional status is impaired and life expectancy correspondingly limited, conservative, nondialytic management focused on symptom control may be more appropriate. Kurella Tamura et al. published a study in which functional capacity and mortality were examined in a national cohort ($n = 3702$) of nursing home residents initiating dialysis. Mortality one year after initiation of dialysis was a staggering 58%. Initiation of dialysis was associated with functional decline, regardless of the patient's "functional trajectory" (the ability to perform activities of daily living) during the 3 months preceding initiation of dialysis. One year after starting dialysis, only one in eight patients maintained or improved his or her functional status relative to the start of dialysis.[25]

Elderly patients with multiple comorbidities who initiate HD have a higher likelihood of dying in an acute care facility, often in a critical care setting. The choice of conservative, nondialytic management for patients with progressive CKD recognizes that some patients may prefer a shorter life expectancy, with fewer procedures, less time-consuming therapies, and equivalent or improved quality of life.[26]

The choice of conservative, nondialytic management in advanced CKD implies an understanding between patient and provider that on the one hand, lack of provision of dialysis is likely to be associated with shortened life expectancy. How much so, of course, depends on the disease trajectory of the individual patient. Moreover, pursuing conservative, nondialytic management ideally should result in a concerted effort between the patient and a dedicated nephrology-sensitive palliative care team to address the many symptoms that inevitably develop as kidney function declines. Murtagh et al. reported on a UK-based cohort of 66 elderly patients with stage 5 CKD being managed conservatively. The mean age was 82 years, and mean eGFR was 11 mL/min/1.73 m^2. The most common symptoms reported by patients were fatigue, pruritus, dyspnea, edema, generalized pain, muscle cramps, restless leg syndrome, diminished appetite, inability to concentrate, and sleep disturbance.[27] An individual office-based nephrologist, acting alone, cannot reasonably be expected to successfully address the many day-to-day issues that come up during the progressive decline of such patients.

Students and trainees commonly form the notion that death from untreated uremia is a "slow, peaceful" way to die. As practitioners, we rarely have encountered such situations where patients seem to slip painlessly and quietly into a comatose state and then expire. More commonly, the terminal event in untreated uremia—especially among those not followed closely in CKD clinic or who fail to adhere to dialysis planning—is either sudden cardiac death in the setting of electrolyte imbalance (for example hyperkalemia) or the more distressing picture of acute pulmonary edema. A carefully structured approach by a palliative care team well-versed in the specific needs of the patient with stage 5 CKD can address most of the symptoms such patients are likely to develop.

Most importantly, with judicious use of diuretics, vasodilators, and narcotic analgesics (of which low-dose oxycodone, hydromorphone, and fentanyl may be best tolerated), it should be possible to alleviate the particularly troublesome signs and symptoms of volume overload leading to pulmonary edema, which might otherwise prompt patients (and distressed, on-looking family members) to reverse a deliberately decided-upon course and request emergency care including acute dialysis.[28]

CARDIOVASCULAR RISK FACTOR MANAGEMENT

CV events account for more than 50% of premature deaths among patients receiving HD, including in particular heart failure, stroke, and sudden cardiac death. The excess burden of CVD applies to the predialysis population as well. Nephrologists caring for the patient with advanced CKD need to have a heightened awareness of the excess CV risk in this patient

population. Where possible, nephrologists must address modifiable risk factors, so that as kidney function declines and the patient approaches the need for dialysis, mortality, and morbidity associated with CV risk can be attenuated.

The last several years have seen an increased awareness of the contribution of nondialysis-requiring CKD, even at its early stages (albuminuria, or mild reductions in eGFR), to increased CV risk. Moreover, the association remains strong even in the absence of traditional risk factors such as diabetes, hypertension, dyslipidemia, and smoking.[29]

Foley et al. reported on a 5% sample of the US Medicare population (n = 1,091,201), examining the relation between CKD and diabetes mellitus with respect to CV risk, defined as atherosclerotic heart disease, congestive heart failure, and overall mortality risk. Patients were divided into four groups: those without either diabetes or CKD (79%), those with diabetes but no CKD (16%), those with CKD but no diabetes (2.2%), and those with both diabetes and CKD (1.4%). Over a 2-year follow-up period, rates per 100 patient-years for developing atherosclerotic heart disease, heart failure, and all-cause mortality were higher for patients with CKD and no diabetes (35% vs. 25%, 30% vs. 18%, and 17% vs. 8%, respectively). For patients with both diabetes and CKD, event rates were higher still at 49%, 52%, and 19%, respectively.[30] These findings were confirmed in a recent large Canadian study (n = 1,268,029), again examining the interplay between diabetes and CKD, with regard to CV risk, specifically risk of myocardial infarction (MI), with the reference group against which DM and CKD risk were compared being those with prior MI. Risk of MI was highest in patients with prior MI, regardless of DM or CKD status. Here also, CKD proved to be a stronger predictor for MI than diabetes. In patients with more advanced CKD (GFR <45 mL/min/1.73 m^2), or heavy proteinuria (>300 mg/g creatinine), the risk of MI was roughly twice that compared to the group with diabetes but without CKD (12.4 vs. 6.6 events per 1000 patient-years).[31] Thus, the presence of CKD alone appears to be a stronger predictor of CV events and all-cause mortality than diabetes mellitus. The presence of both conditions is associated with even higher risk, particularly for atherosclerotic disease and heart failure. This risk of CV-related mortality has been shown in multiple studies to increase exponentially as GFR declines, even applied to the earliest stages of CKD.[32–34]

The causes of this increased CV risk remain incompletely understood. In the CKD population, it has been estimated that traditional risk factors for CV-related morbidity and mortality account for only about 50% of risk.[35] CKD-specific physiologic derangements contributing to this increased risk of CV events are still only partially understood. Factors such as increased sympathetic hyperactivity, resistant hypertension, left ventricular hypertrophy, proteinuria and associated hypercoaguable states, oxidative stress, inflammation, malnutrition, and the effects of disordered mineral bone metabolism (hyperphosphatemia, vitamin D deficiency, and abnormal circulating levels of fibroblast growth factor-23 and soluble klotho), leading to vascular calcification and left ventricular hypertrophy, are believed to contribute to this risk.[36–46]

Preparation of the patient with advanced CKD for HD, therefore, involves early and careful attention on the nephrologist's part toward treatment and optimization of modifiable risk factors that have been shown in well-designed studies (nearly all of which were implemented in patients with normal, near normal, or only mildly impaired kidney function) to reduce CV risk.

Goals of management should be aimed at decreasing CV events during the evolution of CKD progression, preserving CV health during later stages of CKD, and to the extent that multiple CV risk factors also affect progression of CKD (such as hypertension, diabetes, and smoking), trying to delay progression of CKD where possible. As the patient approaches the time for planning RRT, the nephrologist should have a thorough knowledge of the patient's CV status, including left and right ventricular function, ischemic burden, presence or absence of left ventricular hypertrophy, history of heart failure, and the presence or absence of significant valvular heart disease, as these may influence dialysis modality choice and help the clinician envision a dialysis regimen that optimizes hypertension control and minimizes risk of heart failure, stroke, atrial and ventricular arrhythmia, endocarditis, and sudden death. Although much has been learned over the past few decades regarding the putative mechanisms of increased CV risk in CKD, the relative contributions of these various physiologic derangements, and their interactions, remain areas of intense investigation, and many questions remain unanswered. Care must be taken to interpret available and emerging data to provide an evidence-based rationale for treatment aimed at reducing CV risk.

What data from well-designed clinical trials can help guide the nephrologist during the care of the patient with progressive CKD to alleviate CV risk? The few CV clinical trials conducted specifically in patients with moderate to advanced CKD have focused on slowing progressive loss of kidney function. Few have focused on modification of CV risk. Indeed, most of the evidence on which we base our practice comes either from extrapolation of clinical trials conducted in the general population or from subgroup analyses of larger clinical trials.[47]

The Study of Heart and Renal Protection trial, addressing the treatment of hypercholesterolemia, randomized 9270 patients (6247 with nondialysis-requiring CKD and 3023 with ESRD) to simvastatin-ezetimibe vs. placebo. Active cholesterol-lowering resulted in a 17% (95% CI 6–26%) reduction in the rate of major atherosclerotic events (nonfatal MI, nonhemorrhagic stroke, any arterial revascularization, or coronary death). Results remained statistically significant in patients with stage 4 CKD (corresponding rate reduction 22%, 95% CI 2–38%).[48]

Several subgroup analyses of heart failure trials have demonstrated consistent benefits of beta-adrenergic antagonists and inhibitors of the RAAS among patients with and without CKD, although few patients in these trials had advanced CKD.[49–52]

The net benefits and risks of aspirin and other antiplatelet agents in patients with advanced CKD are unknown. In a *post hoc* subgroup analysis of the Hypertension Optimal Treatment trial, CV events were reduced by 66% (95% CI 33–83%) and mortality was reduced by 49% (95% CI 6–73%) in patients treated with aspirin. Major bleeding events were modestly increased.

A recent meta-analysis conducted by the Blood Pressure Lowering Treatment Trialists' Collaboration pooled randomized clinical trials completed between 1995 and 2012 that compared two or more active blood pressure–lowering medications, active medications with placebo, or different targets for blood pressure lowering, aiming to determine the importance of blood pressure lowering (and the specific agents used) on CV outcomes. The primary outcome of the meta-analysis was major CV events, defined as the first episode of stroke, coronary heart disease, heart failure, and CV death. Of more than 150,000 participants from 25 clinical trials, 20% had CKD, defined as an eGFR below 60 mL/min/1.73 m^2. Results showed statistically significant and substantial lowering of CV risk with blood pressure lowering, with no obvious difference by antihypertensive drug class. Unfortunately, fewer than one-half of one percent of patients included in this meta-analysis had eGFR below 30 mL/min/1.73 m^2 at baseline.[53]

Although the evidence is relatively sparse, based on the data outlined above and our clinical experience, we usually advise the use of low-dose aspirin, statins, and antihypertensive therapy for CV risk reduction in patients with advanced CKD preparing for dialysis or KTx. We generally favor the use of RAAS inhibitors in combination with diuretic agents and/or beta-adrenergic antagonists, given the potential to attenuate progression and the frequency with which we observe coincident volume overload and heart failure. We generally consider calcium channel blockers, alpha-adrenergic antagonists, and other drugs as third or fourth or fifth line agents for patients with refractory hypertension or other associated health conditions (such as benign prostatic hyperplasia with urinary retention). We recommend mindful limitation of salt intake, despite the confusion and ambiguity introduced with the recent Institute of Medicine report.[54]

ANEMIA MANAGEMENT

We address certain points regarding the use of erythropoiesis stimulating agents (ESAs) and other agents to correct anemia associated with CKD, as they pertain to the preparation of the patient-planning initiation of HD.

The story of the discovery of erythropoietin (EPO), its physiologic regulation, and mechanisms of action (not just on erythrocyte precursors but on target organs throughout the body) is an ongoing and exciting one, with original discoveries pointing to the existence of a circulating, erythropoiesis stimulating factor in the serum, dating to the end of the 19th century.[55,56] The cloning of the EPO gene,[57,58] followed soon after by the introduction of the use of recombinant human EPO to treat the anemia associated with ESRD[59,60] revolutionized the field of clinical nephrology by greatly reducing the need for frequent red blood cell transfusions in patients receiving dialysis. Recognized complications of the frequent transfusions included transmission of infectious diseases (HIV and hepatitis B and C virus infections), systemic iron overload leading to hepatic and cardiac dysfunction, and anti-HLA allosensitization.

Clinical use of ESAs eventually extended to the population of patients with nondialysis-requiring CKD, so that symptomatic anemia could be averted and allowing initiation of dialysis under conditions not requiring transfusion. The optimal target hematocrit or hemoglobin concentration has been a matter of much debate over the past several years, due to the unexpected findings of increased CV morbidity associated with higher hemoglobin concentrations, although specific adverse CV events have not been consistently observed in different trials. The reason(s) for CV morbidity related to ESA use is still a matter under intense investigation.[61–63]

We consider that optimal medical management of the patient with advanced CKD approaching HD should result, among other things, in the patient not requiring blood product administration during the course of their CKD leading up to dialysis initiation. More specifically, this recommendation applies to patients who meet criteria for future KTx. Not uncommonly, patients with limited or inadequate access to comprehensive CKD management eventually present with advanced uremia in the terminal phases of CKD, often accompanied by

severe, symptomatic anemia, prompting transfusion when hospitalized and dialysis is initiated.

Soon after the broad introduction of transplantation in the 1960s and 1970s, it was recognized that prior blood transfusion during a patient's period of dialysis requirement resulted in the development of immune sensitization against HLA antigens, and that this resulted in longer waiting times for transplantation. These effects were reversed following widespread implementation of ESAs, beginning after the approval of recombinant erythropoietin (epoetin alfa, or EPO) in the late 1980s.

Grimm et al. reported on a group of five dialysis-dependent pediatric patients who, after the introduction of EPO and the subsequent elimination of "chronic antigenic stimulation" from blood transfusions, demonstrated marked reductions in anti-HLA antibody titers and a mean reduction in percent panel reactive antibodies from 80% to 56%, while a control group matched for age, prior transfusion dependence, and sensitization status, showed no reduction in anti-HLA titer or percent PRA.[64] Subsequently, Vella et al. reported on a cohort of patients receiving dialysis before and then four years after introduction of EPO. Compared to patients receiving dialysis in the pre-EPO era, these authors noted a decrease in the number of transfusions per dialysis treatment from 0.095 to 0.06, representing a relative reduction of 36%. They also found a decrease in the number of patients being sensitized from 63% to 28%, and a resultant decrease in mean waiting time to transplant from 42 to 15 months during that era (current waiting times are considerably longer).[65]

More contemporary methodologies for assessing anti-HLA antibodies have confirmed these earlier findings and highlighted the extent, magnitude, and specificity of anti-HLA antibody formation resulting from transfusion in dialysis patients. Yabu et al. recently analyzed data on patients from our center, linking local data with the US Renal Data System (USRDS), comparing transfused and nontransfused patients awaiting primary KTx, and who had at least two HLA antibody measurements using the Luminex single-antigen bead assay (including before and after transfusion, in the transfused cohort). Twenty percent of transfused patients vs. 4% of nontransfused patients demonstrated an interval increase of at least 10 anti-HLA antibodies, meeting the cutoff of >3000 mean fluorescent intensity (MFI). Of the 50 transfused patients, 6 (12%) demonstrated an increase of 30 anti-HLA antibodies above an MFI of 3000.[66]

Such findings underscore the important adverse effect of blood product administration on HLA sensitization in patients with advanced CKD. It is during the weeks and months preceding the initiation of dialysis that these issues become paramount. Prolonged waiting time on the transplant list due to sensitized status from blood transfusion exposes the patient to increased risks of dialysis-related morbid events (primarily CV and/or infectious), which not uncommonly render the patient subsequently unsuitable for transplantation. A recent review of published studies in the postcyclosporine era has confirmed the deleterious effects of transfusion on anti-HLA sensitization, time to transplantation resulting from sensitization, and increased risk of rejection and decreased overall graft survival among patients sensitized from prior transfusion.[67] Modification of prioritization (the Kidney Allocation System) introduced in December 2014 aims to correct the disadvantages faced by sensitized patients awaiting KTx. Avoiding transfusion in the months and weeks preceding dialysis initiation, nevertheless, remains advisable.

Increased CV morbidity in clinical trial participants targeted to higher hemoglobin or hematocrit targets, along with the changes in CMS reimbursement patterns implemented in 2011, have resulted in the majority of patients being maintained at lower hemoglobin concentrations. At least among patients receiving maintenance HD, lower target hemoglobin concentrations have resulted in a higher frequency of blood transfusions since that time. Findings from the Dialysis Outcomes and Practice Patterns Study indicated a more than doubling of blood transfusions from 2.21% of patients transfused per month in September 2010 to 4.87% of patients transfused per month in September 2011. Data in the US using Medicare claims showed a similar increase in transfusions following introduction of the Prospective Payment System ("bundling") and modification of product labels for ESAs highlighting CV risks. Legitimate concern has grown that an unintended effect of these changes in practice will lead to more patients being transfused, and therefore at risk for sensitization, with consequent prolongation of time to transplantation.[68]

Extending these observations and considerations to the predialysis population, we recommend careful adherence to KDOQI guidelines regarding anemia management. Goals include avoiding the development of symptomatic anemia, preventing over-correction of anemia (which has been shown to be associated with higher CV risk and possibly accelerated decline of GFR), and readying the patient for HD without prior need for transfusion, to the extent that this may affect HLA sensitization status and adversely affect time to transplantation.

VASCULAR ACCESS MANAGEMENT

Experienced nephrologists who care for patients with ESRD will readily recognize that issues surrounding vascular access represent the "Achilles heel" for the patient requiring HD (Table 70.1). Options for vascular

TABLE 70.1 Complications of Vascular Access Catheters

All catheters
Patient discomfort, cosmetic inconvenience, adhesive dressing allergic reactions
Heightened mortality compared with patients initiated with noncatheter vascular access
Internal jugular and/or subclavian catheter (tunneled and nontunneled)
Internal jugular vein thrombosis
Subclavian vein thrombosis → interference with placement of permanent upper extremity vascular access
Superior vena cava syndrome
Distal catheter tip clot with risk of pulmonary embolus
Septic phlebitis
Catheter-associated bacteremia with or without metastatic infection
endocarditis
paraspinal abscess
vertebral osteomyelitis
septic joint
Exit site infection with or without tunnel infection (abscess)
Pneumothorax
Femoral vein temporary catheter
Retroperitoneal bleeding
Inadvertent femoral artery cannulation with pseudoaneurysm formation
Lower extremity DVT

access in maintenance HD patients include the native AVF, synthetic AVGs, and central venous catheters (CVCs). Preparing the patient with advanced CKD for initiation of maintenance HD necessarily involves a careful, patient-centered approach to timely placement of a suitable vascular access that is ready for use when initiation of dialysis is indicated.

When possible, creation of an AVF is the preferred form of vascular access because compared with AVGs and CVCs, AVFs are associated with greater long-term patency rates, decreased need for interventional procedures to maintain patency, decreased rates of infection, decreased rates of hospitalization, decreased overall cost, and, importantly, decreased patient mortality. AVGs do not technically require time to "mature" (i.e. arterialize), although it may take several weeks before local inflammation subsides and the graft can be safely cannulated with minimal discomfort. Some practitioners recommend several weeks of healing without cannulation to allow for migration of endothelial cells although the optimal timing of first graft cannulation is unknown. Relative to AVFs, AVGs are more prone to thrombosis and outflow stenosis due to neointimal hyperplasia, leading to the need sometimes for interventional procedures (often multiple) to reestablish and maintain patency.

CVCs can be placed and be ready for use on a same-day basis when the patient starts HD, yet are associated with multiple short-term and long-term complications (Table 70.1). Infection remains the most important drawback of CVCs. CVC-associated infection can be in the form of a relatively straightforward exit site infection, subcutaneous tunnel infection (which essentially is an abscess-equivalent and generally requires removal of the catheter and sometimes surgical drainage of the infected collection), and catheter-associated bacteremia. HD CVC–associated bacteremias are associated with substantial morbidity and mortality. Sepsis and septic shock may develop in the context of dialysis CVC-associated bacteremia. Metastatic infection including endocarditis, paraspinal abscess, vertebral osteomyelitis, and septic joint are relatively frequent complications of CVC-associated bacteremia. In addition to infectious complications, long-term use of CVCs is associated with development of other vascular complications, including subclavian and internal jugular vein thrombosis, leading to the need for systemic anticoagulation. Superior vena cava syndrome may also develop in patients using CVCs. These vascular complications subsequently render future placement of noncatheter forms of access far more difficult.

These observations have led to several initiatives and guideline-based recommendations to encourage efforts at timely and successful placement of AVFs. Nevertheless, in the US, the most common form of vascular access in incident HD patients remains the CVC. Foley et al. analyzed data regarding type of vascular access at the time of initiation of dialysis in patients starting dialysis for the period June 2005 through October 2007 (n = 220,157), obtained from the Centers for Medicare and Medicaid Services Medical Evidence Report (Form CMS-2728). Only 13% of patients began dialysis with a functioning AVF; 4% began with an AVG; 16% had a CVC with maturing fistula; 3.3% had a CVC with a maturing graft; and the majority, 63.2%, had a CVC alone. Compared with those patients beginning dialysis with a functioning fistula, adjusted mortality hazard ratios (HRs) were 1.39 for AVGs, 1.49 for catheter with maturing AVF, 1.74 for catheter with maturing AVG, and 2.18 for catheter alone.[69] Bray et al. reported on a prospective cohort of all patients starting dialysis in Scotland for the years 2009 through 2011 (n = 2666). Patients dialyzing through a CVC alone were found to have a higher risk of all-cause mortality, including that attributed to CV death as well as infectious causes.

The odds of dying from sepsis were 6.9-fold higher among those dialyzing through a CVC compared with those using an AVF or AVG.[70] A review of 67 cohort studies including 586,337 patients similarly demonstrated higher risks for all-cause mortality, fatal infections, and CV events in patients dialyzing with a CVC opposed to either AVG or AVF.[71]

A critique of many of the observational studies on the relation between vascular access type and mortality risk has centered on the issue of selection bias. Specifically, it is unclear whether or not underlying health status plays a role in eventual type of vascular access at the time of dialysis initiation, which in turn would account for mortality risk. Grubbs et al., looking at 117,277 patients starting dialysis from the USRDS for the period 2005–2007, examined the relation between functional status and number of hospital days in the 2 years prior to dialysis initiation, with respect to type of vascular access at dialysis initiation and subsequent mortality risk. Confirming results from other studies, these authors demonstrated increased mortality risk compared with patients starting dialysis with an AVF, among those starting with an AVG (HR 1.20), catheter plus maturing AVF (HR 1.34), catheter plus "maturing" AVG (HR 1.46), and catheter alone (HR 1.95). They also showed that functional status was strongly associated with access type at dialysis initiation, with previously "sicker" patients more likely to start dialysis with a CVC, whereas the "healthier" patients were more likely to have had a functioning AVF. Mortality risk therefore appears to be modulated not just by type of access at dialysis initiation, but by underlying health status, which in turn appears to correlate with eventual form of access placement.[72]

In addition to underlying health status predating initiation of dialysis, age at initiation of dialysis is strongly associated with type of initial vascular access and subsequent mortality risk. Although the studies cited above show heightened mortality risk associated with CVC use in all patients starting HD regardless of age, when stratified according to access type (highest risk in catheter alone > catheter with maturing AVG > catheter with maturing AVF > AVG alone > AVF alone), DeSilva et al. analyzed data on 115,425 patients above the age of 67. For patients aged 67–79 years, the HR for mortality among those with an AVG as opposed to AVF as first access placed was only marginally worse (HR 1.10), and there was no difference in patients 80 years or older.[73] These results suggest that the net benefit of AVF in older patients is attenuated, possibly related to the lower fraction of AVFs maturing to clinical use. Even among those elderly patients whose AVF does successfully mature, the prolonged use of CVCs pending AVF maturation exposes patients to the many infectious and CV-related adverse events associated with CVCs, such that the strategy in vascular access planning (at least for the elderly CKD patient) has shifted from "fistula first" to "catheter last."

The technical challenges in creating a functional native AVF appear to be more pronounced in the elderly. Several studies have shown a higher rate of primary nonfunction of native AVF placement as patients' age increases, with the result that a higher percentage of such patients will arrive at the need for dialysis requiring either AVG, catheter with maturing AVG, or catheter alone.[74,75] A growing concern is that strict adherence to KDOQI guidelines during ESRD planning in the stage 4 CKD population, when applied to the elderly, may result in an increased rate of failed attempts at AVF creation, while waiting for later placement of an AVG may be a reasonable approach. Moreover, depending on the age of the patient, underlying health status, and trajectory of the progression of CKD, there are many patients with late-stage CKD who die before requiring initiating dialysis, raising concern that many well-intended and guideline-based referrals for access placement in selected patients are futile and current practice should be reassessed. Death with a functional (but never-used) AVF or AVG is an outcome that should ideally be avoided.[76,77] Careful consideration must therefore be paid to the patient's age, life expectancy, and underlying functional status when planning vascular access. Although the "fistula first" initiative represents a sound approach to vascular access planning for younger patients and those with more robust underlying functional status, increasingly, emphasis is being placed on "catheter last," particularly in the elderly, in whom primary placement of an AVG may be an acceptable option. The reader is referred to recent elegant reviews summarizing the dilemmas, particularly surrounding the issue of vascular access placement, faced by the nephrologist caring for the elderly CKD patient.[78,79]

We recommend a patient-centered approach, bearing in mind age and functional status, particularly as we care for an ever-growing population of elderly patients with late stage CKD, in whom the anticipated probability of death prior to need for initiation of dialysis, the inherently high failure rate of primary AVF placement, and what appear to be equivalent mortality outcomes between AVF and AVG, all need to be part of the decision-making process. In younger and more robust patients, because of the overwhelming evidence implicating CVC use as a cause of increased all-cause, infectious, and CV mortality, and because of the confirmed benefit in nonelderly patients of AVF over AVG, we recommend adhering to standard guidelines emphasizing early referral to vascular surgery, at least 6 months before anticipated need for dialysis initiation, to allow maturation of the AVF. This approach also takes into account the relatively high rates of primary access

failure in AVFs, leading to the need for interventional procedures and/or revision surgery, such that ample time is allowed for maturation of a functional AVF at the time of dialysis start. Standard recommendations regarding avoidance of blood draws or IV placements above the wrist, where possible, should be adhered to, as well as avoiding placement of peripherally inserted central catheters, as these carry the risk of phlebitis and thrombosis, which can interfere with creation or placement of permanent vascular access in the affected arm.

TIMING OF THE INITIATION OF HEMODIALYSIS

Once the patient and nephrologist have agreed on eventual initiation of maintenance HD, the patient will logically ask, "when should I begin?" Without meaning to be facetious, one might reply to the patient, "not too early, but not too late"—and this of course would be an accurate response. A more refined and articulate answer might be, "When the benefits of dialysis to your health and survival begin to outweigh the risks and hardships associated with the procedure." The goal should be to preserve patient autonomy as long as possible, free of the requirement for maintenance dialysis and its many restrictions on lifestyle, as long as this does not expose the patient to either short-term or long-term morbidity (or mortality) that would result from lack of provision of dialysis. For most patients with progressive CKD, once they start dialysis, there is "no turning back" (ability to safely come off dialysis for an extended period of time). Therefore, our responsibility is to give our best recommendations to the patient based on science, where available; art, to the extent that there is no "one size fits all" answer to this question; and compassion, bearing in mind that institution of our treatment plan will have wide-ranging lifestyle consequences for the patient and his or her family. How do we come up with a more rational answer to this question? Is there high-quality evidence on which we can we rely to inform our recommendations?

Ultimately of course, the timing of dialysis initiation must be tailored to the individual patient. A common question from patients is, "At what creatinine will I need to start dialysis?" The S[Cr], or its derived eGFR for the patient in question, is only one of many considerations that come into play when deciding on the timing of dialysis initiation. For example, not all patients predictably develop dialysis-responsive uremic symptoms at the same level of eGFR. Occasionally, patients with relatively preserved eGFR (e.g. >10 mL/min/1.73 m^2) and lack of traditional uremic symptoms may have problems with volume management and recurrent hospitalizations for pulmonary edema in spite of maximal medical therapy, due to significant comorbid structural heart disease—most commonly left ventricular hypertrophy with diastolic dysfunction, systolic heart failure, or pulmonary hypertension with severe right-sided congestive symptoms including anasarca. Such patients may benefit from earlier dialysis initiation, to the extent that serial ultrafiltration may help bring the patient closer to his or her optimal volume status and thereby break the cycle of frequent rehospitalizations for heart failure exacerbation.

An important goal of managing the patient with advanced CKD is to avoid initiation of dialysis when the patient has become particularly decompensated requiring emergency hospitalization. The costs associated with "crash landing" initiations are necessarily much higher than outpatient, elective initiations, and significant morbidity may develop in the hospital setting including nosocomial infection. On the other hand, initiation of dialysis before true benefit accrues to the patient, intuitively does not make sense, only adds to cost of delivery of care and deprives the patient of whatever freedom from dialysist may reasonably persist with ongoing close medical supervision.

A common observation during the past few decades had been a trend toward earlier start of patients on dialysis (both HD and PD), often at eGFRs greater than 10 mL/min/1.73 m^2. This practice has probably been based on the supposition that earlier institution of therapy would enhance rehabilitation and prevent complications through a preemptive approach, avoiding the various manifestations uremic toxicity, before they become fully manifest. Hard evidence supporting such a practice, however, has been lacking. Key questions to be addressed include does timing of initiation of dialysis significantly affect patient morbidity and symptomatology? Does timing of initiation of dialysis affect patient mortality? What are the implications of practice guidelines regarding timing of dialysis initiation, in terms of global cost of care to society?

The landmark Initiating Dialysis Early and Late (IDEAL) study examined these questions in some detail.[80] IDEAL was a randomized, multicenter study that examined the effects on mortality from any cause among groups assigned to early-start dialysis (eGFR 10−14 mL/min/1.73 m^2) vs. those in the late-start group (5−7 mL/min/1.73 m^2). The primary outcome was death from any cause. Patients planning both HD and PD were included. Median time to start was 1.8 vs. 7.4 months in the early and late groups, respectively. The median time of follow-up was 3.5 years. The authors observed no significant difference in mortality between those assigned to early start (37.6%) vs. late start (36.6%). Moreover, there was no observed difference in the incidence of CV events, infectious

disease complications, or other dialysis-related complications. A potential limitation of this study, however, is that a substantial number of patients (75.9%) assigned to the late-start group actually needed to start dialysis above the preassigned cutoff of 7 mL/min/1.73 m^2, due to interval development of uremic symptoms. Whether or not a between-group mortality difference would have emerged had these patients actually waited to start dialysis until they reached the late-start eGFR cutoff of 5–7 mL/min/1.73 m^2, is uncertain. In other words, one could criticize IDEAL in that it compared very early start with relatively early start, rather than late start, and the modest separation in kidney function between groups resulted in an underpowered study. Nevertheless, based on the IDEAL results, there is no clinical trials–based evidence to support a very early preemptive initiation of dialysis strategy. It is noteworthy that left ventricular hypertrophy was present in a large fraction of IDEAL participants at the time of study enrollment. A substudy found no difference in left ventricular hypertrophy regression or progression at 12 months.[81] There was no significant difference in mortality, CV events, infections, or access related complications, restricting analysis to those patients in IDEAL who eventually underwent HD as a modality choice. Fluid and electrolyte complications were more common, however, among patients randomized to the "late" start group.[82]

Whether or not these findings apply to a generally healthier population of prospective HD patients—those without diabetes and for whom the only significant comorbid condition in addition to CKD was hypertension—was examined in a large cohort of 81,176 patients starting in-center HD by Rosansky et al.[83] The reference group included those patients assigned to dialysis initiation at an eGFR <5 mL/min/1.73 m^2, who were compared across various strata of ever-increasing eGFRs at time of dialysis initiation, with the highest group being those with eGFR >15 mL/min/1.73 m^2. Among these patients with limited comorbidity, unadjusted 1-year mortality for the reference group was 6.8%, while in the patients with eGFR >15 mL/min/1.73 m^2 was 20.1%. Adjusted mortality hazards were progressively higher among patients starting dialysis at higher eGFR. These findings contradict those reported in the IDEAL study and suggest either that earlier start of dialysis may be harmful—at least in this select group of nondiabetic patients—or, most likely, that there is confounding by indication. In other words, patients sicker in ways that were not measured and/or adjusted for received dialysis earlier. Although confounding is likely to explain the findings reported by Rosansky et al., one should consider the possibility that early initiation of dialysis may in fact be harmful. In addition to risks associated with creation or placement of vascular access, initiation of HD may accelerate loss of residual kidney function or lead to other untoward effects.

Taken together, these observations suggest that in the majority of patients, initiation of HD can be delayed until eGFR is somewhere between 5–10 mL/min/1.73 m^2, but that the ultimate decision should be patient-specific. Initiation of dialysis at eGFRs closer to 10 mL/min/1.73 m^2 is reasonable if unequivocal symptoms of uremia have begun to develop. Special populations, such as those with heart failure, may also benefit from earlier initiation, for volume control. For the majority of patients, initiation of dialysis at eGFR greater than 10 mL/min/1.73 m^2 appears to confer no survival benefit, is associated with increased cost, and in the nondiabetic subgroups, may actually be associated with higher 1-year mortality risk.

CONCLUSION

Decisions regarding the initiation of RRT are critical in the relationships among nephrologists, patients, family members, and other health personnel. The transition from CKD to ESRD requires the nephrologist to have a clear understanding of the disease trajectory in the individual patient, and to function as a teacher for the patient and the important members of his or her family, and professional and social networks. Recent advances in clinical research allow the nephrologist to advise patients regarding timing of initiation of HD, and factors related to successful creation of vascular access, which will promote the best health outcomes. The nephrologist, while managing a complex set of medical problems in patients with late stages of CKD, can play a key role in determining the characteristics of the start of RRT with HD. Patient education, CV risk factor management, anemia management, vascular access placement, and timing the initiation of HD are all critical to patient care. When these issues are properly addressed, the safe and successful initiation of HD may be more likely.

QUESTIONS AND ANSWERS

Question 1

You are following a 62-year-old man with progressive CKD secondary to diabetic nephropathy. His current eGFR is 22 mL/min/1.73 m^2. He comes to clinic to discuss renal replacement options.

Which **one** of the following is true regarding his options for dialysis?

A. PD is associated with enhanced survival compared to HD
B. HD is a less costly form of RRT
C. PD is associated with preservation of residual kidney function
D. HD is associated with superior quality of life and patient independence

Answer: C

PD is associated with preservation of residual kidney function. This is important because persistence of residual kidney function is associated with improved fluid and blood pressure control, phosphate and middle molecule clearance, nutritional status, and attenuation of left ventricular hypertrophy and CV risk, decreased inflammatory markers, and prolonged survival.[6–8] Answer A is incorrect as long-term survival among patients receiving HD and PD are generally similar. PD is typically associated with improved perception of quality of life and patient independence and is less costly on an annual basis than HD making Answers B and D incorrect.[4,5]

Question 2

In preparing for RRT, discussions should take place with the patient and family regarding which of the following:

A. Symptomatic consequences of progressive kidney failure
B. The different modalities of RRT including HD, PD, and KTx
C. The expected scheduling and logistic requirements
D. Dietary restrictions with which the patient will need to adhere
E. All of the above

Answer: E

From the educational point of view, the patient and family should have a reasonable understanding of the functional and symptomatic consequences of progressive kidney failure. Patients and families should have a good understanding of the various modalities of RRT, with the eventual modality choice being tailored to the individual circumstances, taking into account medical and surgical comorbidities, age and projected life expectancy, lifestyle and occupation, social support system, and of course, personal choice. Patients should have a reasonable set of expectations regarding what HD can and cannot replace for the failing kidneys. Patients should have a clear understanding of the scheduling and logistic requirements that will be expected and how new dietary restrictions will be necessary. For selected patients, because of either advanced age or other significant co-morbid conditions, there should be an understanding that a conservative, symptom-based and comfort-driven approach may be preferred.

Question 3

Which one of the following is true regarding referring patients for KTx?

A. Patients should be treated with HD for at least one year before they are referred for consideration of KTx
B. Patients can be on the deceased donor waiting list when their eGFR is $\leq$20 mL/min/1.73 m^2
C. Patients must be started on dialysis before they qualify for listing on the deceased donor waiting list
D. Patients can be first placed on the deceased donor waiting list when their eGFR is $\leq$10 mL/min/1.73 m^2

Answer: B

For those patients deemed to be medically and otherwise suitable for transplantation, they should, ideally, be seen and evaluated by a local transplant center and listed for deceased donor transplantation. This should occur well before the actual time of dialysis initiation because an eGFR of 20 mL/min/1.73 m^2 or less qualifies a patient for transplant listing with the UNOS making Answer B true and Answers A, C, and D incorrect. Waiting to refer for transplantation until dialysis is initiated, when eGFR is much lower than 20 mL/min/1.73 m^2, essentially deprives the patient of valuable time (sometimes on the order of years, for those with more slowly progressive CKD) that could otherwise accrue on the deceased donor waiting list. This has the effect of prolonging the waiting time for eventual transplantation and exposing patients to potential interval development of dialysis-related morbid events, not uncommonly rendering them unsuitable for transplantation. Referral for transplantation is appropriate when eGFR is between 20–25 mL/min/1.73 m^2, so that medical and psychosocial evaluations can be completed, the patient tentatively approved, and subsequently listed as soon as the referring nephrologist documents an eGFR consistently below 20 mL/min/1.73 m^2 during serial monitoring.

Question 4

A 54-year-old woman is followed for progressive kidney disease secondary to IgA nephropathy. She is scheduled to see you in a few hours. Which of the following are the goals in planning for HD?

A. The hemoglobin concentration should be at targets defined by clinical practice guidelines without the need for transfusion
B. Patients should have a functional permanent vascular access, preferably an AVF
C. The patient should be followed at close intervals to avoid the need for an emergent inpatient start of HD treatment ("crash landing")
D. If eligible, patients should be listed for KTx when eGFR is $\leq$20 mL/min/1.73 m^2
E. All of the above

Answer: E

The above-listed goals should all be part of the management of the patient being prepared for HD. When these are properly adhered to, the likelihood of safe and successful initiation of HD is increased. Patient education, CV risk factor management, anemia management, vascular access placement, and timing the initiation of HD are all critical to patient care.

Question 5

Which ONE of the following is true regarding formal pre-ESRD educational programs for patients and families?

A. Families should not be included since it violates confidential patient information rules
B. Education has no effect on type of dialysis selected by the patient
C. Patients are started on dialysis earlier than necessary
D. A higher percentage of patients begin dialysis with a mature functioning vascular access

Answer: D

Multiple studies have demonstrated that formal pre-ESRD educational programs for patients and families result in a higher percentage of patients opting for home-based therapies (Answer B is not true), a greater percentage of incident HD patients beginning treatment with a mature, functioning vascular access (Answer D is true and the correct answer), prolongation of time to need for initiation of dialysis (Answer C is incorrect), improved S[Alb] at the time of dialysis start, decreased need for emergent, hospital-based initiation of treatment, fewer hospitalizations at one year, and overall cost savings per patient during the first year of dialysis.[15–19] Involvement of families, with the permission of the patient, is critical to the success of any treatment plan for RRT, making Answer A not true.

Question 6

Which ONE of the following is true regarding the timing of the initiation of HD?

A. Early-start dialysis (eGFR 10–14 mL/min/1.73 m^2) results in lower mortality compared to late-start dialysis (eGFR 5–7 mL/min/1.73 m^2)
B. No significant difference in mortality is seen with late-start dialysis (eGFR 5–7 mL/min/1.73 m^2) compared to early-start dialysis (eGFR 10–14 mL/min/1.73 m^2)
C. Early-start dialysis (eGFR 10–14 mL/min/1.73 m^2) results in a lower incidence of CV and infectious disease complications
D. Early-start dialysis (eGFR 10–14 mL/min/1.73 m^2) results in a lower incidence of dialysis-related complications

Answer: B

The landmark Initiating Dialysis Early and Late (IDEAL) trial was a randomized, multicenter randomized trial that evaluated effects on mortality from any cause among groups assigned to earlier initiation of dialysis (eGFR 10–14 mL/min) vs. those assigned to later initiation of dialysis (eGFR 5–7 mL/min).[80] Patients planning both HD and PD were included. Median time to start was 1.8 vs. 7.4 months in the earlier and later initiation groups, respectively. The median time of follow-up was 3.5 years. There were no significant differences in mortality between those assigned to earlier initiation (37.6%) and later initiation (36.6%), making Answer B correct and Answer A incorrect. Moreover, there was no observed difference in the incidence of CV events, infectious disease complications, or other dialysis-related complications, making Answers C and D incorrect. A potential limitation of this study, however, is that a substantial number of patients (75.9%) assigned to the later initiation group were started on dialysis above the preassigned cutoff of 7 mL/min, due to interval development of uremic symptoms. Whether or not a between-group mortality difference would have emerged had these patients waited to start dialysis until they reached the late-start eGFR cutoff of 5–7 mL/min, is uncertain. In other words, one could criticize IDEAL in that it compared very early initiation with relatively early initiation, rather than late initiation, and the modest separation in kidney function between groups resulted in an underpowered study. Nevertheless, based on the IDEAL results, there is no clinical trials-based evidence to support a very early preemptive initiation of dialysis strategy.

Question 7

A 45-year-old woman presents to clinic for management of progressive CKD secondary to focal and segmental glomerulosclerosis. Her current eGFR is 20 mL/min/1.73 m^2.

Which ONE of the following statements is true regarding vascular access management in this patient?

A. Native AVF is the preferred form of vascular access
B. CVCs are not associated with any long-term complications
C. In the US, the most common form of vascular access in incident HD patients is the AVF
D. The patient should be referred for vascular access placement one month before anticipated start of dialysis

Answer: A

Answer A is correct because compared with synthetic AVGs and CVCs, AVFs are associated with greater long-term patency rates, decreased need for interventional procedures to maintain patency, decreased rates of infection, decreased rates of patient hospitalization, decreased overall cost, and importantly, decreased patient mortality. Answer B is incorrect as long-term use of CVCs is associated with development of vascular complications, including subclavian and internal jugular vein thrombosis. Superior vena cava syndrome may also develop in patients using CVCs. These vascular complications subsequently render future placement of noncatheter forms of access more difficult. In the US, the most common form of vascular access in incident HD patients remains the CVC, making Answer C incorrect.[55] Answer D is incorrect as at least 6 months before anticipated need for dialysis initiation is needed to allow maturation of the AVF. This also takes into account the relatively high rates of primary access failure in AVFs, leading to the need for interventional procedures and/or revision surgery, such that ample time is allowed for maturation of a functional AVF at the time of dialysis start.

CHAPTER

Preparing for Peritoneal Dialysis

Rajnish Mehrotra[a], *Beth Piraino*[b]

[a]University of Washington, Seattle, WA, United States; [b]University of Pittsburgh, Pittsburgh, PA, United States

Abstract

Preparation for home dialysis begins with a robust modality education program because patients cannot make a decision regarding the type of dialysis if they are not provided adequate information. This requires infrastructure that some programs do not have, as well as nephrologists who are welcoming and receptive to their patients' choice of home dialysis. Unfortunately, many dialysis patients in the US do not recall receiving much information about peritoneal dialysis (PD), indicating that the process is often inadequate. This is one barrier to PD. Another is the nephrologist. The nephrologist is the most important influence regarding the decision for PD, so it is critically important that the nephrologist be trained in PD sufficiently to eliminate biases.

The program must have the infrastructure to provide robust and comprehensive modality education to patients and their support persons. This includes a one-on-one session with an educator (often a nurse), videos, visits to a home program, peer-to-peer discussion with a PD patient, and follow-up with the nephrologist. Because many patients with advanced chronic kidney disease present urgently with signs and symptoms that require rapid dialysis implementation, an in-house education program is desirable but requires an investment in a nurse educator on site.

Once the decision is made to start PD, arrangements are made for PD catheter placement. In most centers, scheduling this procedure can be delayed, so careful planning is necessary. Some innovative programs incorporate interventional nephrologists or radiologists in the program who can place PD catheters and thus ensure that rapid start PD is available. These approaches have been shown to greatly increase PD program size and allow a higher proportion of patients to choose PD at the outset. Use of the buried catheter technique is another approach that may facilitate timely PD start.

The home dialysis program must be supported by the dialysis provider or hospital or institution, as appropriate. Adequate staffing is critical to the success of the program, allowing time for training (which is usually one on one), and for meeting the regulations in place for home programs. Space for the home program is also essential, with room for private training and for clinic visits.

INTRODUCTION

The choice of dialysis modality to manage advanced kidney disease is intensely personal. The initiation of dialysis has a tremendous impact on the person's life.[1] If done badly, a person who may have been functioning at a high level may abruptly become a "patient," with disruption of work and other activities. Depression often ensues and is common in patients undergoing maintenance dialysis.[2] Therefore, the process of dialysis preparation is essential for good outcomes.

Unfortunately, many patients do not receive adequate modality education.[3–5] Study after study of patients recently started on dialysis have shown that many treated with in-center hemodialysis (HD) do not recall receiving education about a choice of home dialysis.[3–5] Even allowing for impaired recall, it is clear that modality education in many programs is woefully inadequate. There are many reasons for this, but leading are nephrologist bias against peritoneal dialysis (PD) due to lack of training in PD, as well as a failure of adequate infrastructure for the process.[6–8] The need for urgent start dialysis is another reason given for inadequate or no modality education.

Data suggest that survival is similar on in-center HD and PD.[9–17] Early studies that showed an HD survival advantage were flawed by excluding many who were survivors, such as patients who were transplanted early in the course of dialysis.[18,19] Patients treated with PD are more likely to be transplanted quickly than those on HD.[10] This is one source of bias in such comparative studies. Another is selection bias. In The Choice study, done at Dialysis Clinic Inc units plus one unit in Connecticut, almost all the PD patients in the centers participating were included, whereas HD patients were a convenience sample, because the social workers recruited those that were available (that is those who

https://doi.org/10.1016/B978-0-12-815876-0.00071-1

were not in the hospital on the recruitments days, and who had arrived for dialysis).[20] Such an approach can impact the survival outcomes because some of the sicker patients on HD (as opposed to PD) were not included in the sample. More recent studies using large databases and controlling for all important variables show similar 5-year survival.[9–17] Therefore, choice should be made by the patient after being fully informed of the options based on the patients' preferences and the impact on lifestyle.

Access plays an important role in subsequent survival on dialysis. Those with a HD catheter are more likely to die than those with a PD catheter or with an arteriovenous fistula (AVF) or graft.[21] Therefore, proper and timely education of modality choice is very important to ensure that the right access is placed at the right time for each patient.

INDICATIONS AND CONTRAINDICATIONS FOR PD

There are only a few contraindications for PD (Table 71.1). These include inability to do PD, or lack of a helper to perform the procedure for the patient. Most people can perform PD or may have a family member who is willing to assist. An attempt at a randomized controlled trial done in the Netherlands found that ~65% of people had no contraindication to doing either PD or in-center HD.[22] Once these patients were fully informed regarding PD and HD, to permit consent for randomization, almost everyone refused to be randomized after learning of the difference. Patients had a distinct preference for one dialysis method vs. another.[22] 45% chose PD. This study, although unsuccessful in its recruitment efforts, provides an important lesson, in that it clearly showed that given full information, patients want a choice of modality.

TABLE 71.1 Contraindications to Peritoneal Dialysis (PD)

ABSOLUTE CONTRAINDICATIONS
Nonfunctioning peritoneum (for example, history of abdominal radiation)
Inability to perform PD combined with lack of a partner to perform PD
Homeless state
RELATIVE CONTRAINDICATIONS
Ostomy (presternal catheter allows PD)
Right-sided heart failure with ascites
Ligation of thoracic duct and chylous ascites
Active colitis

Dementia, if severe, may lead to problems with both in-center HD and PD. More attention is being given to conservative care approaches in older patients, those with considerable comorbidity and demented patients who will gain little benefit from starting dialysis.[23] Patients who require nursing home care are often provided HD, and this is sometimes done on site. Nursing home PD programs are not common, but have been successful, and may lead to lower costs.[24] One issue is ensuring that those doing the PD are adequately trained on the technique to prevent high peritonitis rates.[24]

Those patients with mental illness are problematic when treated with in-center HD. Paranoid patients have anxieties and fear increased by being attached to a machine and may lash out at healthcare providers and even prove dangerous. Such patients if able to perform PD and have a safe home environment may be offered PD and may do well.

Nonadherence and anger expressed by those starting in-center HD may reflect in part lack of control and lack of autonomy. Having control over the dialysis such as is the case with self-care HD or PD may improve adherence and sense of control. Therefore, nonadherence should not be a reason to deny a patient full modality education.

A nonfunctioning peritoneum is likely to be the case in someone with a prior ruptured viscus, or someone with prior history of radiation to the abdomen. Prior surgery is not a contraindication, as it is impossible to determine before the peritoneal catheter placement is attempted whether there will be too extensive adhesion formation to obtain a well-functioning catheter.[25] In some cases, the adhesions may be lysed and PD successfully achieved.[25] Experience of the operator placing the catheter is particularly important in such cases.[25]

Patients who have right-sided heart failure with extensive ascites, as seen with severe pulmonary hypertension or severe tricuspid regurgitation, do not do well on PD as fluid losses tend to be so great that there is profound hypovolemia. Similarly, ligation or damage to the thoracic lymphatic duct leads to chylous ascites; these patients tend to become malnourished and volume depleted on PD. Those with severe ascites from liver failure also are prone to development of hypotension and hypovolemia from excessive fluid removal. Such patients are not likely to do well on HD either. The prognosis is dictated by the underlying liver disease and not by the choice of dialysis modality.

Some consider an ostomy to be a contraindication to PD. This issue can sometimes be managed with a sternal exit site for the PD catheter. Again the experience and comfort of the operator placing the PD catheter is key in these situations. There are few data on outcomes of PD patients with ostomies.

Some patients do particularly well on PD, such as those that are younger with less comorbidity.[26] However, PD is underutilized in the elderly, who sometimes prefer to stay at home for dialysis, and is underutilized in certain racial and ethnic groups.[27] Asian Americans are somewhat more likely to do PD and African Americans are least likely.[27–29] This is not based on outcome data, but is likely a consequence of inadequate preparation for dialysis based on bias, either implicit or overt, of the healthcare provider team. Implicit bias training of all healthcare providers might be an approach to ensure equity of care for our patients.

EDUCATION OF THE CKD PATIENT ABOUT DIALYSIS MODALITIES

PD is a good choice to manage end-stage renal disease for many.[30] Studies have shown that approximately three-fourths to two-thirds of patients may be suitable for modality education.[17,31] With full education, a substantial proportion chose PD.[32–34] The most important reason for the low uptake of home dialysis in many developed countries, and particularly in the US, is inadequate dialysis modality education, not contraindications to PD. Surveys of nephrologists from different parts of the world suggest that ideally approximately half of patients starting dialysis would start with in-center HD, either due to contraindications to home dialysis or patient choice, with about 11% on home HD and 38% on PD.[35,36] In countries with a PD first approach, such as Hong Kong and Thailand, as many as 80% start dialysis with continuous ambulatory PD (CAPD)[37–41] mostly due to economics. In such situations, patient choice is confined by the government's wish to save money with a high proportion of PD patients.

PD is easy to learn and does not require a partner. Nighttime PD allows the patient to continue daytime activities including attendance at jobs and school. Perhaps, for this reason, children are often started on PD. CAPD, on the other hand, is a good choice for those who prefer not to be attached to a machine and for those who are restless sleepers and get up frequently at night. Cycler PD and CAPD, from the patient's perspective, are quite different. Therefore, modality education needs to cover both options, outlining the differences and the advantages and disadvantages of each. CAPD is easier to learn than the cycler. Therefore, some older patients who wish to remain independent may chose CAPD, but not find cycler PD attractive. Although PD is usually performed by the patient independently, in some situations, there is a helper, who may be a spouse or an adult child, who performs the dialysis.

TABLE 71.2 Approach to Education of the Patient on Modality Choice

Introduction of the topic by the nephrologist as CKD advances.
Referral for education and decision support
By physician or advanced care practitioner
By nurse educator
By social worker
Videos
Online information
Visit to the home program
Peer-to-peer education
Follow-up visits with the nephrologist for decision support

Because incremental dialysis is possible in many who start dialysis with residual kidney function, CAPD does not have to be prescribed initially as four exchanges per day. For some patients, two or three exchanges per day may initially suffice.[42] Similarly, cycler PD may only need to be done at nighttime with no day dwell or exchanges.[42] This information can impact the decision made by the patient regarding modality.

It has been shown time and time again that most patients treated with in-center HD have received inadequate education about the modality choice. There may be multiple reasons for this. The physician has been shown to be the person who most influences patient choice of modality, but most nephrologists and almost no internists have training or experience in supporting informed modality choice (decision support). Discussion of modality takes time and an adequate knowledge of the details of PD, including management of supplies, access, infection risk, different types of PD, training time, follow-up procedures, and support. Most nephrologists are familiar with in-center HD, but many have little training and are uncomfortable with home dialysis including PD.[6,8] Many trainees make inappropriate assumptions about who might be "suitable" for PD or home HD. This is likely due to insufficient knowledge of the modalities by both the trainee and the faculty mentors.

A comprehensive approach to modality education is shown in Table 71.2. Modality education is best done in a stepwise fashion.[43] Patients when hearing about the upcoming need for dialysis are often frightened and in denial. Thus, many do not hear much of the initial information on this topic. The introduction of the topic of dialysis choice can begin with the patient once estimated glomerular filtration rate (eGFR) approaches around 20 mL/min/1.73 m^2, although this must be tailored to rapidity of progression. This initial

introduction should be followed by a referral to an educator. The patient should be encouraged to visit the home program, as well as meeting with the home training nurse, viewing the equipment, and understanding the storage space needed, and, as appropriate, meeting other patients doing home dialysis. Subsequent follow-up with the nephrologist then can begin to pin down the choice with which the patient is most comfortable. This needs to be an iterative process, as many have such a fear of dialysis that the initial discussions are not fully absorbed.[43] The partner or any significant support person should be present at some of these education sessions. Group sessions can be used to supplement the information, but alone are not adequate for education. One-on-one sessions allow the teacher to explore the level of understanding of the modalities. Because the physician is the most influential person in the patient's final decision, the information process should not be entirely assigned to educators. The nephrologist should be the leader in the education process and ensure that sufficient steps are taken to guarantee understanding. Having the patient reflect back on information received is a helpful technique to ensure that misconceptions and biases have not crept into the process. Many patients have misconceptions about home dialysis that can be explored in conversations. Sometimes this misinformation comes from support persons who have not been part of the process. In other cases, misinformation can come from the primary care physician who may not be acquainted with PD.

Fully informed patients have many reasons for their choices.[1] One patient may elect to choose PD simply because of a fear of needles, another because it allows the patient to continue with a job or school or both. Yet another patient may like the independence and flexibility home dialysis brings vs. in-center HD.[1] Patient autonomy is an important reason that patients choose home dialysis.[1]

It is important to understand that patients will not pick home dialysis without substantial and detailed education about this choice. Patients do not choose a modality they know little or nothing about. Many patients find the entire concept of dialysis frightening and intimidating. Therefore, a full understanding of the choices, and the impact this choice will have on lifestyle, requires considerable investment by the program. Most patients are capable of doing PD but have little confidence in their ability. Some develop depression on learning dialysis will be needed. This depression may paralyze decision making. Reassurance that patients can learn the technique if they chose to and a supportive approach are key parts of the process.

Too often, the default is inadequate, cursory modality education and a default to in-center HD. This is one reason why the majority of patients in most western countries are treated with in-center HD. A survey of nephrologists showed that a minority would pick in-center HD for themselves.[44] Therefore, it is ironic that most patients in Canada and the US are maintained on in-center HD.

In the US, with the implementation of the expanded prospective payment bundle for dialysis, PD became more economically advantageous for dialysis units.[45,46] This is in part because PD patients require less erythropoietin and intravenous iron (drugs which are now included in the bundled rate) than HD patients. This incentive encouraged dialysis programs to enhance their modality education programs. One such program developed by Fresenius Medical Care, Treatment Options Program, was quite successful in increasing the uptake of patients on PD.[47] However, many patients were not referred for the educational program. More recently, dialysis providers are employing nephrologists and thus have more control over the chronic kidney disease (CKD) clinics and the education process. Many patients once started on one modality are reluctant to make a switch.[48] Therefore, education is best done before starting dialysis. This allows avoidance of placement of a HD catheter as a way of starting dialysis. However, late-referred patients should not be denied a choice, and all patients should receive iterative modality education with decision support.

PLANNED VERSUS NONPLANNED (URGENT) START PD

Patient education on modality choice may take months to achieve. However, a large number of patients present with very advanced CKD, requiring urgent start dialysis due to uremia, hyperkalemia, volume overload, or other indications. The default approach is to place a HD catheter and start HD in the hospital. Discussion of modalities does not happen in most of these cases. However, several publications have shown that by implementing an in-house modality education program, the uptake of home dialysis, particularly PD, can be greatly increased.[49,50] This requires that the program makes an educator available for late-referred patients and may involve visits to the home program and contact with a current PD patient for peer-to-peer education.[51] The nephrologists in the program need to be supportive of this approach for it to be successful. Such an approach can be cost-effective.[52,53] Numerous reports from around the world have shown that such an approach results in a significant proportion of late-referred patients starting with PD with good results.[51,54–62] Infrastructure needed for a successful PD program, including one with an urgent start capability, is shown in Table 71.3.

TABLE 71.3 Infrastructure Needed for Peritoneal Dialysis (PD) Including Urgent Start

Ability to provide modality education and decision support on short notice
Resources for rapid placement of PD catheter
Ability to provide supine PD until patient can be trained
Available nurse trainers, protected from in-center HD demands
Adequate space for PD training and follow-up visits

ASSISTED HOME DIALYSIS

There was a period of time in the US when assisted home HD was supported by the payors for dialysis, such that a nurse or dialysis technician would go to the home to do the HD. Because of costs, this quickly fell out of favor and is now rarely if ever an option. However, innovative programs in different parts of the world have implemented assisted PD.[63–68] In such a situation, mostly involving elderly patients who prefer to do PD at home at night on a cycler, but do not feel capable of being completely independent, a visiting nurse travels to the home and sets up the cycler each day, sometimes also attaching the patient. Often the patient is able to disconnect from the cycler (which is an easy maneuver) in the morning. A proportion of these patients will eventually be able to perform dialysis at home independently.[65] In France, there is a substantial home PD assisted program for elderly patients.[64] This approach has not been implemented in the US, but given the economic advantage of PD over in-center HD for the dialysis provider, should be tested in the US on a trial basis. For now, patients in the US can benefit from assistance from their family members. In some states, publicly funded compensation is available for the provision of in-home support services.

TIMING AND PREPARATION FOR CATHETER PLACEMENT

Once the patient has decided on PD, there is no need to put the access in until close to the timing of PD start. However, once the patient arrives at stage 5 CKD, follow-up should be performed with frequent laboratory checks to ensure that the timing of PD catheter placement is optimal. It is often prudent to send the patient to the person placing the PD catheter ahead of time to ensure there are no barriers.

The PD catheter is most often placed by a surgeon. Although this is not a difficult surgery, it is important that each program finds surgeons who are interested in working as a team, will appreciate feedback, and who are good communicators. Some programs have had good success by having a nephrologist or radiologist train in PD catheter placement, which allows quick access to PD and PD training. This approach has led to dramatic increases in the size of already large PD programs.[69] Because interventional nephrology as a subspecialty is gaining attention, PD catheter placement should be part of this training.

Actual placement of the catheter should be timed so that there remain 10 days to two weeks for healing before training begins. There is no need to place the PD catheter earlier than this, although there are programs who prefer to use the buried catheter approach. With this approach, the tunneled portion of the catheter is completely within the subcutaneous tissue, with no external portion.[70,71] The advantage of this approach is that when the patient is ready to start dialysis, the PD catheter can be brought to the exterior with the creation of an exit site, and because the cuffs are fully embedded, the catheter can be used immediately. Furthermore, during the waiting period to start dialysis, no care is needed for the catheter. Limited research indicates that catheter outcomes are no different with this approach, and there is no reduction in early PD-related infections as was posited. While offering the advantage of elective start of PD, in some patients the placement may be futile, as they may die before needing dialysis or start with HD, either because they may change their mind or may have had a change in health or social condition that may preclude home dialysis. In 10–15% of the cases, the catheter may have problems with drainage, which are generally readily resolved with vigorous flushing. Some programs routinely use this approach with good results.[71–73]

There is no preferred type of PD catheter. At one time, the literature suggested that a downward directed exit site would decrease the risk of exit site infection. However, there is little research to support this hypothesis and a laterally directed exit site may provide the same results.[70] A skilled operator is the key to successful outcomes with a PD catheter.

Generally, the catheter is placed when the eGFR is around 10 mL/min/1.73 m^2. Placing a HD catheter in a patient who wants PD should be avoided as much as possible, as this leads to increased risk of infection and exposes the patient to HD which may decrease residual kidney function, lead to cardiac arrhythmias, and cause emotional distress to the patient and interfere with daily activities. PD catheter placement should be elective and done as an outpatient as much as possible, as a planned event.

Once PD catheter placement is scheduled, the patient should be carefully instructed in the preparations for the placement. The skin should be clean and without

infections. The patient should take a cathartic before the procedure to ensure that the colon is relatively empty. The patient should void before the procedure and if there is any suggestion of a neurogenic bladder, a bladder scan should be done to ensure that the bladder is empty. A single dose of preoperative intravenous antibiotics reduces the risk for early infection and should be the standard of care.[74]

After the catheter is placed, the patient will be generally discharged home, but should be instructed to keep the dressing dry and clean and to not change the dressing. Approximately one week later, the patient should visit the training center, where the nurse will do a dressing change, inspect the exit site, and, in some programs, flush the catheter to ensure proper function.[70] Training can generally start 10 days to 2 weeks after catheter placement. Only when the exit site is well healed is the patient to resume showers and start performing daily exit site care.

BARRIERS TO PATIENT-DRIVEN MODALITY CHOICE

Unfortunately, one of the major barriers to patient choice is the lack of training about home dialysis in many countries, including the US. Early in the growth of PD, in the 1980s, most PD patients were dialyzed at centers with a particular interest in PD, and at least one nephrologist who was a champion of PD. As HD centers became more and more common, there was pressure to fill HD seats, and less emphasis on providing modality education to patients. The proportion of patients starting dialysis with PD fell from a peak of about 15% to 6%.[75] Training programs had small numbers of patients on PD, and some programs had no patients.[6] This led to a cycle of newly graduated nephrologists being quite comfortable with in-center HD (although even training in this area sometimes was lacking) and with very little knowledge about home dialysis (either home HD or PD).[8] Because the nephrologist is the main influencer on the patient's decision about dialysis, this led to even fewer patients starting PD.

Modality education takes time. If the program does not have a robust predialysis education program for patients, the burden falls almost entirely on the nephrologist. Modality education is best done with repetitive information sessions and multiple modalities, and nephrologists may not be able to schedule the necessary sessions.

Economic barriers are greater with frequent home HD than with PD. With the implementation of the expanded prospective payment system in the US, PD became quite profitable for the dialysis providers who increased efforts to educate patients about home modalities.[45] This has led to about 10% of new patients starting dialysis with PD.[75,76] However, with increased demands for training patients, which in US is done one on one with the PD nurse trainer and the patient with or without family member, staffing needs to be adequate to still run the clinics, answer phone calls, complete paper work, and do home visits. In addition, there needs to be adequate support by the social worker and the dietician. Data particularly hospitalization and infection rates, especially peritonitis and exit site infections, and outcomes of catheter placement must be tracked. In some programs, the home dialysis nurses are also part of the modality education program. Such personnel are ideal for assessing a patient's ability to learn PD and are often better at this than the nephrologist (especially an inexperienced nephrologist).

Support for the home program by the dialysis provider, hospital, or institution is critical for the success of the home program. This includes provision of adequate space for the home program and deployment of adequate personnel.

SUMMARY

Preparation for PD involves a comprehensive education process for the patient and the patient's support person(s). This takes infrastructure from the program, but the nephrologist needs to take the lead. Unfortunately, in the US, in particular, nephrologists are often inadequately trained in PD and many have significant biases against PD and biases about who can perform PD. Until these barriers can be overcome, despite the economic advantages of PD over in-center HD in the US, PD growth will be limited.

QUESTIONS AND ANSWERS

Question 1

You are seeing a 65-year-old woman with diabetes mellitus who has advancing CKD, now with eGFR of 11 mL/min/1.73 m^2. She is asymptomatic at this time and has trace edema and clear lungs on examination. Her BMI is 32 kg/m^2. She lives alone and is fiercely independent. Her diabetes is reasonably well controlled. You explain to her that her kidney disease is quite advanced and she needs to consider her options. What options do you discuss with her?

A. In-center HD is the best choice given she lives alone and is a diabetic
B. Kidney transplantation should be the focus as perhaps she can receive a kidney without going on dialysis
C. In-center HD and PD are both reasonable choices and referral for education about these is appropriate
D. Refer her for placement of a central venous catheter to start dialysis as soon as possible as her kidney disease is so advanced
E. PD is the best choice given that she is fiercely independent

Answer: C

Both in-center HD and home PD are choices for this woman. She may well prefer one over the other. Until the choice is made based on full information, no access should be placed. Although renal transplantation is certainly an option, the referral, workup, and wait time make the timing not very feasible for preemptive kidney transplantation unless she has a living donor. While her kidney disease is advanced, she is asymptomatic and there is no need to initiate dialysis urgently.

Question 2

A 24-year-old single woman who still lives with her parents is followed for chronic glomerulonephritis, which despite immunosuppression is progressing. She has a full-time desk job working from 8 a.m. to 5 p.m. She has been reluctant to receive much information about dialysis. The family's plan is to have the father donate a kidney to her. Once the evaluation is done, the father is found to have unrecognized coronary artery disease, and the transplant team refuses to consider him further as a donor. The mother is not a suitable donor. The sister is 21 years old, and the parents ask you about her as a candidate. Now the patient's creatinine is 13 mg/dL, and even though she is still asymptomatic and the rest of the laboratory not worrisome, you are concerned about the very advanced state of her renal function (eGFR 4 mL/min/1.73 m^2).

A. You call her once you receive this laboratory result and tell her to go to the emergency department to get admitted to start HD *via* a HD catheter
B. You tell her that the nurse is going to schedule outpatient placement of a tunneled HD catheter, following which she will start in-center HD
C. You again explain the choice of in-center HD vs. PD to her and encourage her to consider nighttime PD so she can continue with her job
D. You tell her that home HD is the best choice given that her parents can do this with her
E. You encourage her to ask her sister to be a living donor to avoid dialysis

Answer: C

Because she is asymptomatic, there is no need to admit her to the hospital. However, dialysis needs to be implemented very soon, within a few weeks. If she agrees with PD, a PD catheter would need to be placed promptly and then urgent start PD can be implemented, with training starting simultaneously. There is insufficient time to get a transplant from the sister even if the sister is willing. If she does not want PD, then a tunneled HD catheter can be placed as an outpatient and she can be started on in-center HD at a center convenient, but this should be a choice, not mandated by the nephrology team.

Question 3

All of the following are absolute or relative contraindications to PD except?

A. A 68-year-old woman who has received radiation to her abdomen for metastatic ovarian cancer
B. A 50-year-old man with pulmonary hypertension and severe right heart failure with large ascites
C. A 72-year-old woman with mild dementia who lives with her devoted husband and adult son
D. A 48-year-old woman with diabetes mellitus who has a BMI of 42 who wants to undergo bariatric surgery to become eligible for a kidney transplant
E. A 70-year-old man who lives alone, who has marked impaired vision due to macular degeneration

Answer: C

Radiation to the abdomen makes PD not very feasible as the peritoneum is likely somewhat damaged. Those with severe right-sided heart failure and large ascites, tend to lose too much fluid with PD, leading to profound hypotension, difficult to manage. PD in a person with a BMI of 42 and wants to undergo bariatric surgery is challenging. The patient with impaired vision who lives alone and is therefore unlikely to have a helper is at high risk for peritonitis, unless an assisted PD program is available. The woman with dementia who lives with

supportive family may well decide with her family that home dialysis is best, because the son and/or the husband could do the PD for her. Therefore, Answer C is the correct answer.

Question 4

You follow a 55-year-old man who works as an electrician, BMI 35, who is approaching the need to start dialysis. He is interested in kidney transplantation and has been accepted on the transplant list but has no donors. After appropriate education about modalities, he has chosen cycler nocturnal PD, because he wants to keep his job and hates needles. His eGFR is now 10 mL/min/1.73 m^2. He has mild symptoms of fatigue and has lost 5 pounds in the last month. S[K] is 5 mEq/L and Hb is 10 g/dL. Which of the following is your course of action at this time?

A. Refer to the surgeon for placement of PD catheter, then start PD training 1−2 weeks later
B. Admit him to the hospital, place HD catheter, and place on HD, with a plan to start PD later
C. Tell him that as he has few symptoms that it is fine to wait longer before starting dialysis
D. Have the PD catheter placed and then have the nurse train him on CAPD before allowing him to train on the cycler. He can miss work while on CAPD because he says it is not feasible to do an exchange while working
E. Explain to him that both a PD catheter and an AVF will be placed by the surgeon because HD backup access is necessary

Answer: A

Because the eGFR is now 10 mL/min/1.73 m^2, it is better to plan on PD catheter placement and starting because sometimes it takes a bit of time to arrange the PD catheter placement. In addition, the patient needs to be alert to train on PD. There is no need to place him on HD first, and this places the patient at risk of infection from the HD catheter, and possibly some harm to residual kidney function. Backup AVF is not needed at this time, as he may get a kidney transplant and never need HD. Choice D is somewhat controversial and depends on the program—some train directly on the cycler and others place the patient on CAPD first. Nevertheless, even such programs will likely make an exception for the patient to accommodate the limitations on his schedule imposed by work.

Question 5

You are the medical director of a dialysis program that has 70 patients treated with in-center HD and 5 patients in the PD program and no home HD patients. The nurse assigned to PD is also expected to work on the in-center HD side if there are shortfalls in staffing. The space for the home program consists of one room that is a combined storage space and home nurse office and one clinic room. Five physicians send their patients to the clinic and all seem eager to expand the home program. The modality education program is done at a separate location by a nurse educator who is eager to do a good job but is not being referred many patients. Which of the following might be the most effective approach by the director to increase the home program census?

A. Focus on the current HD patients and ask the home nurse to talk to them about home dialysis
B. Meet with the five physicians and the nurse educator and develop an approach to referring all patients anticipated to transition to dialysis for iterative modality education
C. Arrange a group modality education program to which you invite the current in-center HD patients and all CKD stage 4 patients
D. Talk to the HD staff about promoting PD to the in-center HD patients
E. Put posters about the advantages of home dialysis in the in-center waiting room

Answer: B

The physicians need to be behind the effort to educate the patents on modality choice as the physician has the most influence in this process, not only by the referral but by speaking positively about home dialysis. Although A, C, D, and E can be easily implemented, these approaches will be much less effective than B.

Question 6

You provide care to a 35-year-old man with IgA nephropathy with progressive decline in kidney function and now with advanced CKD. His last eGFR was 12 mL/min/1.73 m^2. He has undergone iterative modality education and has decided to be treated with PD when he needs dialysis. He has no potential living donor. He has recently been placed on a deceased donor transplant list (wait time, 5−7 years). You recommend the placement of an embedded PD catheter and he wants to understand the potential risks with such an approach.

Which of the following are the risks associated with placement of embedded PD catheters?

A. Problems with catheter drainage on exteriorization from fibrin thrombi
B. Higher risk of peritonitis in the 3-month period following exteriorization

C. A higher likelihood of internal leaks on initiation of PD
D. More frequent occurrence of hernias
E. Greater need to replace the PD catheter because of primary nonfunction

Answer: A

Placement of an embedded PD catheter allows for an elective start of PD while precluding the need for caring for an externalized PD catheter for long before patients need dialysis. The catheter can be exteriorized in the office setting and can be used for full-dose PD from day 1. Up to 15% of patients have problems with drainage on exteriorization, but these are often readily resolved with vigorous flushing. The rate of primary nonfunction is <5% and it is rare to need to replace the PD catheter. There is no difference in rates of peritonitis or herniae, and there is a lower likelihood of leak.

Abstract

Chronic kidney disease (CKD) is likely to be the public health epidemic of the 21st century. Despite the magnitude of the clinical problem, there are currently no truly effective therapies for this condition. Novel therapies could influence the way we manage CKD patients in the future. Combining biology, technology, and processes of care to develop therapies that are not only clinically effective but which are also patient friendly and cost-effective and which lend themselves to being used within existing or improved process of care paradigms may affect outcomes.

SCOPE OF THE PROBLEM

Chronic kidney disease (CKD) is currently a global health epidemic. In the US, it is estimated there are approximately 30 million people with CKD. Recent USRDS data describe the Medicare CKD population as comprising 11.1% of the total Medicare population, but consuming 21.2% of overall Medicare costs, likely due to the high incidence of cardiovascular complications.[1] The greatest impact of CKD, both with regard to morbidity/mortality and cost, however, is likely to be in the developing world (particularly in the large emerging economies of Brazil, China, and India), due to expected huge increases in the incidence of both diabetes and hypertension over the next 20 or more years in these locations.[2,3] It is projected that there will be 366 million people with diabetes worldwide by 2030, of which 298 million (81%) will be in the developing world with limited resource utilization.[3] Thus, it is critical for the renal community and for overall healthcare delivery systems that we develop innovative and cost-effective therapies for both the prevention and treatment of CKD, to prevent a future increase in end-stage renal disease (ESRD), for which most developing and indeed developed economies may simply not have the healthcare resources.

While recognizing the significant depth and breadth of emerging therapies for CKD, this chapter will focus on the following therapy domains (recognizing that these address most but not all aspects of innovation and entrepreneurship in CKD):

- Prevention of CKD progression
- Novel therapies for CKD-associated anemia
- Therapies for vascular calcification
- Renal denervation therapies
- Novel therapies for vascular access dysfunction
- Innovative renal replacement therapy (RRT)

Our hope for the future is that the availability of a wide spectrum of safe, effective, and financially viable therapies for the prevention and treatment of both CKD and its complications will allow individualization of care for every CKD patient worldwide (regardless of whether they live in the developed world or in emerging economies).

PREVENTION OF CKD PROGRESSION

There exist data on agents that may have a future role in the prevention of the final common pathway of interstitial fibrosis and tubular atrophy, albeit through the modulation of a variety of different pathways. Renal inflammation plays a key role in the progression of kidney disease. There are a number of drugs in clinical trials that decrease albuminuria, but whether this effect always translates to decreasing progression of kidney disease is yet to be studied. Only agents that have been used in clinical studies in humans are described.[4]

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00072-3

Pentoxifylline

Pentoxifylline is a nonselective phosphodiesterase inhibitor with antiinflammatory and immunomodulatory activities. Clinical studies in patients with primary glomerular diseases, diabetic nephropathy, and CKD suggest the drug decreases proteinuria, possibly through the MCP-1 pathway, albeit without changing the rate of decline of glomerular filtration rate (GFR).[5–7] The benefits of proteinuria reduction were more evident in patients with type 1 diabetes mellitus, earlier stages of CKD, and higher baseline proteinuria.[8] In a *post hoc* analysis of the PREDIAN trial (Effect of pentoxifylline on renal function and urinary albumin excretion in patients with diabetic kidney disease), pentoxifylline decreased serum and urinary TNF-α levels, but increased urinary and serum klotho levels in CKD stage 3–4 diabetic kidney disease, likely due to its antiinflammatory and antiproteinuric effects.[9] More studies with longer follow-up and meaningful renal endpoints are needed to support use of this agent to prevent progression of CKD.

Statins

In addition to their cholesterol-lowering effects, the statins as a group have important antiproliferative, antimacrophage, and endothelium stabilization effects, all of which could be beneficial in preventing the progression of CKD.[10,11] In an observational prospective study of HIV-infected patients with CKD and hyperlipidemia, the rosuvastatin and atorvastatin groups had a lower decline in estimated GFR (eGFR) compared with the omega-3 fatty acid group.[12] However, in the effects of atorvastatin on renal function in patients with dyslipidemia and chronic kidney disease: Assessment of clinical usefulness in CKD patients with atorvastatin (ASUCA) trial no renal protection was observed in the atorvastatin group.[13] In patients with hypertensive nephropathy, statins were found to be renoprotective by downregulating the angiotensin II-AT1 pathway in hypertensive nephropathy.[14] Although there may be a reduction in proteinuria, this has not translated into reduction in decline of eGFR.[15]

Mammalian Target of Rapamycin Inhibitors

Based on *in vitro* and experimental data which suggested a central role for mammalian target of rapamycin (mTOR) in the pathogenesis of autosomal-dominant polycystic kidney disease (ADPKD), two clinical trials have examined the role of these agents in early and late ADPKD patients.[16] Unfortunately, the results from these studies did not document a role for mTOR inhibitors in ADPKD. Serra et al.[17] demonstrated no decrement in kidney size in ADPKD patients treated with sirolimus. In contrast, Walz et al.[18] demonstrated a decrease in kidney size in patients with more advanced ADPKD treated with everolimus, but no benefit in GFR. There was no difference in the decline in GFR in patients in the everolimus group compared with the controls. Whether there is a role for mTOR inhibitors, perhaps in a subset of patients with ADPKD, is presently unclear.

V2 Receptor Antagonists

V2 receptor antagonists, such as tolvaptan, decrease renal cAMP levels, thereby inhibiting cytogenesis and preventing renal enlargement in patients with polycystic kidney disease.[19] In the tolvaptan in ADPKD (TEMPO 3:4 Trial), tolvaptan slowed the increase in total kidney volume and decline in kidney function over a period of 3 years. However, there was a higher discontinuation rate owing to aquaresis and hepatic events in the tolvaptan group.[20] In the REPRISE trial (Tolvaptan in Later-Stage Autosomal Dominant Polycystic Kidney Disease), patients with later-stage ADPKD treated with tolvaptan had a slower decline in kidney function, if they could tolerate the drug.[21] Tolvaptan is therefore now FDA approved to slow progression of kidney disease in patients with ADPKD. An important reason for this somewhat rare "success" in the CKD arena likely includes the availability of a surrogate endpoint (total kidney volume), which facilitated the product development pathway for ADPKD therapies.

Anti-Uric Acid Agents

In addition to precipitating acute attacks of gouty arthritis, high levels of uric acid have significant proinflammatory and profibrotic effects, which could contribute to the progression of CKD. Current data suggest an association between high uric acid levels and CKD progression. However, there have only been a handful of interventional studies that have attempted to address the question of whether lowering uric acid levels results in slowing CKD progression. While studies suggest that there may be a role for uric acid-lowering therapy in patients with CKD, more data are needed before this approach can be routinely recommended.[22,23] A large randomized trial (PERL) is underway to study the efficacy of allopurinol vs. placebo on change in measured GFR in patients with type 1 diabetes.[24]

SGLT-2 Inhibitors and Other Newer Glucose-Lowering Drugs

Sodium-glucose cotransporter type 2 (SGLT-2) inhibitors are a new class of antidiabetic drugs which have demonstrated promising results on cardiovascular and renal endpoints, that are distinct from their glucose lowering effects. Animal studies have shown that they inhibit glomerulosclerosis, with alteration of tubular cell metabolism to a more ketone-prone pathway.[25] In the EMPA-REG OUTCOME trial, empagliflozin, a member of the SGLT-2 inhibitor family, reduced progression to ESRD in patients with type 2 diabetes mellitus and established cardiovascular disease.[26] Similarly in the CREDENCE study, the risk of kidney failure and cardiovascular events was lower in the canagliflozin group than in the placebo group in patients with type 2 diabetes mellitus and kidney disease[27] (Figure 72.1). The exact mechanisms that result in empagliflozin's and canagliflozin's renal protective effects are not fully understood, but it seems likely that the increase in sodium delivery to the macula densa results in a tubuloglomerular feedback loop that decreases afferent arterial blood flow.[28,29] This results in an initial well-documented decrease in GFR, following which the decrease in intraglomerular pressures could potentially result in longer-term improvements in microalbuminuria and GFR slope (Figure 72.2).

The SGLT-2 inhibitor agents are not the only glucose-lowering drugs that appear to have beneficial cardiovascular and renal endpoints. In the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial, the glucagon-like peptide-1 analogue (GLP-1 analogue) liraglutide was shown to decrease proteinuria with an albumin: creatinine ratio approximately 20% lower in the treatment compared with the control arm, regardless of the baseline level of eGFR.[30]

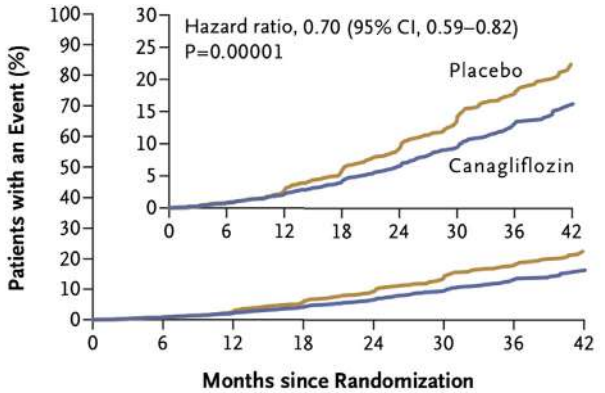

FIGURE 72.1 30% relative risk reduction in the primary composite endpoint of ESRD, doubling of serum creatinine and renal or cardiovascular death, with line segments diverging as early as 12 months after randomization. *Adapted from reference 27.*

There is excitement at present regarding the potential impact of the SGLT-2 inhibitors on the progression of CKD. Their effects on the reduction of cardiovascular endpoints can only augur well for patients with diabetes, who in addition to the risks of diabetic kidney disease also have very high cardiovascular morbidity and mortality. Thus, the SGLT-2 inhibitors and drugs such as finerenone (see below) could potentially have opened a whole new therapeutic area of cardiorenal intervention which focuses on the cotargeting of cardiovascular and renal pathogenesis, pathology, morbidity, and mortality.

The beneficial cardiovascular and renal effects of drugs such as the SGLT-2 inhibitors and GLP-1 analogues were initially discovered as a result of an FDA requirement for the conduct of cardiovascular outcome studies (CVOT) for glucose-lowering agents to identify adverse cardiovascular outcomes. These same agents are now being described by cardiologists and nephrologists as primarily cardiorenal agents that also have a glucose-lowering effect!

There are three key issues that need to be addressed for these agents to have their true kidney and cardiovascular impact. First and foremost, we need more data from clinical studies with renal endpoints such as CREDENCE in both diabetic and nondiabetic patients. Secondly, we need to analyze these data to develop and inform clinical algorithms for the use of these agents in different clinical settings. Finally, we need to develop a comprehensive safety profile for these agents and identify whether different agents in the same class have differing adverse event rates and profiles.

Finerenone

Finerenone is a nonsteroidal chemical entity that functions as a mineralocorticoid receptor antagonist in a fashion similar to spironolactone, but without steroid-induced side effects such as gynecomastia. Initial Phase II studies demonstrated a decrease in proteinuria compared with controls. There are currently two large ongoing Phase III clinical trials to elucidate both the cardiac and renal benefits of this agent, in the setting of diabetic kidney disease. The FIDELIO study has a primary cardiac endpoint with a secondary kidney endpoint, whereas the FIGARO study has a primary renal endpoint with a secondary cardiac endpoint. Similarly to the SGLT-2 inhibitors and GLP-1 analogue agents, the data from these two large studies should help to inform an algorithm for the most appropriate

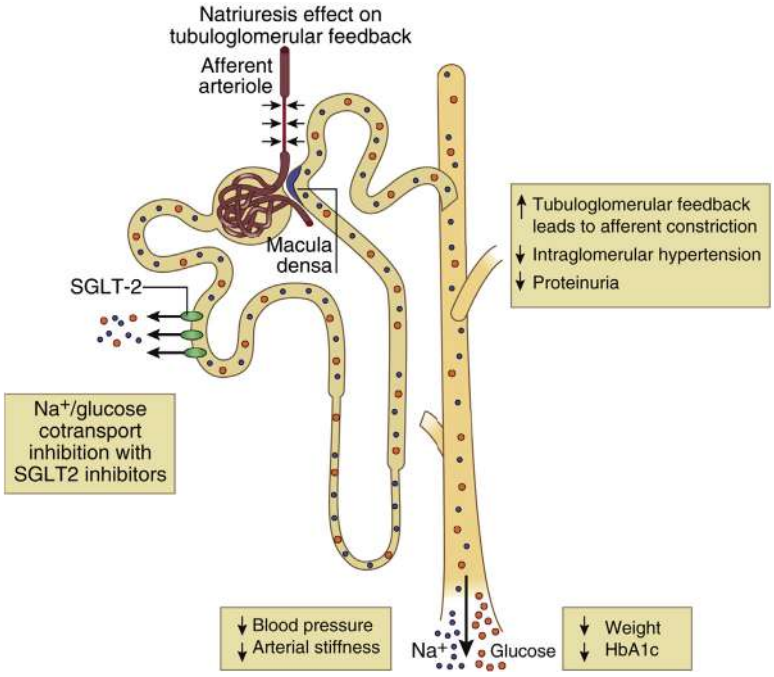

FIGURE 72.2 Mechanism of action of the sodium-glucose cotransporter type 2 (SGLT-2) inhibitors. The key mechanism appears to be a tubuloglomerular feedback loop due to increased sodium delivery to the macula densa, resulting in afferent arteriolar constriction (*arrows*) and a decrease in intraglomerular pressures, which could then result in decreased albuminuria. *Adapted from reference 28.*

clinical use of both finerenone and the SGLT-2 inhibitors and GLP-1 analogue agents in patients with chronic kidney disease (diabetic or non-diabetic).[31]

Endothelin Receptor Antagonists

Endothelin (ET) has vasoconstrictive and profibrotic properties which could contribute to the progression of renal disease. The specific ETa receptor antagonists atrasentan and sitaxsentan have been shown to result in significant reductions in albuminuria.[32,33] The major side effect of this class of drugs is fluid overload. More trials with harder clinical outcomes are needed to clearly study the effect of this class of drugs on renal disease progression. The results from the SONAR (NCT01858532) study which compared the incidence of a composite renal endpoint in patients treated with atrasentan as compared to placebo were recently published and showed a significant reduction in renal events even though the the study was terminated early as a result of a business decision.[34]

Cellular Therapies

Taking their lead from other branches of medicine, investigators are looking at the role of stem cells and bioengineering, in exploring the potential of human renal tissue to form patient-matched identical kidney tissues. With the help of cellular reprogramming technology, one can develop nephron progenitor cells which can be converted into structurally complex and functionally rudimentary kidney tissues. This technology has the potential to replace renal transplantation and thus avoid expensive immunosuppressive medications. Based on *in vitro*[35,36] studies, a prospective study is currently underway looking at the role of injecting neo-kidney augment, which is made from expanded autologous renal cells obtained from each individual participant's kidney biopsy, back into the kidney.[37]

Other Potential Agents

There is increasing interest in fibrotic pathway modulators such as bone morphogenetic protein (BMP)-7 and connective tissue growth factor which have a protective role against TNF-β1 in kidney fibrosis.[38] However, further clinical trials aimed at specific renal endpoints are needed to recommend changes in clinical practice.

Activation of the sirtuin-1 enzyme, a nicotinamide adenine dinucleotide-dependent deacetylase, which plays a role in preventing the diseases of aging, might be an important evolving therapy pertinent to the deterrence of age-related chronic diseases such as CKD. Resveratrol found in red wine and similar activators of sirtuin-1 are also in the development phase.[39]

Knowledge regarding the role of oxidative stress in the progression of vascular disease as well as CKD has led to the development of nuclear factor E2-

related factor 2 activators, such as bardoxolone methyl.[40] Bardoxolone, which attenuates inflammation, was studied in patients with type 2 diabetes with nephropathy. Unfortunately, the study had to be terminated due to an excess of serious adverse events and mortality in the bardoxolone methyl-treated group, likely related to fluid retention.[41] Such agents may still have role in the treatment of CKD, if selection of patients is done more carefully.

B7-1 receptors are present in podocytes and are involved in the pathogenesis of proteinuria through beta 1 integrin activation and cell motility. Abatacept, which is an antibody against B7-1 used in the treatment of rheumatoid arthritis, might help in reducing proteinuria and the ensuing reduction in GFR. This agent has also been used in the treatment of focal segmental glomerulosclerosis resistant to current therapies in patients who had high expression of B7-1.[42]

NOVEL THERAPIES FOR CKD-ASSOCIATED ANEMIA

The introduction of erythropoietin (EPO) into clinical practice in the late 1980s completely changed the care of CKD and ESRD patients.[43] More recently, conventional wisdom about the benefits of normalizing hemoglobin levels with EPO has not turned out to be accurate. Several nephrology and oncology studies have documented a higher incidence of cardiovascular events in patients treated to target higher hemoglobin levels.[44–47] While the exact reasons for this remain unclear, much attention has focused on the potential proliferative effects of exogenous EPO as a possible mechanism. Prolyl hydroxylase domain (PHD) inhibitors have therefore been developed as oral erythropoiesis-stimulating agents. Studies suggest an intriguing linkage between this class of drugs and oxygen biology, hypoxia, inflammation, and renal fibrosis.[48–50]

Mechanism of Action of PHD Inhibitors

EPO gene transcription is under the control of the transcription factor hypoxia-inducible factor 2 alpha (HIF-2α). The stability and transcriptional activity of HIFα molecules is regulated by molecular oxygen–dependent hydroxylation of two prolyl residues. These hydroxylation reactions are mediated through a family of PHD enzymes (Figure 72.3). Inhibition of these enzymes, which require oxoglutarate as substrates, theoretically should increase HIF and subsequently EPO levels.[51–55] Oxoglutarate mimics could therefore serve as competitive inhibitors, which could potentially result in the development of a new class of PHD inhibitors, without the cardiovascular side effects of conventional ESAs.

Clinical Experience with PHD Inhibitors for the Treatment of Anemia

There are currently a number of oral PHD inhibitors at different stages of clinical development. Initial published data on FG-2216 (FibroGen) demonstrated that the drug increases EPO levels not only in HD patients

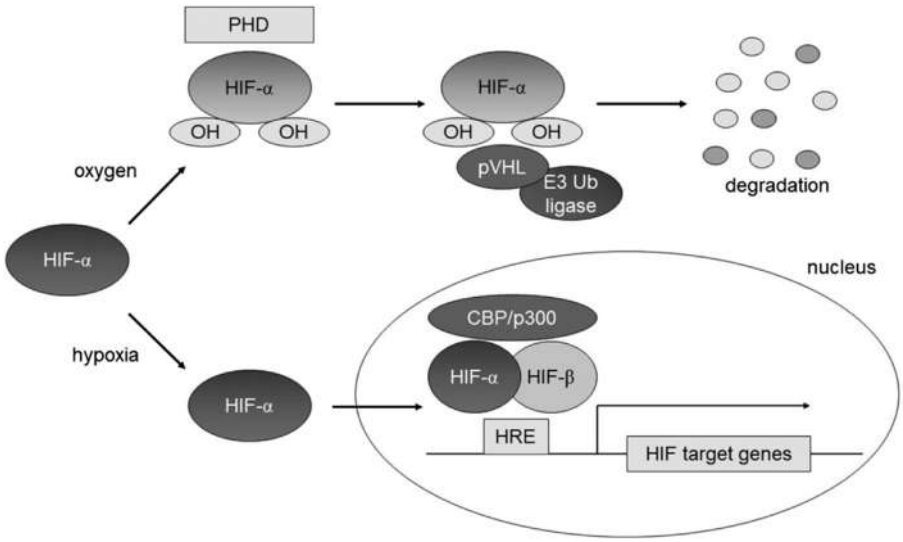

FIGURE 72.3 Erythropoietin (EPO) regulation through hypoxia-inducible factor (HIF). Under normoxic conditions, the transcription factor HIF alpha is hydroxylated by prolyl hydroxylase domain (PHD) enzymes, which results in its ultimate degradation and an inability to increase EPO (an HIF target gene) levels. The obverse occurs under hypoxic conditions because of a decrease in PHD activity resulting in an increase in EPO levels. The presence of PHD inhibitors stabilizes HIF and results in an appropriate (hopefully not excessive) increase in EPO levels. *Adapted from reference 64.*

who still had native kidneys but also in anephric HD patients.[48] The increase in EPO in HD patients who still had native kidneys was more than in the anephric patients, who had increases in EPO levels similar to that of normal healthy volunteers. These results shed light on some important potential mechanisms linked to EPO gene regulation, and the source of EPO in patients with renal failure. The greater increase in EPO levels in patients who still had native kidneys, compared not only with anephric patients but also healthy volunteers, suggests that there could be an element of dysregulated EPO gene expression in uremia, because the nonfunctional kidneys still retained the ability to significantly increase EPO levels. Important proof to support this hypothesis comes from experimental data which suggest that indoxyl sulfate, which is increased in the circulation of uremic patients, could have independent effects on HIF transcription.[56] In addition, the increase in EPO levels in response to PHD inhibitors in anephric patients suggests the presence of EPO-producing cells in organs other than the kidney, even in adults.[57]

Modulating physiological mechanisms related to EPO gene transcription and activation of downstream pathways may therefore be critical in ameliorating factors associated with the pathogenesis of cardiovascular disease linked with exogenous EPO administration that results in high hemoglobin levels.

Links Between Oxygen Biology, Inflammation, and Fibrosis

Oxygen biology pathways affected by therapeutic strategies for renal anemia could have unexpected ancillary benefits on mechanisms associated with renal fibrosis. Tissue hypoxia occurs in the setting of experimental models of CKD.[58,59] Hypoxia can activate downstream inflammatory, oxidative stress and fibrotic pathways.[60] The resolution of tissue hypoxia could be potentiated through the use of PDH inhibitors. Unfortunately, all the currently available inhibitors are nonspecific. Thus, in addition to potentially beneficial effects on tissue hypoxia, they would also likely increase erythrocytosis and angiogenesis. Alteration of angiogenic pathways might then promote fibrosis[50] or predispose to tumorigenesis.

However, more specific PHD-1 inhibitors that could protect hypoxic tissues through a reduction in oxidative stress without affecting angiogenesis and erythropoiesis might have beneficial effects on mechanisms associated with fibrosis.[61] Phase II clinical trials demonstrating safety and efficacy signals have been conducted using at least 5 PHD-1 inhibitors. Three large pivotal trials with roxadustat, vadadustat, and daprodustat are currently in progress, and the results are eagerly awaited. If successful, these data could allow targeting of normal hemoglobin values in CKD and ESRD patients, without the fear of cardiovascular events and the potential for other beneficial effects on fibrogenesis.[62–64]

THERAPIES FOR VASCULAR CALCIFICATION

Premature cardiovascular disease (including sudden cardiac death, coronary heart disease, acute myocardial infarction, and congestive heart failure) in CKD patients is perhaps the single most important problem currently faced by the renal community. To place the magnitude of this risk in perspective, the chances of a cardiovascular event in a 20- to 40-year-old treated with HD is equivalent to that of an 80-year-old without renal disease.[65–68] Traditional cardiovascular interventions such as lifestyle changes and treatment of blood pressure and dyslipidemia do not appear to have the same beneficial impact on cardiovascular mortality as in patients without renal disease. This paradox has resulted in increased attention paid to interventions that target novel pathways such as bone mineral disorder, inflammation,[69] oxidative stress,[70] endothelial dysfunction,[71,72] retention of uremic toxins,[73] and vascular calcification.[74,75] Perhaps the most exciting area in the context of emerging therapies for vascular disease in CKD patients is vascular calcification.[74–76] Vascular calcification in the general population occurs mainly within the neointima and in atherosclerotic plaques, resulting in vascular stenosis and dysfunction, especially in the setting of a thrombotic event. In CKD and ESRD patients, however, vascular calcification could be due to either neointimal calcification in the context of accelerated atherosclerosis or medial vascular calcification, which results in increased arterial stiffness, left ventricular hypertrophy, heart failure, and sudden cardiac death.[74,77]

Mechanisms of Vascular Calcification

The major mechanisms and mediators of vascular calcification have been well described.[74] They include failed anti-calcific processes involving a decrease in Fetuin A and an increased serum osteoprotegerin (OPG)/RANKL ratio, promotion of vascular smooth muscle cells by Prelamin A, the induction of osteochondrogenesis involving diabetic/inflammatory pathways and specific microRNAs such as miR-125b, cell death, and apoptosis, dysregulated calcium-phospate homeostasis which is particularly relevant to CKD, calciprotein particles, and various effects on matrix degradation/modification. Additional proteins that have associations with vascular calcification include matrix Gla protein and osteopontin, which inhibits calcium crystal growth,

ectonucleotide pyrophosphatase phosphodiesterase which regulates extracellular phosphate, and inhibition of VSMC apoptosis. Novel therapies may inhibit vascular calcification through modulation of some of these pathways.

RANK/RANKL/OPG Pathways

RANK is a type I membrane protein expressed on osteoclasts. When RANK binds to its ligand RANKL,[78] osteoclasts are activated. The resulting release of calcium from bone can then cause increased vascular calcification. In contrast, OPG is produced by osteoblasts and is a potent inhibitor of osteoclast differentiation and survival by functioning as a decoy receptor for RANKL.[78] OPG appears to protect against vascular calcification because $OPG^{-/-}$ mice develop spontaneous arterial calcifications.[79] RANKL on the other hand increases vascular smooth muscle cell calcification by increasing BMP-4 production.[80] Interest in the RANK/RANKL/OPG pathway as a mechanism to inhibit vascular calcification is particularly topical because of the availability of a monoclonal antibody (denosumab; indicated for patients with osteoporosis), which binds to RANKL, thus preventing RANK–RANKL interactions and subsequent osteoclast activation. Studies with denosumab have demonstrated reduced vascular calcification in a mouse model of glucocorticoid-induced calcification.[81] An important caveat, however, is that treatment with denosumab has been associated with significant and prolonged hypocalcemia in some patients with CKD.[82,83]

Vitamin D Receptor Agonists

Vitamin D receptor antagonists are thought to work by increasing levels of osteopontin and klotho. Vitamin D receptor antagonism reduces aortic calcification in uremic mice fed high phosphate diets.[84] There are no available human data on the ability of this therapy to reduce vascular calcification in CKD patients, although lower levels of vitamin D may be associated with increased mortality in incident hemodialysis patients.[85]

Vitamin K

CKD patients are often deficient in vitamin K, an important cofactor for a number of metabolic pathways, especially one involving matrix GLA protein.[74] A specific mechanism by which vitamin K repletion may reduce vascular calcification is by more efficient utilization of menaquinone-4, which could then inhibit arterial calcification.[86]

Calcimimetics

Cinacalcet is a calcimimetic agent which acts *via* allosteric activation of the calcium-sensing receptor on parathyroid tissue.[87] A large multicenter study (EVOLVE) evaluated the impact of cinacalcet on a composite endpoint of time to death or first nonfatal cardiovascular event and demonstrated a nonsignificant, 7% reduction in treated HD patients vs. placebo. A parallel analysis with lag censoring of data at 6 months after study drug discontinuation, however, demonstrated a nominally significant 15% relative reduction in the primary endpoint and a 17% relative reduction in mortality (absolute reduction of 2–3%).[87] In another large randomized clinical trial, the ADVANCE trial, cinacalcet plus vitamin D vs. vitamin D alone did not show a significant difference in the percentage change of coronary artery calcification scores.[88]

Role of Glucocorticoid-Inducible Kinase 1 Receptors

Both glucocorticoids and aldosterone act on the kidney though serum and glucocorticoid-inducible kinase 1 receptors. These receptors are responsible for the deleterious effects of these hormones on the cardiovascular system such as cardiac hypertrophy, cardiac fibrosis, and promotion of arrythmias. An inhibitor to this receptor has been developed called EMD638683.[89]

In summary, emerging therapies for vascular calcification must still be developed. Although the field is rapidly moving forward with regard to understanding the mechanisms involved in vascular calcification, there are still no truly effective clinical therapies shown to reduce vascular calcification in CKD.

RENAL DENERVATION THERAPIES FOR HYPERTENSION AND CKD

Despite the fact that a large array of effective therapeutic agents for the treatment of hypertension are available, treatment on a population and perhaps on an individual basis is still suboptimal. Indeed, if the target is set at 140/90 mm Hg, the success rate in the US is only 29%.[90] An important reason for this remains the side effect profile of antihypertensive agents in the context of an asymptomatic disease. Another important issue is poor compliance with both follow-up and medication adherence.[91]

An alternate approach to the therapy of hypertension is the use of renal denervation. Renal denervation could potentially address the previously described problems with conventional treatment approaches to hypertension.[92,93]

Biologic Rationale for Renal Denervation Therapy

The sympathetic nerve supply to the kidney is responsible for multiple renal effects, including increased production of renin, increased tubular reabsorption of salt and water, and renal vasoconstriction.[94] The potential benefit of completely blocking the sympathetic nerve supply of the kidney could therefore be particularly effective in patients with renal disease because of increased sympathetic activity.[95]

Interventional Technique

An important technological step forward that has allowed this concept to become a therapeutic reality was the development of an interventional technique that allowed selective renal sympathetic denervation. This was possible primarily because the sympathetic nerve supply to the kidney runs along the renal artery. As a result, the placement of a special catheter within the renal artery could allow low intensity radiofrequency ablation of the entire renal sympathetic nerve supply. There are currently a number of such catheters available for clinical use. The radiofrequency ablation (RFA) catheter is positioned in the distal portion of the renal artery and then gradually withdrawn in a spiral fashion while administering RFA charges.

Early Human Studies of Current Renal Denervation Approaches

A landmark study documented significant reduction in renal sympathetic spillover, 30 days after bilateral renal denervation.[96] This was followed by a nonrandomized 50-patient study of bilateral renal denervation, which documented blood pressure decreases of 14/10 mm Hg (systolic/diastolic) at 1 month and 27/17 mm Hg at 1 year.[91]

Randomized Clinical Trials

These initial nonrandomized studies were followed by the Symplicity HTN-2 clinical trial, a randomized study of over 100 subjects with refractory hypertension (blood pressure greater than 160/90 mm Hg in a patient taking three antihypertensive medications).[97,98] The results documented significant decreases in systolic blood pressure, from a 20-point reduction at 1 month to a 32-point reduction at 6 months. There was no change in blood pressure in patients in the control arm. There were, however, a number of drawbacks to this study, including the lack of a sham procedure and also the use of office blood pressures only, which could be more dependent on sympathetic nerve activity compared with 24-hour ambulatory blood pressures. These weaknesses were addressed in the Symplicity HTN-3 study, a prospective, single-blind, randomized, sham-controlled trial of renal denervation in participants with resistant hypertension. The primary safety endpoint was a composite of death, ESRD, embolic events resulting in end organ damage, renovascular complications, and new renal artery stenosis. The primary efficacy endpoint was a change in office systolic blood pressure of greater than 5 mm Hg compared with the control group, with a secondary efficacy endpoint of a 2-mm reduction in ambulatory systolic blood pressure. In marked contrast to the results from the Symplicity HTN-1 and Symplicity HTN-2 studies, Symplicity HTN-3 study did not demonstrate a statistically significant improvement in either the primary or secondary endpoints. There were no differences between the control and treatment groups with regard to the safety endpoint.

Why were the results from Symplicity HTN-3 so different from the earlier Symplicity studies, and what do the results of this study mean for the future of renal denervation therapy? Above all, the Symplicity HTN-3 study once again emphasizes the importance of having a true control group. The control group in Symplicity HTN-3 (as opposed to Symplicity HTN-2) underwent a sham procedure and therefore believed that they had received therapy. This together with participation in the trial (Hawthorne effect) could have had a beneficial impact on blood pressure. A *post hoc* analysis of the data appears to demonstrate a statistically significant benefit in non-African Americans in the study.[99] In addition, some concerns have been raised about the lack of experience of the Symplicity HTN-3 investigators[100] as opposed to the greater experience currently available in Europe (over 15,000 cases have gone into the European Registry). In summary, while the results of the Symplicity HTN-3 study do not support use of renal denervation therapy, there is ongoing speculation about whether there are in fact certain subgroups such as non-African Americans who might still benefit from this therapy. It is also unclear regarding whether there could be some benefit from its use in CKD patients. While an eGFR of less than 45 mL/min/1.73 m^2 was an exclusion for the Symplicity HTN-3 study, there are some data which suggest that renal denervation therapy does not have a negative impact on GFR[101] and may in fact have a beneficial effect on microalbuminuria.[102] A recent study in a mouse model of renal fibrosis due to unilateral ureteral obstruction documented a significant reduction in renal fibrosis in animals subjected to sympathectomy.[103] Future research is likely to be directed

toward the identification of such niche populations. More than anything else, however, the Symplicity HTN-3 study emphasizes once again the absolute necessity of using an appropriate control group.

One of the technical factors that might have been responsible for the failure of the Symplicity trial is incomplete denervation of the renal nerves due to inadequate cauterization. The Paradise Ultrasound Renal Denervation System (PRDS)-001 which uses ultrasound might be a solution to this issue. This system allows sufficient periarterial nerve damage using ultrasound. At the same time, it uses a cooling balloon which reduces the risk of overheating the arterial wall and prevents tissue damage.[104] The safety and effectiveness of this technique has been demonstrated in porcine models and in humans. A clinical trial (REQUIRE), in which an ultrasound renal denervation system is being used to treat resistant hypertension, is ongoing in Japan and Korea.[105]

There are also two other ongoing clinical trials, the REDUCE HTN REINFORCE study which uses the Vessix system (Vessix Reduce™ Catheter and Vessix™ Generator) and the SPYRAL HTN OFF-MED trial using the Symplicity Spyral catheter. Both will use advanced catheters which can more precisely induce nerve damage without injuring surrounding arterial tissue.[106]

A Holistic View of Renal Denervation

The currently available data on renal denervation therapy is exciting, while also deserving of a note of caution. There is no question that the ability to have a significant impact on blood pressure levels using a one time interventional procedure that targets renal sympathetic nerves, does not require long-term therapy with medications, and which may have a role in the prevention of renal fibrosis is a step forward. On the other hand, we should be cognizant of the fact that (a) long-term efficacy data using a sham intervention and 24-hour ambulatory blood pressure monitoring are still pending and (b) we are perhaps evaluating a potentially expensive and invasive therapy because lack of adequate processes of care addressing issues such as compliance and physician/patient fatigue pose challenges to current therapeutic approaches. It is possible that the advantages of a one-stop shop approach may be particularly valuable in the context of CKD patients in many parts of the world (both developed and developing), where poor compliance and a lack of adequate early referral and follow-up continue to be important deficiencies within CKD programs. The downstream result of poorly controlled blood pressure in CKD patients is of course ESRD, with its associated morbidity, mortality, and economic costs.

NOVEL THERAPIES FOR VASCULAR ACCESS DYSFUNCTION

Dialysis vascular access is currently considered to be both the "lifeline" and the "Achilles heel" for patients on hemodialysis.[107–111] Perhaps the most disturbing statistic regarding vascular access is that approximately 80% of incident patients start HD with a tunneled dialysis catheter (TDC),[112] with as much as a fivefold increase in mortality in the first 90 days of treatment, compared with patients who start with an arteriovenous fistula (AVF) or arteriovenous graft (AVG).[113] The battle for vascular access will therefore likely be won or lost during the CKD phase. The way to achieve vascular access success during the CKD phase is likely through a combinatorial approach that includes both process of care interventions and the development of novel and innovative therapies. Process of care interventions would include early referral to kidney disease specialists, prevention of delays in referrals by nephrologists to radiology and surgery for vessel mapping and surgery, availability of committed and dedicated vascular access surgeons, close patient and vascular access follow-up post surgery, and the use of master cannulators for the initial cannulations of an AVF (Figure 72.4). Investing in a dedicated vascular access coordinator would address many of the above issues.

Biology of AVF Maturation Failure

Early AVF maturation failure is probably due to a combination of aggressive neointimal hyperplasia in combination with a lack of outward remodeling.[108–111,114] At a more pathogenic level, it is likely that the interaction between hemodynamic shear stress and the vascular response of the uremic vein to these stressors determines ultimate AVF success or failure. Our group and others have documented a

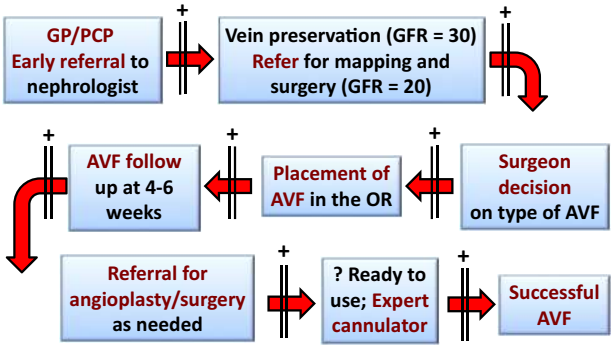

FIGURE 72.4 Process of care barriers for arteriovenous fistula (AVF) maturation. Note that each of these barriers (parallel lines) is also an opportunity (+) for local and meaningful process of care innovation. GFR units mL/min/1.73 m^2.

significant amount of neointimal hyperplasia within venous segment tissue collected from the site of AVF surgery, suggesting that uremia, oxidative stress, and endothelial dysfunction can result in preexisting neointimal hyperplasia even before AVF creation.[115,116] This preexisting neointimal hyperplasia does not seem to be linked to future AVF stenosis and failure.[117]

Novel Therapies for AVF Maturation

The goal of the therapies described in this section is primarily to enhance AVF maturation during the CKD phase, so that patients are able to start dialysis with a mature ready-to-use AVF.

PRT 201 Elastase

The rationale for this intervention is that the application of a recombinant elastase will destroy elastin fibers in both the artery and the vein and allow rapid AVF dilation and maturation. This concept is particularly important, because it goes to the heart not only of "fistula first" but also incorporates the "catheter last or catheter out" concept, because rapid AVF maturation would allow for the rapid removal of TDCs. Initial Phase II studies suggest that the mechanism may be somewhat more complex, in that the best results were seen in the low dose group,[118] suggesting that fragmentation of elastin fibers into protein fragments with potential biological activity could be the mechanism of action. An initial large Phase III randomized clinical trial in the setting of radiocephalic fistulae using unassisted primary patency as the primary endpoint did not show a statistically significant difference between the control and treated arms. There was, however, a difference in the secondary endpoint of cumulative patency. The results from a larger Phase II study with cumulative patency as the primary endpoint have just been described and there was once again disappointingly, no difference between the treatment and control arms.

Sirolimus COL-R Wraps

Sirolimus is an antiproliferative agent that blocks neointimal hyperplasia in the setting of coronary restenosis. The COL-R wrap comprises a biodegradable sirolimus-eluting wrap (antiproliferative agent) which is placed around the arteriovenous anastomosis of an AVF, or around the graft-vein anastomosis of a PTFE (polytetrafluoroethylene) graft (Figure 72.5). An initial Phase II study demonstrated primary unassisted AV graft patencies of 75% and 38% at 1 and 2 years, in patients treated with the COL-R wrap, albeit in the absence of a control arm.[119] Similar pilot studies in AVFs have documented excellent AVF maturation rates. A Phase III randomized controlled trial to assess the safety, efficacy, and maturation outcomes of a perivascular sirolimus-eluting implant placed at the AVF anastomosis in hemodialysis patients is currently ongoing. Results are expected by 2022.

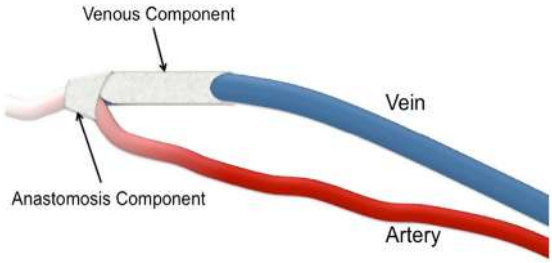

FIGURE 72.5 Sirolimus COL-R wraps for arteriovenous fistula maturation. Elution of sirolimus from these biodegradable wraps is expected to enhance arteriovenous fistula maturation. *Courtesy Dr. Iyer.*

Vascugel Endothelial Cell–Loaded Wraps

This comprises a gel-foam wrap, embedded with endothelial cells. The biological rationale behind "Vascugel" is that endothelial cells are bioreactors for "good" mediators. Thus, the delivery of "good" endothelial cells to the local vicinity of the AVF should allow a local milieu that inhibits neointimal hyperplasia and enhances outward remodeling. Initial experimental studies documented a beneficial effect of endothelial cell–loaded gel-foam wraps in porcine models of AV fistula and graft stenosis.[120,121] More recently, human studies have described the technical feasibility of improvement in primary patency when Vascugel wraps were used in diabetic patients with PTFE grafts.[122,123] Patients on an active transplant list or who are likely to get a transplant in the future should not be treated with this therapy because of some risk of sensitization to HLA antigens. Shire Regenerative Medicine recently initiated two large studies using these wraps in the setting of AVFs and AVGs, respectively. Both studies were unfortunately stopped due to business considerations. It is therefore unclear as to whether this therapy will enter into clinical practice.

Nitroglycerine Ointment

Glyceryl trinitrate (GTN) is a nitrate-based vasodilator that can increase blood flow and prevent platelet aggregation. Use of GTN at the time of creation of an AVF may help in the maturation process. Although there were some positive results in early trials, a randomized controlled trial evaluating the role of locally administered nitroglycerin ointment to enhance local nitric oxide bioavailability in improving AVF maturation did not show significant effect on maturation.[124]

Percutaneous AVF Creation

An important cause of AVF maturation failure is thought to be the surgical handling and potential vascular torsion that occurs at the time of its surgical creation, which then predisposes to perianastomotic stenosis. Recently, there have been some exciting technological advances that have resulted in FDA approval of two techniques for the creation of percutaneous AVFs. One of the techniques uses ultrasound to place a percutaneous device across a vein and artery in the upper forearm that is close together and then delivers a burst of energy to create an AVF (Figure 72.6). The other technique uses catheters with magnets to bring the appropriate artery and vein close together and then creates a connection through a burst of energy (Figure 72.7). The important advantages of this technique include the avoidance of a surgical procedure, no need for preoperative evaluation, and the lack of a surgical scar. In addition, the initial nonrandomized data describe outstanding patency for these techniques. It is important, however, for additional real-world data to be collected and evaluated. Perhaps the greatest impact of the percutaneous techniques could be on the process of care for AVF creation, because these technologies now allow the creation of AVFs by endovascular and ultrasound specialists (interventional radiologists and interventional nephrologists in particular). This more egalitarian approach to AVF creation may result in better access to care for AVF creation, and potentially for the ultrasound-based technology, in parts of the world where there is limited access to endovascular suites.[125,126]

Bioengineered Vessels

The creation of a bioengineered vessel that could be used as a vascular conduit has for long been the holy grail for vascular surgery and applied vascular biology. In the context of dialysis vascular access, the availability of a vascular conduit that could be used in patients who are not suitable candidates for an AVF, without the

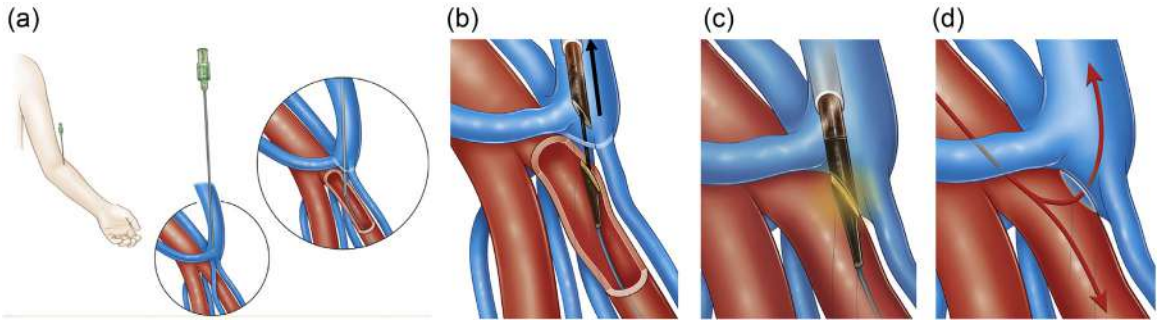

FIGURE 72.6 Percutaneous arteriovenous fistula (AVF) creation with the Ellipsys device. The proximal radial artery is initially punctured through the deep communicating vein and a guide wire is placed through the vein into the artery (a). The Ellipsys catheter is then advanced over the wire and traction (*arrow*) is applied to make sure that the device has captured the arterial wall (b). The device is then closed and activated with thermal energy, resulting in a communication between the DCM and the radial artery (c), to create an AVF (d). *Adapted from reference 126.*

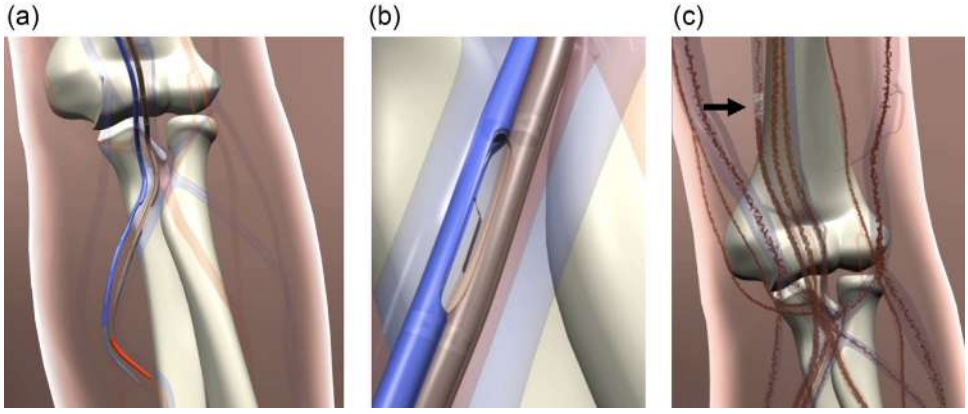

FIGURE 72.7 Percutaneous arteriovenous fistula (AVF) creation with the WavelinQ device. Guidewires and special catheters are placed into an adjoining artery and vein (a). Catheter magnets are then activated resulting in the vessels coming close together, following which an electrode delivers a burst of radiofrequency energy to create an AVF (b). In a final step, a deep vein is coiled (*horizontal arrow*) in an attempt to preferentially drive blood through the superficial venous system (both basilic and cephalic; c).

stenosis and thrombosis that characterizes PTFE graft use, would be an important advance. Humacyte recently described a bioengineered vessel in which a biodegradable scaffold in the form of a dialysis access graft is seeded with mesenchymal cells which then produce matrix proteins, resulting in a collagenous tube. This device is then treated to remove all living cells to minimize allorecognition and potential sensitization to HLA antigens. The final device, which looks like a vessel, has been placed in a number of patients on hemodialysis in the form of an AVG. Initial results demonstrate a primary patency similar to PTFE grafts, but perhaps with less infection and with the need for fewer interventions to maintain patency. Humacyte is currently conducting two large randomized studies where these grafts are compared with standard ePTFE. The results will be available shortly.[127]

INNOVATIVE RENAL REPLACEMENT THERAPIES

Since the advent of chronic hemodialysis at Northwest Kidney Centers, in Seattle in the early 1960s, this technology has saved millions of lives. Dialysis still remains the only form of organ replacement therapy that is effective over prolonged periods of time. The huge success of this technology, however, has perhaps lulled the kidney community into a false sense of complacency, in that the basic construct of hemodialysis has not changed significantly over the last 40 years. The current survival on hemodialysis for all patients in the US is a dismal 41% at 5 years, which is lower than the five-year survival of most cancers (Figure 72.8). More importantly, patients treated with maintenance hemodialysis have poor quality of life, with an extremely limited ability to do the things that are important to them (such as being able to travel and not feeling washed out after dialysis). To address this issue, there has been a great deal of interest recently in home hemodialysis, portable and wearable hemodialysis, and in sensors that could create a real-time feedback loop (Figure 72.9).[128–130] There has also been some exciting experimental work on an implantable kidney by a group led by Drs. Shuvo Roy and William Fissell (Figure 72.10).[131] In addition, the Kidney Health Initiative, a public–private partnership between the American Society of Nephrology and the FDA[132,133] has recently described a road map for innovative RRT which we hope will serve as a catalyst to focus interest, investment, and innovation in this area.[134] In parallel with the description of the innovative RRT road map, the Kidney Innovation Accelerator or KidneyX, a public–private partnership between the Department of Health and Human Services and the American Society of Nephrology recently announced a prize competition which focuses on "Redesigning Dialysis."[135] We feel that these two policy and funding initiatives will nicely complement each other to truly jump start advances in this area. Thus, while the road map

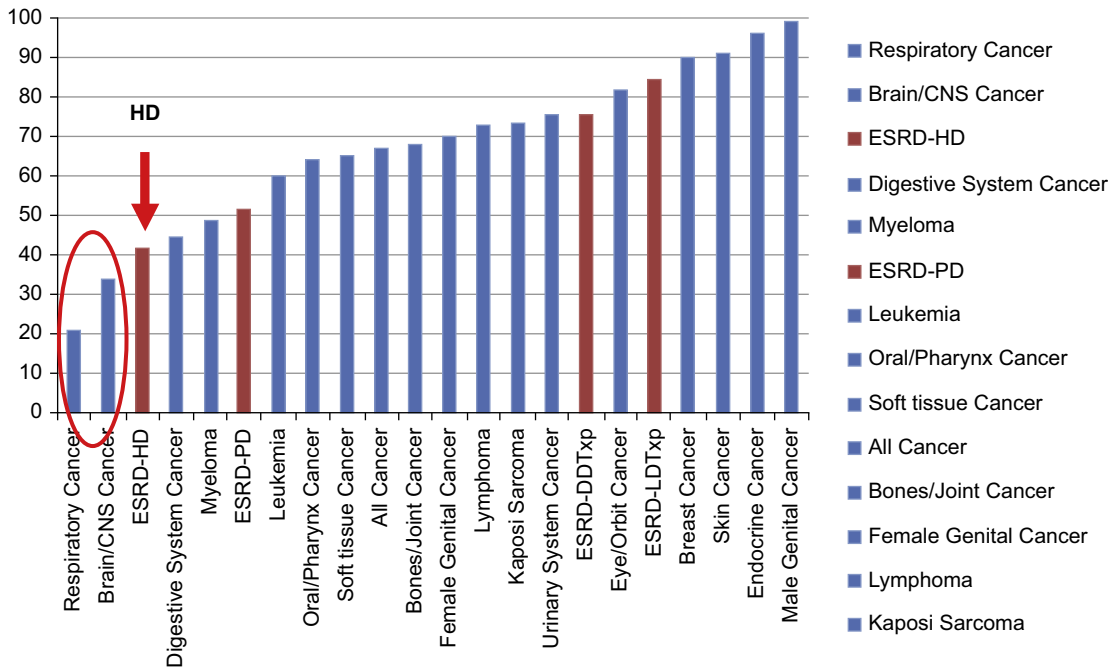

FIGURE 72.8 Poor survival of hemodialysis patients. The 5-year survival of end-stage renal disease (ESRD) patients treated with hemodialysis is worse than many forms of cancer. *Adapted from an original figure; courtesy Frank Hurst.*

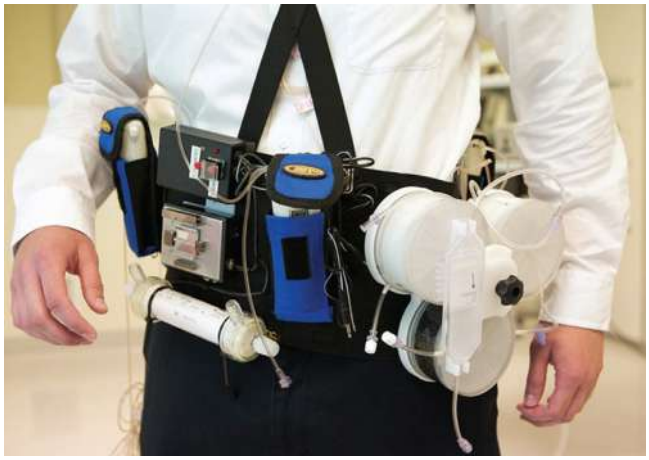

FIGURE 72.9 Prototype of a wearable artificial kidney. This would allow better quality of life using slow continuous dialysis. *Adapted from reference 129.*

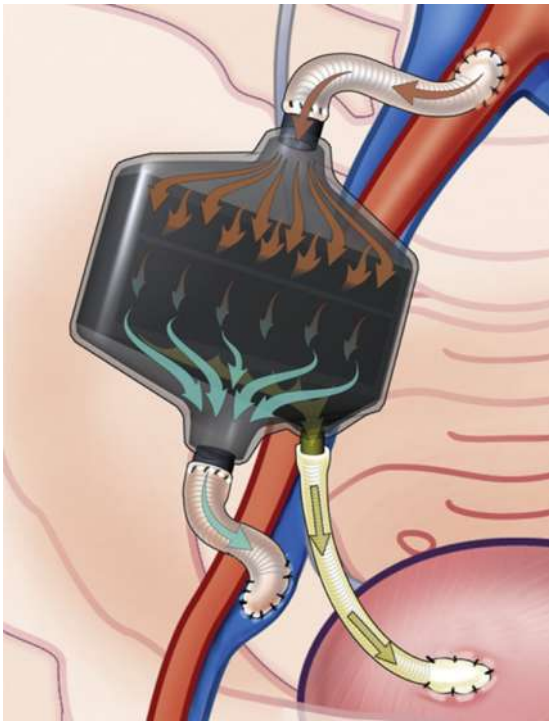

FIGURE 72.10 Implantable artificial kidney. could serve as the technical construct for the Redesign Dialysis initiative, the funds available for the Redesign Dialysis competition could function as the implementer arm for the milestones described in the innovative RRT road map.

CONCLUSION

In summary, we have presented data on a number of novel therapeutic concepts that could completely change the way we care for CKD patients in the coming years. The true way to move any field forward, however, is to synergize biological and technological advances with the clinical setting/process of care pathways and with regulatory/reimbursement pathways. The presence of public–private partnerships such as the Kidney Health Initiative, which aims to create an innovation substrate for kidney diseases, is an important step forward to achieving this goal. Our hope for the future is that the availability of a number of novel therapies to individualize the management of CKD and its complications will allow us to get the right therapy to the right patient at the right time.

CHAPTER

73

The Renal Biopsy in Chronic Kidney Disease

Casey N. Gashti, Pravir V. Baxi, William L. Whittier, Stephen M. Korbet

Division of Nephrology, Rush University Medical Center, Chicago, IL, United States

Abstract

The renal biopsy remains the gold standard for diagnosis, therapeutic management, and outcome prediction in patients with renal parenchymal disease. The indications for a renal biopsy in evaluation of proteinuria, microscopic hematuria, renal manifestations of systemic disease, and unexplained acute kidney injury are discussed. The utility of renal biopsy in patients with chronic kidney disease (CKD) is less defined. Given higher risk of complications and a lower chance of diagnostic or therapeutic success in CKD, the risk–benefit analysis in the context of clinical setting is of utmost importance. Percutaneous renal biopsy is the most widely accepted approach to obtaining renal tissue. Absolute and relative contraindications to the percutaneous approach are discussed. Alternative methods such as transvenous or an open renal biopsy can be used as substitute in high risk patients. Finally, the spectrum of minor and major complications and associated risk factors are explored.

INTRODUCTION

Prior to the introduction of the percutaneous kidney biopsy (PRB) in the 1950s, the majority of our study of kidney parenchyma was limited to evaluation at autopsy. The clinical–pathological correlation of this postmortem tissue was challenging because autolysis and global scarring hampered insight into disease processes. The development of the kidney biopsy procedure was essential in the establishment of nephrology as a separate subspecialty in internal medicine.[1] In 1951, Iversen and Brun first introduced the PRB based on their experience performing liver biopsies. Using intravenous pyelography for localization and the liver aspiration needle, they biopsied the right kidney with patients placed in the sitting position. The procedure was successful in only 53% of attempts, with less than adequate tissue for diagnosis in 60% of samples.[2] Despite these limitations, their experience fueled interest in the PRB and led to increased biopsy attempts around the globe. The success rate nevertheless continued to remain unacceptably low. In 1954, Kark and Muehrcke published a modified technique that would change the course of the renal biopsy field. By placing the patient in the prone position and using a Franklin-modified Vim-Silverman needle, as opposed to an aspiration needle, they were able to achieve a success rate of 96% without major complications.[3,4] Although there have been other minor advances in biopsy technique since that time, their approach still remains the foundation of the practice today.

The role of the kidney biopsy in the evaluation of proteinuria, microscopic hematuria, renal manifestations of systemic disease, and unexplained acute kidney injury (AKI) are well established.[5] However, the utility in patients with chronic kidney disease (CKD) is less defined. We review the PRB biopsy procedure, discuss indications, contraindications, and complications with a focus on the role in patients with CKD and consider potential future applications of the procedure.

INDICATIONS AND CONTRAINDICATIONS

The renal biopsy remains the gold standard for diagnosis, therapeutic management, and outcome prediction in patients with renal parenchymal disease. The primary indications for a renal biopsy in the clinical setting include evaluation of proteinuria, microscopic hematuria, renal manifestations of systemic diseases, and unexplained AKI or CKD.[5] The results of the renal biopsy have a significant impact in patient care, in that they change the diagnosis in greater than 60% of cases and affect therapeutic management decisions in a third of patients.[6,7] The impact on management is greatest in patients being evaluated for nephrotic proteinuria, unexplained AKI, and renal involvement with systemic disease.[8] Given the invasive nature of the procedure, nephrologists must weigh the risks of a kidney biopsy in

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00073-5

the context of the perceived benefits a patient may derive from a histologic diagnosis.[9] As such, the indications for renal biopsy may vary among nephrologists based on an individual patient's presentation and the consideration of the risk–benefit ratio.

Despite its utility in establishing a diagnosis and guiding therapeutic management in patients with near-normal renal function, the value of renal biopsy in patients with CKD is more controversial. The indications for renal biopsy in a CKD patient should be the same as that in a patient without CKD, though certain considerations apply. CKD patients have a higher risk of bleeding and a lower chance of diagnostic or therapeutic success, particularly when the kidney size is small.[10] CKD tends to progress in most but not all patients.[11] The rate of progression varies considerably within each diagnostic group and within each patient category.[12] Whatever the mechanism involved in renal disease progression, there is a "point of no return": a stage of structural and functional damage beyond which progression of renal disease occurs independent of pharmacologic intervention.[13] Although different diseases likely have different "points of no return," in adults, a serum creatinine concentration (S[Cr]) value of around 2 mg/dL or estimated glomerular filtration rate of approximately 50 mL/min/1.73 m^2 might be regarded as a critical level discriminating the results of treatment.[13] Institution of currently available therapies with high levels of potential toxicity and narrow therapeutic windows is not advisable if much of the renal parenchyma is already scarred. Patients who present with CKD of unknown etiology or duration, based on clinical and serologic work up can benefit from a renal biopsy to establish a diagnosis, confirm the likelihood of benefit from therapeutic intervention, clarify prognosis, and guide future management regarding transplantation. When considering a renal biopsy in a CKD patient, the challenge for the nephrologist is to weigh the higher risks and the lower benefits of a renal biopsy in the context of the overall clinical setting. Indications for and contraindications to performing a renal biopsy in the native kidney according to clinical presentation will be considered. We have intentionally excluded such discussions in the kidney transplant patient.

ISOLATED GLOMERULAR HEMATURIA

The diagnostic approach to isolated glomerular hematuria changes according to the patient's age. In children, isolated glomerular hematuria is often due to hypercalciuria, hyperuricemia, or glomerular diseases such as IgA and thin basement membrane nephropathy.[14] Thus, in the absence of other abnormal urinary, serologic, or radiographic findings, a metabolic work up is often undertaken and a renal biopsy is deferred given the excellent overall long-term prognosis.[15] In adult patients who present with persistent microscopic hematuria but have no coexisting proteinuria, hypertension, renal insufficiency, or other structural abnormalities of the urinary tract, the etiology of hematuria is often due to a mild glomerular abnormality such as IgA nephropathy (50%) or a form of hereditary nephritis (Alport syndrome or thin basement membrane disease) and a renal biopsy is often deferred.[16] Remarkably, 25% of such patients have normal renal biopsies.[17] Most patients with either IgA nephropathy or hereditary nephritis without proteinuria have a good long-term prognosis. Renal biopsy may be more useful to assess an individual's risk of progressive renal disease (suitability for kidney donation) or inspire the screening of relatives (in the case of Alport syndrome) than to guide management. Thus, renal biopsy should be performed only if defining the source of hematuria is necessary to obviate further expensive or hazardous evaluations, to define the therapeutic approach (including providing no therapy), or to reassure the patient. If the decision has been made not to perform a renal biopsy in a patient with isolated glomerular hematuria, ongoing follow-up to monitor for the development of proteinuria or disease progression is warranted. A general consensus on performing a biopsy occurs when glomerular hematuria coexists with proteinuria.[18]

ISOLATED NONNEPHROTIC PROTEINURIA

Patients who present with low-grade proteinuria of <1 g/day without hematuria, renal insufficiency, or serologic abnormalities may be monitored without undergoing a renal biopsy. The majority of these patients will have a mild form of focal segmental glomerulosclerosis (FSGS).[19] These patients are not presently candidates for immunosuppressive therapy as the clinical significance of this lesion remains uncertain. It must be noted that all glomerular diseases can cause mild to moderate proteinuria as their only manifestation. Tubulointerstitial diseases can also present with mild to moderate proteinuria, but renal biopsy is generally not useful in identifying a specific cause. Most often, the biopsy reveals nonspecific findings such as inflammation and fibrosis. Occasionally, infiltration of the interstitium with eosinophils, deposition of immune complexes, or immunoglobulins in tubules may suggest a specific diagnosis.[20] The rationale for performing a renal biopsy in these patients with low-grade proteinuria is therefore similar to patients with asymptomatic hematuria. Factors such as the presence of abnormal urinary sediment such as hematuria or pyuria, serologic abnormalities, or the presence of

renal insufficiency should be considered in decision-making. Many nephrologists routinely perform renal biopsies in patients who have higher levels of proteinuria (1–3 g/day) unless explained by conditions such as long-standing diabetes mellitus.

NEPHROTIC SYNDROME

Primary nephrotic syndrome in adults is the most universally accepted indication for a renal biopsy. Although the incidence and distribution of primary glomerulopathies vary throughout the world and by race, the most common findings are often FSGS, membranous nephropathy (MN) or minimal change disease (MCD).[21,22] However, diabetic nephropathy, systemic lupus erythematosus (SLE), IgA nephropathy, amyloidosis, or multiple myeloma (MM), among others, are also found. The findings on renal biopsy in patients with the nephrotic syndrome influence therapeutic management in 86% of cases.[7] Establishing a firm diagnosis is especially prudent in the age of novel and targeted therapies to avoid unnecessary side effects. The overall prognosis and response to treatment depend on the severity of the histologic lesion and the potential for reversibility.[23] Glomerulosclerosis, arteriosclerosis, interstitial fibrosis, and tubular atrophy are all suggestive of irreversible changes that are less likely to respond to treatment.

The utility of renal biopsy in children with nephrotic syndrome is more limited. In the original studies of the International Study of Kidney Diseases in Children (ISKDC), biopsies of children between the ages of 1–6 years with nephrotic syndrome, highly selective proteinuria, who did not have microscopic hematuria, hypertension, or renal failure, MCD was the diagnosis in greater than 80% of cases.[24] Those children had a greater than 90% chance of achieving a remission within 4 weeks of initiation of steroid therapy. As such, an initial trial of steroids without pursuing a renal biopsy is warranted. If there is no response to steroids within 8 weeks, then a renal biopsy should be considered to establish the diagnosis. In children under the age of a year, there is a high probability of the congenital nephrotic syndromes. Therefore a renal biopsy should be considered in these infants.

In adult patients who present with nephrotic syndrome, a biopsy may be deferred in certain cases. Patients with diabetes mellitus, who exhibit the expected natural history of diabetic nephropathy along with microvascular complications such as retinopathy, are often not offered a renal biopsy, given that blockade of the renin–angiotensin–aldosterone system is indicated in all stages of CKD, and the histological confirmation of diabetic nephropathy alone does not change therapeutic management.[25] On the other hand, atypical features such as rapid deterioration in renal function, sudden onset of proteinuria, presence of microscopic hematuria, or the onset of nephropathy in patients with diabetes less than 5 years warrant performance of a renal biopsy to exclude nondiabetic or coexisting parenchymal disease.[26] Of the patients with diabetes who underwent a renal biopsy, 37% demonstrated diabetic nephropathy alone, whereas nondiabetic renal disease (NDRD), either alone (36%) or superimposed on diabetic nephropathy (27%) was more common.[27] Duration of diabetes mellitus is the best predictor of the presence of diabetic nephropathy alone on the renal biopsy. IgA nephropathy and MN are among the most frequently observed NDRD lesions.[27]

Anti-phospholipase A2 receptor antibody (anti-PLA2R) has emerged as a reliable biomarker for diagnosis, monitoring of disease activity and response to therapy in primary MN.[28] In cases of nephrotic syndrome with a positive serum anti-PLA2R, the necessity of a renal biopsy has been questioned, as seropositivity for anti-PLA2R has not been found in any proteinuric kidney disease other than membranous nephropathy.[29] Depending on the state of disease activity, characteristics of assay used, and perhaps ethnicity (i.e. Japanese patients with primary membranous have a lower rate of anti-PLA2R positivity), the sensitivity of the anti-PLA2R evaluation is between 50–80%.[30,31] In addition, cases of membranous nephropathy with a positive test result for Anti-PLA2R have been described in patients with cancer, lupus, hepatitis B viral infection, and other inflammatory or autoimmune diseases.[32–34] For now, a renal biopsy remains an integral component of the workup of nephrotic syndrome, even in anti-PLA2R seropositive patients, as histological features such as mesangial or subendothelial deposits may indicate a secondary process.

PARAPROTEINEMIAS

Paraprotein-related kidney disease represents a complex group of diseases caused by an abnormal monoclonal immunoglobulin (Ig) secreted by a clone of B cells. The spectrum ranges from monoclonal gammopathy of undetermined significance (MGUS), by definition a benign condition characterized by abnormal serum paraproteins without any evidence of organ involvement, to the malignant condition MM, characterized by either the possibility or presence of end-organ damage, such as renal failure secondary to cast nephropathy.[35] Monoclonal gammopathy of renal significance (MGRS) is a heterogeneous group of disorders characterized by renal involvement with paraproteins that

are no longer MGUS but also do not meet criteria for the malignant hematologic conditions of MM or Waldenstrom's macroglobulinemia.[36] Paraproteins can play a direct role in pathogenesis of kidney disease independent of their concentration or the tumor burden. The deposition of monoclonal Ig can occur in the glomeruli leading to AL Amyloidosis, cryoglobulinemia, immunotactoid GN, monoclonal immunoglobulin deposition disease, proliferative GN with monoclonal Ig deposits, and C3 GN with monoclonal deposits.[36] Tubulointerstitial diseases resulting from monoclonal deposition include light chain proximal tubulopathy, Fanconi syndrome, and light chain cast nephropathy. Vascular Ig deposition can be in the form of amyloid fibrils, cryoglobulinemia, or crystaloglobulinemia.[37] The decision to treat a paraproteinemia relies heavily on the proof of end-organ damage. The diagnosis of MM can often be established through a combination of bone marrow biopsy and a myeloma defining event (anemia, hypercalcemia, osteolytic bone lesion, or renal failure). If the bone marrow biopsy with or without one of the myeloma-defining events confirm the diagnosis of MM, treatment is often initiated without the need for a renal biopsy. However, in the absence of a definitive MM diagnosis, a renal biopsy should be performed in all patients with the finding of a monoclonal Ig and either urinary abnormalities (proteinuria or hematuria) or abnormal glomerular filtration rate (GFR).[38] One of the critical aspects of the renal biopsy is to correlate the specific Ig found on the biopsy with that found during hematologic workup to ensure a direct link is present. Surprisingly, only 37% of patients with a monoclonal gammopathy who undergo a renal biopsy have a kidney disease associated with the paraprotein.[39] This highlights the importance of a renal biopsy in establishing a correct diagnosis in such patients to avoid prescribing potentially toxic therapies.

NEPHRITIC SYNDROME

The acute nephritic syndrome, characterized by glomerular hematuria, cellular casts, proteinuria, and frequently hypertension and renal insufficiency, is one of the main indications for a renal biopsy. Often, the initial clinical presentation or the subsequent serologic workup suggests a diagnosis, in which case, a renal biopsy is useful in confirming the diagnosis and providing information on the extent of injury and potential response to therapy. For example, the presence of circulating antineutrophil cytoplasmic antibodies (ANCA) or antiglomerular basement membrane (Anti-GBM) antibodies is highly suggestive of the diagnosis of ANCA-associated vasculitis or Anti-GBM disease respectively. In such cases, a renal biopsy is useful to evaluate the extent of inflammation and the likelihood of response to potentially toxic therapies. In other scenarios, the results of the renal biopsy can offer a new diagnosis, which can completely alter management. The presence of AKI with the nephritic syndrome increases the urgency to establish a diagnosis, given the improved outcomes when early treatment is instituted.[40] If rapidly progressive glomerulonephritis is suspected, treatment with glucocorticoids is often initiated while awaiting the renal biopsy.

The kidney biopsy is important to define the nature of renal involvement in patients with SLE. Although immune complex–mediated glomerulonephritis is the most common cause of kidney disease in SLE, other coexisting pathologic processes such as thrombotic microangiopathy (TMA), lupus podocytopathy, pauci-immune glomerulonephritis, or interstitial nephritis may result in renal injury and can only be diagnosed by renal biopsy.[41–44] As treatment of lupus nephritis moves beyond the nontargeted immunosuppressive regimen of high-dose steroids plus cyclophosphamide or MMF, a more detailed knowledge of kidney pathology becomes crucial. Presently, there is little consensus on the duration of maintenance therapy in lupus nephritis. Repeat protocol biopsies in patients with lupus nephritis can inform ongoing treatment decisions and predict long-term renal prognosis, as considerable discordance exists between clinically and histologically defined active disease.[45] Repeat renal biopsy for a flare may be most beneficial for patients with previous class II or V lupus nephritis because there is a reasonable likelihood that therapy may be intensified.[43] On the other hand, rising S[Cr] or proteinuria often do not reflect active lupus nephritis, and a repeat renal biopsy may allow reduction in therapy in inactive disease.

Renal biopsy is usually not performed in patients with a presumptive diagnosis of infection-related glomerulonephritis, unless there are features that make the diagnosis doubtful. This cluster of diagnoses, which includes poststreptococcal GN or IgA-dominant poststaphylococcal GN often present with an episode of infection, resolution of infection, and a latency period followed by an episode of acute GN. Treatment is conservative and the glomerulonephritis often resolves with supportive care. In endocarditis or shunt nephritis, the glomerulonephritis often resolves with control of the underlying infection, and a renal biopsy is not indicated. Persistent hypocomplementemia, progressive worsening of renal function, or recurrent gross hematuria should be indications for a renal biopsy to rule out other diagnoses.

ACUTE KIDNEY INJURY

In most patients with AKI, the cause of renal failure can be determined clinically without a renal biopsy. Urinary obstruction, reduced renal perfusion, acute tubular necrosis, and systemic diseases with renal involvement are often evident from clinical, serologic, radiographic, and urinary sediment examinations. In a small percentage of patients, the initial workup is either unremarkable or misleading. For example, a patient with AKI and urine sediment examination showing red blood cells, white blood cells, renal tubular cells, and granular casts can have a proliferative glomerulonephritis, acute interstitial nephritis, ATN, or a combination of these entities. In such scenarios, a renal biopsy can be very helpful to establish a diagnosis and help guide management, although the risk of a biopsy-related complication in AKI is greater.[46,47] On the other hand, renal biopsy in a patient with a prolonged period of AKI presumed to be due to ATN should be considered, to ascertain prognosis or diagnose an unsuspected disease.

CONTRAINDICATIONS TO PERCUTANEOUS RENAL BIOPSY

Because the percutaneous renal biopsy is an invasive diagnostic procedure that is elective, nephrologists are obligated to assure the safest possible setting that poses the least amount of risk to the patient, particularly because there are alternative ways to procure tissue. Settings in which the risks for the percutaneous renal biopsy are felt to be too great and thus the procedure is absolutely contraindicated are (1) uncontrolled bleeding diathesis, (2) uncontrolled severe hypertension, (3) an uncooperative patient, and (4) a solitary native kidney.[8] Relative contraindications to percutaneous renal biopsy include small hyperechoic kidneys often indicative of chronic irreversible disease, advanced uremia, the presence of multiple bilateral renal cysts, renal tumor, hydronephrosis, active renal or perirenal infection, horseshoe kidney, and inability to provide informed consent.

A major contraindication to performing a percutaneous renal biopsy is a bleeding diathesis. In most circumstances, the bleeding disorder is due to chronic anticoagulation (i.e. warfarin) or drugs that alter hemostasis (salicylates or nonsteroidal antiinflammatory agents) and can be corrected prior to the procedure. Ideally, chronic anticoagulation should be stopped long enough prior to the procedure to allow near normalization of coagulation parameters. It may become necessary to use intravenous heparin as a bridge, while chronic anticoagulation is being held, such as is the case with mechanical heart valves. For patients who require treatment with unfractionated heparin, it should be held at least 6 hours prior to the biopsy procedure to allow normalization of partial thromboplastin time (PTT). After the procedure, anticoagulation should not be resumed for at least 24 hours, but ideally one week after the procedure, given that bleeding may occur several days after the biopsy.[48,49] If the bleeding diathesis cannot be corrected and the biopsy is deemed indispensable, a transvenous or an open surgical biopsy can be considered[50–52] (see below). In such instances, consultation with a hematologist or a cardiologist can provide an assessment of risk stratification.

Uncontrolled hypertension is an absolute contraindication to a percutaneous renal biopsy. Hypertension is a risk factor for spontaneous bleeding in other vascular beds throughout the body, including intracerebral vasculature. In the kidneys, the combination of traumatic injury from the biopsy needle and elevated blood pressure has been linked to an increased risk of bleeding.[53] The risk of bleeding after renal biopsy increased more than seven times when the systolic blood pressure was >170 mm Hg.[54] Patients with history of hypertension have a greater than threefold risk of bleeding after a renal biopsy regardless of their blood pressure at the time of the procedure. The increased risk in patients with a history of hypertension is possibly due to changes in arterial compliance. Monitoring blood pressure the day of the procedure is important, as patients may not take their routine antihypertensive medications if advised to avoid eating before the procedure. In such cases, administration of antihypertensive medications with a goal reduction in blood pressure ideally to <140/90 mm Hg but at minimum systolic blood pressure to <160 mm Hg, diastolic to <100 mm Hg, and MAP <120 mm Hg is sensible prior to the procedure.

The presence of a solitary kidney as an absolute contraindication has been debated.[55] The concern for a percutaneous renal biopsy in a patient with a solitary kidney is the occurrence of a major complication that may lead to loss of renal function or require a nephrectomy, rendering the patient dependent on renal replacement therapy. However, this same reasoning would apply to the routinely performed transplant renal biopsy, although this procedure is known to be safer.[56] The practice of biopsy in a solitary native kidney is based on limited experience, but it has been suggested that it can be performed because advances in technology and techniques, which have improved the safety of the procedure, have minimized the need for such drastic interventions such as nephrectomy.[57] Despite the improvement in safety, the patient would need to be appropriately counseled on the risks, benefits, and alternatives to the percutaneous renal biopsy of a solitary kidney prior to the procedure.

The contraindication to percutaneous renal biopsy in an uncooperative patient also requires clarification. Patients on mechanical ventilation who are unable to follow commands can successfully undergo a percutaneous renal biopsy with temporary bag mask valve ventilation during the procedure.[58] As such, the contraindication is pertinent to a patient that increases risk by interfering with the procedure. Suitability of the procedure should be determined on an individual basis.

Uremic bleeding is a well-recognized complication in patients with renal failure.[59] The pathophysiology of uremic bleeding is not well understood and is thought to be multifactorial, due to platelet dysfunction associated with weakened von Willebrand factor (vWF) interaction with GPIb/IX, increased levels of cyclic AMP leading to reduced thromboxane A_2, anemia, and the action of uremic toxins.[60] Evaluation of bleeding time is arguably the most useful test to assess clinical bleeding in uremic patients (see below).[61] Lowering of uremic toxins with hemodialysis or peritoneal dialysis (PD better than HD) improves platelet aggregation and may normalize bleeding time in certain patients.[62] Desmopressin, through stimulation of factor VIII and increasing vWF activity, is a commonly used first-line agent in patients with active bleeding or who are being prepared for a renal biopsy.[63] Prior to a renal biopsy, assessment of uremic bleeding, either directly through measurement of bleeding time or platelet function analyzers when available, or indirectly through evaluation of S[Cr], blood urea nitrogen (BUN), estimated GFR, and kidney size, should be an integral component of biopsy risk stratification (see below).

SPECIAL CIRCUMSTANCES

When considering a percutaneous renal biopsy, special circumstances require attention. Pregnancy is one such special circumstance, not only because the prone positioning may need to be altered based on gestational age or patient comfort but also because the risk of the biopsy or the underlying disease may affect the mother and her fetus.[54] Although the risk of bleeding complications in pregnant patients is equivalent to that of nonpregnant patients, extreme caution must be exercised to minimize maternal–fetal harm.[64] Ideally, the procedure should be deferred, if possible, until the postpartum period, unless it may alter management during pregnancy.[65]

Another patient factor that influences the risk of a percutaneous renal biopsy is morbid obesity. Though there are no studies directly measuring complication rates in obese patients, it is widely assumed that poor ultrasound visualization would lead to higher bleeding risk.[66] This has resulted in alternative methods of tissue sampling in obese patients, such as CT-guided, transjugular or open renal biopsies (see below). Altering the prone position to the supine anterolateral has also been described as safe and effective.[67]

Kidney disease is highly prevalent among elderly persons. The aging kidney is characterized by structural and functional changes due to age and coexisting systemic disease, which lead to glomerulosclerosis, tubulointerstitial fibrosis, and subsequent loss of renal function leading to CKD.[68] Although in some cases, a renal biopsy cannot differentiate between the sequelae of chronic disease and the aging kidney, there are special conditions, such as those indicated in nonelderly adults, which may require histologic evaluation to establish a clear-cut diagnosis and therapeutic planning.[69] The elderly are more likely to present with decreased renal function, cardiovascular, pulmonary or hematologic comorbidities, and poorer general health. As such, a complete evaluation of risk factors is warranted. However, advanced age is not a contraindication to a renal biopsy. Percutaneous renal biopsy can be safely performed in the elderly (age >60 years) or the very old (age >80 years) with complication rates similar to that of adult patients.[70] Because the most common indications for a renal biopsy in the elderly are AKI or rapid onset nephrotic syndrome, treatable histologic findings such as membranous nephropathy, amyloidosis, ANCA-associated vasculitis, or interstitial nephritis are prevalent.[71,72] The histologic confirmation of diagnosis in the elderly patient leads to targeted and successful treatment in a significant proportion of cases (40–67%).[73,74]

Nephrologists have always addressed renal disease in cancer patients. Due to the explosion of new chemotherapeutic agents and their renal side effects, a new area in nephrology, called onconephrology, is being promoted to specifically address such complex issues. Membranous nephropathy is the most common glomerular pathology seen in patients with solid tumors.[75] MCD is classically associated with Hodgkin's lymphoma and usually presents around the time of diagnosis of malignancy.[76] Patients who present with nephrotic syndrome after an established diagnosis of overt malignancy may not undergo a renal biopsy, as the nephrotic syndrome often resolves with effective treatment of the malignancy. Patients with hematopoietic stem cell transplant (HSCT) can present with nephrotic syndrome due to a spectrum of glomerular diseases including MN, MCD, FSGS, and membranoproliferative glomerulonephritis.[77] There is often a close relationship between the onset of nephrotic syndrome and withdrawal of immunosuppression, leading to the development of chronic graft-versus-host disease (GVHD). Reinstitution of immunosuppression and treatment of GVHD is often the cornerstone of management of nephrotic syndrome in patients with HSCT. In

such cases, a renal biopsy can be deferred unless atypical features are present or treatment is ineffective.

Another group of kidney-related complications in patients with cancer is related to chemotherapy. TMAs have been associated with the use of gemcitabine, mitomycin C, vascular endothelial growth factor (VEGF) inhibitors, and proteosome inhibitors, such as carflizomib.[78–80] Platinum-based chemotherapy (cisplatin more than carboplatin) has long been known to be associated with tubulointerstitial nephrotoxicity and Fanconi syndrome.[81] The newest antineoplastic agents belonging to the class of immune checkpoint inhibitors have also been implicated in acute autoimmune interstitial nephritis.[82] Renal biopsies have allowed determination of the exact mechanism of injury in cancer patients, whether due to the underlying disease or side effects of treatment. In the vast majority of cases, treatment can be instituted by effective treatment of the cancer or withdrawal of the nephrotoxic chemotherapy, without performing a renal biopsy. However, renal biopsy remains a valuable tool for the nephrologist in cases where diagnosis is unclear or when newer chemotherapeutic agents, without known toxicity, are introduced.

PREBIOPSY EVALUATION

The prebiopsy evaluation comprises three major components: patient history, physical examination, and select laboratory tests. A thorough history should be obtained with special attention to a history of bleeding with prior surgeries, along with any family history of bleeding. Active medications need to be reviewed to identify agents that may increase risk of bleeding complications, including aspirin, nonsteroidal antiinflammatory drugs, and anticoagulants. On physical examination, the patient should be alert, oriented, and be able to follow simple directions for the PRB. The overlying skin at the planned biopsy site should be without signs of infection. A comprehensive metabolic panel, complete blood count with platelet count, prothrombin time, PTT, and blood type with antibody screen for cross-matching are routinely recommended prior to the procedure.[8,83]

The value of the bleeding time prior to the PRB is debated due to the lack of randomized prospective studies, operator skill, and variable availability of the test. The College of American Pathologists and American Society of Clinical Pathologists concluded in their 1998 consensus statement that the bleeding time was not clinically beneficial in predicting surgical bleeding and thus is not indicated as a routine preoperative test.[84] However, the bleeding time has been shown to be associated with increased risk of hemorrhage in closed percutaneous liver and kidney biopsies in both prospective and retrospective studies.[85–88] In one prospective study of 1055 biopsies, patients with a bleeding time greater than 7.5 minutes were twice as likely to have a bleeding complication when undergoing real-time ultrasound-guided PRB.[48] Furthermore, major complications (transfusion requirement, invasive radiologic or surgical procedure, severe hypotension, readmission, or death) were twice as likely when the bleeding time was greater than 9 minutes in this study.[48] The issue of bleeding times becomes even more important in the PRB of patients with CKD. Patients with underlying CKD are at a higher risk for having prolonged bleeding times due to platelet dysfunction associated with uremia. Desmopressin (DDAVP), a vasopressin analogue, has been used in patients to correct elevated bleeding times. Although effective in patients with hemophilia and von Willebrand's disease, the use of DDAVP in the setting of patients with prolonged bleeding times undergoing PRB is more controversial. In one randomized, placebo-controlled trial of 162 patients with normal GFR, the indiscriminant use of DDAVP (without checking bleeding times) reduced the incidence of silent postbiopsy hematomas.[89] However, there was no change in the hemoglobin level or major complications between the groups.[90] Furthermore, there still is an increased risk of bleeding despite the correction of the bleeding time with DDAVP based on the observations from several studies.[91,92] Given the added potential risk of thrombosis and hyponatremia with DDAVP use, its application in the PRB remains practice dependent.[93,94]

METHODS OF THE RENAL BIOPSY

The PRB procedure today is performed by both certified nephrologists and radiologists, with an increase in the frequency being done by the latter.[95–98] A major change in the field has been in the development of imaging techniques. Real-time ultrasound guidance has replaced the need for intravenous pyelograms and thus the need for iodinated contrast agents. Furthermore, ultrasound guidance is not dependent on the level of renal function and allows continuous visualization of the kidney and the needle, allowing the procedure to be done at the bedside. Real-time ultrasound guidance also has been shown to provide further benefits in terms of achieving a higher diagnostic yield with lower major hemorrhagic complication rates compared to the "blind" approach in which ultrasound is used for localization purposes only.[99,100] The patient is placed in the prone position and the lower pole of the right kidney is preferentially targeted to avoid the renal vasculature and blood-rich spleen. Rarely, the biopsy may be performed in the seated, lateral decubitus, or supine

anterolateral positions when patients are unable to remain in the prone position, typically due to respiratory issues.[67]

A variety of different needle types and gauges can be used for the PRB procedure. Both manual needles, such as the TruCut, and automated, spring-loaded needles are available, with the latter being used primarily today. The different sizes used for the procedure are the 14-gauge, 16-gauge and 18-gauge.[9] Although the diagnostic yield between the 14-gauge and 16-gauge needles does not differ significantly, these larger needles have consistently been shown to produce better yield than the 18-gauge needle.[8,97,101,102] Despite the larger size, in head to head studies, the 14-gauge and 16-gauge needles do not result in higher complication rates.[8] In one large series of over 9000 renal biopsies done in Norway, there was no difference in the complication rate between the 14-, 16-, or 18-gauge automated needle.[97] However, in a large meta-analysis, the 14-gauge needle has been associated with higher rates of blood transfusion after PRB compared to the 16-gauge needle.[103] Thus, most recommend the use of an automated 16-gauge needle.[9]

Computed tomography (CT) guidance for the PRB can be used in clinical situations when ultrasound imaging does not provide adequate visualization. This route is often used in patients with advanced CKD who may have small, echogenic kidneys that are difficult to visualize by ultrasound. The CT-guided PRB is also preferred in patients who have complex anatomies, such as a horseshoe kidney or in obese patients.[9,66] The CT-guided technique has been shown to be safe, with low complication rates and still provides adequate tissue for diagnosis. In one large retrospective study reviewing 146 outpatient CT-guided biopsies, diagnostic tissue was obtained in 98.6% of cases with only one patient requiring a transfusion.[104]

Immediately after the biopsy, the patient is placed in the supine position with strict bedrest. Vital signs are monitored frequently and the urine is examined for gross hematuria. Although there is debate regarding its value and timing, a repeat renal ultrasound one hour after the biopsy has been shown to predict an uncomplicated procedure. In a study of 162 adult patients who underwent real-time ultrasound renal biopsies, the absence of a hematoma one hour after PRB had a negative predictive value of 95% for clinical complications.[92]

The postprocedural observation duration is also subject to debate. In one prospective study of 750 real-time ultrasound-guided PRBs, 89% of complications were detected when patients were observed for 24 hours, but 33% of complications occurred after 8 hours,[49] proving that complications can present in a delayed fashion and that a prolonged period of observation is warranted. The risks and costs of an overnight hospital admission play a large role in the attempt to shorten the postprocedural observation time. In select patients without a bleeding diathesis, with normal blood pressure, preserved kidney function, stable hematocrit, and a negative one-hour post-PRB ultrasound, same day discharge within 6 hours can be considered.[54] However, the duration of the observation time and criteria for discharge still remain hospital- and nephrologist-dependent. We recommend an observation period of at least 6 hours and ideally up to 24 hours. Patients are also instructed to avoid blood thinners (including aspirin and nonsteroidal antiinflammatory agents), vigorous activity, and heavy lifting for 7–14 days after the biopsy. There are clinical situations that necessitate restarting anticoagulants after PRB. These should be handled in a case-specific manner and typically require consultation with other specialists including hematologists and/or cardiologists.

COMPLICATIONS

Although the percutaneous native kidney biopsy is generally safe, complications can occur and range in severity from minimal to disastrous. Due to the vascular nature of the organ, the most common complications are related to bleeding,[54] which is typically in the perinephric area and/or collection system, but rarely may occur with laceration of a lumbar[105] or mesenteric vessel.[106] Complications have traditionally been divided into two types (Table 73.1). Major complications are defined as requiring a treatment or an intervention to stop the problem. Examples include embolization for persistent or acute bleeding, transfusion of blood products for a significant drop in hemoglobin concentration, or even the occasional case of sepsis[107] or gross hematuria leading to AKI from obstruction.[108] Minor complications are defined as those that spontaneously resolve without the need for intervention or further treatment, such as gross hematuria or a symptomatic hematoma that resolves with time. Rarely (<0.1%), catastrophic complications could occur, such as a nephrectomy or even death.[48,93,109] Relatively routine consequences of the biopsy, but not necessarily complications, include microscopic hematuria (nearly 100%), minor postprocedure lumbar pain lasting up to 12 hours, a mild drop in hemoglobin concentration, or a silent perinephric hematoma detected by routine screening imaging evaluation (up to 90% in prospective series).[110]

The most common major complications are acute anemia requiring a transfusion of blood products and/or a perinephric hematoma that can occasionally require an intervention to stop the bleeding.

Acute anemia, however, can occur in uncomplicated biopsies as well. A fall in hemoglobin concentration of 1 g/dL after PRB has been reported in large series to

TABLE 73.1 Complications after Percutaneous Renal Biopsy

MAJOR COMPLICATIONS
Bleeding
Perinephric hematoma Requiring procedure to stop the bleeding With acute anemia requiring blood transfusion
Nephrectomy
Laceration of aorta, lumbar or mesenteric vessel
Outlet obstruction with acute kidney injury
Hemorrhagic shock
Sepsis
Prolonged hospitalization
Nonkidney organ puncture
Death
MINOR COMPLICATION
Bleeding
Symptomatic perinephric hematoma
Gross hematuria
Acute anemia (>1 g/dL drop in Hgb) without transfusion
Page kidney
Pain (>12 hours)
Local infection
Arteriovenous fistula
CONSEQUENCES
Microscopic hematuria
Pain (<12 hours)
Silent perinephric hematoma

dL, deciliter; *g*, gram; *Hgb*, hemoglobin concentration.

occur in up to 50% of uncomplicated cases.[48,111] In one series of 1055 patients,[48] the average change in hemoglobin concentration was 0.9 ± 0.8 g/dL in patients without complications. However, in the same series, patients with major complications had, on average, a drop in hemoglobin concentration of 2.3 ± 1.7 g/dL ($p < 0.001$ compared with uncomplicated biopsies), suggesting that a minor drop can occur in any biopsy, but a greater degree of acute anemia may herald a major complication. Possible mechanisms to explain why acute anemia may occur in uncomplicated biopsies include a dilutional effect[111] (due to routine administration of intravenous fluids or even resorption of interstitial fluid in patients with nephrosis[112]), or possibly due to the development of undocumented silent hematomas.[110]

Another group of investigators evaluated the change in hematocrit in a retrospective cohort of 83 PRBs.[113] They found that the decrease in hematocrit at 6 hours after PRB had a linear correlation with the hematocrit at 24 hours, implying that if the 6-hour hematocrit was stable, then it would likely remain stable at 24 hours. However, there was no correlation with actual hemorrhage or complications in this study.

Acute anemia can also result in the need for transfusion of erythrocytes. Similar to use of transfusions in patients on hemodialysis,[114] the trigger for transfusion after PRB is closely related to the prebiopsy hemoglobin concentration, as opposed to clinically significant bleeding or drop in hemoglobin level.[115] For example, a patient with a prebiopsy Hgb concentration of 7.5 g/dL who drops 1 g/dL after the biopsy is more likely to get a transfusion, compared to one who starts at 14 g/dL and drops to 11 g/dL, regardless of the development of a hematoma. This has implications regarding the absolute frequency of major complications in the literature, as they are defined by interventions, including the administration of blood products, even in the absence of hemorrhage. Thus, the major complication rate is actually lower than what is reported.

Another common complication is the development of a perinephric hematoma, which can lead to pain, acute anemia, transfusions, and/or procedures to stop the hematoma from expanding. The majority of perinephric hematomas, when detected by routine screening, are small and clinically silent[116] and therefore not considered actual complications. Typically, a hematoma will tamponade and stop enlarging but can continue to expand into a major complication, requiring an intervention or surgical procedure to stop the bleeding. Rarely, Page kidney can occur, where a perinephric hematoma causes renal parenchymal compression and leads to renin-mediated hypertension.[117]

RISK FACTORS FOR COMPLICATIONS

The risk factors for developing a hemorrhagic complication after PRB (Table 73.2) are divided into those that are patient-related (i.e. age, bleeding diathesis, uncontrolled HTN, inpatient vs. outpatient) and those that are related to the technique itself (i.e. needle size or type, use of imaging or not).[54]

One of the most important patient-related clinical risk factors associated with an increased risk of bleeding is an elevated BUN and/or S[Cr].[10,46–48,118–120] Azotemia is strongly associated with bleeding, as well as anemia. In one large prospective series of 910 patients undergoing PRB, the average baseline S[Cr] was 4.0 ± 2.9, 2.9 ± 2.6, and 1.7 ± 1.4 mg/dL in patients with a baseline Hgb of <9.0, 9.0–11.0, and >11.0 g/dL

TABLE 73.2 Features Predictive of Complication after Percutaneous Renal Biopsy

Patient Related	Range	Risk
BP systolic	>170 mm Hg	7×
Hemoglobin concentration	<11 g/dL	3×
S[Cr]	<2.0–3.5 mg/dL	3–5×
Bleeding time	>8 minutes	2×
Platelet count	<200 K/μL	2–4×
Procedure Related		
Needle gauge	14- vs. 16/18-gauge	4×
Number of passes	<3 vs. ≥ 3	NS

dL, deciliter; *g*, gram; *mm Hg*, millimeters of mercury; μL, microliter.
From references 48,97,103,120,137.

($p < 0.0001$), respectively.[115] Using a multivariate analysis of known risk factors, however, both S[Cr] and anemia were independently associated with complications,[48] highlighting the importance of renal dysfunction as an actual risk factor. In this study, patients with a S[Cr] > 3.5 mg/dL were 1.8 times more likely (95% confidence interval (CI) 1.2–2.9, $p = 0.009$) to develop a complication and 2.7 times more likely (95% CI 1.5–5.1, $p = 0.001$) to require an erythrocyte transfusion.[48]

The S[Cr] is elevated in AKI as well as in CKD, and both disease states have been found to be associated with complications. In one study, complications occurred in 11% of patients with AKI compared to 6.7% of patients without AKI, and 10% of patients with AKI required a blood transfusion. Patients with AKI had more risk factors for a complication, including anemia, higher S[Cr], higher blood pressure, and female gender.[46] CKD is also a risk factor for bleeding after a PRB. Joseph et al.[10] evaluated patients undergoing PRB with an elevated S[Cr] in addition to baseline renal function within 6 months prior to the procedure. They found that with prolonged elevations in the S[Cr] (CKD), bleeding after a biopsy was more frequent. In addition, they found that the higher the S[Cr], the greater the likelihood of finding an irreversible or untreatable condition. Thus, AKI and CKD both increase the risk of bleeding after a biopsy, and in more severe stages of CKD, there is less chance of finding a reversible lesion.

Some have suggested that a diagnosis itself may be associated with an increased risk of bleeding. However, this is most likely due to confounding variables, as an increased risk has been reported for diseases such as acute tubular necrosis,[91,121] end-stage renal disease,[91] and hypertensive kidney disease,[121] all which are known to have elevated S[Cr] as well as greater degrees of anemia.

NONPERCUTANEOUS RENAL BIOPSY

Several nonpercutaneous renal biopsy techniques are available when contraindications exist with the percutaneous route, but a biopsy is still required for diagnosis and treatment considerations. This is often the case in patients with bleeding diathesis, patients being mechanically ventilated, or when attempts with the percutaneous method have been unsuccessful.

The transvenous renal biopsy (TVRB), most often transjugular, was first introduced in 1990[122] and is an alternative to the PRB, which is often used when biopsies of multiple organs are required (such as with simultaneous liver and kidney biopsies).[52,123] Studies have demonstrated that the TVRB can provide adequate tissue for diagnosis, and a comparable safety profile as the PRB when contraindications exist for the latter.[52,83,123] The major limitations of this method include the need for administration of contrast with accompanied risk of allergic reactions and nephrotoxicity, variable operator experience, and the potential higher costs associated with this procedure. Capsular perforation resulting in gross hematuria has been reported with TVRB. However, the resulting bleeding is typically self-limiting, owing to the tamponade effect from the perinephric fat and with the return of the blood back into the venous vessels.[9,83,122,124] A potential benefit of the TVRB in patients at higher risk for bleeding complications is the ability of the interventionalist to rapidly apply hemostasis to a bleed if it is identified immediately after the procedure.

The open renal biopsy (ORB) procedure is an established surgical approach for obtaining kidney tissue when contraindications exist with the PRB. Although one of the largest studies with 934 patients showed tissue adequacy of 100% without major complications, the risk of anesthesia and the associated postsurgical recovery time remain significant limitations of this technique.[125] In a recent retrospective study of 115 patients, the mortality rate after the ORB was 0.8%, with a 27% rate of minor complications, including wound infection, pneumonia, and deep vein thrombosis.[126] With advances in laparoscopic techniques, the laparoscopic renal biopsy (LRB) has also been used. Advantages include the reduction of the operation time down to one hour and decrease in mean blood loss to 10 mL.[127] However, the LRB still requires anesthesia and is subject to the same postoperative complications as the ORB. Furthermore, the costs of LRB are also higher than the PRB. Nevertheless, this modality remains a viable alternative to the PRB.

FUTURE APPLICATIONS

Despite the high burden of CKD, there are few effective therapies for management of patients across the CKD spectrum.[128,129] There are fewer clinical trials compared to other medical specialties, and the results are often negative.[130] Even when clinical trials launch, as with many chronic disease states, the low trajectory of meaningful clinical events requires long follow-up times associated with significant financial burden.[131] These setbacks often stem from lack of understanding the pathophysiology of CKD, the weak pipeline of bench to bedside research, and ineffective animal models that do not appropriately mimic human disease or human drug effects.[132,133] To address these challenges, The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) has put forward initiatives from the perspective of precision medicine, and pragmatic clinical trials and population health, each supported by efforts in health information technology, to advance kidney health.[134] Part of this project involves the use of 'omics' techniques (genomics, proteomics, metabolomics) on human kidney tissue to gain a deeper understanding of disease process and ultimately develop targeted therapies.[135,136] Given the poor fidelity of animal models and the limitations of tissue from transplant, nephrectomy, and autopsy, obtaining research biopsies from patients with AKI and CKD is a necessary first step in this process.[134] Because kidney biopsies pose a risk of complications and the tissue that is obtained may not provide immediate benefit to the tissue donor, ethical and patient safety considerations are of primary concern.

Ultimately, renal biopsies have the greatest utility in cases where there are available therapies. Lupus nephritis is an excellent example of variability in histology and therapy to the extent that almost all lupus patients with clinical or laboratory evidence of renal involvement should undergo a renal biopsy. On the other hand, acute tubular necrosis is almost never intentionally biopsied as there is no effective therapy at this time. As new therapies emerge, the utility of renal biopsy in different clinical presentations will change.

QUESTIONS AND ANSWERS

Question 1

What is the mortality rate associated with a renal biopsy?

A. 0.001%
B. 0.01%
C. 0.1%
D. 1%
E. 10%

Answer: C

The established mortality rate is 1/1000 in the largest series which followed complications, making C the correct choice.[48]

Question 2

A patient has nephrotic range proteinuria and progressive reduction in his GFR over the last year (S [Cr] 1.3 mg/dL one year ago, now 2.2 mg/dL). He refused a renal biopsy one year ago but now is willing to have the procedure. What is true regarding his risk of complication?

A. His risk is the same now as it was one year ago
B. His risk is lower now than one year ago
C. His risk is higher than it was one year ago
D. His risk is dependent on his biopsy diagnosis
E. His risk is dependent on the degree of proteinuria

Answer: C

Patients with reduced GFR have higher rates of complication, both in the acute and chronic setting. Patients with CKD more commonly have azotemia, anemia, and bleeding diathesis as shown by the template bleeding time, but in the studies using multivariate analysis of risk factors, patients with a S [Cr] of 2.0−3.5 mg/dL are 2−5 times more likely to experience a complication. Cause of CKD and degree of proteinuria have not been linked to complications. Thus, C is the correct answer.[48,97,103,120,137]

Question 3

A percutaneous renal biopsy is considered in all the cases below EXCEPT:

A. A 32-year-old woman with recent diagnosis of SLE and hematuria
B. A 60-year-old man with 20-year history of diabetes, CKD with rapidly progressive diminution in renal function, 10 g/24 h proteinuria, and new onset hematuria
C. A 50-year-old man with sudden onset nephrotic syndrome and normal renal function
D. A 45-year-old IV drug abuser with history of HIV infection and rapidly rising S[Cr]
E. A 70-year-old Chinese male with microscopic hematuria, no proteinuria and normal renal function

Answer: E

Renal biopsy is often deferred in patients with isolated glomerular hematuria in the absence of proteinuria or renal insufficiency as the etiology is often due to IgA nephropathy or a hereditary form of nephritis such as Alport's or thin basement membrane disease, all of which have good prognoses. In a 70-year-old Chinese man who is more likely to have IgA nephropathy, conservative management without undergoing a renal biopsy is acceptable.[16,17]

Question 4

A 65-year-old woman presents for evaluation of proteinuria of 6 g/24 h and normal renal function. As part of the initial serologic workup, a serum PLA2R antibody was ordered. Results are positive. Which one of the following statements is correct?

A. A renal biopsy is not indicated as the positive serum PLA2R is an indication of primary membranous nephropathy
B. A renal biopsy is indicated as there are cases of membranous nephropathy secondary to malignancy in patients with positive serum PLA2R
C. Serum PLA2R levels do not correlate with response to therapy in primary membranous nephropathy
D. Japanese patients with positive PLA2R have a much higher finding of primary membranous nephropathy on the renal biopsy
E. A renal biopsy is indicated to determine alternative diagnoses as serum PLA2R antibodies are also found in primary focal segmental glomerular sclerosis

Answer: B

Serum anti-PLA2R has been recognized as a good biomarker for primary membranous nephropathy. However, positivity has been reported in patients with membranous nephropathy secondary to malignancy, autoimmune diseases, Hepatitis B virus infection, and other inflammatory diseases. As such, a renal biopsy is still indicated to establish a histologic diagnosis and remains an integral component of the evaluation of nephrotic syndrome despite seropositivity of PLA2R. Serum levels of PLA2R correlate with response to therapy, where a reduction in proteinuria is seen after decrease in serum PLA2R levels. Japanese patients with primary membranous nephropathy have a lower rate of anti-PLA2R positivity.[28–34]

Question 5

A patient is referred to you for evaluation of AKI and microscopic hematuria. It is determined that the patient requires a kidney biopsy. A renal ultrasound is done but demonstrates poor visualization of the kidneys due to the patient's obese body habitus. Thus, a CT-guided kidney biopsy is recommended. Which of the following is the *best true* statement?

A. A kidney biopsy is contraindicated and thus empiric treatment should be initiated
B. An ORB is the preferred alternative in this patient
C. The CT-guided approach represents a safe and viable alternative to obtain tissue in this patient
D. The CT-guided approach has a much higher complication rate when compared to the ultrasound-guided technique
E. The CT-guided approach results in insufficient tissue for a diagnosis compared to the ultrasound-guided technique

Answer: C

The CT-guided technique has been shown to be a safe alternative to the ultrasound-guided approach with low complication rates. CT-guided approaches provide adequate tissue for a diagnosis (thus choices D and E are incorrect). The CT route is typically pursued in patients with complex anatomies (such as horseshoe kidney), obese patients, as well as in patients with CKD with smaller, echogenic kidneys. The ORB represents an alternative to obtain tissue, but would not be the preferred route given the unnecessary risk of general anesthesia in this setting (B is incorrect). Obesity is not an absolute contraindication to a kidney biopsy (Choice A is incorrect).[9,66,104]

Question 6

Which of the following patients would be the best candidate for a PRB?

A. A patient with a history of von Willebrand disease presenting with nephrotic syndrome
B. A patient with a history of chronic cellulitis presenting for evaluation of proteinuria; the patient's cellulitis involves the bilateral flank regions
C. A patient with new AKI and hematuria. Patient's BP is 220/120 mm Hg
D. An elderly patient (age 84) presenting with unexplained AKI and hematuria
E. An uncooperative patient with new onset of HTN, AKI, and hematuria

Answer: D

Patients with uncontrolled bleeding diathesis or uncontrolled severe hypertension are at higher risk for complications, and thus the procedure is generally avoided until the modifiable diseases can be managed. Percutaneous biopsies in solitary native kidneys have been performed safely in a small subset of series but are relatively contraindicated due to the possibility of having to perform a nephrectomy if complications develop. An uncooperative patient is also not the best candidate due to the potential for complication or movement during the procedure. Therefore, Choices A, C, and E are incorrect. Patients with evidence of infection overlying the area of the potential biopsy site are also not good candidates for the percutaneous route as the needle may need to traverse the infected area (Choice B is incorrect). Age alone is not a restriction to the percutaneous renal biopsy.[8,70]

Pregnancy and Kidney Disease

Sharon E. Maynard[a], *Ravi Thadhani*[b,c]

Abstract

Chronic kidney disease (CKD) affects almost 4% of women of childbearing age. In women with early stage CKD (serum creatinine concentration [S[Cr]] less than 1.4 mg/dL) and well-controlled blood pressure, the likelihood of successful pregnancy is high and of pregnancy-associated deterioration in kidney function is low. Nevertheless, CKD is associated with several adverse maternal and neonatal outcomes, including preeclampsia, intrauterine growth restriction, and preterm delivery. Pregnancy in more advanced CKD (S[Cr] > 2.0 mg/dL) can result in an accelerated and often irreversible decline in renal function. CKD can present *de novo* during pregnancy. Management and outcomes must be individualized based on the severity, etiology, and gestational age at presentation. Medical management of kidney disease and its complications during pregnancy is affected by the impact of therapy on the developing fetus. This chapter reviews the evaluation and management of pregnant women with CKD.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Important changes in renal physiology occur in pregnancy. Glomerular filtration rate (GFR) increases by 40–65%, due primarily to a large increase in renal blood flow.[1] This pregnancy-induced increase in renal plasma flow and GFR is mediated by a variety of hormones, including relaxin, which is secreted by the corpus luteum, placenta, and decidua.[2] Creatinine clearance also increases in pregnancy in women with CKD.[3] The plasma volume expands by 30–50%,[4] resulting in hemodilution. As a result, the normal serum creatinine concentration (S[Cr]) in pregnancy is 0.4–0.7 mg/dL,[5] approximately 0.4 mg/dL below nonpregnant values. Other blood chemistries are also altered in pregnancy (Table 74.1).[5] Both kidneys increase by 1.0–1.5 cm in length, and kidney volume increases by up to 30%[6] during normal pregnancy. Urinary protein excretion during normal pregnancy rises[7] due to a combination of increased GFR and increased permeability of the glomerular filtration barrier.[8]

Endocrine and hormonal functions of the kidney are also affected by pregnancy. Erythropoietin production increases, resulting in increased RBC mass. Due to an even larger increase in plasma volume, the hemoglobin concentration in healthy pregnancy falls, with a nadir in the second trimester.[9] Blood pressure (BP) falls during normal pregnancy due to generalized vasodilation, mediated by relaxin and vascular resistance to the effects of angiotensin II and other vasoconstrictors.[2,10] There is a physiologic increase in plasma renin activity, angiotensin 2 concentration, and aldosterone concentration, which contribute to plasma volume expansion and the tendency for edema formation.[11]

Fertility is maintained in mild CKD. As CKD progresses, the uremic milieu often results in infertility by CKD stage 5, and spontaneous pregnancies in women on conventional renal replacement therapy are unusual. This may be mediated by hypothalamic anovulation, with absent normal cyclicity of gonadotrophin release.[12] Fertility is typically restored after kidney transplantation.[13]

DIAGNOSIS

Estimating GFR in Pregnancy

Estimation of GFR is important in the diagnosis and management of CKD in pregnancy. CKD affects almost 4% of women of childbearing age.[14] Methods to estimate GFR include creatinine clearance by 24-hour urine collection and estimating equations based on S[Cr] measurement. The 24-hour urine collection for creatinine clearance (24-hour CrCl) is cumbersome and has several limitations, including inaccuracy due to overcollection or incomplete collection. Use of the 24-hour CrCl

TABLE 74.1 Normal Ranges of Common Laboratory Results in Pregnancy

	Normal Range (2.5th–97.5th percentile)[5]		
	7–17 weeks of Gestation	17–28 weeks of Gestation	28–38 weeks of Gestation
Sodium (mEq/L)	133.2–140.5	128.9–139.7	128.0–139.8
Potassium (mEq/L)	3.24–4.86	3.27–4.61	3.36–5.00
Chloride (mEq/L)	100–107	98–108	98–108
BUN (mg/dL)	5.80–11.79	4.57–12.16	4.60–10.50
Creatinine (mg/dL)	0.41–0.70	0.37–0.68	0.37–0.66
Calcium (mg/dL)	8.72–10.12	8.24–9.70	8.21–9.60
Magnesium (mg/dL)	1.70–2.34	1.61–2.12	1.53–2.21
Phosphate (mg/dL)	2.63–5.11	2.55–4.52	2.54–4.50
Uric acid (mg/dL)	2.04–5.28	2.45–5.15	2.67–5.70
Albumin (g/dL)	3.22–4.32	2.75–3.58	2.42–3.37
Hemoglobin (g/dL)	>10.6	>10.7	>11.4

requires assessment of the completeness of the collection by comparing measured compared with predicted creatinine excretion. Normal creatinine excretion has not been studied in pregnancy, and it is unknown whether prepregnancy weight or current (lean) body weight should be used to estimate creatinine excretion. A study of pregnant women with hypertensive disorders found 54% of 24-hour urine collections were incomplete, using 15–20 mg/kg/day and prepregnancy weight to estimate creatinine excretion. Inaccurate collections were evenly split between overcollections and incomplete collections.[15]

The MDRD study equation[16] and the CKD-EPI equation[17] are creatinine-based methods that are widely used to estimate GFR. Both equations were derived from patient populations that excluded pregnant women. In pregnancy, the MDRD and CKD-EPI estimating equations underestimate true GFR by 12–40 mL/min/1.73 m^2.[18–20] Based on the lack of validation data, guidelines on the use of the MDRD and CKD-EPI formulas specifically exclude use in pregnant women. Despite its limitations, 24-hour CrCl remains the preferred method for estimating renal function in pregnancy.

Proteinuria in Pregnancy

Because of the physiologic increase in proteinuria during pregnancy, urinary protein excretion is considered pathologic only when >300 mg/day.[21] Even higher levels of proteinuria occur in normal multiple gestation pregnancies.[22]

Routine antepartum care includes dipstick urine protein testing at each prenatal visit. The purpose is detection of urinary tract infection and preeclampsia. Although inexpensive and commonly used, the urinary dipstick has a high false-positive and false-negative rate for proteinuria screening in pregnancy.[23] Thus, positive dipstick testing for proteinuria should always be followed by a quantitative method, such as 24-hour urine collection, or determination of a random urine protein:creatinine ratio (UPCR) or albumin:creatinine ratio (ACR).

As with the 24-hour creatinine clearance, the 24-hour urine protein excretion in pregnant women is frequently inaccurate.[15] The adequacy of collection should be assessed by comparing the observed with expected 24-hour creatinine excretion (15–20 mg/kg prepregnancy body weight). In addition to the high rate of inaccurate and/or incomplete collections, the 24-hour urine collection is cumbersome for ambulatory patients, and the result is not available for at least 24 hours. Hence, there has been longstanding interest in alternative methods to quantify urine protein excretion in pregnancy.

The UPCR measured on a random urine sample has become the preferred method for the quantification of proteinuria in the nonpregnant population due to high accuracy, reproducibility, and convenience. Most studies evaluating the accuracy of the protein:creatinine ratio (PCR) in pregnancy have focused on women with hypertensive pregnancy undergoing evaluation for preeclampsia. A systematic review, which included 2790 women from 15 studies, concluded that a PCR <0.13 mg protein/mg creatinine has good sensitivity (89–90%) for excluding proteinuria (>300 mg/day) in hypertensive pregnancy.[24] There are no data validating the use of the PCR to follow changes in proteinuria in pregnant patients with CKD, but based on

TABLE 74.2 Criteria for Diagnosis of Preeclampsia and Superimposed Preeclampsia

PREECLAMPSIA	
In a woman without preexisting hypertension or proteinuria	Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic on two occasions at least 4 hours apart after 20 weeks of gestation AND the new onset of one or more of the following:
	Proteinuria (any one of the following): ≥300 mg/24 hours (or this amount extrapolated from a timed collection) Protein:creatinine ratio ≥0.3 mg protein/mg creatinine Dipstick proteinuria 1+ or greater (if quantitative methods are unavailable)
	Thrombocytopenia (platelet count <100,000/mcl)
	Renal insufficiency (S[Cr] >1.1 mg/dL or doubling from baseline in the absence of other renal disease)
	Impaired liver function (≥twofold increase in transaminase levels)
	Pulmonary edema
	Cerebral or visual symptoms
SUPERIMPOSED PREECLAMPSIA	
In a woman with chronic hypertension that was previously well controlled	New onset of proteinuria or end-organ dysfunction (see above) after 20 weeks gestation
In a women with proteinuria prior to, or early in, pregnancy	New, worsening, or resistant hypertension or end-organ dysfunction (see above), after 20 weeks gestation

Adapted from report of the American College of Obstetricians and Gynecologists' task force on hypertension in pregnancy. Obstet Gynecol *2013;**122**:1122–31.*

strong data supporting its use in the nonpregnant population, we recommend its use in pregnancy for this purpose.

The urine albumin:creatinine ratio (UACR) may be used as an alternative to the UPCR to quantify proteinuria in pregnancy. The ACR may be performed using an automated analyzer, allowing immediate point-of-care testing that could be utilized in an antenatal clinic. An ACR >2.5–8.0 mg/mmol is strongly predictive of proteinuria in high-risk pregnant patients[25] and in women with hypertensive pregnancies.[26] Although more data are needed, the ACR has the potential to supplant the urinary dipstick as a rapid and accurate screening method for proteinuria in routine obstetric care.

When proteinuria is first documented after 20 weeks gestation, preeclampsia is the most likely cause. In women without kidney disease or chronic hypertension, preeclampsia is usually diagnosed by the new onset of hypertension (BP > 140/90 mm Hg) and proteinuria (24-hour urine protein >300 mg, or spot UPCR >0.3 mg/mg) after 20 weeks gestation. Current guidelines from the American College of Obstetrics and Gynecology no longer require proteinuria for the diagnosis of preeclampsia if other severe preeclampsia features are present (Table 74.2). In women with CKD or chronic hypertension, the diagnosis of preeclampsia can be challenging, as diagnostic criteria are less clear-cut.

If preeclampsia has been excluded, diagnostic evaluation of proteinuria proceeds similarly to nonpregnant individuals. In women with mild proteinuria and intact or stable renal function, conservative management is often prudent, with consideration of renal biopsy and/or RAAS blockade after delivery. In patients with nephrotic syndrome or rapid loss of renal function, particularly early in pregnancy, renal biopsy should be considered. A multicenter cohort study of 173 women who underwent kidney biopsy during pregnancy or during the first postpartum year reported the most common diagnoses were focal segmental glomerulosclerosis (FSGS), lupus nephritis, IgA nephropathy, interstitial nephritis, membranous nephropathy (MN), and minimal change disease.[27]

MANAGEMENT

Counseling

Ideally, women with CKD who are considering pregnancy should be counseled regarding pregnancy and renal risks prior to conception. Careful attention to timing of pregnancy and transition to medications that are safe in pregnancy are important preparatory steps that maximize the likelihood of a healthy, successful pregnancy. Counseling women with CKD who are pregnant or considering pregnancy should include education regarding potential adverse pregnancy outcomes, the impact of pregnancy on kidney disease and overall maternal health, and interventions and monitoring to

TABLE 74.3 Risk of Adverse Pregnancy Outcomes in Chronic Kidney Disease

	Preeclampsia	Preterm Birth (<37 weeks)	Extremely Preterm Birth (<34 weeks)	SGA[a]	Perinatal Mortality
Normal renal function	3–5%	5–10%	1.5%	10.5%	0.1%
CKD1-2[30,58,124]	14–22%	13–40%	13–15%	13–25%	1%
CKD3-5[29–31]	40–60%	59–90%	50–55%	37–65%	4–7%
Diabetic microalbuminuria[125,126]	40–42%	62%	13%	4%	n/a
Diabetic nephropathy (>300 mg/day proteinuria)[41,127]	41–65%	22–60%	n/a	25–50%	5%
Lupus nephritis[81,90]	23%	31–48%	n/a	24–28%	6–11.3%
IgA nephropathy[99,100]	9%[c]	8.4–10%	n/a	14–25%[b]	3%
Kidney transplant recipients	27%	45.6%	n/a	n/a	2.5%

[a]*SGA, Small for gestational age defined as birthweight below the 10th percentile.*
[b]*Low birthweight (<2500 g).*
[c]*severe preeclampsia.*

minimize these risks and maximize the probability of a good pregnancy outcome.

CKD confers an increased risk of preeclampsia, preterm birth, cesarean section, small for gestational age (SGA) infant, and perinatal mortality (Table 74.3). Women with CKD are at increased risk for adverse pregnancy outcomes even when renal function is normal (stage 1 CKD due to isolated proteinuria, microscopic hematuria, or congenital urinary tract abnormalities).[28] However, risks are highest with more advanced CKD,[29] hypertension, or urinary protein excretion greater than 1 g/day.[30–32] Among women with chronic hypertension, the presence and severity of proteinura is correlated with adverse perinatal outcomes.[33]

Most pregnancies in women with CKD result in live births. However, more than half are preterm, with associated neonatal morbidity.[30] Notably, preterm offspring have an increased risk of hypertension and CKD later in life.[34] Although late preterm infants (delivery between 34 and 37 weeks gestation) usually do well with appropriate neonatal care, they still have a sixfold increase in neonatal death and fourfold increase in infant death in the first year after delivery.[35]

Women who enter pregnancy with mild CKD, absent or well-controlled hypertension, and mild or absent proteinuria have a low risk for pregnancy-associated loss of renal function.[32,36] In women with advanced CKD, pregnancy may lead to an accelerated decline in renal function.[31] Physicians should anticipate increased proteinuria during gestation, which must be distinguished from superimposed preeclampsia.

The physiologic increase in GFR characteristic of normal pregnancy is attenuated in CKD, and absent in women with severe renal dysfunction.[37] Hyperfiltration of remaining intact nephrons may exacerbate renal damage in this setting. Indeed, women who enter pregnancy with S[Cr] greater than 2.0 mg/dL have a high likelihood (>30%) for accelerated decline in renal function, with progression to end-stage renal disease (ESRD) within 1 year postpartum.[29] For women with moderate CKD prior to pregnancy (S[Cr] 1.4–2.0 mg/dL), the risk for rapid progression to ESRD is lower (2%), but loss of renal function is still observed in 30–40% of cases. Whether this loss of function is accelerated by pregnancy remains uncertain. Imbasciati et al. studied renal function in 49 pregnant women with CKD stage 3–5. They found no difference in the rate of estimated glomerular filtration rate (eGFR) decline before, during, or after pregnancy.[31] However, a pregnancy-associated acceleration in the rate of eGFR loss was observed in the subgroup with both prepregnancy eGFR <40 mL/min/1.73 m^2 and proteinuria greater than 1 g/day.[31]

Risks of adverse pregnancy outcomes are lowest when women with CKD enter pregnancy with well-controlled BP, minimal proteinuria, and stable renal function. For women with glomerular disease, pregnancy outcomes are better when the renal disease is stable or in remission on medications that are safe in pregnancy.

KDIGO (Kidney Disease: Improving Global Outcomes) and NICE (the National Institute for Health and Care Excellence) guidelines recommend that women with CKD without proteinuria achieve stable BP less than 140/90 mm Hg prior to conception. For women with proteinuria (ACR >70 mg/mmol per NICE, ACR >30 mg/mmol per KDIGO) or diabetes, a

TABLE 74.4 Treatment of Hypertension in Pregnancy

	Advantages	Disadvantages/Side Effects
FIRST-LINE AGENTS		
Nifedipine (PO)	Extended release formulation/once-daily dosing	Edema, headache
Labetalol (PO or IV)	Theoretical benefit of α-blockade on placental blood flow	May exacerbate reactive airway disease
Methyldopa (PO)	Extensive safety data	Fatigue, sedation, poor efficacy, short duration of action
SECOND-LINE AGENTS		
Verapamil, Diltiazem		Limited safety data
Metoprolol (PO or IV)	Extended release formulation/once-daily dosing	Limited safety data
Hydralazine (PO or IV)	Extensive clinical experience	Maternal tachycardia, delayed maternal hypotension
Nicardipine (IV)	Extensive clinical experience as tocolytic	Requires intravenous administration in a monitored setting
AVOIDED		
Thiazide, loop diuretics	No known adverse fetal effects	May interfere with physiologic increase in maternal plasma volume
Spironolactone	Effective in primary aldosteronism	Theoretical risk of feminization of male fetuses
Atenolol		Associated with fetal growth restriction
Nitroprusside (IV)	Rapidly effective for short-term use if other agents fail or are contraindicated.	Risk of cyanide poisoning to fetus
CONTRAINDICATED		
ACE inhibitors	May be safe in the early first trimester	Multiple fetal defects with second and third trimester exposure
Angiotensin receptor antagonists	Similar to ACEI	Simiar to ACEI

IV, intravenous; *PO*, by mouth.

lower BP target of <130/80 mm Hg is recommended. Medications should be reviewed to ensure they are safe in pregnancy, including avoidance of ACE inhibitors and angiotensin receptor antagonists (ACEIs/ARBs) in most cases (Table 74.4).

Prevention of Preeclampsia

Low-dose aspirin (ASA) reduces preeclampsia risk, with the greatest benefit in high-risk women. For example, a 2017 randomized controlled trial of 1776 women with singleton pregnancies at high risk for preeclampsia showed 150 mg ASA daily started before 14 weeks gestation reduced the risk of preterm preeclampsia from 4.3% in the placebo group to 1.6% in the aspirin group ($p = 0.004$).[38] However, the authors did not report whether patients with CKD were included in the study population. Similarly, a 2018 meta-analysis of trials of aspirin in average-risk pregnancies showed that when ASA is initiated prior to 16 weeks gestation at a dose of at least 100 mg daily, the risk of preterm preeclampsia was reduced by almost 80% (relative risk, 0.33; 95% confidence interval, 0.19–0.57).[39] Hence, low-dose ASA is recommended in women at high risk for preeclampsia—a category that includes women with CKD and chronic hypertension—by several national and international organizations, including the US Preventive Services Task Force, the American College of Obstetrics and Gynecology, NICE, the World Health Organization, and the American Heart Association.

Calcium supplementation reduces preeclampsia risk in women with low baseline dietary calcium intake.[40] A benefit in women with adequate dietary calcium intake has not been demonstrated. Therefore, oral calcium supplementation (1–2 g/day) is recommended in women with dietary calcium intake less than the recommended daily allowance of 1000 mg/day.

Available data do not support the use of anticoagulation, vitamin C, vitamin E, vitamin D, folate, diuretics, or antihypertensive medications for the prevention of preeclampsia.

Hypertension

Hypertension is associated with adverse maternal and neonatal outcomes among women with CKD,[30] so hypertension control prior to conception is recommended.[41] BP usually falls in early pregnancy, sometimes allowing medications to be reduced or discontinued. BP rises again toward term, frequently requiring uptitration of antihypertensive medications.

BP treatment targets in women with hypertension in pregnancy are controversial. A 2015 randomized trial comparing intensive (DBP target 90 mm Hg) vs. less-tight (DBP target 100 mm Hg) BP control in 987 women with chronic or gestational hypertension showed no difference in preeclampsia or neonatal outcomes.[42] However, women in the intensive control group had a lower rate of several maternal complications, including severe hypertension (BP > 160/110 mm Hg), thrombocytopenia, and elevated liver function tests. For pregnant women with CKD and diabetes mellitus, KDOQI (Kidney Disease Outcomes Quality Initiative) recommends pharmacologic treatment when BP is greater than 140/90 mm Hg.[41]

Preferred medications for treatment of hypertension in pregnancy include long-acting nifedipine, labetalol, and methyldopa (Table 74.4). Severe hypertension (systolic BP >160 mm Hg or diastolic BP >110 mm Hg) requires urgent treatment, often in a monitored setting. Oral nifedipine, intravenous nicardipine, and oral and intravenous labetalol are safe and effective for rapid BP lowering in this setting.[43] Nicardipine is a tocolytic and should not be used during labor.

ACEIs/ARBs are contraindicated in the second and third trimesters of pregnancy. Exposure during this time leads to major fetal malformations including renal dysgenesis, perinatal renal failure, oligohydramnios, pulmonary hypoplasia, hypocalvaria, and intrauterine growth restriction.[44,45] Evidence for teratogenicity with first trimester exposure is less compelling. In a large population-based study, Cooper et al. reported congenital malformations of the central nervous and cardiovascular systems were higher among women with first-trimester exposure to ACEIs.[46] However, this study has been criticized for the presence of potential confounders and ascertainment bias. Subsequent studies have failed to confirm evidence of teratogenicity with first-trimester ACEI exposure when controlling for potential confounders.[47] Women with a compelling indication for ACEIs/ARBs (such as diabetic nephropathy) can probably continue these agents while attempting conception, with discontinuation as soon as pregnancy is diagnosed. However, risks and benefits of this strategy should be discussed with the patient, with shared and individualized decision-making. Women inadvertently exposed in early pregnancy can be reassured by a normal mid-trimester ultrasound examination.

Atenolol has been linked to decreased placental perfusion and subsequent fetal growth restriction.[48] Therefore, pure beta-agonists are generally avoided in pregnancy. Although thiazide diuretics are not typically initiated during pregnancy, some have supported their continuation in women on stable doses prior to pregnancy.[49] Spironolactone is avoided in pregnancy due to the potential for ambiguous genitalia in male infants.[50] There are case reports of the successful use of eplerenone, which has fewer antiandrogenic effects, in patients with primary aldosteronism and Gitelman's syndrome during pregnancy.[51]

Edema

Edema is common in the third trimester of pregnancy. Women entering pregnancy with proteinuric CKD can develop severe edema as pregnancy progresses, affecting functional status and quality of life. Worsening edema after 20 weeks gestation should always prompt consideration of superimposed preeclampsia, especially when accompanied by high or worsening BP, increasing proteinuria, or other symptoms of severe preeclampsia (Table 74.2). Diuretics are contraindicated in preeclampsia, where there is already contraction of the intravascular volume.

Initial management of edema should include conservative measures, such as low sodium diet, compression stockings, and elevation of the legs. Diuretics are avoided unless symptoms are severe, due to theoretical interference with the normal pregnancy-associated increase in plasma volume. Although safety data are limited, loop and thiazide diuretics do not appear to cause fetal harm[52] and may be used cautiously to manage severe edema in pregnancy. The amniotic fluid index should be monitored, and diuretics stopped if oligohydramnios develops.

Anemia

There is a physiologic fall in hemoglobin concentration during pregnancy (Table 74.1). Iron requirements increase due to fetal demands. Iron deficiency is common and should be treated using oral or intravenous iron supplementation. Intravenous iron is safe and widely used when oral iron is ineffective or not tolerated. Women with advanced CKD, and especially ESRD, may require treatment with erythropoietin. Recombinant erythropoietin does not appear to cross the

placenta and is safe in pregnancy.[53] Increased doses are often required to maintain hemoglobin levels within the target range (Hb 10–11 g/dL).[54]

Secondary Hyperparathyroidism

Adequate vitamin D levels are important in pregnancy for fetal skeletal mineralization and growth.[55] In normal pregnancy, maternal 1,25-dihydroxyvitamin D increases substantially. In CKD, it is reasonable to measure and replace 25-hydroxyvitamin D if low, and to administer active vitamin D (i.e. calcitriol) if PTH remains elevated despite adequate 25-hydroxyvitamin D stores. There are inadequate safety data to support the use of vitamin D analogs (i.e. paracalcitol) in pregnancy. Calcium-containing phosphate binders are probably safe but may reduce absorption of some vitamins. Sevelamer has been associated with irregular ossification of fetal bones in animal studies and should be avoided in pregnancy. There is inadequate safety data regarding the use of cinacalcet in pregnancy.

Venous Thromboembolism

Pregnancy is a prothrombotic state, and women with nephrotic syndrome in pregnancy are at particularly high risk for thromboembolic complications. Prophylactic anticoagulation should be considered in women with nephrotic-range proteinuria in pregnancy, particularly in the setting of severe hypoalbuminemia, MN, the presence of anticardiolipin antibodies, or prescribed bed rest. Warfarin crosses the placenta and is associated with a high rate of fetal loss.[56] Heparin (including low-molecular weight heparin) does not cross the placenta and is considered safe.

Superimposed Preeclampsia

Preeclampsia is a pregnancy-specific disorder of hypertension, proteinuria, and thrombotic microangiopathy, which affects 3–5% of all pregnancies.[57] Women with CKD are at increased risk for preeclampsia, with an overall preeclampsia rate of 14–33%.[58] For women with advanced CKD (S[Cr] > 2.5 mg/dL), the risk of preeclampsia is over 40%.[29] Complications can include seizures (eclampsia), cerebral hemorrhage, liver failure, acute renal failure, pulmonary edema, and maternal death. Neonatal complications include intrauterine growth restriction and consequences of preterm delivery, which is often necessary when the maternal status is deteriorating.

Distinguishing superimposed preeclampsia from exacerbation of (or *de novo*) underlying kidney disease can be challenging. Standard diagnostic criteria for preeclampsia—which include the new onset of hypertension and proteinuria after 20 weeks gestation—often cannot be applied, and diagnosis rests on astute clinical judgment and close evaluation of BP and proteinuria trends throughout gestation. In women with preexisting proteinuria, the diagnosis of superimposed preeclampsia is suggested by new, worsening, or resistant hypertension after 20 weeks gestation, with or without severe preeclampsia features (Table 74.2).

Women with CKD should have proteinuria quantified frequently throughout gestation, using UPCR, ACR, or 24-hour urine protein measurement. Increasing proteinuria in the context of worsening hypertension can signify preeclampsia. Uterine artery Doppler flow may be useful in distinguishing CKD and preeclampsia among pregnant women with proteinuria and hypertension.[59] Alterations in maternal serum levels of angiogenic biomarkers, such as placental growth factor and soluble fms-like tyrosine kinase-1, may distinguish preeclampsia from CKD in pregnancy.[60] Further studies are needed before angiogenic biomarkers can be recommended for routine clinical practice, and angiogenic markers are not yet approved by the US Food and Drug Administration (FDA) for use in pregnancy.

Treatment of preeclampsia is supportive and ultimately requires delivery, particularly when there is clinical deterioration of the mother or fetus. When preeclampsia is diagnosed, urgent consultation with an obstetrician is imperative. Mild preeclampsia remote from term can sometimes be managed with bed rest, antihypertensive medication, and close maternal and fetal monitoring.[61] However, progression to severe preeclampsia over days to weeks is typical, requiring hospitalization, intensive fetal monitoring, antihypertensive medication, intravenous magnesium sulfate, and—if preterm—antenatal corticosteroids to accelerate fetal lung maturity. Delivery remains the only definitive treatment and should be undertaken immediately with women who develop even mild preeclampsia at or near term.[62]

Dialysis

Pregnant patients with advanced CKD may require dialysis initiation during pregnancy if progressive loss of kidney function occurs. Women who initiate dialysis after conception have relatively high live birth rates, compared to women who are already on dialysis at the time of conception (91% vs. 63%).[63] This difference may be attributable to the effect of residual renal function. Although there are no data to guide timing of dialysis initiation at a specific GFR or BUN threshold, dialysis should probably be started well before uremic symptoms develop. According to the Toronto experience, pregnant women with ESRD requiring dialysis who received intensive dialysis (6–8 hours, 6–7 times

per week, totaling >36 hours/week) had markedly better pregnancy outcomes compared to women from an American registry who received conventional dialysis (<20 hours per week). Women from the Canadian cohort had a higher live birth rate (86.4% vs. 61.4%, $p = 0.03$) and higher median gestational age at delivery (36 weeks vs. 27 weeks, $p = 0.002$).[64] A meta-analysis that included 681 pregnancies in women with ESRD confirmed that rates of preterm birth and SGA are lower with greater dialysis intensity.[65] To achieve >35 hours/week of dialysis, most pregnant women will require nocturnal and/or home hemodialysis. Late in gestation, dialysis may be performed in a hospital setting with continuous fetal monitoring. Peritoneal dialysis is usually avoided in pregnancy, with some data suggesting an increased incidence of SGA infants as compared with hemodialysis[65]

DISEASE-SPECIFIC CONSIDERATIONS

Diabetic Nephropathy

Women with diabetes in pregnancy are at increased risk for preeclampsia, macrosomia, and preterm birth. Women with diabetic nephropathy (proteinuria >300 mg/24 hour) are at highest risk, with very high rates of preterm delivery (34–60%) and SGA infants (25–50%).[66,67] Table 74.3 outlines the incidence of several adverse pregnancy outcomes among women with diabetic albuminuria and nephropathy. Although the majority of studies focus on women with type 1 diabetes, pregnancy risks in type 1 and type 2 diabetic nephropathy appear to be similar.[68]

Data are reassuring regarding the impact of pregnancy on progression of diabetic kidney disease. Pregnancy itself does not lead to progression from microalbuminuria to diabetic nephropathy (proteinuria >300 mg/day) or deterioration in renal function in women with diabetic nephropathy,[69] so long as pre-pregnancy renal function is preserved (S[Cr] <1.4 mg/dL).[70] There is a higher likelihood (32–45%) of pregnancy-associated deterioration in renal function in women with moderate or severe renal dysfunction (S[Cr] >1.4 mg/dL) prior to pregnancy,[71] possibly related to the inability to use ACEIs/ARBs in pregnancy.

ACEI/ARB use after the first trimester leads to severe fetal malformations. Because women frequently have their first prenatal visit weeks after pregnancy self-diagnosis, education of diabetic women of childbearing age regarding the teratogenic effects of ACEIs/ARBs is an important provider responsibility. Although preconception use of ACEIs/ARBs is probably safe, women must be educated to discontinue these agents as soon as pregnancy is suspected (i.e. after first missed period or positive pregnancy test).[41] These medications should be resumed immediately postpartum in women with diabetic nephropathy and are safe in breastfeeding.

The American Diabetes Association recommends a target HbA1c of 6–6.5% in most pregnant women.[72] Higher HbA1c before and during pregnancy is associated with several adverse outcomes, including preeclampsia, macrosomia, and fetal malformations.[73–75] Insulin is the preferred agent for management of type 1 and type 2 diabetes mellitus and (when pharmacologic therapy is needed) gestational diabetes mellitus in pregnancy.

Intensive BP control in early pregnancy (target BP <135/85 mm Hg) is associated with lower risk of preterm delivery among women with diabetic nephropathy in uncontrolled studies.[76,77] Hence, it is reasonable to aim for tighter BP control in women with diabetic nephropathy than in women with uncomplicated essential hypertension. Unfortunately, randomized controlled trials are lacking and controversy remains regarding appropriate BP goals in pregnancy. As with all women at high risk for preeclampsia, low-dose aspirin is recommended beginning in the first or early second trimester.[78]

Lupus Nephritis

Systemic lupus erythematosus (SLE) is one of the most common autoimmune diseases in women of childbearing age. Pregnant women with SLE are at increased risk for preterm birth, intrauterine growth restriction, spontaneous abortions, and preeclampsia.[79] A history of lupus nephritis, and especially active lupus nephritis at the time of conception, increases the risk of these complications even further.[79–81] Recent improvements in disease management and perinatal monitoring have improved rates of pregnancy loss and preterm delivery,[82] although outcomes remain suboptimal in developing countries.[83] With careful planning, monitoring, and management, most patients with SLE, particularly those with normal baseline renal function, can have successful pregnancies without serious maternal or fetal complications.[84]

There are conflicting data regarding whether pregnancy itself increases the risk for lupus flare.[85] The likelihood of renal flare during pregnancy is highest when there is evidence of active renal disease (proteinuria greater than 0.5 g/day or active urinary sediment) at the time of conception.[86,87] Predictors of poor obstetric outcomes include previous lupus nephritis, active renal disease at conception, poor renal function at conception, hypertension, and presence of the antiphospholipid syndrome.[85,86,88–90] Proliferative (WHO class III or IV) lupus nephritis carries a higher risk of preeclampsia

and delivery of a low–birthweight infant than mesangial (class II) or membranous (class V) lupus nephritis.[91]

According to guidelines from the Joint European League Against Rheumatism and European Renal Association–European Dialysis and Transplant Association, pregnancy may be safely planned in stable patients with inactive lupus and no more than minimal proteinuria for at least six months.[92] Women receiving mycophenolic acid or mycophenolate mofetil as maintenance therapy for lupus nephritis should be switched to azathioprine at least 3 months prior to conception.[92] It is recommended that use of biologic agents, such as rituximab, be avoided for at least 4 months prior to conception.[92] Steroids, azathioprine, and hydroxychloroquine are useful in pregnant women with SLE, particularly for the management of extrarenal symptoms.[85] Women receiving these drugs prior to pregnancy should be continued on them during pregnancy, as their withdrawal can precipitate a lupus flare.

The most important intervention to minimize pregnancy-associated risk in women with lupus nephritis is to delay pregnancy until renal disease is in remission on a medication regimen that is safe in pregnancy. If remission cannot be attained, consideration should be given to delaying pregnancy until after renal transplantation. Although steroids can be safely continued during pregnancy, prophylactic steroid therapy does not reduce the risk of a lupus flare during pregnancy.[93] Low-dose aspirin is recommended to reduce preeclampsia risk.[92] Women with the antiphospholipid syndrome and SLE are at particularly high risk for developing thrombosis.[94] Anticoagulation with low-molecular weight heparin should be considered in women with SLE and the antiphospholipid syndrome.[92]

Women with pregnancy in the setting of prior lupus nephritis need careful and close monitoring before, during, and after pregnancy by a multidisciplinary team, including an obstetrician, rheumatologist, and nephrologist.[87] Prenatal care should include frequent monitoring of urinalysis for hematuria, quantification of proteinuria, and regular measurement of renal function and serum complement levels. BP should be closely monitored, particularly after 20 weeks gestation, for detection of preeclampsia.

Lupus nephritis flare and preeclampsia share many clinical features, including hypertension, proteinuria, thrombocytopenia, and renal impairment. Though challenging, accurate diagnosis is critical because treatments for these entities differ.[95] Several clinical clues can suggest the correct diagnosis, and the approach will vary based on gestational age at the time of presentation. For women presenting with worsening proteinuria and hypertension prior to 20 weeks gestation, preeclampsia is very unlikely, and the diagnosis of lupus nephritis should be strongly considered. For women presenting after 37 weeks gestation, consider immediate delivery, with timely renal biopsy postpartum if clinical and serologic features suggest lupus nephritis. Clinical clues suggesting lupus nephritis include hypocomplementemia, increased anti-dsDNA titer, neutropenia, hematuria, active urinary sediment, and the presence of extrarenal lupus symptoms.[52,87] As for nonpregnant individuals, renal biopsy is necessary for definitive diagnosis of lupus nephritis in pregnancy and should precede initiation of immunosuppressive treatment. Although data on the safety of renal biopsy during pregnancy are limited, clinical experience suggests it is safe if undertaken prior to approximately 30 weeks gestation.[96] As gestation progresses, kidney biopsy becomes technically difficult as the gravid uterus precludes usual prone positioning. In these cases, the lateral decubitus or seated position may be used.

Treatment of lupus nephritis in pregnancy is challenging, as conventional induction therapies are contraindicated due to risk of congenital malformations associated with mycophenolate[97] and fetal loss associated with cyclophosphamide.[98] In severe proliferative lupus nephritis early in pregnancy, cyclophosphamide or mycophenolate should be considered despite adverse fetal effects because untreated or inadequately treated severe lupus nephritis may result in both maternal and fetal jeopardy. Maternal counseling regarding the fetal effects of treatment, including the option of pregnancy termination, should be provided in these cases. Calcineurin inhibitors are nonteratogenic and can be used to treat lupus nephritis in pregnancy, with some data to support their efficacy in the nonpregnant population.[92] Tacrolimus may increase the risk of gestational diabetes, and screening with a glucose tolerance test is recommended at 28 weeks or earlier. Rituximab lacks safety data in pregnancy, and it is not recommended for use in pregnancy.[92] Azathioprine, despite assignment to category "D" (evidence for human fetal risk based on human studies) by the FDA, is considered relatively safe in pregnancy and can be used as adjunctive or maintenance therapy in pregnant patients with lupus nephritis.

IgA Nephropathy

Pregnancy-associated risks in patients with IgA nephropathy and other forms of chronic glomerulonephritis appear to parallel the risks for CKD more generally (Table 74.3). Women with IgA nephropathy who enter pregnancy with normal renal function have a low risk of pregnancy-associated deterioration in kidney function.[99] Persistent proteinuria at the time of conception may be associated with more rapid decline in renal function postpartum.[100]

There are no clinical trials to guide the treatment of IgA nephropathy in pregnancy. The same treatment principles used in nonpregnant individuals can generally be applied to pregnant patients, with a few important caveats. RAS inhibitors are contraindicated in pregnancy and should be discontinued at pregnancy diagnosis. Prednisone, azathioprine, tacrolimus, and cyclosporine can be safely used in pregnancy.

IgA nephropathy sometimes presents during pregnancy, possibly because screening urinalysis is routinely performed. When renal function is stable, kidney biopsy can usually be safely deferred until after delivery.

Focal Segmental Glomerulosclerosis

FSGS is the most common cause of kidney disease diagnosed by kidney biopsy during or within 1 year of pregnancy.[27] Nevertheless, published literature on treatment and pregnancy outcomes among women with FSGS in pregnancy is very limited. The rate of eGFR decline and need for RRT was not different when comparing 31 women with FSGS diagnosed during or within 1 year of pregnancy, to control women of childbearing age.[27] Glucocorticoids are first-line when treatment is necessary. Risks include development of gestational diabetes mellitus. *De novo* diagnosis of FSGS has been described after preeclampsia, and it has been suggested that podocyte damage in preeclampsia may contribute to the pathogenesis of FSGS in these cases.[101,102]

Membranous Nephropathy

There are few case reports and no large clinical studies of MN in pregnancy. Early reports suggested women with MN have a lower rate of fetal loss than women with other forms of glomerulonephritis. Treatment is generally supportive; ACEIs/ARBs are contraindicated. Standard first-line agents for MN (chlorambucil, cyclophosphamide) should be avoided during pregnancy. There are minimal data on potential fetal effects of rituximab, and it should be avoided in pregnancy.

Polycystic Kidney Disease

In most women with autosomal dominant polycystic kidney disease (ADPKD), renal function usually remains intact until after completion of childbearing, and pregnancy outcomes are generally favorable. Chapman and colleagues compared pregnancy outcomes in 485 women with ADPKD and 205 unaffected family members.[103] Most ADPKD subjects had S[Cr] $\leq$1.2 mg/dL before pregnancy. Women with ADPKD were more likely to experience preeclampsia (11% vs. 4% of controls) and new or worsening hypertension (23% vs. 7% of controls), but there were no significant differences in adverse fetal or neonatal outcomes. Subsequent studies have reported similar results.[104] Prepregnancy hypertension is an important risk factor for maternal complications.

Screening for intracranial aneurysms by magnetic resonance angiography, if indicated by a family history of cerebral aneurysm or intracranial hemorrhage, should be performed prior to term. If an aneurysm is detected, labor should be avoided and Cesarean section planned because pushing during labor can result in aneurysm rupture.[105]

Genetic counseling is an important component of pregnancy care in women with polycystic kidney disease, ideally prior to conception. Offspring of individuals with ADPKD have a 50% chance of having the disease. Prenatal genetic diagnosis is available for both ADPKD and autosomal recessive PKD, particularly when the specific genetic mutation has been identified in a proband.[106] Preimplantation genetic diagnosis is an option among couples receiving *in vitro* fertilization and other assisted reproductive technologies.[107]

Alport Syndrome

Of women with X-linked Alport syndrome (AS), 15–30% may develop renal failure and hearing loss, and autosomal recessive AS affects men and women equally. The literature on AS in pregnancy is largely limited to case reports, and little is known about pregnancy risks. A case series of seven pregnancies in six women with AS reported a high incidence of low birthweight and worsening proteinuria, especially among those with proteinuria prior to pregnancy.[108]

As with ADPKD, genetic counseling is an important component of pregnancy management. For pregnant female carriers of X-linked AS, male fetuses have a 50% chance of being affected, and female fetuses have a 50% risk of being carriers. For pregnant women whose partner has X-linked AS, male fetuses will not be affected, whereas female fetuses have a 100% chance of being carriers.

Kidney Transplant Recipients

Pregnancy outcomes are generally favorable in kidney transplant recipients, compared to women with ESRD on dialysis or with advanced CKD. For this reason, women with advanced CKD who desire pregnancy are sometimes advised to wait until after kidney transplantation. Nevertheless, transplant recipients are at risk for adverse pregnancy outcomes, including preeclampsia, preterm birth, intrauterine growth restriction, cesarean section, and perinatal mortality.[109–111]

The risk of preterm delivery is highest when the eGFR is <90 mL/min/1.72 m^2, or if hypertension is present.[112]

Women are usually advised to wait at least 12 months after kidney transplantation before pursuing pregnancy, because the early posttransplant period has a higher risk of acute rejection and requires more intensive immunosuppression. A 2011 systematic review and meta-analysis that included data from 4706 pregnancies in 3570 kidney transplant recipients found a higher risk of obstetric complications in women with a shorter interval between transplant and pregnancy.[109] Because kidney transplantation rapidly restores fertility in women with ESRD and advanced CKD, patients should be counseled on the importance of using appropriate contraception until pregnancy is desired and safe. The American Society of Transplantation Consensus Conference suggests transplantation can be safely pursued if all the following conditions are met[113]:

- No rejection in the past year
- Adequate and stable graft function (S[Cr] <1.5 mg/dL)
- No acute infections are present that may impact the fetus (e.g. CMV, toxoplasmosis)
- Stable maintenance immunosuppression is present

Maintenance immunosuppression usually includes a calcineurin inhibitor, azathioprine, and/or glucocorticoids (e.g. prednisone). Cyclosporine and tacrolimus are both safe in pregnancy, though increased metabolism often requires an increase in dosage, requiring frequent therapeutic monitoring.[114] Mycophenolate and rapamycin are teratogenic and should be stopped at least 6 weeks prior to conception.[115] There are few data on the safety of antithymocyte globulin, alemtuzumab, belatacept, bortezomib, and eculizumab in pregnancy, so these agents are generally avoided.

The indications for transplant kidney biopsy in pregnancy are similar to those in nonpregnant individuals. Worsening graft function during pregnancy should generally be evaluated by kidney biopsy, which is generally well-tolerated. The incidence of acute rejection in pregnancy is about 4%, similar to that in nonpregnant individuals.[109] High-dose glucocorticoids are the first-line treatment for acute cellular rejection. Intravenous immunoglobulin and therapeutic plasma exchange can be safely used for the treatment of antibody-mediated rejection in pregnancy.

Pregnancy does not appear to have a negative effect on the rate of graft loss. For example, in one Norwegian study, women who had pregnancy after kidney transplantation had a 50% lower risk of graft loss compared to women who did not have a pregnancy after kidney donation.[116]

DRUGS AND LACTATION

Breastfeeding is recommended by the American Academy of Pediatrics and the World Health Organization as the preferred form of infant nutrition during the first 6 months of life. Women should be encouraged to breastfeed whenever feasible, but women receiving medications for CKD should be advised on the safety and appropriateness of medications in breastfeeding. The LactMed database, freely available online at the National Library of Medicine's TOXNET system, is a useful clinical resource that provides updated information from multiple sources (https://toxnet.nlm.nih.gov, accessed 8/30/2018).

Antihypertensive Agents

There are few well-designed studies of the safety of antihypertensive medications in breastfeeding women. In general, agents considered safe during pregnancy are considered safe when breastfeeding. Methyldopa and nifedipine are safe. β-Blockers with high protein binding, such as labetalol and propranolol, are preferred over atenolol and metoprolol, which are concentrated in breast milk. Most diuretics decrease milk production and should be avoided in breastfeeding mothers.[117] Spironolactone is safe.[21,118] Captopril and enalapril are poorly excreted in breast milk and generally considered safe in lactating women.[119] Hence, in women with proteinuric renal disease, reinitiation of ACEIs/ARBs should be considered immediately after delivery. There are presently no data on the safety of angiotensin receptor antagonists in lactation.

Immunosuppressive Agents

Because of lack of definitive data, breastfeeding is generally discouraged in women taking immunosuppressive drugs. Studies on transfer of calcineurin inhibitors to the babies of breastfeeding mothers are inconsistent, with some studies reporting undetectable levels,[120,121] but one reporting infant blood levels in the therapeutic range.[122] There are no reports on adverse neonatal effects with cyclosporine use in breastfeeding. Limited data suggest tacrolimus levels are very low in breast milk. Investigators from the National Transplantation Pregnancy Registry suggest that breastfeeding should not be discouraged in women taking tacrolimus.[123] When cyclosporine or tacrolimus is used in a lactating mother, consideration should be given to monitoring neonatal blood concentrations for potential toxicity. Theoretically, mycophenolic acid should be safe in breastfeeding because the active

metabolite secreted in breast milk, methylmalonic acid, is not bioavailable. Human evidence of safety is lacking, however.

CONCLUSIONS

Pregnancy offers unique challenges in the evaluation and management of women with CKD. The assessment of renal function and proteinuria in pregnancy requires an understanding of the physiologic changes of pregnancy. CKD, even in its early stages, is associated with an increased risk of preeclampsia, preterm birth, and fetal growth restriction. However, women with early stage CKD and well-controlled BP usually have good pregnancy outcomes, with minimal risk of pregnancy-associated deterioration in kidney function. Pregnancy outcomes in kidney transplant recipients are generally favorable, so long as graft function is stable and immunosuppression is adjusted appropriately. Management of CKD and hypertension in pregnancy and the postpartum period requires a recognition of maternal and fetal effects of pharmacologic agents.

QUESTIONS AND ANSWERS

Question 1

A 25-year-old woman with a history of lupus nephritis and chronic hypertension is evaluated for worsening kidney function. She is currently 32 weeks gestation with a singleton pregnancy. She was diagnosed with class 4 lupus nephritis several years ago. She had received induction therapy with mycophenolate mofetil and was in full remission at the time of conception on azathioprine. Her current medications include nifedipine, labetalol, and azathioprine. Her BP is 150/86 mm Hg, increased from 132/68 mm Hg at her last visit 4 weeks ago. The physical examination is otherwise normal, except for mild lower extremity edema. She denies joint complaints or skin rash. She denies headache, vision changes, or abdominal pain.

Laboratory studies:

S[Cr] 1.0 mg/dL (increased from 0.5 mg/dL 1 month ago)
C3 34 mg/dL (normal 55−120)
C4 8 mg/dL (normal 15−48)
WBC 5900/μL
Hemoglobin 8.8 g/dL
Platelets 76,000/μL
24-hour urine protein excretion 1255 mg/day (increased from 260 mg/day 1 month ago)
Urinalysis 3+ blood, 2+ protein
The urine sediment examination reveals 10−20 RBC/hpf

Which ONE of the following findings MOST favors the diagnosis of relapse of lupus nephritis, rather than severe preeclampsia?

A. Low hemoglobin
B. Thrombocytopenia
C. Proteinuria
D. Hematuria
E. Increasing S[Cr]

Answer: D

Hematuria is a characteristic finding in lupus nephritis but is not typically seen in preeclampsia. An active urinary sediment, with dysmorphic RBCs and/or cellular casts, would further support the diagnosis of lupus nephritis. Anemia, thrombocytopenia, hypertension, worsening renal function, and increasing proteinuria can all be seen in both lupus nephritis flare and in the preeclampsia/HELLP syndrome. The presence of extrarenal lupus symptoms, hypocomplementemia, and a positive anti−double-stranded DNA antibody titer are other clinical clues favoring the diagnosis of lupus nephritis flare.

Question 2

A 36-year-old woman with chronic hypertension and CKD stage 3 (eGFR 55 mL/min/1.73 m^2) presents after a positive pregnancy test. Ultrasound confirms 10 week singleton gestation. Prior to pregnancy she was taking hydrochlorothiazide and lisinopril, which she stopped when she noted her positive pregnancy test. Her BP in the office is 155/95 mm Hg.

Which of the following is the most appropriate agent to treat this patient's hypertension?

A. Labetalol
B. Candesartan
C. Hydrochlorthiazide
D. Atenolol
E. No pharmacologic therapy; repeat visit for BP check in 4 weeks

Answer: A

KDOQI recommends maintaining BP <140/90 mm Hg in pregnant women with CKD. Hence, pharmacologic therapy is indicated in this patient. Labetalol is a safe and appropriate antihypertensive agent for use in pregnancy. Methyldopa and dihydropyridine calcium-channel blockers, such as long-acting nifedipine, are also appropriate for use in pregnancy. ACEIs/ARBs are contraindicated in pregnancy, as they cause birth defects with second and third trimester exposure. Hydrochlorothiazide and other loop and thiazide diuretics are not teratogenic, but can theoretically interfere with the normal plasma volume expansion of pregnancy, and are generally avoided in pregnancy. Atenolol has been associated with impaired fetal growth in some studies. Agents with combined alpha- and beta-blockade, such as labetalol, maintain placental perfusion and are not associated with this adverse effect.

Question 3

A 28-year-old woman with a history of IgA nephropathy presents at 30 weeks gestation with the new onset of edema in her hands and face. Her BP, previously normal, is 168/105 mm Hg. Physical examination shows edema in her upper and lower extremities bilaterally. Two months ago, S[Cr] was 0.8 mg/dL and UPCR was 0.10 mg/mg. Which of the following findings would establish the diagnosis of preeclampsia?

A. Uric acid >8 mg/dL
B. Urine protein excretion >150 mg on a 24-hour urine collection
C. Total bilirubin >2.0 mg/dL.
D. Platelet count <100,000/mm^3
E. Microscopic hematuria

Answer: D

The 2013 ACOG diagnostic criteria for preeclampsia include the new onset of hypertension after 20 weeks gestation and either proteinuria (see below) or another feature of severe preeclampsia. Severe diagnostic features include thrombocytopenia (platelet count $<100{,}000/mm^3$), elevated liver enzymes, acute kidney injury, cerebral symptoms, or visual symptoms. Hence, the new onset of thrombocytopenia, together with the new onset of hypertension, would be considered diagnostic of preeclampsia.

The diagnosis of preeclampsia based on proteinuria requires >300 mg/day on 24-hour collection, PCR > 0.3 mg/mg on a random urine sample, or dipstick urinalysis 1+ or greater if quantitative methods are unavailable. Hyperuricemia is common in preeclampsia but is not reliable for diagnosis. Transaminitis is a diagnostic feature of preeclampsia, but hyperbilirubinemia is not. Microscopic hematuria is not a feature of preeclampsia, and if present would likely be due to this patient's underlying IgA nephropathy.

Question 4

A 32-year-old woman with diabetic nephropathy and hypertension is evaluated 3 months postpartum. During her pregnancy, her ACE-inhibitor was held, and her hypertension was well controlled on 100 mg labetalol twice daily. She reports no headache or blurry vision. On physical examination, her BP is 150/95 mm Hg, and there is no edema. S[Cr] is 1.2 mg/dL, and UPCR is 1.8 mg/mg, unchanged from last measurement. She is currently breastfeeding.

Which one of the following is the MOST appropriate treatment?

A. Start hydrochlorthiazide
B. Increase labetalol dose
C. Start enalapril
D. No medication changes
E. Admit to the hospital for management of postpartum preeclampsia

Answer: C

ACEI are recommended for breastfeeding women with proteinuria and hypertension. Enalapril, captopril, and quinapril are poorly excreted in breast milk and are considered safe. Diuretics, such as hydrochlorthiazide, may decrease breast milk production and are usually avoided in breastfeeding women. Postpartum preeclampsia is an important cause of worsening hypertension between 2 days and 6 weeks postpartum but does not occur this long after delivery.

Question 5

A 37-year-old woman with CKD stage 3 due to vesicoureteral reflux is currently 14 weeks gestation. She had preeclampsia during her last pregnancy 3 years ago. Her only medication is a prenatal vitamin. The BP is 130/80 mm Hg.

Which one of the following is MOST effective to reduce her risk of recurrent preeclampsia?

A. Dietary sodium restriction
B. Vitamin C and E supplementation
C. Labetalol
D. Low-dose aspirin
E. Calcium carbonate

Answer: D

This patient is at high risk for preeclampsia, due to the presence of CKD and prior preeclampsia. Low-dose aspirin reduces the risk of preterm preeclampsia and its complications and is recommended in all high-risk women.

Low-sodium diet, antihypertensive medication, and vitamin C and E do not reduce the risk of preeclampsia. Calcium supplementation (>1 g/day) appears to reduce the risk of severe hypertensive disorders in patients with low baseline dietary calcium intake, but a benefit has not been shown in US populations with a well-balanced Western diet. Hence, calcium supplementation is recommended only if dietary history suggests intake is less than the recommended 1000 mg/day elemental calcium.

Chronic Kidney Disease in Children

Susan L. Furth[a], *Marva Moxey-Mims*[b], *Rebecca Ruebner*[c]

[a]The Children's Hospital of Philadelphia, Philadelphia, PA, United States; [b]Children's National Health System, The George Washington University School of Medicine, Washington, DC, United States; [c]Johns Hopkins University School of Medicine, Baltimore, MD, United States

Abstract

Chronic kidney disease (CKD) in children has unique etiologies compared to adults, with the majority of pediatric CKD caused by congenital anomalies of the kidney and urinary tract (CAKUT). Additional etiologies include primary and secondary glomerular disorders and cystic and hereditary kidney diseases. The natural history of CKD in children is characterized by a steady decline in kidney function over time, although children with CAKUT tend to have a slower decline compared to children with glomerular disorders. Interventions to slow progressive kidney disease in children and diminish CVD risk factors include strict control of blood pressure and correction of anemia, dyslipidemia, and calcium–phosphate balance. When children with CKD progress to ESRD, preemptive transplantation is the preferred method of renal replacement therapy, but HD remains the most common initial therapeutic modality. CKD has a multitude of effects on childhood health including CVD, impaired nutrition and growth, anemia, bone disease, and neurocognitive deficits. Children with CKD have an increased risk of early mortality.

CKD IN CHILDREN

Progressive CKD in children is a devastating illness. Although mortality rates in children treated with dialysis in the US have decreased over the last 20 years, the expected remaining lifetime for children aged less than 14 years with end-stage renal disease (ESRD) in the US is only 21.7 years on dialysis and 57.8 years with a kidney transplant, compared to 72.4 years for the general age-matched population.[1,2] The diagnostic and therapeutic approach to CKD must therefore emphasize early detection and management to slow CKD progression to ESRD and prevent complications.

Although the definition of CKD in adults is generally applicable to children, there are some very specific differences. One important factor is the age of the child. The time frame defining chronicity as greater than 3 months cannot be used for newborns, or infants less than 3 months of age. Additionally, normal glomerular filtration rate (GFR) increases over time in the newborn and infant. Even the normal GFR in infants and young children would qualify as CKD by adult standards (i.e. less than 60 mL/min/1.73 m^2). Alternatively, a normal S[Cr] or eGFR for age may be associated with structural abnormalities, and the diagnosis of CKD may be made on that basis. By 2 years of age, the normal GFR (accounting for body size) in children is comparable to that of adults. There are numerous equations for estimating GFR in children. The most well-known creatinine-based one is the Schwartz formula. This equation has evolved over time to the current recommended bedside formula[3]:

$$\text{eGFR}\left(\frac{\text{mL/min}}{1.73\ \text{m}^2}\right) = 0.413 \times \left(\frac{\text{height}}{\text{S[Cr]}}\right)$$

$$-\ \text{height in cm},\ \frac{\text{S[Cr]in mg}}{\text{dL}}$$

The staging of CKD by GFR described for adults is probably applicable to children older than 2 years,[4] but there is no comparable GFR staging for children under 2 years of age. The most recent KDIGO Guidelines suggest that the latter group has three categories—normal, moderate, or severely reduced GFR—based on the normal range and standard deviations (SD). Those with GFR values >1 SD but <2 SD below the mean would be in the moderately reduced range, whereas those with values >2 SD below the mean would be in the severely reduced range.[5]

The most recent recommendations for the definition of CKD in adults also include albuminuria categories due to the strong association of urinary albumin excretion and prognosis.[5] However, there is not yet sufficient evidence

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00075-9

to use albuminuria, as opposed to proteinuria, in children. A recent study comparing albuminuria to proteinuria in the Chronic Kidney Disease in Children Study showed that albuminuria did not add any predictive value compared with proteinuria.[6] There may be some value to albuminuria in the adolescent age group, as shown in a recent NHANES study.[7] Prospective cohort studies in children report a faster decline in kidney function in children with higher levels of proteinuria[8,9] As with GFR, normal urinary protein excretion varies with age and height, but sex, weight, and Tanner (pubertal physical development) stage also have an impact.[10] A retrospective followup study from the ESCAPE trial suggests that minimizing proteinuria can slow CKD progression.[11] Immature proximal tubular function results in higher urinary protein excretion in infants and young children with normal renal function,[12] so this will need to be accounted for in future analyses evaluating the association of levels of albuminuria or proteinuria and kidney function decline in very young children.

HISTORY OF CKD IN CHILDREN

CKD in children was described in the literature as early as the late 19th century. In 1897 in the *Lancet*, Dr. L. Guthrie reported on "Chronic Interstitial Nephritis in Childhood."[13] This report as well as other early descriptions of CKD characterized fairly normal intellectual development in these children as well as the main sequelae of CKD in childhood: pallor (due to anemia), growth failure (referred to as "infantilism"), rickets "associated with albuminuria," appetite dysregulation, delayed puberty, and sequellae of hypertension, including headaches, vomiting, and left ventricular hypertrophy (LVH). In late stages, "dropsy" or edema was noted, as well as seizures, tetany, and death due to uremia or stroke. From the earliest reports, astute clinicians noted differences between CKD in childhood and in adults. Although in children polyuria was frequently described, with low specific gravity urine, "in adults with granular nephritis the symptom (polyuria) is rarely the subject of a complaint," as usually low urine output was noted.[14] This pointed to the differences between predominant causes of CKD in children and adults. In children, structural urologic diseases, as opposed to acquired glomerular disorders, are the most common causes of CKD both then and now.[15–21]

EPIDEMIOLOGY OF CKD IN CHILDREN

Reports of the incidence and prevalence of childhood CKD are not available from many areas of the world, and those that are reported from different geographical areas are often not directly comparable due to methodological differences in ascertainment and reporting. In Europe, the ItalKid project provides comprehensive data on the epidemiology of CKD in children. The ItalKid project is a prospective, population-based registry started in 1990, including all incident and prevalent cases of CKD (C_{Cr} <75 mL/min/1.73 m^2) in children younger than 20 years from throughout Italy (total population base: 16.8 million children).[15] The ItalKid project reported a mean incidence of preterminal CKD (C_{Cr} <75 mL/min/1.73 m^2) of 12.1 cases per year per million of the age-related population (marp) with a point prevalence of 74.7 per marp in children younger than 20 years of age.[15] The national survey performed in Sweden from 1986 to 1994 included children (ages 6 months to 16 years) with more severe preterminal CKD (C_{Cr} <30 mL/min/1.73 m^2) and reported a median annual incidence and prevalence of 7.7 and 21 per marp, respectively.[18] Similarly, the incidence rate of severe preterminal CKD in Lorraine, France, has been estimated as 10.5 per marp in children less than 16 years, with a prevalence rate of 66 per marp.[17] In Latin America, the Chilean survey from 1996 reported incidence and prevalence rates of 5.7 and 42.5 per marp, respectively, in children younger than 18 years of age with C_{Cr} <30 mL/min/1.73 m^2, including patients with ESRD. There are now data emerging from regions in the world that report CKD of unknown origin, the etiology of which is thought to be related to environmental contaminants. One example is Mexico, where CKD of unknown origin is endemic in some areas, with a recent report of prevalence rates as high as 45.7%, defined by persistent albuminuria.[22] In Turkey, the estimated incidence of GFR <75 mL/min/1.73 m^2 in children less than 19 years of age is 11.9 per marp.[16] Data are also emerging from the African continent showing high prevalence levels. One recent report from Cameroon showed a CKD prevalence of 15.5% in hospitalized children, consistent with levels reported from other developing countries.[23]

In the US, population-based epidemiologic data are not available, and estimates of the distribution of causes of CKD in children are primarily derived from the CKiD study, and the registry of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) organization. The CKiD study is an observational cohort study funded by the National Institutes of Health (NIH) in which individuals with mild to moderate CKD (estimated GFR 30–90 mL/min/1.73 m^2) aged 1–16 years are recruited from over 50 sites in the US and Canada.[19] The NAPRTCS is a voluntary registry, with data entered by participating centers. In 1994, it was expanded to include data from patients with CKD, characterized by a Schwartz estimated creatinine clearance of ≤75 mL/min/1.73 m^2.[21]

DIAGNOSIS OF CKD IN CHILDREN

Summarized data on the demographics and underlying causes of CKD in children from a number of published reports from different geographic areas are presented in Table 75.1. In general, the three largest categories of causes of kidney disease in children are congenital anomalies of the kidney and urinary tract (CAKUT), glomerulonephritis (GN), and cystic and hereditary disorders. The incidence and prevalence rates of CKD are greater for boys than girls.[20] This gender distribution reflects the higher incidence of CAKUT, including obstructive uropathy, renal dysplasia, and prune belly syndrome in boys than girls.[15] CAKUT causes can be isolated renal anomalies, or part of a variety of genetic syndromes. While congenital causes are the most common reported etiology from developed countries where CKD is diagnosed in its earlier stages, infectious or acquired causes predominate in developing countries where patients are referred in the later stages of CKD.

As the majority of pediatric CKD results from CAKUT, many cases are detected prenatally due to the ubiquitous use of prenatal ultrasound.[24] Reduced amniotic fluid is a common finding when there is poor kidney function resulting in reduced urine production.[25] Abnormal findings in the fetal kidneys (cysts, hydronephrosis, hyperechogenic, hypoplastic, or absent kidneys) must be confirmed after birth, as hydronephrosis detected prenatally sometimes resolves spontaneously.[26] Normative data on fetal kidney lengths exist and are used to diagnose hypoplastic kidneys.[27]

Postnatally, renal dysplasia is identified by radionuclide scanning using technetium-99m-labeled dimercaptosuccinic acid (DMSA), which concentrates only in functional renal tissue. This test is used in cases of suspected multicystic dysplastic kidney (MCDK), as well as for assessing renal damage in the presence of vesicoureteral reflux (VUR). Posterior urethral valves (PUV) and VUR, which can both result in hydronephrosis, are diagnosed by voiding cystourethrography. Although unilateral kidney anomalies (such as renal agenesis, MCDK, and hypoplastic kidneys) carry a lower risk for kidney failure in childhood, there is potentially increased risk for hypertension, proteinuria, and renal impairment in adulthood.[28] CAKUT has a definite genetic basis through various molecular mechanisms that share common pathways and affect kidney development. This is a rapidly growing area of research, but there are currently no specific genetic tests routinely recommended for most CAKUT phenotypes because of varied presentation and varied penetrance.

Glomerular etiologies of CKD in children can be primary or secondary, and their incidence differs by geographic region and the race and ethnicity of the population. In the US CKiD study, focal segmental glomerulosclerosis (FSGS) is the most common glomerular cause of CKD reported. Possibly related to increased vulnerability due to genetic risk factors, specifically coding sequence variants in the APOL1 gene, FSGS is three times more common in Blacks than in Whites (18% vs. 6%) and is particularly common among Black adolescents with CKD.[29] GN due to hemolytic uremic syndrome, systemic lupus erythematosus, and IgA nephropathy are the next most common glomerular diagnoses after FSGS in the US-based CKiD study. "Chronic" GN, idiopathic crescentic GN, membranoproliferative GN, membranous nephropathy, and pauci-immune GN are uncommon in the young, but do occur, and have been reported as causes of CKD in youth in multiple reports. Cystic and hereditary disorders account for a substantial proportion of CKD in children. Autosomal recessive and dominant polycystic kidney disease and the nephronophthisis (NPHP)/medullary cystic disease complex are the predominant cystic disorders, whereas Alport syndrome, congenital nephrotic syndrome (CNS), cystinosis, and oxalosis are the primary genetic disorders causing CKD in childhood.

Ultrasonography is the most common imaging modality used to diagnose autosomal dominant polycystic kidney disease (ADPKD) as in adults. It is not uncommon for children to show asymmetric cyst distribution, or even isolated unilateral cysts.[30] If there is no family history of ADPKD, ultrasonography of both parents is recommended. However, if the ultrasounds of the parents are normal and they are less than 30 years old, ultrasonography of the grandparents may be indicated. Up to 50% of children with autosomal recessive polycystic kidney disease (ARPKD) are diagnosed prenatally.[31] There are clear clinical criteria for the diagnosis of ARPKD—the presence of enlarged, echogenic kidneys, with one or more additional findings (the absence of renal cysts in both parents, history of a previously affected sibling, parental consanguinity, and clinical, laboratory, or pathologic features of hepatic fibrosis).[32,33]

Genetic Testing

ADPKD is caused by mutations in either the PKD1 or PKD2 gene, with PKD1 mutations accounting for about 85% of ADPKD cases.[34] Genetic testing is available but is not necessary in patients who have a positive family history of ADPKD and the typical radiographic appearance of bilateral renal cysts. Additionally, even in families known to have ADPKD, mutation analysis may detect only 85% of mutations and will not change clinical management. One exception may be for the exclusion of family members as potential kidney donors when evaluating living donor candidates for an

ADPKD-transplant recipient.[32] ARPKD is caused by mutations in the polycystic kidney and hepatic disease-1 gene.[35,36] Genetic diagnosis is possible through linkage analysis in families who have already had an affected child or through direct mutation analysis. However, mutation analysis through gene sequencing detects mutations in only 60–75% of patients with known ARPKD.

NPHP encompasses genetically heterogeneous conditions with autosomal recessive inheritance associated with identified mutations in a number of genes that encode proteins involved in the function of primary cilia, basal bodies, and centrosomes. Children with NPHP demonstrate reduced urinary concentrating ability with a bland urinary sediment and chronic tubulointerstitial nephritis with progression to ESRD generally before the age of 20 years. Kidneys in NPHP are of normal or diminished size, cysts are concentrated at the corticomedullary junction, and tubulointerstitial fibrosis is dominant. NPHP can be associated with retinitis pigmentosa (Senior–Løken syndrome), liver fibrosis, and cerebellar vermis aplasia (Joubert syndrome), among other conditions.

CNS, which presents in the first 3 months of life, is a recessively inherited disorder characterized by massive proteinuria detectable at birth, a large placenta, marked edema, and characteristic radial dilatations of the proximal tubules noted on histologic examination. Treatment usually includes bilateral nephrectomy to stop the protein losses, necessitating subsequent dialysis treatment. NPHS1 has been identified as the major gene involved,[37] but other gene mutations including NPHS2, PLCE1, and WT1 have also been detected in patients presenting with CNS. NPHS2 mutations are responsible for most cases of infantile nephrotic syndrome (NS developing between 4 and 12 months of age), as well as a significant proportion of childhood-onset steroid resistant NS, which can lead to early CKD and progression to ESRD.[38,39] An increasing number of genes have been identified as contributors to a variety of kidney diseases in childhood, and newer genetic tests will likely become more widely available and part of clinical care.[40]

In all the reports on etiology of CKD in children, "other" diagnoses comprise a substantial category. Particularly as survival of serious systemic illness in childhood has improved, CKD has become increasingly recognized as a complication of other systemic pediatric illnesses.

ONCOLOGY AND HEMATOPOIETIC STEM CELL TRANSPLANTATION

CKD is a common complication in survivors of pediatric malignancies, with up to 30% having impaired GFR, tubular dysfunction, and/or proteinuria. The long-term burden of such illnesses will likely increase as survival rates continue to improve for patients with pediatric cancers.[41,42] Children with malignancy may develop CKD due to nephrotoxic chemotherapeutic agents, radiation, surgical interventions (as in the case of Wilms' tumors), and exposure to other nephrotoxic medications such as antimicrobials. Hematopoietic stem cell transplantation (HSCT) poses a particularly high risk for long-term kidney dysfunction, with cumulative incidence of CKD reported as high as 66% in adult and 62% in pediatric studies.[43–45] Risk factors for CKD after HSCT include AKI, acute and chronic graft vs. host disease, and lower GFR before transplantion.[46,47] Renal manifestations can also include nephrotic syndrome and thrombotic microangiopathy.[44] CKD in patients after HSCT is associated with a high prevalence of hypertension and proteinuria.[48,49] Among survivors after HSCT, there is a significantly increased risk of ESRD compared to the general population.[50]

NONRENAL SOLID ORGAN TRANSPLANTATION

CKD is a well-described complication after solid organ transplantation.[51] The etiology is multifactorial in most cases, including pretransplant factors (underlying CKD, diabetes, hypertension, and use of nephrotoxic medications), peritransplant factors (hypovolemia, hepatorenal syndrome, and impaired cardiac output), and posttransplant factors (diabetes, hypertension, and long-term exposure to calcineurin inhibitors).[52] The prevalence of CKD in pediatric liver transplant recipients has been reported as 21–33%[53–56] and even higher in other studies based on varying definitions of CKD and followup time. CKD has been reported to occur in as many as 67% of children after heart or lung transplantation.[57–64] The risk of long-term renal dysfunction after intestinal and multivisceral transplants is less well described. The burden of kidney disease in this population may, however, continue to grow as there has been a steady rise in these transplants in recent years.[65–67] Recipients of solid organ transplants who develop CKD may progress to ESRD. In a 20-year national cohort study of over 16,000 pediatric solid organ transplant recipients, 3% developed ESRD, with the highest risk among intestinal and lung transplant recipients.[68] The development of ESRD is associated with increased morbidity and mortality. In a study of almost 9000 pediatric liver transplant recipients, children who developed ESRD had an almost twofold increased risk of mortality.[69] Screening for kidney disease, managing CKD-associated comorbidities, and avoiding additional renal injury are critical in these patients to prevent progressive CKD.

SICKLE CELL DISEASE

CKD due to sickle cell nephropathy is a common complication in adults with sickle cell disease, with up to 12% progressing to ESRD.[70] However, evidence of glomerular hyperfiltration and injury can be present early in childhood, as evidenced by up to 21% of young children with sickle cell disease having albuminuria.[71] Additional renal manifestations of sickle cell disease in children include gross or microscopic hematuria, renal infarction and papillary necrosis, membranoproliferative GN, impaired renal concentrating ability due to tubular injury, and renal tubular acidosis. Children with sickle cell trait may also have kidney involvement including microscopic hematuria, exertional rhabdomyolysis, and papillary necrosis.[72] Sickle cell trait has also been associated with increased risk of albuminuria and CKD.[73] Renal medullary cell carcinoma is a rare but important complication that may present in adolescence or early adulthood with hematuria, flank pain, or abdominal mass, most commonly in African American males with sickle cell trait.[74,75]

PROGRESSION OF PEDIATRIC CKD AND TREATMENT STRATEGIES TO SLOW PROGRESSION

Progression of CKD in children may be the result of ongoing activity of the underlying disease, repeated renal insults such as infections, AKI, and medications, and/or glomerular hyperfiltration. The Brenner hypothesis of renal injury suggests that reduction in functioning nephron mass, either due to congenital or acquired disease, leads to increased filtration in the remaining nephrons through increased glomerular capillary plasma flow rate and increased intraglomerular pressure.[76] This adaptive glomerular hyperfiltration in theory initially leads to preservation of GFR, but subsequently causes progressive glomerular sclerosis, proteinuria, and eventually interstitial inflammation and fibrosis.

The natural history of CKD in children is characterized by a steady decline in kidney function over time. However, the rate of progression of CKD in children is highly affected by the underlying disease process, with a more rapid decline seen in children with glomerular etiologies of CKD compared to congenital anomalies of the kidney and urinary tract. In the CKiD study, children with glomerular disease had a median decline in GFR of 4.3 mL/min/1.73 m^2 per year compared to children with nonglomerular disease whose median decline in GFR was only 1.5 mL/min/1.73 m^2 per year.[77] The rate of CKD progression in children is also affected by periods of rapid growth, as evidenced by a steeper decline in kidney function during infancy and puberty.[78]

As in adults, hypertension and proteinuria are key determinants of CKD progression in children. Hypertension mediates kidney damage through increased glomerular pressure and glomerular hyperfiltration. Large cohort studies of children with CKD have demonstrated the association between hypertension and CKD progression.[79–81] Proteinuria is a marker of disease progression but may contribute to further kidney injury through proinflammatory and prosclerotic effects resulting in further glomerular and tubulointerstitial injury. Proteinuria has been shown to predict renal disease progression in children with CKD, even in those children who have nonglomerular etiologies of CKD.[8,79] Lowering of proteinuria early in the disease process is associated with long-term kidney function preservation.[11] The renin–angiotensin–aldosterone system (RAAS) is an important mediator of CKD progression in children. Angiotensin II increases intraglomerular pressure, activates inflammatory pathways, and may contribute to glomerular and tubulointerstitial fibrosis through cytokines, including transforming growth factor beta.[82]

Many other factors have been implicated in CKD progression in children. In a retrospective cohort study of over 4000 children with CKD from the NAPRTCS registry, anemia, hypocalcemia, hyperphosphatemia, and hypoalbuminemia were independently associated with CKD progression adjusted for age, hypertension, and underlying diagnosis.[81] In the CKiD study, additional risk factors for CKD progression have been identified, including hyperuricemia and elevated plasma fibroblast growth factor 23 (FGF-23).[83,84] Additional mediators of CKD progression in children may include metabolic acidosis, dyslipidemia, chronic inflammation, poor nutrition, and oxidative stress.[85,86] Oxidative stress in CKD is mediated through an increase in reactive oxygen species and a decrease in antioxidative factors including nitric oxide synthase and L-arginine and an increase in nitric oxide inhibitors leading to endothelial dysfunction and a profibrotic state.[87] This oxidative stress may be exacerbated by anemia and chronic inflammation.

Although certain variables contributing to disease progression are uncontrollable, treatments targeted at the potentially modifiable factors can be effective in slowing decline in kidney function in children. Similar to adult studies that have shown a benefit of blood pressure control in slowing progressive kidney damage, the ESCAPE trial (Effect of Strict Blood Pressure Control and ACE Inhibition on Progression of Chronic Renal Failure in Pediatric Patients) demonstrated a benefit of intensified blood pressure control in children. In this randomized controlled trial of 385 children with CKD, all subjects received angiotensin-converting enzyme inhibitor (ACEI), then were randomized to conventional (BP 50th–90th percentile) or intensified (BP<50th

percentile) blood pressure control, with additional blood pressure control achieved through non-RAAS antihypertensive therapies. Children randomized to the intensified arm had significantly lower rates of CKD progression or need for renal replacement therapy (RRT) than children in the conventional arm over 5 years (29.9% of intensified vs. 41.7% in conventional).[88] In addition to their effects on lowering blood pressure, antagonists of the RAAS pathway including ACEIs and angiotensin receptor blockers (ARBs) have other benefits for children with CKD. RAAS inhibitors have antiproteinuric effects mediated primarily by lowering intraglomerular pressure. Numerous studies in adults have shown that RAAS blockade leads to decline in proteinuria and delayed renal disease progression. Similarly, in the ESCAPE trial, subjects who achieved an initial 50% reduction in proteinuria within the first 2 months after initiating ACEI therapy had significantly decreased risk of progressive renal disease.[88] RAAS inhibitors may also have antifibrotic effects by decreasing circulating cytokines involved in glomerular and tubulointerstitial inflammation and fibrosis. ACEIs and ARBs are generally well-tolerated in children but can cause a decline in GFR and/or hyperkalemia in children with more advanced CKD.

Additional interventions that may slow CKD progression in children include correction of anemia, dyslipidemia, and calcium–phosphate balance. In adults, treatment with erythropoietin has been suggested to slow renal disease progression, potentially through decreased oxidative stress and a decrease in tubulointerstitial injury.[89] Treatment of dyslipidemia is important for preventing cardiovascular morbidity but may also slow disease progression. Statins may have renoprotective properties, independent of their lipid-lowering effects, potentially through antiinflammatory and antioxidative effects. There have been conflicting reports in adults on the effects of statins on decreasing proteinuria and slowing CKD progression, with some studies showing a beneficial effect on slowing decline in renal function.[90–93]

However, the SHARP study did not show a benefit of statins on slowing progression of kidney disease.[94] The effects of statins on CKD progression have not been studied in the pediatric CKD population, and statins are not indicated in young children. Correction of hypovitaminosis D may also slow renal disease progression, as vitamin D may suppress renin and renal Klotho expression. Data from the ESCAPE trial showed that lower 25-hydroxyvitamin D levels were associated with greater proteinuria, higher diastolic BP, and greater annualized loss of eGFR.[95] Finally, in adults with diabetes, dietary protein restriction has been shown to be effective in slowing CKD progression in some studies. However, reduced protein intake has not been shown to slow CKD progression in children,[96,97] and protein restriction may impact nutrition and growth. Children with CKD should be given the age-appropriate recommended daily allowance for protein intake.

TREATMENT OF CKD COMORBIDITIES

Cardiovascular Disease

The American Heart Association's guidelines for reduction of cardiovascular risk in pediatrics stratified the child with CKD to the highest risk category.[98] In fact, cardiovascular mortality is the leading cause of death in children with CKD. The most common causes of death in pediatric CKD patients are cardiac arrest and arrhythmia.[1,99] In the CKiD cohort there are high prevalence rates of four traditional cardiovascular risk factors—hypertension, dyslipidemia, abnormal glucose metabolism, and obesity.[100] LVH is the most common cardiac abnormality in children with CKD.[101–103] However, there remains some debate over the ideal way to define pediatric LVH—left ventricular mass index (LVMI) or left ventricular wall thickness z-score. A recent Korean study showed poor concordance between the two methods, which would affect the reported prevalence depending on which is used.[104] Vascular changes such as increased carotid intimal media thickness and arterial stiffness (increased pulse wave velocity) start during mild to moderate CKD stages and progressively worsen as kidney function deteriorates.[105,106] Data support an independent association of cystatin C with increasing LVMI and deteriorating diastolic function, including prediction of the latter in children with CKD.[107]

It is unclear whether lipid-lowering strategies are beneficial in children with CKD and elevated lipid levels. A very small pilot trial of a statin in eight children with CKD resulted in a significant decrease in total cholesterol and LDL, but no change in brachial artery endothelium-dependent flow-mediated dilatation (FMD).[108] However, FMD was in the normal range at baseline. It seems reasonable, however, that the use of statins should be considered for pediatric CKD patients with hyperlipidemia, with age- and renal function–adjusted dosing taken into account. There is no literature on the use of antiplatelet agents for atherosclerotic disease in children with CKD.

Growth and Nutrition

Growth failure in children with CKD is not simply an aesthetic issue. Impaired growth is associated with impaired psychosocial maturation and health-related quality of life,[109] as well as increased morbidity and

mortality.[110,111] The definition of malnutrition, particularly protein-energy wasting (PEW) is not well characterized in children. In adults the components of PEW are low serum albumin concentration or low cholesterol concentration, decreased body mass, decreased muscle mass, and decreased protein intake. It has been suggested that the definition in children should include a growth component, either growth failure or poor growth velocity.[112] The etiology of growth failure in children with CKD is multifactorial—etiology and treatment of the CKD, malnutrition, fluid and electrolyte disturbances, metabolic acidosis, anemia, renal osteodystrophy, and inflammation all have effects.[113–116] Data from the CKiD study indicate that birthweight and gestational age also significantly influence growth in children with CKD.[117] Decreased growth is particularly problematic in infancy because about one-third of a child's postnatal growth occurs in the first 2 years. The improvement of growth as a result of nutritional enhancement from enteral feeding during this critical period has long been advocated. Evidence from very small studies was first published in the 1980s.[118,119] Larger, more recent studies, as well as the KDOQI guidelines recommend early, intensive nutritional management in this group.[120,121] Numerous studies of infants with CKD have shown a significant increase in growth velocity once adequate calories are provided through a nasogastric or gastrostomy tube.[122] Therefore, appropriate nutrition, attention to fluid and sodium balance, along with treatment of metabolic acidosis and hyperparathyroidism, are usually adequate for growth in infants with CKD, with supplemental growth hormone seen as a secondary therapeutic approach.[120] Few, very small studies report a benefit from the use of growth hormone in infants, usually when growth is inadequately responsive to optimized nutrition.[123,124] In children with CKD, there are not many reports of the use and impact of appetite stimulants, although these have proven useful in other chronic diseases in children such as HIV infection, cancer, and cystic fibrosis, as well as in adult dialysis patients. A small retrospective study reported improved weight gain with use of the appetite-stimulant megestrol acetate in pediatric CKD patients,[125] but there are no studies reported on the efficacy of cyproheptadine in children with CKD. Beyond infancy, recombinant human growth hormone (rhGH) use in children with CKD has become a relatively common (although not universal) practice over the past 20 years, as growth hormone resistance is known to be yet another factor contributing to poor growth.[126] Despite concerns about the potential for rhGH to accelerate the decline of renal function in children with CKD, study data have not supported such notions.[127] Puberty is another problematic time—often delayed, and associated with an attenuated growth spurt in patients with CKD.[128–130] There are, however, discrepancies in how adolescents with CKD view the impact of their short stature compared with their parents.[109]

Chronic Kidney Disease—Mineral and Bone Disorder

Chronic kidney disease—mineral and bone disorder (CKD-MBD) is a syndrome that includes biochemical mineral abnormalities, bone fragility, and vascular calcification (even in children) and is associated with increased morbidity and mortality. The biochemical mineral abnormalities include elevated serum phosphate concentration (S[P]) and low serum calcium concentration (S[Ca]), which lead to increased FGF-23 and increased parathyroid hormone (PTH) levels. Bone deformities and fractures are common in children with CKD, and as with poor growth, impaired bone accrual in this population is multifactorial. Contributors include poor growth, decreased physical activity, abnormal mineral metabolism, muscle deficits, and secondary hyperparathyroidism.

Managing pediatric CKD-MBD is quite complex, as one is dealing with the growing skeleton, during the time when calcium accrual in the skeleton has not yet reached its peak. The first line of treatment is dietary phosphate restriction and use of phosphate binders, both of which are generally associated with poor adherence. The most recent KDIGO guidelines recommend that the choice of phosphate-lowering agent should be based on the S[Ca], to avoid development of hypercalcemia and vascular calcification.[131] However, hypercalcemia can result from numerous factors, including both low and high PTH levels and low and high 1,25 hydroxyvitamin D levels, not just calcium-based phosphate binders.[132] The pros and cons of phosphate binders currently on the market for children as well as those under study, including iron-based binders, are still being debated. There are ongoing studies to determine whether the first line of treatment should be to target FGF-23 levels before overt hyperphosphatemia manifests.

Vitamin D levels are low in a majority of children with CKD for a multitude of reasons, including urinary losses of vitamin D binding protein, along with increased renal losses of all vitamin D metabolites in those with proteinuria. The KDIGO guidelines recommend consideration of use of calcitriol and vitamin D analogs to maintain age-appropriate calcium levels, confirming prior recommendations.[131,133] We should also be aware that sodium bicarbonate and proton pump inhibitors, which are prescribed for many children with CKD, inhibit calcium absorption from the gut.[133] The treatment of pediatric CKD-MBD should not target only one metabolic

derangement but must consider the many interacting factors to optimize bone health and growth, while minimizing negative cardiovascular effects.

Optimal noninvasive evaluation of pediatric CKD-MBD is still being studied. Imaging with dual-energy X-ray absorptiometry (DEXA) has been shown to underestimate volumetric bone mineral density in children with growth failure. Evaluation with peripheral quantitative computed tomography may provide more accurate assessments.[134] Although bone biopsy provides the most definitive assessment, it is invasive and not performed routinely at many pediatric CKD programs.

Neurocognitive Function

Apart from the impact of CKD on physical growth, another concern is the impact of CKD on brain development, neurocognition, and behavior. This is known to be particularly problematic in cases of early onset CKD and severe disease or ESRD.[135,136] Compared to healthy controls, children with CKD have poorer performance in multiple areas of neurocognition including attention, memory, and inhibitory control.[137] Studies have also demonstrated lower intelligence quotient (IQ) scores among children with ESRD compared to their unaffected siblings or the general population.[138] In the CKiD study, a large proportion of children with mild to moderate CKD were identified as being at risk for neurocognitive dysfunction, defined as test performance greater than one SD below the normative mean for age in measures of IQ, academic achievement, attention regulation, and executive functioning.[139] These deficits may persist into adulthood. A study in the Netherlands identified persistent difficulties with knowledge, memory, and concentration into adulthood, as well as lower educational attainment in adults with childhood onset of ESRD.[140] Compared to age-matched individuals, adult patients with childhood ESRD were more often involuntarily unemployed at about twice the rate of the age-matched population.[141] Children with CKD have also reported poorer overall health-related quality of life with poorer physical, emotional, and school functioning compared to healthy children.[142]

Risk factors for neurocognitive dysfunction in children with CKD include increased disease severity, longer duration of CKD, and younger age at CKD onset.[143,144] Elevated blood pressure, ambulatory hypertension, and increased blood pressure variability have been associated with decreased IQ scores and neurocognitive dysfunction in children with CKD.[137,145,146]

These data support the need for ongoing neurodevelopmental surveillance of children with CKD and implementation of early targeted interventions to improve school performance and health-related quality of life among those identified at risk. Formal transition programs from pediatric to adult CKD care are critical to provide optimal care and improve overall health-related quality of life for patients with childhood-onset CKD.

TIMING AND INDICATIONS FOR RENAL REPLACEMENT THERAPY

Indications for initiating RRT in children include fluid overload, electrolyte or metabolic derangements that are resistant to medical therapies, fluid restriction limiting adequate nutrition, impairment in growth, and/or refractory hypertension. Preemptive transplantation is the renal replacement modality of choice for pediatric patients with ESRD, given improved survival among pediatric transplant recipients compared to dialysis patients.[147–150] Transplantation also obviates medical and psychosocial comorbidities associated with dialysis. However, preemptive transplantation is not always an option given medical issues precluding transplantion (such as lack of a living donor or insufficient time to prepare for transplant). In those cases, the choice between peritoneal dialysis (PD) and hemodialysis (HD) is guided by both medical and psychosocial considerations.

PD is the preferred modality in most children, particularly for infants and young children in whom HD is technically challenging. PD is associated with decreased mortality compared to HD[2] and allows children to be in their home environments and attend school on a regular basis. However, PD may not be feasible due to abdominal pathologies, peritoneal membrane failure, or insufficient family support. HD remains the more common dialysis modality in children with ESRD in the US.[2]

CONCLUSION

Pediatric CKD has unique etiologies and comorbidities compared to adults. Children with CKD require close monitoring by a pediatric nephrologist with particular focus on cardiovascular health, growth and nutrition, and neurocognition. Despite improvements in survival, children with CKD still face an increased risk of early mortality.

QUESTIONS AND ANSWERS

Question 1

A newborn male is referred to your clinic because of an abnormality of the kidneys noted on prenatal ultrasound. Review of the images suggests unilateral antenatal hydronephrosis. On physical examination the infant has normal growth parameters, a normal urinary stream and a normal physical examination. Which ONE of the following is the LEAST likely cause of the abnormality in this patient?

A. Transient dilatation of the collecting system
B. Ureteropelvic junction obstruction
C. VUR
D. PUV
E. ARPKD

Answer: E

Prenatal ultrasound can often identify many of the major causes of CKD in children, including CAKUT.[24] Abnormal prenatal ultrasounds should however be repeated postnatally, as transient dilatation of the collecting system can be seen which can completely resolve and abnormalities of the fetal kidneys (cysts, hydronephrosis, hyperechogenic, hypoplastic, or absent kidneys) must be confirmed.[26] Antenatal hydronephrosis, which is confirmed postnatally, can be due to UPJ, VUR, and PUV. In contrast, ARPKD does not usually present with evidence of hydronephrosis. Up to 50% of children with ARPKD are diagnosed prenatally.[31] The clinical criteria for the diagnosis of ARPKD include the presence of enlarged, echogenic kidneys by ultrasound, in the context of one or more additional findings (the absence of renal cysts in both parents, history of a previously affected sibling, parental consanguinity, clinical, laboratory, or pathologic features of hepatic fibrosis).[31,32]

Question 2

A 13-year-old boy with CKD secondary to PUV with VUR and hydronephrosis has an estimated GFR of 40 mL/min/1.73 m^2 by the CKiD formula.

Which ONE of the following should not be part of his clinical treatment plan?

A. Assessment of height, height velocity, and pubertal development
B. Immediate referral for kidney transplant
C. Maintenance of blood pressure below the 90th percentile for age, height, and gender
D. Monitoring S[Ca], S[P], PTH, and vitamin D levels
E. Monitoring hemoglobin levels

Answer: B

Growth failure, delayed puberty, hypertension, anemia, and disorders of bone and mineral metabolism are all common features of CKD in children. Assessing growth, hemoglobin levels, and bone health should be part of routine CKD care. The ESCAPE trial and subsequent KDIGO guidelines on the treatment of hypertension showed slower progression of kidney function decline in individuals with blood pressure lower than the 90th percentile for age, gender, and height, compared to those with BP greater than the 95th percentile and even slower rate of reaching the need for renal replacement therapy in those with BP below the 50th percentile, particularly in those with significant proteinuria.[88] Immediate referral for kidney transplantation in this young boy with CKD secondary to VUR is probably not indicated at this level of GFR, as rates of progression for individuals with nonglomerular causes of CKD are slow.[77] However, when this child enters puberty, he will likely be at risk for accelerated decline in kidney function.

Question 3

A prenatal ultrasound reveals a fetus with unilateral hydronephrosis and hyperechogenic kidney. What is the appropriate first step to evaluate these findings?

A. Postnatal renal ultrasound
B. Radionuclide scanning using technetium-99m−labeled DMSA
C. Voiding cystourethrography
D. Genetic testing for CAKUT
E. None of the above

Answer: A

Abnormal findings in the fetal kidneys (cysts, hydronephrosis, hyperechogenic, hypoplastic, or absent kidneys) must be confirmed postnatally, as hydronephrosis detected prenatally sometimes resolves spontaneously.[26] If the hydronephrosis persists postnatally, then further evaluation is warranted. PUV and VUR, which can both result in hydronephrosis, are diagnosed by voiding cystourethrography. Renal dysplasia is identified by radionuclide scanning using technetium-99m−labeled DMSA, which concentrates only in functional renal tissue.

Question 4

Which of the following statements is true about growth failure in children with CKD:

A. It is particularly problematic during infancy and puberty
B. Birthweight and gestational age play important roles

C. It is associated with increased morbidity and mortality
D. Anemia, renal osteodystrophy, and inflammation contribute to impaired growth
E. All of the above

Answer: E

Impaired growth is associated with impaired psychosocial maturation, decreased health-related quality of life, and increased morbidity and mortality.[109–111] The etiology of growth failure in children with CKD includes the etiology and treatment of the CKD, malnutrition, fluid and electrolyte disturbances, metabolic acidosis, anemia, renal osteodystrophy, and inflammation.[113–116] CKiD study findings indicate that birthweight and gestational age are also associated with growth in children with CKD.[117] Decreased growth is particularly problematic in infancy because about one-third of a child's postnatal growth occurs in the first 2 years. Puberty in children with CKD is often delayed and associated with an attenuated growth spurt.[128–130]

Question 5

A 9-year-old boy with PUV is seen for routine followup. He has an appendicovesicostomy due to inadequate bladder voiding. He has a history of recurrent urinary tract infections. His blood pressure is at the 90th percentile for age/gender/height. His urinalysis has 2+ proteinuria. His current estimated GFR using the bedside CKiD formula is 40 mL/min/1.73 m^2. His hemoglobin is 11.8 g/dL, S[Ca] is normal, and S[P] is elevated at 6.8. All of the following may help to slow progressive kidney disease in this patient EXCEPT:

A. Targeting blood pressure to the 50th percentile for age/gender/height
B. Maintenance of a regular bladder catheterization schedule
C. Institution of a low-protein diet
D. Initiation of therapy with an ACEI
E. Institution of a low phosphorus diet and use of phosphate binders

Answer: C

One of the most important modifiable risk factors of CKD progression is hypertension. The ESCAPE trial demonstrated that intensified blood pressure control (<50th percentile) slowed progressive kidney disease in children.[88] CAKUT is the leading cause of CKD in children, with PUV being one of the most common anomalies in males. In patients with obstructive uropathy and bladder dysfunction, maintenance of a regular voiding schedule is key in preventing urinary stasis, which can predispose to urinary tract infections. Repeated infections may contribute to decline in kidney function. ACEIs and ARBs are important in slowing CKD progression, as they improve blood pressure control and have antiproteinuria effects and antifibrotic effects.[85] Additional factors that may slow CKD progression in children include correction of anemia, dyslipidemia, and calcium–phosphate balance. Reduced protein intake has not been shown to slow CKD progression in children,[96,97] and protein restriction may affect nutrition and growth. Children with CKD should be given the age-appropriate recommended daily allowance for protein intake.

Question 6

A 13-year-old prepubertal girl was recently diagnosed with FSGS. She currently has an estimated GFR of 65 mL/min/1.73 m^2 and 1 gram of urinary protein excretion per day. Her blood pressure is at the 85th percentile for age/gender/height on a small dose of an ACEI. She wants to know about her risk for needing dialysis or a transplant. Which of the following is correct?

A. Her rate of decline in kidney function is expected to be slower than that of a child with a congenital anomaly of the kidney
B. When she reaches ESRD, HD will be the modality of choice
C. FSGS is a rare cause of ESRD in children
D. Lowering her blood pressure further may help to slow progressive kidney disease
E. Her kidney function may improve when she reaches menarche

Answer: D

Children with glomerular disease such as FSGS have a more rapid decline in GFR than children with nonglomerular disease such as CAKUT. In the CKiD prospective multicenter cohort of children with CKD, children with glomerular disease had a median decline in GFR of −4.3 mL/min/1.73 m^2 per year compared to children with nonglomerular disease whose median decline in GFR was only −1.5 mL/min/1.73 m^2 per year.[77] The rate of CKD progression in children is also affected by periods of rapid growth, as evidenced by a steeper decline in kidney function in puberty.[78] In the US, FSGS is the most common glomerular cause of CKD. Although it is likely that this girl will progress to ESRD, preemptive transplantation would be the preferred modality of renal replacement therapy as dialysis (in particular HD) is associated with significant morbidity and mortality. Targeting blood pressure to the 50th percentile for age/gender/height was associated with a decrease in progression of CKD in children in the ESCAPE trial.[88] This patient may benefit from an increased dose of ACE inhibition to improve blood pressure and decrease proteinuria.

Reflux Nephropathy

Tej K. Mattoo[a], *Marva Moxey-Mims*[b]

[a]Children's Hospital of Michigan, Wayne State University School of Medicine, Detroit, MI, United States; [b]Children's National Health System, The George Washington University School of Medicine, Washington, DC, United States

Abstract

Vesicoureteral reflux (VUR) is the most common congenital urological abnormality in children and is most often diagnosed after an episode of urinary tract infection (UTI). Reflux nephropathy is the renal scarring associated with VUR. VUR may be congenital, a result of abnormal renal development leading to focal renal dysplasia, or acquired, from pyelonephritis-induced renal injury. High-grade VUR increases the risk of recurrent UTIs and renal scarring and the associated subsequent morbidity, although the exact mechanism for renal scarring following UTI is not known. The complications of renal scarring are more common in adults. Complications include proteinuria, hypertension, preeclampsia, and end-stage renal disease. There is no conclusive evidence to support a routine use of antimicrobial prophylaxis in the prevention of renal scarring in all children with VUR. Prophylaxis should be used "selectively" in high-risk patients such as those with a high-grade VUR, recurrent UTI, presence of bladder–bowel dysfunction, or coexisting renal scarring.

INTRODUCTION

Vesicoureteral reflux (VUR) is the commonest congenital urological abnormality in children. It is most often diagnosed after an episode of urinary tract infection (UTI), although an increasing number of patients with VUR are diagnosed during follow-up for antenatally diagnosed renal abnormalities, particularly hydronephrosis. The gold standard for diagnosing VUR is a voiding cystourethrogram (VCUG). In the past, the standard of care for a child with a UTI included a routine VCUG to determine the presence and grade of VUR.[1,2] However, currently VCUG is done selectively in high-risk patients as reflected in guidelines published in the United Kingdom and the US.[1,3] According to the International Reflux Grading Scheme, VUR is categorized as grade I through V, mildest to most severe (Figure 76.1).

Reflux nephropathy (RN), previously called chronic pyelonephritis, is the renal scarring associated with VUR. RN may be congenital (also called primary), a result of abnormal renal development leading to focal renal dysplasia, or acquired, resulting from pyelonephritis-induced renal injury. The differentiation of congenital from acquired RN on the basis of a preceding UTI can be arbitrary because the possibility of a preexisting renal scar before UTI cannot always be ruled out. Acquired RN is more common in females, whereas congenital RN occurs mostly in males. Some other important differences between acquired and congenital RN are shown in Table 76.1. A review of some more recent prospective studies revealed that the number of patients with renal scars was higher in studies that included more male patients even though UTI is significantly more common in females, indicating the possibility of more patients with congenital scarring in studies with more males.[2] Renal scars also occur with acute pyelonephritis in the absence of VUR. The current gold standard for diagnosing renal scarring is dimercaptosuccinic acid scintigraphy (^{99m}Tc-DMSA). Imaging does not differentiate between congenital and acquired RN.

INCIDENCE AND PREVALENCE

Primary VUR, which is the most common congenital anomaly of the urinary tract, has a prevalence of about 1% in newborns. It is found in 30%–40% of children with UTI. The genetic predisposition for primary VUR is well known as demonstrated in identical twins (80%), siblings of index cases (27%), and children of a parent with VUR (36%). VUR can occur with some chromosomal anomalies or due to mutations in developmental genes such as PAX2, EYE1,

Chronic Renal Disease, Second Edition

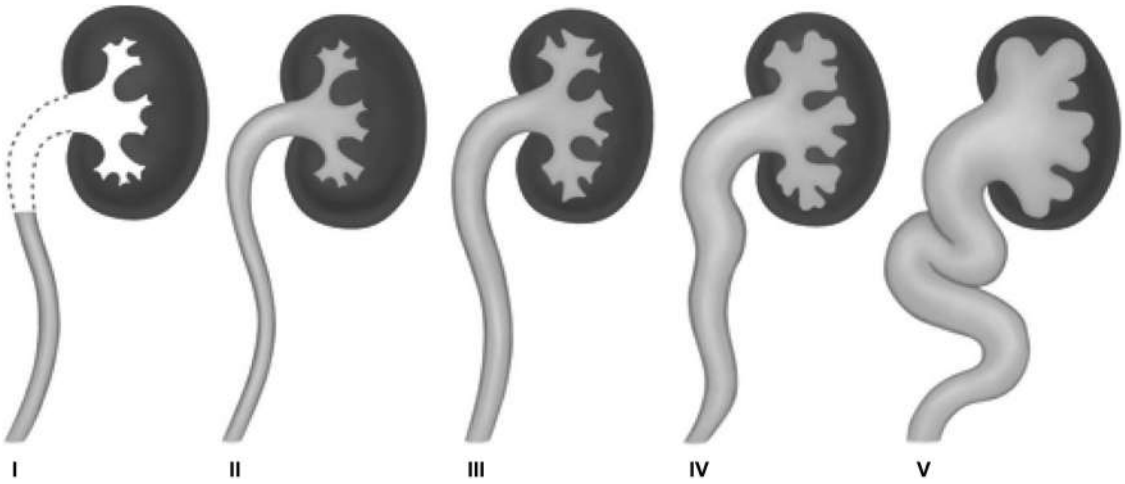

FIGURE 76.1 International Reflux Study grading scheme. Grade I—reflux into nondilated ureter. Grade II—reflux into the renal pelvis and calyces without dilatation. Grade III—mild/moderate dilatation of ureter and pelvicalyceal system. Grade IV—dilation of the renal pelvis and calyces with moderate ureteral tortuosity, blunting of fornices. Grade V—gross dilatation of the ureter, pelvis, and calyces; ureteral tortuosity; loss of papillary impressions.

TABLE 76.1 Congenital Versus Acquired Reflux Nephropathy (RN) in Children

	Acquired RN	Congenital RN
Time of occurrence	Postnatal	Prenatal
UTI before diagnosis	Common	Uncommon
Age distribution	All pediatric age groups	Mostly in younger children
Gender distribution	Predominantly females	Predominantly males
Grade of VUR	Mostly low grade	Mostly high grade
Dysplastic features on renal histopathology	No	Yes

UTI, urinary tract infection; *VUR*, vesicoureteral reflux.

and WT-1,[4,5] which are associated with infection and scarring. Secondary VUR may occur in children with posterior uretheral valves. Some secondary forms of VUR in adults occur due to bladder outlet obstruction as seen in men with enlarged prostates, and neurogenic bladder due to spina bifida—meningomyelocele, spinal cord injury, or multiple sclerosis. Primary VUR is seen predominantly in Caucasians, although the reason is unclear. 81% of the 607 patients randomized in the Randomized Intervention in Children with VUR (RIVUR) study were Caucasians.[4]

The risk of renal scarring after acute pyelonephritis is 5%–10%.[5,6] A systematic review of 33 studies that included DMSA renal scans in children with UTI revealed that 57% (95% confidence interval [CI]: 50–64) had changes consistent with acute pyelonephritis and 15% (95% CI: 11–18) had evidence of renal scarring on the follow-up DMSA scan.[7] In children with VUR and UTI, the incidence of renal scarring is higher at 30%–56%.[8–10] A systematic review of 23 studies that included a total of 2106 children with renal scarring after pyelonephritis revealed some regional variations between Australia (26.5%), Asia (49%), Europe (39.4%), the Middle East (34.3%), and the US (48.5%). The prevalence of renal scarring in healthy populations is not known. In a study in healthy children and adolescents who were evaluated for newly diagnosed hypertension, DMSA renal scans revealed renal scarring in 33 (21%) of 159 patients.[11] In a study in adults with hypertension, radionuclide VCUG revealed VUR in 19.1% (30/157) of the patients. 7 of the 30 (23%) had bilateral VUR, which was graded as severe. The patients were not evaluated for renal scarring.[12] Renal scars that occur in the absence of UTI (congenital RN) are seen in 30–60% of children with VUR diagnosed mostly during follow-up for antenatal hydronephrosis.[13–15]

RISK FACTORS FOR REFLUX NEPHROPATHY

Risk factors for renal scarring include patient age, severity of VUR, frequency of UTI, promptness of antibiotic treatment for pyelonephritis, coexisting bladder–bowel dysfunction (BBD), and genetic susceptibility. A meta-analysis of studies that included a total of 1280 patients aged 0–18 years with first UTI revealed that a temperature of at least 39° C, an etiologic organism other than *Escherichia coli*, an abnormal ultrasonographic finding, polymorphonuclear cell count of greater than 60%, C-reactive protein level of greater than 40 mg/L, and presence of VUR were all associated with the development of renal scars ($p \leq 0.01$ for all).[16]

Children with VUR are at a higher risk of having acute pyelonephritis (relative risk: 1.5 [95% CI: 1.1–1.9]) and renal scarring (relative risk: 2.6 [95% CI: 1.7–3.9]) compared with those without VUR. Those with VUR grades III or higher are more likely to develop scarring than children with lower VUR grades (RR: 2.1 [95% CI: 1.4–3.2]). The risk of renal scarring involving more than 25% of the renal parenchyma is significantly higher in patients with grade III–IV VUR (40%) compared with those with grade I–II VUR (14%) or no VUR (6%).[7] In the RIVUR study, the proportion of new scars due to UTI in kidneys with grade IV VUR was significantly higher than in those without VUR (odds ratio (OR), 24,2; 95% CI, 6.4–91.2).[3] Patients with VUR may have cortical abnormalities even in the absence of a UTI. Such abnormalities are more common in high-grade VUR. A meta-analysis of the published data revealed that renal abnormalities (per 100 renal units) occurred with a mean of 6.2% in those with grades I–III VUR and 47.9% in those with grades IV and V VUR. The abnormalities occurred in 2%–63% (mean 21.8%) of patients with VUR and 26%–42% (mean 32.3%) of the renal units.[17] VUR-related renal scarring is more common in patients with UTI. The OR of renal scarring with acute pyelonephritis in the presence of VUR is 2.8 for patients and 3.7 for renal units compared with those without VUR.[18]

The risk of renal scarring increases with BBD. The presence of BBD increases the risk of febrile UTI in children on antimicrobial prophylaxis for VUR to 44% compared with 13% in those without BBD. BBD delays VUR resolution at 24 months (31% with BBD and 61% without BBD). The frequency of postoperative UTI is greater in children with BBD (22% compared with 5% without BBD). Combined data from longitudinal studies (RIVUR and Careful Urinary Tract Infection Evaluation (CUTIE)) revealed that among toilet-trained children who are not on antimicrobial prophylaxis, those with both BBD and VUR are at higher risk (51%) of developing recurrent UTIs than children with isolated VUR (20%) or children with isolated BBD (35%).[19] In another study from the same cohorts, BBD was a risk factor for renal scarring (OR, 6.44; 95 CI, 2.89–14.38).[20]

Delay in the treatment of febrile UTI increases the risk of renal injury.[21] A multivariate analysis of 158 children with febrile UTI showed therapeutic delay of greater than 48 hours was associated with significantly increased risk of acute lesions on renal scan. However, the Italian Renal Infection Study Trials reported that a delay of the antibiotic treatment of acute pyelonephritis from <1 to ≥ 5 days after the onset of fever was not associated with any significant increase in the risk of scarring. The risk of scarring remained relatively constant at $30.7 \pm 7\%$ over the range of days of delayed antibiotic initiation. Clinical and laboratory indices of inflammation were comparable in all groups, as was the incidence of VUR. In another study, early and appropriate treatment of UTI, especially during the first 24 hours after the onset of symptoms, diminished the likelihood of renal involvement during the acute phase of the infection but did not prevent scar formation.[10] Analysis of the data from the RIVUR and CUTIE patient cohorts revealed that the median duration of fever before antimicrobial therapy in children with and without scarring was 72 and 48 hours, respectively ($p = 0.003$). A delay of 48 hours or more increased the risk of scarring by about 47%.[20]

Younger age has long been believed to be a risk factor for renal scarring due to UTI.[22] However, scarring occurs in adult kidneys as well, as seen in adult transplanted kidneys. Additionally, adult pig kidneys with VUR and UTI scar as quickly as those of piglets with the same comorbidities. Recent studies have reported that age may not be a risk factor for renal scarring and the risk in older children is the same[23–25] or even higher[26] compared with younger children. In the RIVUR study, children with renal scarring were significantly older compared with those with no scarring (median age 26 months vs. 11 months; $p = 0.01$).[3]

Recurrent UTI is a risk factor for renal scarring. In the RIVUR study, significantly more renal scarring was noted in children with a second UTI before enrollment compared with those with a single febrile UTI (OR 2.85; 95% CI, 1.38–5.92).[3]

Some studies suggest the involvement of vasomotor and inflammatory genes in the development of renal scarring after UTI. A meta-analysis of cumulative studies showed association with the angiotensin-converting enzyme insertion/deletion polymorphism [ACE I/D; recessive model for D allele; OR 1.73, 95% CI 1.09–2.74, $p = 0.02$] or transforming growth factor-beta 1 c.-509 T > C polymorphism (dominant model for T allele; OR 2.24, 95% CI 1.34–3.76, $p = 0.002$).[27,28]

COMPLICATIONS OF RENAL SCARRING

The complications of renal scarring are well known, but poorly defined because of their insidious onset, slow progression, and a lack of well-designed prospective studies in children and in adults. Hypertension and proteinuria are the most common reported complications. Other complications include focal segmental glomerulosclerosis (FSGS), urinary concentration defects, hyperkalemia, and acidosis, chronic kidney disease (CKD), and end-stage renal disease (ESRD).

Hypertension

Hypertension occurs in 17–30% of pediatric patients and 34–38% of adult patients with renal scarring.[29,30] In adults, confounding factors such as increasing frequency of primary hypertension and renal scarring due to other renal pathologies make interpretation difficult. According to a survival analysis, it was estimated that 50% of patients with unilateral and bilateral renal damage would have sustained hypertension at about 30 and 22 years of age, respectively. In a follow-up lasting 15 years in pediatric patients with renal scarring, about 13% of patients at age 20–31 years were hypertensive. In a 5-year prospective study of patients with long-standing RN, there was no correlation between blood pressure (BP) and plasma renin activity, plasma creatinine concentration, or degree of scarring.[31]

Some studies have reported no increase in BP after many years of follow-up. In a study of 146 subjects with VUR diagnosed at a mean age of 5 years, no hypertension was seen after a mean follow-up of about 10 years. The cohort included 34.3% patients with renal scarring. In another study of 53 patients with renal scarring following childhood UTI, there was no significant difference in ambulatory BP measurements 16–26 years later, compared with 47 matched subjects without scarring. Mean systolic or diastolic BP above +2 SD was found in 5/53 (9%) and 3/47 (6%) in the scarring and nonscarring group, respectively.[32]

Proteinuria

Overt proteinuria, which has been reported in 21% of adult patients with RN, is rare in pediatric patients. Proteinuria results from glomerular and/or tubulointerstitial damage caused by immunologic injury, macromolecular trapping, and mesangial dysfunction, hypertension, and glomerular hyperfiltration.[33] Microalbuminuria, which indicates glomerular damage at a very early stage and precedes the development of overt proteinuria, progressive renal damage, and renal failure, has been reported in 51% of pediatric patients (mean age 9.8 ± 4.2 years) with renal scarring.[34] Patients with RN also have increased urinary excretion of low molecular weight proteins (LMWPs) such as beta 2-microglobulin, retinol-binding protein, alfa 1-microglobin, and N-acetyl-β-D-glucosaminidase (NAG).[35,36] Microalbuminuria occurs around the same time or soon after the appearance of LMWP in urine. Urinary albumin excretion increases with the severity of renal scarring.[36–38]

FSGS is known to occur in patients with RN. The pathogenesis of FSGS in patients with RN is not clear. The development of FSGS has been attributed to glomerular hyperfiltration, deposition of antigen–antibody complexes, failure of the mesangium to clear macromolecules, and glomerular injury due to circulating immune complexes. FSGS is progressive and can occur in nonscarred parts of the kidney or in the normal contralateral kidney in patients with unilateral RN.[39]

CKD

Renal scarring is responsible for 5%–10% of pediatric and adult cases of ESRD.[40,41] According to the 2008 North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) report, RN is the fourth most common cause of CKD in 8.4% of the children and is present in 5.2% of transplanted patients and 3.5% of dialysis patients. In the CKiD study following a cohort of 586 children aged 1–16 years, with an estimated glomerular filtration rate of 30–90 mL/min/1.73 m^2, RN was the underlying cause of CKD in 87 (14.8%) patients, constituting 19% of the patients with a nonglomerular etiology of CKD.[42]

RN in Adult Patients

The complications of renal scarring are more common in adults, who may present with recurrent UTI, proteinuria, hypertension, increased S[Cr], and diminution in glomerular filtration rate. Adult males with RN generally present with hypertension, proteinuria, and renal failure (Table 76.2). Females present mostly with UTI

TABLE 76.2 Reflux Nephropathy in Adults

	Males	Females
UTI	Uncommon	Frequent
Plasma creatinine	Higher	Normal
End-stage renal failure	More common	Less common
VUR	High-grade/bilateral	Low-grade/unilateral
Proteinuria	Frequent/severe	Infrequent/less severe
Hypertension	More common	Less common

UTI, urinary tract infection; *VUR*, vesicoureteral reflux.

and pregnancy-related complications. Males have poorer outcomes compared with females. This difference has previously been attributed to a delayed diagnosis in males because of an insidious onset of proteinuria and renal failure compared with an earlier diagnosis in females due to recurrent UTI and pregnancy-related complications.[43] However, in view of the knowledge gained in pediatric patients, it is possible that gender differences in the clinical outcome in adults may be more a result of males having mostly congenital RN compared with acquired RN in females.[44]

In a study of 293 adults with RN (mean age at presentation 31 ± 13.4 years), females outnumbered males by a ratio of 5:1. The most common presenting complaints for both genders were UTI (65%), hypertension (20%), and proteinuria (6%). However, UTI as a presenting complaint was significantly more common in females compared with males (72% vs. 31%). In contrast, proteinuria was significantly more common in males (20% vs. 4%). Hypertension was also more common in males than females (29% vs. 18%). VUR was present in 65% of females and 75% of males. Of the 147 patients who were followed for a mean period of 6.9 ± 3.6 years, 21 (14%) developed ESRD after a mean follow-up of 7.0 ± 3.1 years.[40]

Potential complications during pregnancy in women with RN include UTI, hypertension, proteinuria, edema, deterioration in renal function, hematuria, preterm delivery, development of preeclampsia, and fetal loss.[45–47] The degree of renal function at conception seems to be associated with the outcome during pregnancy. A review of literature on the outcome of pregnancy in women with a history of VUR revealed that VUR increases the risk of UTI from 6% to 22%, which increases to 42% when associated with renal scarring. The incidence of hypertension and preeclampsia was significantly higher in women with VUR and renal scarring compared with patients with VUR without scarring.[47]

PREVENTION OF REFLUX NEPHROPATHY

Antimicrobial Prophylaxis

Many randomized studies, including the RIVUR trial, have evaluated the role of antimicrobial prophylaxis in the prevention of recurrent UTI and renal scarring in children with and without VUR.[48–52] The RIVUR study was a randomized, placebo-controlled trial that evaluated the role of antimicrobial prophylaxis in the prevention of UTI and renal scarring in 607 children less than 6 years old with grade I to IV VUR diagnosed after UTI.[53] In the other studies, patients were also randomized to antimicrobial prophylaxis or placebo/surveillance only. One of the studies used endoscopy treatment as the third intervention. Three studies included patients with UTI and VUR. The others included patients with UTI with or without VUR. Altogether, 2042 patients (74% females) were randomized (Table 76.3). A total of 1430 patients had DMSA renal scans to evaluate renal scarring (Table 76.3). None of the six studies showed any difference in the rate of scarring in patients who received prophylaxis/endoscopy compared with patients who did not. A meta-analysis of these studies (including those who underwent Deflux® procedure in a Swedish study) revealed renal scarring in 29% of cases with prophylaxis and endoscopy (Swedish trial) compared with 25% in those who received no intervention or placebo (RR 1.10 [95% CI: 0.98–1.22; p = NS]). Very few new scars were reported during the follow-up period.[44] Another recent meta-analysis of eight prospective studies revealed that the continuous antibiotic prophylaxis significantly reduced the risk of recurrent febrile or symptomatic UTI (pooled OR=0.63, 95% CI=0.42–0.96) in children with VUR but not renal scarring.[54]

TABLE 76.3 Renal Scarring in Recent Randomized Studies in Patients with UTI with or without VUR

Authors and Year of Study	Number of Patients with DMSA Renal Scan	Renal Scarring on DMSA		Relative Risk (95% CI)
		Prophylaxis/Endoscopy*	No Prophylaxis	
Garin et al., 2005	218	7/100 (7%)	6/118 (5%)	1.37 (0.47–3.96)
Pennesi et al., 2008	100	22/50 (44%)	18/50 (36%)	1.22 (0.75–1.98)
Montini et al., 2009	295	50/187 (27%)	33/108 (30.5%)	0.87 (0.60–1.26)
Craig et al., 2009	154	35/71 (49%)	38/83 (46%)	1.07 (0.77–1.50)
*Swedish Reflux Trial, 2010	201	82/133 (62%)*	45/68 (66%)	0.93 (0.75–1.15)
RIVUR Study	462	27/227 (12%)	24/235 (10%)	1.08 (0.78–1.40)
COMBINED	1430	223/768 (29%)	164/662 (25%)	1.10 (0.99–1.22)

UTI, urinary tract infection; *VUR*, vesicoureteral reflux.
* *Includes 40/68 patients on prophylaxis and 42/65 patients who underwent endoscopy.*

Reanalysis of the RIVUR data by using a risk classification system to identify children who are more likely to benefit from antibiotic prophylaxis revealed that high-risk children with VUR benefit even more with prophylaxis. The number needed to treat to prevent UTI recurrence was 5 compared with 18 in low-risk children. The study supported a risk-based approach for management of VUR.[55]

Based on the results of these studies, none of which were designed or powered to evaluate the development of scarring, there is no conclusive evidence to support routine use of antimicrobial prophylaxis for the prevention of renal scarring in children with VUR. Prophylaxis should be used "selectively" in high-risk patients such as those with high-grade VUR, recurrent UTI, presence of BBD, or coexisting renal scarring.[56,57]

Surgical Intervention

Surgical correction of VUR has not been shown to be superior to antimicrobial prophylaxis in the prevention of recurrence of UTI or renal scarring by the International Reflux Study,[58–60] the Birmingham Study, or more recently the Swedish Reflux Trial.[61,62] However, surgical intervention has the advantage that patients do not require follow-up VCUGs to the extent needed in patients on antimicrobial prophylaxis. Surgical treatment is generally recommended for patients with high-grade VUR, breakthrough febrile UTIs while on prophylaxis, allergies to antimicrobials, poor adherence, worsening of scars, and sometimes because of parental preference.[63] Currently, endoscopic treatment of reflux involving subureteral or intraureteral injection of dextranomer hyaluronidase (Deflux®) is offered as first-line surgical treatment in most cases. The success rate (reflux resolution measured by voiding cystography) for the endoscopic procedure is 83% compared with 98.1% for open surgical reimplantation.[18]

Other Management

Appropriate management of BBD is necessary to prevent recurrence of UTI, help resolution of VUR, and possibly prevent further renal injury. Management of BBD includes the treatment of constipation, training in frequent and complete voiding, biofeedback, and/or use of anticholinergic medications or alpha blockers, and continuous intermittent catheterization in extreme cases. Although there are no evidence-based guidelines for the management of increased BP, microalbuminuria/proteinuria, or other complications related to RN, the use of an ACEI or an ARB is recommended. In patients with a poorly functioning kidney due to unilateral RN, removal of the affected kidney may be considered, keeping in mind that the nephrectomy may not cure the hypertension.

SUMMARY

The longstanding dogma about pediatric VUR has been that UTIs are preventable with the use of prophylatic antibiotics, and reduction in the number of UTIs would lead to a reduction of renal scarring, thus preserving renal function. Therefore, the current management of VUR focuses on the prevention of UTI, with "selective" antimicrobial prophylaxis in high-risk patients and curative surgery limited primarily to children that fail conservative measures. Progress has been made in the understanding of the risk factors for RN after UTI. Appropriately designed studies are needed to evaluate the role of any intervention, including antimicrobial prophylaxis, in the prevention of renal scarring with UTI with or without VUR. Better understanding of genetic susceptibility for renal scarring after UTI could greatly enhance the management of VUR and help maximize the preservation of renal function.

QUESTIONS AND ANSWERS

Question 1

A 15-year-old patient is seen in the nephrology clinic for hypertension. The patient has a past history of UTIs. Laboratory investigations reveal normal blood chemistry and urinalysis. The renal ultrasound examination shows a normal right kidney and a smaller left kidney. Renal scarring of the left kidney is suspected. Of the following, which one is most associated with renal scarring that occurs after UTI in children?

A. Male gender
B. African-American ethnicity
C. Renal dysplasia
D. VUR
E. Ureteropelvic junction (UPJ) obstruction

Answer: D

Renal scarring may occur after acute pyelonephritis with or without VUR, but the risk is higher in those with VUR.[18] Such renal scarring (RN) is more common in females. VUR and hence renal scarring associated with VUR and UTI is less common in non-Caucasians. Renal dysplasia is seen in patients with congenital RN. UPJ obstruction can predispose to UTI and thereby cause renal scarring, but this is less common in children compared with renal scarring associated with VUR and UTI.

Question 2

A 13-year-old girl presents with a history of recurrent UTI for the last year. She denied sexual activity. The parents believe that she had a couple of UTIs in early childhood. Of the following, which one would be the most helpful investigation?

A. VCUG
B. DMSA renal scan
C. CT scan
D. Renal ultrasound
E. Diuretic renal scan

Answer: B

Doing a DMSA renal scan goes with a "top-down" approach, in which instead of doing a VCUG to see if patient has VUR, a DMSA renal scan is done to see if the patient has any renal scarring. If the DMSA renal scan is normal, there is no need to do a VCUG. However, if the DMSA is positive, it might be worth considering a VCUG to see if she has VUR that needs to be managed appropriately. Renal ultrasound or a CT scan is not the investigation of choice for renal scarring. The latter is helpful in diagnosing renal stones, which is an important cause of UTI and scarring in adult patients. A diuretic renal scan is indicated in patients with hydronephrosis with suspected UPJ obstruction, but it is not indicated in this patient.

Question 3

An 8-year-old boy was seen recently in an Emergency Department because of abdominal trauma. A CT scan of the abdomen revealed scarring in the right kidney. He has a past history of VUR on the right that was treated surgically at the age of 2 years. The patient is suspected of having right RN. Which one is true of RN?

A. VUR is present when renal scarring is diagnosed
B. VUR may occur in the absence of a UTI
C. Adult males most often present with recurrent UTI
D. FSGS is seen in scarred renal tissue
E. In patients with VUR, surgical correction is better than antimicrobial prophylaxis in preventing recurrent UTI

Answer: B

VUR may have resolved by the time renal scarring is diagnosed. Absence of VUR does not rule out the possibility of RN. Renal scarring (evaluated by a DMSA renal scan) can be present in association with VUR with no history of UTI, which is called congenital RN. It is adult females with RN who most often present with recurrent UTI compared with male. FSGS occurs in nonscarred portions of the kidney and can even occur in the contralateral kidney. Multiple studies have demonstrated no difference between surgical correction and long-term antimicrobial prophylaxis in the prevention of recurrent UTI.[60,61]

Question 4

An infant is evaluated postnatally due to a history of antenatal hydronephrosis. He is found to have VUR and renal scarring. Which of the following is true of congenital RN?

A. Congenital RN results from abnormal renal development and focal renal dysplasia
B. Congenital RN requires a history of UTI
C. Congenital RN occurs more commonly in females
D. Congenital RN is also known as primary RN
E. Both A and D

Answer: E

RN may be congenital, a result of abnormal renal development resulting in focal renal dysplasia, or acquired, from pyelonephritis-induced renal injury. Congenital RN includes patients with antenatal hydronephrosis who on postnatal evaluation are found to have VUR and renal scarring with no history of UTI.

The differentiation of congenital and acquired RN on the basis of a preceding UTI can be arbitrary because the possibility of a preexisting renal scar before UTI cannot always be ruled out. Acquired RN is seen more often in females, whereas congenital RN occurs mostly in males.

Question 5

A 5-year-old child with VUR is found to have elevated S[Cr] and significant scarring on DMSA scan. Mechanisms underlying post-UTI renal scarring include which of the following?

A. Hemodynamic alterations
B. Focal ischemia
C. Inflammatory responses
D. Macromolecular trapping
E. All of the above

Answer: E

The mechanism for renal scarring following UTI is believed to result from a combination of factors that include focal ischemia, inflammatory response to released toxins, immunological mechanisms, macromolecular trapping, and mesangial dysfunction, vascular alterations, hypertension, and hemodynamic alterations.[33] Antioxidant-mediated renal tubular injury is attributed to the release of superoxides during tissue reperfusion.

Question 6

A woman with a history of VUR goes to the emergency room at 30 weeks gestation with symptoms consistent with a UTI. Potential complications for this pregnancy include which of the following?

A. Preterm delivery
B. Hypertension
C. Preeclampsia
D. Fetal loss
E. All of the above

Answer: E

The potential complications during pregnancy in women with RN include UTI, hypertension, proteinuria, edema, deterioration in renal function, hematuria, preterm delivery, preeclampsia, and fetal loss.[45–47] The incidence of hypertension and preeclampsia is significantly higher in women with VUR and renal scarring compared with those with VUR without scarring.[47]

Chronic Kidney Disease in the Elderly—Who Has It? Who Does One Treat? and How are They to be Treated?

Samir S. Patel

Renal Section, Veterans Affairs Medical Center, Washington, DC and George Washington University Medical Center, Washington, DC, United States

Abstract

Age is a major risk factor for chronic kidney disease (CKD). The world population that is elderly is growing dramatically, making CKD and end-stage renal disease (ESRD) a significant public health concern worldwide. The aging kidney undergoes changes that lead to a decline in glomerular filtration rate (GFR) and possibly increased susceptibility to injury. The diagnosis of early CKD vs. normal aging in the elderly by GFR estimation equations is controversial, but level of albuminuria remains an important prognostic indicator. Advances in prediction of progressive CKD in the elderly will assist in the important task of advance care planning. Nephrologists will need to consider illness trajectory, comorbidities, frailty, and overall functional status in the management of the elderly patient with failing kidneys. For certain elderly individuals, conservative, or nondialytic, management for ESRD may be appropriate because extension of life is minimal and diminished quality of life is almost certain. Early and ongoing discussions of goals of care are critical to nephrologic care in the elderly. Palliative care is an important concept for nephrologists to understand and utilize in the care of all elderly patients with CKD regardless of treatment with renal replacement therapy or conservative care.

INTRODUCTION

The term "elderly" has traditionally been defined as greater than 60 for demographers, but is often defined as above 65 in many developed nations due to its association with retirement and pension benefits. With improvements in public health in the modern era, functional and chronological age has increasingly been dissociated and has resulted in an expanding elder population throughout the world. Concomitant chronic illnesses, including chronic kidney disease (CKD), have increased along with higher individual and societal costs. The overall burden of CKD in the older population has been increasingly recognized and was the topic of World Kidney Day 2014.

The high prevalence of CKD in the elderly has multiple causes including not only increased longevity and rising rates of risk factors such as obesity and diabetes mellitus but also greater recognition based on diagnostic criteria for CKD. Although there is clearly a need to address CKD in the aging population, advanced age often presents challenges in the management of CKD. Aging is often associated with complicating factors such as orthostatic hypotension, labile blood pressure, and decline in vision, hearing, cognition, and balance. In addition, reduced social support, limited financial resources, and polypharmacy add to the challenges involved in management of CKD in the elderly. The nephrology community has become increasingly aware of the special considerations for the care of the elderly with CKD including decisions regarding renal replacement therapy (RRT).

EPIDEMIOLOGY AND PUBLIC HEALTH IMPLICATIONS

The world population has been growing dramatically since the beginning of the 20th century. There exist 7.6 billion individuals in mid-2017, of whom 13% are greater than 60 years of age.[1] People are living longer, leading to a larger percentage of elderly worldwide.

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00077-2

Although the segment of the population defined as elderly has increased disproportionately in developed nations, life expectancy is projected to rise further in high-income areas of the world, as well as in low- and middle-income regions. Life expectancy exceeds 75 years in Europe, North American, and Oceania. Life expectancy is projected to rise from 71 years in 2010−2015 to 77 years in 2045−2050 for the entire world population.[1] The reported prevalence of CKD worldwide increases with age and is highest in the elderly population. An analysis of adults living in 32 countries, accounting for nearly one half of the world population, found a CKD (stages 1−5) prevalence of 10.4% in men and 11.8 % in women. Approximately 50% of those individuals were greater than 60 years of age.[2] However, there is considerable variation in estimates between countries and reported studies.

The wide range of reported CKD prevalence is likely a result of the number of S[Cr] measures taken, estimation equations used to determine glomerular filtration rate (GFR), incorporation of albuminuria in the diagnosis, and varying laboratory standards.[3] Estimates of CKD in the US, based on a large representative sample of the noninstitutionalized US population, found approximately 7% of the US population has a reduced GFR, defined as less than 60 mL/min/1.73 m^2, based on an estimated GFR (eGFR) using both S[Cr] and cystatin C.[4] Also in the US, the prevalence of CKD appears to have increased dramatically in the elderly, perhaps reaching over 45% of the 70 years or older population.[5] Most of these individuals are categorized in the CKD stage 3a group (eGFR between 45 and 60 mL/min/1.73 m^2).

Regardless of the exact prevalence of CKD, the health consequences of CKD are substantial. The Global Burden of Disease study (2013) estimated 956,000 deaths worldwide in 2013 were attributable to CKD.[2] Most of the elderly with CKD die before reaching end-stage renal disease (ESRD) from cardiovascular disease (CVD).[6,7] The associated disease burden attributable to CKD is based on the related burden of hypertension and associated coronary, cerebral, and peripheral vascular disease. CKD has been tightly associated with CVD risk, and kidney disease accounts for the mortality risk in patients with diabetes mellitus.[8]

Costs for earlier stages of CKD are difficult to define due to inaccurate reporting and inability to attribute costs directly to CKD, because it is frequently associated with other costly comorbidities such as congestive heart failure and diabetes mellitus. The US Renal Data System reported that, in 2016, Medicare spending for beneficiaries with CKD exceeded 67 billion dollars for those aged 65 and older.[9] CKD is considered a cost multiplier, because individuals with recognized CKD represent 13% of the point prevalent aged Medicare population, yet account for 25% of total expenditures.

The incidence of ESRD in the elderly and the cost of treatment have major public health implications throughout the world. In the US, the highest incidence rate for ESRD is in those aged 75 and greater. The estimated cost of the ESRD program in the US for Medicare was 35 billion dollars in 2016, representing approximately 7% of the entire Medicare budget.[9] The tremendous economic and health burden of ESRD and its treatment in the elderly population underscores the need to slow progression of CKD and prevent ESRD.

KIDNEY SENESCENCE

The biologic aging of the kidneys from maturity to death, or kidney senescence, involves both structural changes involving all compartments of the kidney (renal blood vessels, glomeruli, tubules, and interstitium) and physiologic changes in renal blood flow, GFR, filtration fraction, and electrolyte and water handling. A number of theories of aging exist, broadly described as a natural process influenced by both genetic and environmental factors. Genetic and environmental factors likely combine in any individual aging kidney to different levels, explaining the variability seen in human studies.[10] Factors associated with progressive loss of renal function are listed in Table 77.1. Greater knowledge of the biology of aging will be needed to develop strategies to limit age-related decline in renal function. However, cellular senescence *in vivo* and the link to whole organ senescence as seen clinically remain to be elucidated.[11]

TABLE 77.1 Factors Associated With Renal Aging

ENVIRONMENTAL
Hypertension
Smoking
Dyslipidemia
Obesity
Male gender
Atherosclerotic disease
GENETIC
Epigenetic changes (DNA methylation, acetylation, microRNAs)
Replicative termination (telomere shortening)
Oxidative stress
Klotho signaling

Oxidative stress (a result of increased free radical generation and decreased antioxidant capacity) and inflammation both increase with aging and are likely agents of age-related renal decline. Increased circulating inflammatory cytokines are seen in CKD and aging, even before a measurable decrease in GFR.[12] Oxidative stress is hypothesized to be a critical factor in age-related chronic inflammation, leading to cell senescence and DNA damage.[13] Chronic inflammation leads to fibrosis because inflammatory factors stimulate proliferation of fibroblasts. The proinflammatory cytokines TNF-α and interleukin-1 induce apoptosis, particularly when oxidative stress is at high levels.

Inflammation may lead to cell senescence, and senescent cells release high amounts of inflammatory factors leading to the development of a vicious cycle. One other important component of the aging process is advanced glycation end products (AGEs), which can generate reactive oxygen species (ROS). On the other hand, ROS enhances glycation, leading to another vicious cycle. AGEs induce proinflammatory genes and activate NF-κB and mitogen-activated protein kinase in various cell types *in vitro*. Ultimately, inflammatory cytokines, AGEs, and oxidative stress may be the mediators that impair repair and regeneration of the kidneys.[10]

THE AGING KIDNEY

Early studies showed renal mass *in vivo* declined from approximately 400 to 300 g with age, but not until individuals were very old. In addition, renal blood flow (per unit of kidney mass) was found to decline slowly after the fourth decade with reduced blood flow to the cortex relative to the medulla.[14] New insights into the structural changes in the kidney have been gained from imaging studies of the general population and also of kidney donors. One study of 1852 adults using magnetic resonance imaging to measure kidney volume found total kidney volume decreased by about 16 cm^3 per decade. Most of the decline was seen in those over 60 years old.[15] Another study of 1334 living kidney donors by computed tomography scan found volume only declined after age 50, and then at a rate of 22 cm^3 per decade. Furthermore, the investigators found cortical volume decreases with age, but medullary volume increases to maintain relatively stable kidney volume until after age 50 years.[16]

Hemodynamic changes including decreased afferent arteriolar resistance and decreased ultrafiltration coefficient, corresponding to reduced filtration surface, have been found in animal models of aging. Studies performed in healthy human kidney donors seem to confirm these animal studies.[17] Changes in the renin–angiotensin–aldosterone system, particularly reduced circulating levels of renin and aldosterone, are seen with aging.[18] The finding of decreased afferent arteriolar resistance with an overall enhanced sensitivity to vasoconstriction at the efferent arteriole may predispose to the development of glomerular hypertension, contributing to renal decline.[19] There may be a normal and also pathologic decline in nitric oxide (NO) with aging as a result of oxidative stress, reduced L-arginine, and increased asymmetric dimethylarginine. The reduced NO is thought to be responsible for the reduced vasodilatory capacity or increased sensitivity to vasoconstriction in the kidneys of elderly people.[20] Endothelin regulation is impaired in the aging kidney, leading to heightened vasoconstriction.[21] The balance of vasodilation and vasoconstrictive responsiveness may be related to susceptibility to acute kidney injury (AKI) in the elderly.[22,23]

Histologic changes in the kidney are difficult to attribute specifically to aging. The findings of an increased proportion of globally sclerotic glomeruli (glomerulosclerosis), increased arteriosclerosis (fibrointimal hyperplasia), medial hypertrophy, arteriolar hyalinosis, and tubular atrophy with surrounding areas of interstitial fibrosis, designated often as arterionephrosclerosis of aging, may be the result of injuries from environmental factors.[24] Traditional tissue pathology is not clearly helpful because healthy kidney donors have vascular changes and glomerulosclerosis. Increased global glomerulosclerosis is often cited as indicative of renal senescence, but as much as 10% of glomeruli may be globally sclerosed in people up to age 40.[25]

Most individuals demonstrate a decline in GFR over time. GFR remains normal until the fourth decade when it gradually declines in a linear fashion, as seen in the landmark Baltimore Longitudinal Study. This was confirmed subsequently in 254 subjects, who had a mean decrease in creatinine clearance of 0.75 mL/min/year.[26] Of note, approximately one-third of the subjects had no absolute decrease in renal function, and a small group of patients had an increase in creatinine clearance with age.[27] A natural decline in renal structure and function appears inevitable once an individual is elderly, but it does not culminate in the development of ESRD. The individuals that progress to substantial decrements in renal function and ESRD must have other contributing factors.

DIAGNOSIS OF CKD IN THE ELDERLY

As with other age groups, screening for renal disease in the elderly may be done by a combination of measurement of GFR using serum markers such as S[Cr] and a urinary protein (preferably albumin) measurement in a spot sample, as recommended by the KDIGO

guidelines.[28] Urinary abnormalities (primarily proteinuria), imaging, or histologic evidence of renal damage or disease qualifies as CKD if present for longer than 3 months. Once CKD is diagnosed, evaluation for associated systemic disease and determination of the anatomic location of the kidney lesion (e.g. vascular, glomerular, tubular, and interstitial) is advocated by the KDIGO guidelines. Estimation equations for GFR using S[Cr] along with age, gender, and ethnicity have been commonly used for both clinical practice and epidemiological studies.

Accurate GFR estimation is needed for diagnostic and epidemiological purposes but has been problematic in the elderly population. Initially, the MDRD estimation equation underestimated GFR in patients with near normal GFR and in the elderly. This was partially addressed by use of the CKD-EPI equation and use of a standardized laboratory measurement technique to measure S[Cr], although some sources of variation remain.[29] The CKD-EPI equation was found to be superior to the MDRD equation for patients 65 or older and with a GFR greater than 60 mL/min/1.73 m^2.[30]

Despite a general tendency toward declining renal function with age, S[Cr] often does not change as patients age due to decreased muscle mass, reduced creatinine generation, and/or reduced protein intake in the diet of elderly patients. Therefore, estimation equations using cystatin C may be more accurate in the elderly, because cystatin C is not affected by muscle mass, particularly for those with GFR 60 mL/min/1.73 m^2 or above. Cystatin C-based estimation equations were better than S[Cr]-based equations for predicting both cardiovascular and kidney outcomes in the elderly without CKD.[31]

The distinction between age-related decline in GFR and significant CKD in an elderly person may be difficult. Although renal changes associated with aging in basic science studies using animal models demonstrate proteinuria, urinary protein excretion greater than 300 mg/g creatinine (overt proteinuria), should not be considered a consequence of normal aging in humans.[32] This proposition is primarily buttressed by the fact that proteinuria is an independent risk factor for progression to ESRD. Both eGFR and proteinuria are predictive of ESRD in the elderly.[33] Indeed, proteinuria is more predictive and reliable for progression of CKD and development of ESRD than eGFR. The KDIGO guidelines incorporated proteinuria, specifically, albuminuria, into its staging. The combination of using eGFR assessed by S[Cr] and cystatin C, as well as consideration of albuminuria, may be the best strategy to diagnose CKD in the elderly.[34–36]

The accurate diagnosis of CKD in the elderly remains a challenge in epidemiological studies. As mentioned earlier, the elderly population has varying muscle loss and changes in protein intake that may affect serum creatinine concentration. Aging women reach the arbitrary threshold of an eGFR of less than 60 mL/min/1.73 m^2 sooner than men. In a comprehensive review of the subject, Glassock et al. noted that prevalence estimates of CKD vary widely throughout the world despite good calibration of S[Cr] measurement by the IDMS (isotope dilution mass spectrometry) reference method.[3] Age, estimation equation used, biomarkers used (e.g. cystatin C, albuminuria), and number of S[Cr] measures (one at initiation of study vs. follow-up measures) all add to the variance. Furthermore, calibration of cystatin C remains an issue. Age-based cutoffs for GFR in the definition of CKD have been proposed based on studies that indicate an overdiagnosis of CKD (vs. age-related decline in GFR) using S[Cr]-based GFR estimation equations. However, it remains controversial if this will help achieve the goal of accurate diagnosis and prognosis.

PROGRESSIVE CKD TO ESRD IN THE ELDERLY

The development of ESRD is of great concern on both the individual and societal level. Although the incidence rate has slowed in the US, the prevalence of ESRD continues to grow. The average age at initiation of dialysis is greater than 60 years of age, and the greatest rise in incidence rates has been in the very old.[9] Unfortunately, mortality remains very high, particularly in the first year of dialysis. Many elderly patients initiate hemodialysis (HD) after prolonged hospitalization and with central venous catheters.[37] In the US, worsening functional decline or death in the year after initiation of dialysis occurs in the majority of elderly nursing home residents.[38] Although alive on RRT, elderly patients suffer from high rates of depression, decreased quality of life, pain, and sleep disturbances.

To better serve elderly individuals with CKD, better methods to determine risk for ESRD would be of tremendous value in healthcare decision-making. As in younger patients, the baseline eGFR and proteinuria predict progressive loss of renal function. Prediction equations have been developed for risk of ESRD, most notably the Kidney Failure Risk equation by Tangri and colleagues.[39] Rate of progression, as estimated by changes in eGFR over time, has been advanced as an additional parameter to further refine prediction. Tangri and colleagues later developed a dynamic predictive model for progression of CKD and found that eGFR changes improved prediction vs. prediction based on one baseline value of eGFR.[40]

In the elderly patient with advanced CKD, rate of decline tends to be slower than in younger patients. A number of studies indicate risk for ESRD declines vs. the competing risk for death with advancing age until

the eGFR is less than 15 mL/min/1.73 m^2, or with elevated proteinuria.[6] Drawz and colleagues developed a model to predict one year risk for ESRD in 1866 elderly (65 years or older) US Veterans with eGFR less than 30 mL/min/1.73 m^2.[41] Risk factors for ESRD in the final model were age, congestive heart failure, systolic blood pressure, eGFR, potassium, and albumin. The researchers found that the Tangri model also had good predictive ability on their validation cohort, with a concordance index of 0.78. Clinicians should use prediction equations to help determine timing of clinical follow-up and whether discussion about RRT is prudent.

RENAL REPLACEMENT THERAPY VERSUS CONSERVATIVE MANAGEMENT

Although life may be prolonged with RRT, it does not necessarily improve quality of life, because treatment with dialysis for elderly patients is associated with more time spent in healthcare settings, decreased satisfaction with life, and increased risk of dying in the hospital rather than at home.[42–44] For elderly CKD stage 5 patients with poor prognostic factors, such as ischemic heart disease, peripheral vascular disease, and dementia, a time-limited trial of dialysis may be offered with a commitment to review goals of care after the patient has stabilized on RRT (e.g. 4 weeks). Based on the patient progress in terms of goals of care, dialysis may be stopped or continued. Shared decision-making must be part of the process of making a decision for RRT vs. conservative care.

There is a growing literature of observational studies that indicate RRT does not prolong survival in those aged >80 years, and with poor baseline health as assessed by comorbidities such as congestive heart failure or poor functional status.[45–49] Given the poor survival and quality of life of many elderly CKD patients beginning RRT, conservative care, or nondialytic management of such patients, has become a valid fourth option for management of incident ESRD along with HD, peritoneal dialysis, and transplantation. Detailed guidelines on withholding and withdrawal of dialysis are available to assist clinicians regarding shared decision-making.[50]

To aid the clinician, prognostic tools have been developed to determine mortality risk for individuals who are initiated on RRT. A risk calculator for six-month mortality after initiation of dialysis was developed from data on nearly 2200 individuals 65 years or older in Canada. AKI was excluded, and the 19 point scale uses commonly available clinical data: age 80 years or older (two points), GFR of 10–14.9 mL/min/1.73 m^2 (one point) or ≥15 mL/min/1.73 m^2 (three points), atrial fibrillation (two points), lymphoma (five points), congestive heart failure (two points), hospitalization in the prior 6 months (two points), and metastatic cancer (three points). Although estimating prognosis for any single individual is difficult, prediction equations may help inform decisions about dialysis or conservative management that fit with the patient's values and goals of care.[51]

IMPACT OF FRAILTY

In addition to estimating prognosis with chronological age and comorbid conditions, the geriatric syndrome of frailty may be useful in estimating outcomes for elderly CKD patients considering RRT. The term frailty can be considered to encompass age-related decline and increased vulnerability to adverse health outcomes. Frailty may herald other geriatric syndromes such as falls, fractures, delirium, and incontinence.[52,53] Although no gold standard exists to determine frailty, it is usually measured in terms of physical parameters and described as the frailty phenotype. The most common measure for the frailty phenotype was identified by Linda Fried and colleagues. It is based on five parameters (weight loss, muscle weakness, fatigue or exhaustion, low physical activity, and gait speed) in participants of the Cardiovascular Health Study (CHS). The frailty phenotype (if three of the five criteria are present) was associated with increased risk of falls, hospitalization, and death in CHS.[54]

A systematic review of 32 studies of frailty and CKD found that 72% of studies determined frailty by the phenotype outlined by Fried.[55] Several studies found an increasing prevalence of frailty with worsening CKD, although the prevalence of frailty depends on the measure and the population studied. Of note, a decline in muscle mass seen with frail elders may affect S[Cr] and therefore eGFR and CKD diagnosis. Studies using cystatin C showed a tighter association between GFR decline and frailty. Frailty predicts adverse outcomes in both the CKD and ESRD populations.[56,57] Bao et al. showed that frailty was associated with a higher eGFR at dialysis initiation, perhaps in part explaining the observed association of mortality with higher eGFR at the start of dialysis.[58] The finding of frailty in elderly patients with advancing CKD should lead to earlier discussions of prognosis and discussions regarding conservative care once ESRD develops.

ILLNESS TRAJECTORY AND ADVANCE CARE PLANNING

In making treatment decisions for elderly patients with CKD, clinicians must consider the illness trajectory to help decision-making for conservative care vs. RRT. An estimation of rate of renal loss would help determine if, and approximately when, ESRD will develop. This may be estimated from age, baseline GFR, level of proteinuria, and rate of decline in GFR. CKD illness trajectory may not be a linear decline from year to year, but rather characterized by events causing an abrupt drop in GFR from AKI with incomplete recovery of renal function.[59] In addition, acute changes in functional status may also occur with supervening illness (such as a myocardial infarction, prolonged hospitalization, or amputation). The high rates of initiation of RRT with a central venous catheter and after intensive medical care in the Medicare population[37] may be due to unexpected deterioration of renal function in elderly patients with stable but advanced CKD.

The decision to start or withhold RRT begins with a discussion about prognosis between the patient and physician. This information can be used to assist in shared decision-making regarding management of ESRD. Advance care planning (ACP) includes a discussion in which the patient's values, preferences, and goals are identified which will be used to inform future healthcare decision-making. ACP is appropriate for all patients with CKD and should be done early in the disease course when the patient has healthcare decision-making capacity and is not suffering from the effects of uremia or acute illness.[50] The goal of ACP is to ensure the patient's wishes (fulfilling the right to autonomy) and the communication of those wishes to family, significant others, healthcare proxies, and healthcare providers. It is important to note that patients and families expect physicians to introduce the topic and to facilitate such discussions among families.[60,61] Furthermore, nephrologists need to address and readdress goals of care throughout the course of progressive CKD in an elderly patient because the illness trajectory can be unpredictable.

Advance directives (ADs) are legal documents that allow patients to record their wishes for future healthcare, including end-of-life (EOL) care. AD may result from ACP but are not necessarily the goal of the process. Although associated with decreased healthcare costs, decreased in-hospital deaths, and increased use of hospice, ADs are often not completed.[62,63] In the ESRD population, AD completion rates are lower than in other chronic illnesses.[63] A detailed evaluation of the contents of AD among 808 patients treated with chronic HD (mean age of 68.6 years old; men = 61.2%) found that 49% had ADs, of which 10.6% mentioned dialysis and only 3% specifically addressed dialysis management at EOL.[64] Small studies in the dialysis population indicate completion of AD may improve surrogate bereavement and increase hospice utilization.[65,66] At the minimum, the designation of a healthcare surrogate or proxy and do-not-resuscitate preferences should be documented as AD in accordance with guidelines.[50]

ISSUES FOR ELDERLY PATIENTS CHOOSING RENAL REPLACEMENT THERAPY

Modality and Timing of Initiation

Elderly patients who choose to include RRT in their care for ESRD should be offered all forms of RRT, including in-center HD, Home HD, peritoneal dialysis (PD), and transplantation based on similar criteria for younger individuals with ESRD. No modality has been proven to be superior to the other in the elderly population, although transplantation, as with the younger population, is still the preferred treatment in suitable candidates and based on life expectancy.[67] In general, candidates for RRT make a selection based on personal preferences that are usually influenced by lifestyle and social circumstances.

Early initiation of RRT has not been supported by observational trial data and one large randomized trial.[68,69] Observational studies show that many are initiated with an eGFR between 10 and 15 mL/min/1.73 m^2, but this is associated with worsened survival. This finding may be due to overestimation of GFR in individuals with muscle wasting, frailty, or reduced functional status (including amputations). Recent guidelines support starting RRT when eGFR is less than 10 and closer to 6 mL/min/1.73 m^2.[70] However, in the elderly population, symptoms have frequently been cited as a reason for starting dialysis rather than decline in eGFR below a cutoff level.[71] In the elderly, poor nutrition, reduced ability to perform activities of daily living, and nonspecific gastrointestinal symptoms are commonly cited reasons for dialysis initiation over traditional indications (e.g refractory hyperkalemia, fluid overload, uremic pericaridits, or neuropathy). However, functional decline and nutritional deficiency have both been shown to worsen despite initiation of dialysis. The option to delay initiation until definitive indications present may be valid in the elderly patient and should be included in shared decision-making.[72,73]

Hemodialysis Access

Initiation of HD with an arteriovenous fistula (AVF) is associated with better outcomes and lower costs; however, successful creation and development of a fistula is a challenge in elderly individuals. The reduced risk of infection conferred by an AVF over an arteriovenous graft (AVG) is attenuated considerably by advanced age and limited life expectancy, making AVG a viable initial access for HD.[74] Early discussions about RRT can not only allow additional time for AVF creation but can also lead to a significant number of AVF that are never used, leading to an unfavorable balance in harm to benefit. Based on modeling of data on US Veterans, O'Hare and colleagues found only one in five AVF would be unnecessary for those over 85 years old if guidelines are followed.[75] Decision-making regarding AVF creation has to be individualized to account for likelihood of development of ESRD and perhaps rate of progression.[76] For some elderly patients, despite their risks, central venous catheters may be an appropriate permanent access if it fits with their goals of care.

Peritoneal Dialysis

Few elderly patients are started on PD in the US.[9] Concerns over ability to perform the procedure in elderly patients with the frailty phenotype or cognitive decline may dissuade the treating nephrologist from recommending this modality. Observational studies regarding survival are mixed, but it is generally accepted that PD is a viable option for the elderly.[77,78] Advantages of PD over HD that may be appealing for the elderly patient with goals of care that emphasize quality of life include reduced time away from home, reduced transportation requirements, avoidance of HD-associated discomfort such as muscle cramping, needle cannulation, and posttreatment fatigue.[79] Additional training by the PD nurse and center, as well as support at home by caregivers to assist in the procedure, may overcome barriers to PD in the elderly patient with ESRD.[80] Reported experiences on assisted PD in the elderly population from Europe support this as a reasonable alternative to in-center HD.[81]

Kidney Transplantation

Kidney transplantation remains the modality of choice for RRT even in the elderly population. Wolfe and colleagues reported a 61% reduction in long-term risk of death and increase in life span by 4 years for older dialysis patients (ages 60–74) who received a cadaveric transplant over those that remained on the wait list.[82] In a similar study of wait-listed individuals on dialysis and over the age of 70 years, Rao and colleagues found a 56% lower mortality in cadaveric transplant recipients, including a 47% reduction in mortality for diabetic patients.[83] Age is not a contraindication to transplantation but transplantation occurs less frequently in the elderly then in other age groups. Many elderly patients on dialysis die on the transplant wait list. The kidney allocation system was changed in January 2015 to prioritize longevity matching. This is likely to increase waiting times for the elderly population.[84] Schold and colleagues demonstrated that it may be advantageous for elderly individuals treated with dialysis to receive an expanded criteria donor over waiting for a standard deceased donor kidney. Similar survival rates were obtained with the benefit of reduced time on dialysis.[85,86]

PALLIATIVE AND END OF LIFE CARE FOR ESRD

The burden of disease is high for the elderly with ESRD, with high mortality rates, particularly in the first several months after initiation of HD. Dialysis patients over the age of 65 years have substantially higher mortality compared with Medicare populations with cancer, diabetes, or CVD at a rate of 164 per 1000 patient years in 2016.[9] Morbidity and mortality in ESRD are largely due to extensive CVD and increased risk of infection. Additional morbidity from uremia, as well as dialysis treatment and its complications, may be found in elders with ESRD on RRT. Although not well characterized, it appears that patients on dialysis suffer from numerous symptoms. Davison and colleagues found an average of 7.5 symptoms per patient on HD, with 4.5 characterized as moderate or severe.[87] Using the Dialysis Symptom Index, Weisbord and colleagues found a median of 9.0 symptoms among dialysis patients, with the majority reporting dry skin, fatigue, itching, and musculoskeletal pain.[88]

A palliative approach to care of the elderly patient with ESRD is reasonable in patients with low potential for rehabilitation and high risk of death in one year. A predictive tool validated for elderly dialysis patients that incorporates age, serum albumin concentration (S[Alb]), dementia, and peripheral vascular disease along with a "surprise" question ("Would I be surprised if this patient died in the next 12 months?") could be used to prioritize palliative care for those that are at risk for early mortality.[89] Palliative care differs from the standard approach of disease-oriented care to one that prioritizes patient quality of life and relief of symptoms. The approach is molded by the patient's goals of care and preferences. Palliative care, by a proposed definition from the International Association for Hospice and Palliative Care, is "active holistic care of individuals across all ages with serious health-related suffering due to severe illness

TABLE 77.2 Key Aspects of Palliative Care

Includes prevention, early detection, comprehensive assessment, and management of physical symptoms, psychological distress, and social needs.
Provides support to help patients live as fully as possible until death by facilitating effective communication, helping them and their families determine goals of care.
Is applicable in conjunction with disease-modifying therapies whenever needed.
May positively influence the course of illness.
Intends neither to hasten nor postpone death, affirms life, and recognizes dying as a natural process.
Provides support to the family and caregivers during the patient's illness and in their own bereavement.
Is delivered recognizing and respecting the cultural values and beliefs of the patient and the family.
Is applicable throughout all healthcare settings (place of residence and institutions) and at all levels (primary to tertiary).
Can be provided by professionals with basic palliative care training.
Requires specialist palliative care with a multiprofessional team for referral of complex cases.

Adapted from Consensus based definition of palliative care. *International Association for Hospice and Palliative Care. www.hospicecare.com.*

and especially at the EOL. It aims to improve quality of life in all patients, their families, and caregivers." This definition includes key aspects which are listed in Table 77.2.

Standard care focuses on provision of RRT to achieve quality metrics such as urea clearance and phosphate levels. However, this may not coincide with the patient's priorities in the final year of life. Palliative care emphasizes relief of suffering by treatment of pain and other physical, psychological, and spiritual problems. It is important to communicate to patients and their families that palliative care is not equivalent to hospice care, but referral to hospice may be part of palliative care. Life prolonging therapies may still be continued with the palliative care approach, but there is no intention to prolong, or shorten, life with this approach.[90,91]

Palliative care can be part of conservative care (nondialytic care of ESRD) or can be provided with continued RRT. Conservative care, or comprehensive conservative care, for ESRD may be everything in standard care except initiation of RRT.[92] It often includes palliative care, particularly in the final months, weeks, or days of life. However, palliative care may also be part of the management plan for patients treated with RRT.[93] Incremental or reduced HD, assisted PD, liberalized diet, catheter as permanent access, and prudent reduction in pill burden are potential strategies in palliative care in elderly patients treated with dialysis.

Palliative care involves determination of patient preferences and therefore emphasizes the need for early and ongoing discussions of patient's goals of care, or ACP. ACP is an integral part of palliative care and may include AD and Physician Orders for Life-Sustaining Treatment (POLST). Importantly, the palliative care approach is more likely to be beneficial to the patient and family when provided in a multidisciplinary setting that includes social workers, physical and occupational therapists, dietitians, clergy or the equivalent, nephrologists, primary care physicians, and specialists in palliative medicine. Studies have identified physician factors as barriers to ACP and EOL discussions, such as timing of discussions, reluctance to discuss death, and poor communication during EOL discussions.[94–96] Multiple resources exist to assist nephrologists in the palliative care of CKD and dialysis patients (Table 77.3).

Nephrologists and other healthcare providers may be reluctant to discuss EOL or withdrawal of dialysis due to concerns over depression. It has long been recognized that the burdens of CKD and ESRD, including RRT itself, are associated with high rates of depressive affect and depression.[97] Furthermore, suicide rates are higher in those with ESRD than the general population for those over 29 years of age, with age greater than 75 years as an additional risk factor.[98] The role of depression in withdrawal of dialysis remains unclear and requires further study. However, screening for depression in all patients with ESRD has been advocated and should be part of management of those considering withholding or withdrawal of dialysis.[99] It is reasonable to attempt treatment of depression before a final decision regarding withholding or withdrawal of dialysis is undertaken.

All patients who stop dialysis and many patients who choose not to begin dialysis should be offered hospice care to facilitate symptom management and bereavement care for families and loved ones. Discontinuation of dialysis before death has been the case in approximately 20% of all US dialysis patients and approximately 30%

or more for those aged 75 years or older.[9] Average survival after discontinuation of dialysis is reported to be between 7 and 10 days.[100] However, extended survival may occur if there is residual kidney function. Symptoms such as fatigue, dyspnea, and pain are fairly common among those with ESRD near the EOL. Symptoms may be addressed appropriately with involvement of palliative medicine specialists and avoidance of emergent initiation of RRT that may be incongruent with the patient's goals of care. In general, hospice care is available for individuals with a predicted survival of less than 6 months and may be provided on an inpatient or outpatient basis. In the US, dialysis patients who discontinue dialysis are eligible for hospice under Medicare. In cases in which the admitting diagnosis to hospice is a terminal condition outside of ESRD (e.g. metastatic cancer), dialysis may be continued under the ESRD Medicare benefit. Although hospice is underutilized by patients with ESRD in comparison with patients with terminal cancer, the rates may be rising with enhanced palliative care services over the past two decades.[101,102]

SUMMARY AND CONCLUSIONS

The prevalence of CKD in the elderly is rising worldwide with the potential for tremendous individual and societal burdens. Early diagnosis of disease or impairment in renal function along with improved prognostication regarding development of ESRD is critical in managing this challenge. Scientific discovery regarding the aging kidney may help to prevent age-related decline in renal reserve, renal function, and susceptibility to AKI. Determination of illness trajectory and mortality risk and establishing goals of care are essential considerations for the caring nephrologist. Management of failing kidneys in elderly patients requires ongoing discussions between the physician and the patient and family. Nephrologists should be skilled in facilitating shared decision-making. Nephrologists should be knowledgeable regarding the risks and benefits of dialysis in the elderly and, if appropriate, the implementation of conservative and/or palliative care in the treatment of elderly patients with renal failure.

QUESTIONS AND ANSWERS

Question 1

A number of functional changes have been attributed to the aging kidney. Which of the following is **false**?

A. GFR declines in most individuals at an average rate of approximately 0.8 mL/min/year
B. Renal blood flow declines with age, with greater reduction in cortical compared with medullary blood flow
C. Although glomerular size may increase, renal mass may decline with age, primarily in the very elderly population
D. Increased afferent arteriolar resistance and decreased Kf (ultrafiltration coefficient) are common features
E. There is a general reduction in vasodilatory capacity and/or increased sensitivity to vasoconstriction.

Answer: D

Afferent arteriolar resistance decreases with age. Both animal and human studies support such findings.[19] This is distinct from the general reduction in vasodilatory capacity or increased sensitivity to vasoconstriction in the kidney, thought to be mediated by reduced NO in older individuals. Of note, Answer **A** is true because GFR declines with age in most but not all individuals. The Baltimore Longitudinal study demonstrated that approximately one-third of the patients did not show a decline in renal function.

Question 2

A 65-year-old man with a history of well-controlled hypertension for 10 years and osteoarthritis presents with concern for renal disease based on a recent serum chemistry panel performed at his primary care provider's office as part of a routine annual examination. He is on a low dose of diltiazem alone for blood pressure control. His blood pressure is 130/70 mm Hg, heart rate is 65 bpm. His examination is unremarkable. His urinalysis is normal.

In consideration of diagnosing renal disease in this elderly patient, which of the following is **false**?

A. S[Cr] rises gradually with age greater than 60 in most individuals, making the estimation equations for GFR less accurate than a traditional 24-hour urine collection for creatinine clearance
B. The MDRD estimation equation underestimates GFR in elderly patients
C. The CKD-EPI estimation equation was found to be superior to the MDRD equation in patients greater than 65 years of age and with GFR greater than 60 mL/min/1.73 m^2
D. Cystatin C-based estimation equations for GFR are better than both creatinine-based equations (MDRD and CKD-EPI) for prediction of both cardiovascular and kidney outcomes in the elderly without CKD
E. Proteinuria is associated with the development of ESRD in patients greater than 65 years of age

Answer: A

The S[Cr] tends to remain unchanged with increasing age, despite reduction in GFR. This has been attributed to decreasing muscle mass, decreased creatinine generation, and reduced protein in the diet. The MDRD equation does underestimate GFR, particularly in those with GFR greater than 60 mL/min. Cystatin C is not affected by muscle mass, making it a more promising marker for the elderly, particularly with GFR greater than 60 mL/min/1.73 m^2. Despite evidence that glomerular basement membrane permeability may increase with age, proteinuria remains predictive of renal disease and failure in the elderly.

Question 3

The patient in Question 2 is seen by another physician who recommends a renal biopsy to determine the presence of disease. Which of the following is **true**?

A. Thickening of the glomerular basement membrane and increased mesangial matrix expansion are consistent and specific findings of age-related changes in renal tissue
B. As much as 10% global glomerulosclerosis can be seen in healthy individuals before the age of 40
C. Medial hypertrophy, arteriolar hyalinosis, and increased arteriosclerosis (fibrointimal hyperplasia) are all specific for hypertensive kidney disease and not associated with aging alone
D. Glomerular changes are associated with increased peritubular capillary density
E. The degree of interstitial fibrosis seen on biopsy directly corresponds to the degree of kidney senescence

Answer: B

Histologic renal changes are difficult to attribute specifically to aging.[24] The finding of an increased proportion of globally sclerotic glomeruli (glomerulosclerosis) may be the result of injuries from environmental factors, but is also seen in healthy kidney donors. Answers **A** and **E** are incorrect because the changes are proposed markers but inconsistent and nonspecific findings. Answer **C** is incorrect because vascular changes can be seen in healthy kidney donors as well. Answer **D** is incorrect because glomerular changes are associated with decreased rather than increased peritubular capillary density, probably the

result of reduced vascular endothelial growth factor from oxidative stress.

Question 4

An 83-year-old man with hypertension has slowly progressive CKD with a recent eGFR of 15 mL/min/1.73 m^2 and albuminuria of 200 mg/g creatinine. He has steadily lost weight over the past 3 years, without a discernible cause. He has mild dementia and now lives in an assisted living facility. His only complaint is fatigue. Blood pressure is 140/65 mm Hg and weight is 50 kg. He is a thin male who ambulates slowly and has some difficulty sitting and getting up from the chair. In consideration of his severe renal insufficiency and RRT, which would be the most appropriate to advise the patient and his family?

A. Early start of RRT (before when eGFR is greater than 10 and closer to 15 mL/min/1.73 m^2) is associated with overall improvement in health outcomes
B. RRT would likely improve his functional status
C. RRT is unlikely to significantly prolong life and is associated with reduced quality of life in elderly patients with disabilities
D. HD is associated with superior outcomes vs. PD in the elderly
E. An AVF should be created now

Answer: C

Multiple observational studies in elderly patients show little to no prolongation in survival for those who initiate dialysis after the age of 80 years with significant comorbidities. This patient has weight loss, fatigue, and low physical activity and likely meets the criteria for the frailty phenotype. Frailty has been shown to be a risk factor for mortality in dialysis patients. Poor functional status, age, low S[Alb], and comorbid conditions including dementia, peripheral vascular disease, and heart disease are all risk factors for mortality in patients with ESRD. RRT has not improved functional status for elderly patients residing in extended care facilities. Early initiation of RRT has not been shown to improve outcomes in a large randomized trial and has even been associated with worse outcomes in the elderly. Dialysis modality does not appear to affect survival in elderly patients. Creation of AVF automatically at stage 4 or 5 CKD may not be appropriate in the very elderly because a large percentage may go unused depending on illness trajectory.

Question 5

A 69-year-old with atrial fibrillation, CHF, COPD, liver cirrhosis, and Parkinson's disease develops AKI during a hospital admission for a fall and urinary tract infection. He has baseline CKD stage 3b with low grade albuminuria (less than 100 mg/g creatinine). In the six months before admission, he developed worsening diuretic-resistant fluid overload. On presentation to the hospital, he is encephalopathic and has nonoliguric AKI. HD is initiated for massive fluid overload and possible uremic encephalopathy. After initiation of HD with a central venous catheter and treatment for urinary tract infection, his mental status improves. Over the next 12 weeks, attempts to discontinue HD fail due to continued massive fluid overload that is diuretic-resistant and his intolerance to high rates of fluid removal at dialysis. He remains bed-bound and totally dependent for all activities of daily living. What would be the next appropriate step for his physician?

A. Discussion of quality of life and goals of care
B. Vascular surgery consultation for arteriovenous access for HD
C. Referral to hospice with continued dialysis
D. Palliative care consultation
E. Ask patient to complete ADs

Answer: A

The patient probably has severe cardiorenal syndrome with multiple other comorbidities. His 1-year mortality is very high and can be estimated with various tools such as the Charlson Comorbidity Score and a predictive tool for survival in dialysis patients as described in Ref. 89. He is now unlikely to recover renal function or even be discharged from a chronic healthcare facility. At this transition from CKD to probable ESRD, it is appropriate to perform ACP. The other choices may be appropriate, but only after clarification of the patient's wishes after discussion of prognosis and goals of care. Once this is established, ADs such as designation of a healthcare surrogate do not resuscitate orders, and completion of a living will or POLST (physician orders for life-sustaining treatment) may occur. A palliative care consultation certainly is reasonable even if dialysis is to be continued, but this would be after discussions with the patient and ACP. Referral to hospice is premature at this point and cannot be guaranteed to include dialysis. Depending on this patient's prognosis and wishes, an arteriovenous access may be advised but it seems unlikely to be of benefit in his case.

[a]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States; [b]Department of Medicine, University of Alberta, Edmonton, AB, Canada

Abstract

Several studies evaluate the deleterious impact of pain in patients with chronic kidney disease (CKD). The prevalence of pain has been estimated at approximately 50%–70% in patients with advanced CKD. The causes of pain in CKD patients are often unrelated to the kidney disease and can be categorized as neuropathic (pain due to nerve damage) or nociceptive (pain due to tissue damage) in nature. There are a variety of validated screening tools available to determine the location, degree, and quality of a patient's pain, and any exacerbating or alleviating factors. These tools include, but are not limited to, the McGill Pain Questionnaire, Edmonton Symptom Assessment System-revised:Renal and the Brief Pain Inventory. A thorough evaluation should be undertaken to determine the underlying etiology of a patient's acute or chronic pain syndrome. Management of pain can be divided into nonpharmacologic and pharmacologic options. Nonpharmacologic alternatives should be considered before prescribing chronic pain medications. Pharmacologic treatment should follow specific guidelines with careful selection of appropriate analgesics and dose reduction for reduced estimated glomerular filtration rate, as most commonly used pain medications and their metabolites are renally cleared with a higher risk for adverse events in CKD. Opioids should only be used for severe pain refractory to other measures, including nonopioid and adjuvant analgesics. Greater provider awareness and a multidisciplinary approach including assessment and management of concurrent psychosocial issues are likely required to adequately address pain in CKD patients.

INTRODUCTION

Perception of pain is an often overlooked yet prevalent condition in patients with chronic kidney disease (CKD).[1,2] Perception of pain in patients with advanced CKD is associated with decreased quality of life (QOL), increased depressive affect, and increased perception of illness burden.[3–8] Psychosocial parameters including perception of decreased QOL and increased depressive affect have been associated with worse clinical outcomes, including increased mortality, higher rates of hospitalizations, and decreased compliance with prescriptions in patients with CKD or end-stage renal disease (ESRD).[6–10] Perceived pain severity is a potentially modifiable risk factor for poor clinical outcomes in CKD patients who often have multiple comorbid conditions. This chapter reviews the literature on the epidemiology of pain in patients with CKD worldwide, options for the screening for and diagnosis of pain, and the various management approaches to ameliorate the perception of pain in patients with CKD.

EPIDEMIOLOGY

The high prevalence of chronic pain is well documented in patients with ESRD treated with dialysis.[10–14] It is estimated that approximately 30–50% of patients with ESRD have chronic pain. Many of these patients are prescribed opioids, which have many adverse effects.[10–14] Based on 2010 US Renal Data System data,[15] approximately two-thirds of all dialysis patients were prescribed opioids. Opioid prescriptions in dialysis patients are associated with adverse effects including increased mortality, hospitalizations, and dialysis discontinuation.[15,16]

In the general population, prescription opioid overdoses continue to increase across the US, leading the US Department of Health and Human Services to declare a public health emergency in 2017.[17] In 2016, more than 42,000 deaths were attributed to opioid overdoses, and 40% of these were attributed to prescription opioids.[17] Given the magnitude of the problem and the adverse health impacts, there is an urgent need to address proper management approaches for pain in patients with CKD.

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00078-4

There are few data on the prevalence of pain in predialysis CKD patients. Cohen et al.[6] studied 92 predialysis CKD patients and found 69% of the cohort reported pain. There was no difference between patients' pain intensity scores across CKD stages. There was also no difference between CKD patients' perception of pain when compared with pain ratings of a control group of 61 general medical patients without CKD. In contrast, another study of 130 CKD patients reported a prevalence of 72.9% for acute and chronic pain[1]. This compared with a pain prevalence of only 9% for 100 control non-CKD ambulatory medicine patients. The majority of CKD patients reported musculoskeletal pain. Pain intensity and duration were higher in patients with CKD stages 3–5 compared with earlier stages of CKD. Data from SPRINT show no difference in pain between hypertensive patients with and without CKD.[18] The disparate results likely reflect the heterogeneity of the CKD population and differences in study design.

Grams et al.[19] recently evaluated the prevalence of opioid, gabapentinoids, and nonsteroidal antiinflammatory drug (NSAID) use among patients with CKD in the Geisinger and John Hopkins health systems. Patients with CKD stages 4 and 5 were significantly more likely to receive an opioid prescription compared with patients with earlier stages of CKD. Gabapentinoid prescriptions were also more commonly prescribed in those with advanced stages of CKD but were prescribed at significantly lower rates compared with opioids.

The incidence of symptoms, including pain, in earlier stages of CKD, also appears high. Twenty five symptoms were assessed in a cohort of 1118 patients with stage 1–5 CKD.[20] The most prevalent symptom in stages 1–3 were bone and joint pain, which was reported by 86% of patients. Muscle cramps were also reported commonly in 71% of patients. There was a slight trend toward increasing incidence of pain with stage of disease such that 97% of dialysis patients in this cohort reported bone and joint pain and 92% reported muscle cramps.

There are a variety of potential causes for pain in CKD patients.[7] Many causes of pain are not unique to CKD but are due to comorbidities such as osteoarthritis, inflammatory arthritis, peripheral neuropathy, peripheral vascular disease, and traumatic injuries. Pain can result from the underlying kidney disease, such as with polycystic kidney disease (PKD). PKD has its own unique pain syndromes, often related to the enlarging cysts or cyst rupture. Pain may also be due to complications of poor kidney function such as secondary or tertiary hyperparathyroidism, particularly in advanced CKD stages. Patients often have more than one cause of pain.

SCREENING FOR AND DIAGNOSIS OF PAIN IN CKD

A variety of tools have been validated to screen for pain in CKD patients. The McGill Pain Questionnaire,[10,21] first developed in 1975, remains one of the foremost tools used to assess pain. The questionnaire asks participants to describe the quality and intensity of their pain. The scale is rated from 0 to 78, with higher scores reflecting worse degrees of pain.

The Brief Pain Inventory[22] has been used to assess the location, type, and intensity of pain in patients with chronic medical illnesses including CKD. The questionnaire also evaluates the impact of pain on parameters such as general activity, mood, walking ability, work, relationships, sleep, and enjoyment of life. The standard instrument characterizes pain based on a 32-question survey, while the short form has been condensed to nine questions.

The Edmonton Symptom Assessment System-revised:Renal (ESAS-r:R)[23–25] can be used to screen for pain and psychosocial parameters. The ESAS-r:R consists of visual analog scales with a 0–10 likert scale representing "no" to "worst possible" for pain, tiredness, drowsiness, nausea, lack of appetite, shortness of breath, depression, anxiety, well-being, sleep, itch, and restless legs. Total scores range between 0 and 130, with higher scores indicating greater symptom burden. Similar global symptom assessment tools with evidence of validity for use in CKD patients include the renal version of the Palliative (or Patient) Outcome Scale, symptom module (POSs renal)[26] and the Dialysis Symptom Index.[27] All three of these patient-completed symptom screening tools can be downloaded from websites.

If a patient screens positive for pain, further evaluation by a pain history is required. This includes documenting location, type of pain, alleviating or exacerbating factors, effect on physical and psychosocial functioning, and associated symptoms. All these variables affect treatment strategies. It is important to differentiate between acute, chronic, and episodic pain as the management differs (Table 78.1).

The patient's experience of chronic pain is affected by psychosocial factors as well as pathology that originally caused the pain. These psychosocial factors typically need to be addressed to manage pain adequately. A further psychosocial assessment may be warranted to better determine any underlying aggravating factors.[7] In a study of 92 patients with CKD, pain intensity and frequency were associated with multiple psychosocial variables including depressive affect, perception of social support, and satisfaction with life.[6] These results

TABLE 78.1 Types and Categories of Pain

TYPES OF PAIN	
Acute pain	Occurs following tissue damage and activation of nociceptors at the site of injury, such as after surgery. Acute pain can occur over long periods with repeated injury. This is termed recurrent pain and tends to be episodic with periods without pain.
Chronic pain	Initiated by tissue injury but perpetuated by peripheral and central nervous system changes leading to continuation of pain in the absence of the original injury/pain stimulus. Chronic pain is not defined by duration but rather by the absence of persistent nociceptor damage. Chronic pain is typically present for long periods of time and is often out of proportion to the extent of the originating injury.
Episodic, incident, paroxysmal, and breakthrough pain	Pain that breaks through, i.e. occurs despite regular analgesic medication.
CATEGORIES OF PAIN	
Nociceptive	Pain due to tissue damage. Pain may be described as sharp or dull. Nociceptive pain typically responds well to traditional analgesics.
Neuropathic	Pain due to nerve damage. Pain is characteristically described as burning, painful, cold, or like electric shocks. Neuropathic pain may be associated with tingling, feeling pins and needles, numbness, and itching. It may also be associated with episodes of spontaneous pain, hyperalgesia, and allodynia. Neuropathic pain is typically poorly responsive to opioids and generally requires the use of adjuvant analgesics such as anticonvulsants and antidepressants.

highlight the importance of integrating a psychosocial evaluation into the management of patients' pain syndromes.

For the purpose of treatment, it is also helpful to categorize pain into nociceptive, neuropathic, or mixed nociceptive and neuropathic pain. Patients and their significant others should be educated on the nature of the pain, potential causes of pain, and on the proposed management plan. Complete relief of pain is not always possible, and it is important that patients and their families as well as their physicians have realistic expectations.

MANAGEMENT OF PAIN IN CKD PATIENTS

Management of chronic pain should first focus on nonpharmacologic options.[7,28] These include topical therapies such as heating pads or ice to reduce local inflammation.[7,28–31] Physical therapy programs often form an essential component of pain management. Other nonpharmacologic therapies include transcutaneous electrical stimulation (TENS) and ultrasound technology.[28] Arthritis and other musculoskeletal causes of pain are felt to be the most responsive to TENS.[28,32] Lifestyle modifications including diet and exercise and mind-body interventions such as cognitive behavioral therapy have been shown to be effective.[33,34] Surgical options and referral to a pain subspecialist may be appropriate in certain circumstances, depending on the underlying etiology of a patient's pain. For example, patients with inflammatory arthritis may require evaluation by a rheumatologist and patients with traumatic injuries may need orthopedic evaluation. PKD patients may require laparoscopic cyst decortications (unroofing and collapse of cysts) and marsupialization if pain is related to cyst growth.[35]

The World Health Organization (WHO) advocates a stepwise approach to pain management that was demonstrated to be useful and efficacious in cancer patients and is now adopted for use in nonmalignant pain (Figure 78.1). Preliminary data suggest this approach may be used effectively for patients with ESRD and CKD.[36,37] Caution with prescription opioids is strongly advised given the multitude of adverse health outcomes associated with this medication class. When prescribing analgesics, five principles should be followed (Table 78.2).

The choice of analgesic in stage 4 or 5 CKD is challenging because of the pharmacokinetic and pharmacodynamic consequences associated with severe diminution in glomerular filtration rate. Drug metabolism is altered significantly, and the risk of toxicity from accumulation of renally excreted drugs and their metabolites is high. In view of the potential for toxicity, short-acting rather than long-acting preparations should be used until stable pain relief has been achieved. There are a variety of analgesic options for the management of pain in CKD patients (Table 78.3). Dose adjustments are usually necessary in patients with advanced CKD.

WHO Ladder Step 1

Acetaminophen is the first-line step 1 analgesic for most CKD patients. The dose of acetaminophen does not need to be adjusted for kidney function. Recent evidence suggests that lifetime cumulative doses of

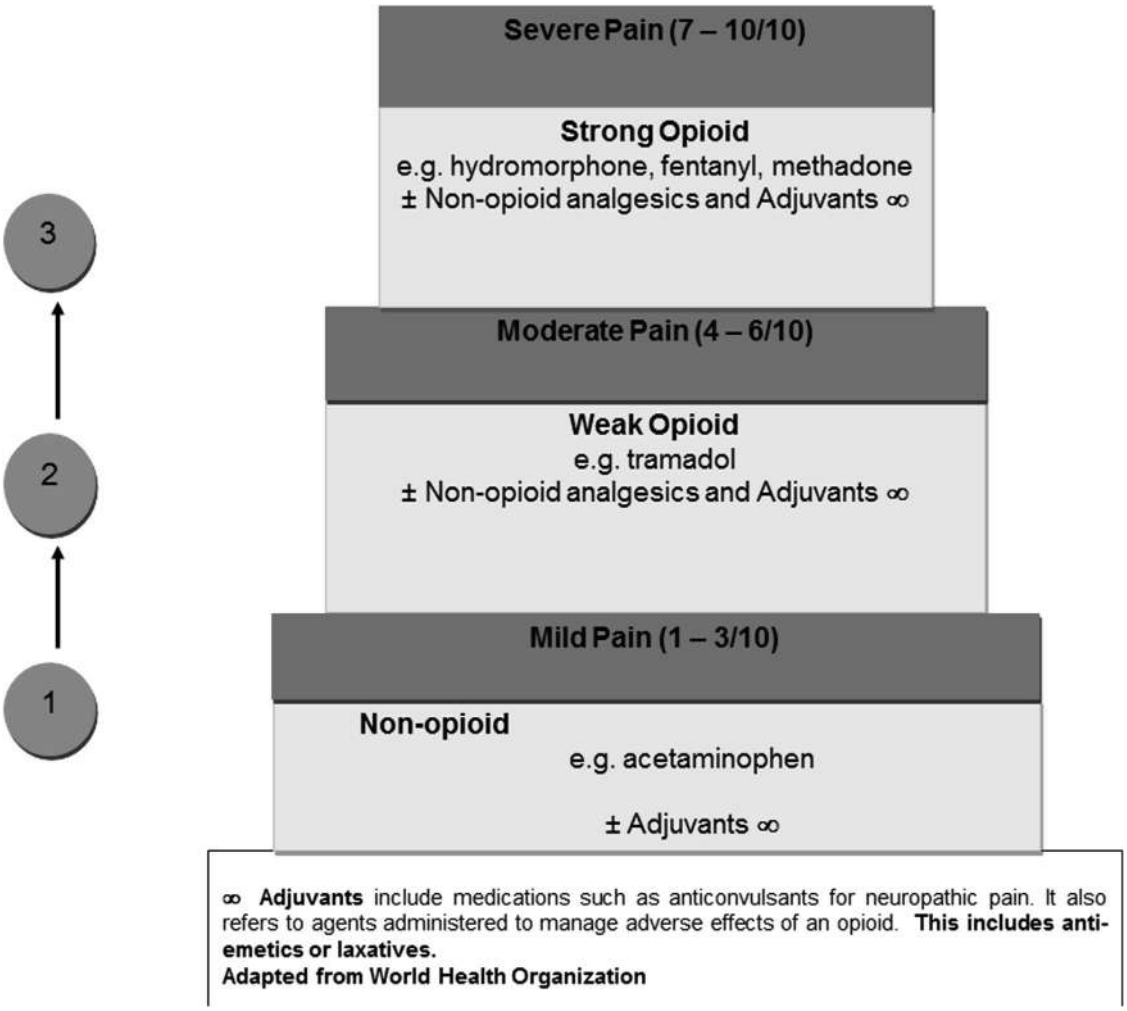

FIGURE 78.1 World Health Organization 3 Step Analgesic Ladder, ∞ Adjuvants include medications such as anticonvulsants for neuropathic pain. It also refers to agents administered to manage adverse effects of an opioid. This includes antiemetics or laxatives. *Adapted from World Health Organization.*

acetaminophen do not have an adverse effect on CKD progression. Despite its widely accepted use in CKD patients, acetaminophen may have nephrotoxic potential. Fored et al.[38] found an increased risk for CKD in those patients who used acetaminophen either alone or in combination with aspirin. Patients on combination acetaminophen and aspirin therapy had 2.2 higher odds for development of CKD. Perneger et al.[39] also found an increased risk of ESRD among patients who took increasing cumulative doses of acetaminophen over time. Other studies have not confirmed these findings. When patients with CKD have been prescribed therapeutic doses of acetaminophen, there is no evidence to support a risk for development of worsening renal function.[40] However, patients with chronic alcoholism and malnutrition may be at increased risk for hepatotoxicity.[41–43] To avoid toxicity, it is recommended to not exceed 3 g/day of acetaminophen. In high-risk patients, such as malnourished or alcoholic patients, ingestion should be limited to 2.6 g/day.[44]

The renal hemodynamic effects of NSAIDs are related to inhibition of renal prostaglandin synthesis, thereby causing renal afferent arteriolar vasoconstriction and hemodynamically mediated acute kidney injury (AKI).[45] Kidney injury in the setting of NSAIDs may result from acute interstitial nephritis, which rarely can be associated with minimal change disease. Other complications associated with NSAID use include hyperkalemia, edema, hypertension, and papillary necrosis.[7,28,45–47] Even in dialysis-dependent patients with no residual kidney function, NSAIDs are associated with an increased risk of gastrointestinal bleeding, and studies have suggested that there might be an increased risk of myocardial infarction.[48] For these reasons, chronic NSAID use, including NSAIDs with supposedly less potential for AKI, such as sulindac and

TABLE 78.2 Principles of Pain Management

By mouth	Use the oral or transdermal route whenever possible.
By the clock	Where pain is continuous, analgesics should be given regularly. Additional breakthrough medication should be available on an "as needed" (PRN) basis.
By the ladder	Initial analgesia should be started at the lowest appropriate WHO analgesic ladder level based on severity of pain. The drug should be used to its full-tolerated dose before titrating up to the next level on the ladder. Adjuvant drugs can be added to all three steps of the ladder. There are no safe step 2 analgesics for patients with advanced CKD. Step 1 analgesics can be added to step 3 drugs.
For the individual	There is no standard dose of strong opioids. The "right dose" is that which relieves pain without causing unacceptable side effects. Sensitivity to adverse effects varies between patients and must be monitored closely.
Attention to detail	Pain changes over time, thus there is a need for ongoing reassessment.

salsalate,[26,47–49] should be avoided in patients with advanced CKD. Low-dose aspirin for cardioprotection can be used safely in CKD patients.[50]

WHO Ladder Step 2

There are no weak opioids considered safe for use in patients with advanced CKD. For example, tramadol, a weak synthetic opioid related to codeine, is extensively metabolized in the liver. Both the parent drug and the main active metabolite O-desmethyltramadol (M1) are renally cleared. There is an unpredictable risk of serious overdosing or underdosing after administration of standard doses.[51] In addition, patients with advanced CKD are at an increased risk for seizures and respiratory depression with increased levels of M1.[52–54] There is no evidence that weak opioids are less risky than strong opioids if the strong opioid is used at its lowest effective dose.[55] There is also no evidence that at equivalent analgesic efficacy, weak opioids carry a lower risk of addiction than low-dose strong opioids. A recent study of 140,899 hemodialysis patients in the US showed the risk for altered mental status, falls, and fractures were greater with codeine rather than with strong opioids.[2,51]

TABLE 78.3 Analgesic Options for Chronic Pain Management in CKD Patients

Pain Category	Recommend	Recommend with Caution and Adjust Dose for Renal Function	Avoid
WHO STEP I (MILD PAIN)			
Acetaminophen	X		
NSAIDs			X
WHO STEP II (MODERATE PAIN)			
Tramadol			X
Codeine			X
Hydrocodone			X
WHO STEP III (SEVERE PAIN)			
Morphine sulfate			X
Hydromorphone		X	
Methadone		X	
Fentanyl		X	
Oxycodone		X	
ADJUVANTS			
Gabapentin		X	
Duloxetine		X	
Pregabalin		X	
Tricyclic antidepressants		X	

Adjuvant Therapy

Adjuvant drugs are those that have a primary indication other than pain but are analgesic in some situations. Adjuvant therapy is the first pharmacological step for people with a neuropathic component to their pain. Anticonvulsants and tricyclic antidepressants (TCAs) are the two classes of drugs for which there is the most evidence of efficacy in neuropathic pain. In patients with normal kidney function, TCAs are considered first-line treatment options for the treatment of neuropathic pain. However, due to the increased potential for anticholinergic and cardiac adverse events in CKD patients, this class of medications is considered second-line in patients with CKD.

Anticonvulsants are considered first line for the pharmacologic treatment of chronic neuropathic pain in patients with advanced CKD. There is no evidence that they are effective for acute pain. Gabapentin, an analog of the neurotransmitter gamma-aminobutyric acid, is increasingly being used for the management of chronic neuropathic pain and fibromyalgia.[56] The drug undergoes renal clearance and elimination is reduced markedly in patients with advanced CKD.[57,58] Therefore, patients are at increased risk for adverse effects such as neurotoxicity and AKI.[57,58] Caution must be used and appropriate dose reduction applied. A recent study in ESRD patients demonstrated an association between prescription of gabapentin and adverse events such as falls.[59] In patients with an estimated glomerular filtration rate (eGFR) between 15 and 30 mL/min/1.73 m^2, the suggested maximum daily dose is 600 mg, and for patients with an eGFR <15 mL/min/1.73 m^2, the suggested maximum daily dose is 300 mg. Neuropathic pain often tends to be worse at night. Because of a delayed onset of action, the drug should be taken two to three hours before going to bed.

Pregabalin is another anticonvulsant that can be used to treat refractory neuropathic pain. There have been case reports of neurotoxicity when using pregabalin in CKD patients.[60,61] Pregabalin has also been associated with peripheral edema. A recent study in ESRD patients found an association between pregabalin use and increased risk for falls and altered mental status.[59]

Dose reduction is required based on GFR. The maximum recommended dose for eGFR 30–60 mL/min/1.73 m^2 is 150 mg twice per day. For eGFR 15–30 mL/min/1.73 m^2, the maximum recommended dose is 150 mg once per day, and for eGFR <15 mL/min/1.73 m^2, the maximum daily dose is 75 mg daily. Carbamazepine appears as effective as both gabapentin and pregabalin. Although carbamazepine may have more adverse effects, it requires no dose adjustment in CKD.

Duloxetine, a selective norepinephrine and serotonin reuptake inhibitor, is increasingly being used for the treatment of neuropathic pain in a variety of clinical scenarios including diabetic and chemotherapy-associated neuropathy, fibromyalgia, and chronic musculoskeletal pain in the general population.[62–64] Serotonin and norepinephrine play an essential role in mediating chronic pain signals. Similar to gabapentin and pregabalin, duloxetine and its metabolites are renally cleared.[65] There is very limited experience with its use in patients with advanced CKD. Duloxetine is not recommended in patients with eGFR less than 30 mL/min/1.73 m^2. For patients with lower stages of CKD, duloxetine may be started at a reduced dose of 30 mg daily with cautious upward titration based on the patient's tolerance and symptoms.

Lidocaine patches are another option for the management of neuropathic pain, because they have less systemic absorption. This topical analgesic is particularly effective for the treatment of postherpetic neuralgia.[66,67] Caution is advised in patients with severe renal impairment who use lidocaine patches due to concern for toxicity.

WHO Ladder Step 3

Strong opioids should only be reserved for severe pain that is refractory to other measures. Opioids should be prescribed in close consultation with the patient and with the patient's primary care provider. In the setting of CKD, opioids carry an increased risk for adverse events including hypotension, depression of the central nervous and respiratory systems, seizures, and myoclonus.[68–70] As with other medications, appropriate dose reduction should be applied when prescribing to patients with advanced CKD.

Morphine undergoes hepatic metabolism and its metabolites are renally cleared.[71] Therefore, CKD patients are at higher risk for morphine toxicity. Morphine should be avoided in patients with advanced CKD stages.[71] Methadone, hydromorphone, fentanyl, and buprenorphine may have more favorable pharmacokinetic characteristics (Table 78.3).[72–74] Hydromorphone has a shorter half-life, lower volume of distribution, and lower molecular weight compared with morphine.[71] Hydromorphone may also cause less nausea, pruritus, and sedation compared with morphine.[71] Methadone may be preferable to other opioids in the setting of CKD, because its metabolites undergo both gastrointestinal and renal clearance.[72] There is believed to be increased gastrointestinal clearance of methadone in CKD patients.[72] The metabolites of fentanyl are reportedly "inactive" and less toxic. The drug can be given topically *via* a transdermal

patch.[74] Compared with morphine, fentanyl may cause less constipation, hemodynamic instability, and histamine release.[71] Fentanyl undergoes predominately hepatic metabolism, with only 5–10% of it undergoing renal clearance. Caution must be exercised with prescription of fentanyl because of its potential for abuse and its therapeutic/toxic ratio.

Strong opioids should be considered a last resort option due to risk of addiction and adverse effects. A complete history and physical examination should be performed before prescribing to determine the underlying cause of the patient's pain, and to ascertain if the patient may be at increased risk for adverse events. A thorough social history should be documented to determine if patients have a previous history of drug-seeking behaviors, which places them at a higher risk for addiction. Once opioids are prescribed, close medical follow-up and monitoring is indicated to screen for signs of aberrant use or addiction such as inappropriate or escalating doses.

CONCLUSION

Pain is prevalent in CKD patients and can be associated with psychosocial variables including poorer QOL and increased depressive affect. There are a variety of screening tools available to determine the severity and impact of a patient's pain. Management of pain in CKD patients should follow specific guidelines and appropriate dose reduction for reduced eGFR. Many of the commonly used pain medications and their metabolites are renally cleared, with a higher risk for adverse events in CKD. Nonpharmacologic alternatives should be considered before prescribing chronic pain medications for CKD patients. Patients' psychosocial needs should be addressed, as treatment of depression and anxiety may be associated with decreased perception of pain. In the midst of the opioid epidemic and increasing data regarding the multiple deleterious health consequences of prescription of opioids, additional studies are urgently needed to determine the optimal management approach for the treatment of pain in patients with CKD. With more provider awareness and using multidisciplinary approaches, the pain epidemic in CKD patients may be more effectively managed.

QUESTIONS AND ANSWERS

Question 1

A 64-year-old man with stage 4 CKD, baseline eGFR 25 mL/min, presents to his nephrologist reporting lower back pain for the past week. He reports lifting heavy objects before the onset of pain.

Which of the following statements is correct?

A. Pain prevalence consistently decreases as CKD stages advance
B. The back pain is likely secondary to nephrolithiasis
C. Pain is a common symptom reported in CKD patients
D. You should immediately refer the patient to a pain specialist

Answer: C

Pain is prevalent in patients with CKD. Studies have estimated the prevalence of reported pain to be up to 70% in patients with CKD. The prevalence of pain did not change across the different CKD stages in one study; however, in another study pain was perceived as more intense in those with advanced stages of CKD. Immediate referral to a pain specialist is not appropriate until other measures are tried in close consultation with the patient's primary care provider.[1,6]

Question 2

The patient has tried acetaminophen and heating pads with no relief and requests "something stronger" for pain.

Which of the following analgesic medications would be most appropriate to treat this patient's chronic pain?

A. Amitriptyline
B. Morphine Sulfate
C. Ibuprofen
D. Tramadol
E. None of the above

Answer: E

Based on current recommendations, the analgesics listed should be avoided in CKD patients and none of the above is the correct answer.[52–54]

Question 3

The patient returns 2 weeks later reporting shooting pains radiating down the back of his right leg down to his foot. You recommend physical therapy and that he consult with his primary care physician for additional options. Which of the following medications would you recommend to the primary care physician as the best adjuvant to help with this patient's pain?

A. Gabapentin
B. Ibuprofen
C. Morphine sulfate
D. Amitriptyline

Answer: A

This patient has sciatic neuropathic pain which is best managed with an adjuvant analgesic such as the anticonvulsant gabapentin. The other medications listed are contraindicated in patients with advanced CKD. Recent studies in ESRD patients suggest more data are needed regarding results of treatment with gabapentin in patients with CKD.[56,59]

Question 4

A 58-year-old woman with breast cancer metastatic to the bone and stage 4 CKD, GFR 20 mL/min, reports severe diffuse bone pain. She requests stronger analgesics. She currently takes acetaminophen with no relief of her symptoms. You discuss the case with the patient's primary care physician to develop an optimal therapeutic plan. Which of the following medications would you recommend as the next best option for this patient?

A. Fentanyl patch
B. Amitriptyline
C. Ibuprofen
D. Morphine sulfate

Answer: A

This patient has severe bone pain from metastatic disease which often requires the strongest analgesic options. Fentanyl patch is the best choice of the options listed. Fentanyl undergoes primarily hepatic clearance; however, clearance of the drug is reduced in patients with several renal failure, therefore a reduced dose should be considered. The other medications should be avoided in patients with advanced CKD.[73,74]

Question 5

A 64-year-old woman with a history of type 2 diabetes mellitus for 25 years and stage 4 CKD, GFR 25 mL/min, reports painful burning in both feet for the past month. She requests analgesic relief. Which of the following medications may be most effective in relieving her symptoms?

A. Morphine sulfate
B. Duloxetine
C. Ibuprofen
D. Acetaminophen

Answer: B

This patient has neuropathic pain, which is best managed with an adjuvant such as duloxetine. Other

appropriate options might include gabapentin or pregabalin which are not listed as answer choices. These medications, in light of recent data in the ESRD population, need study in the CKD population. The other medications listed are either not appropriate for patients with CKD or not shown to be effective for neuropathic pain.[59,62–64]

Question 6

A 53-year-old woman with stage 3a CKD, GFR 50 mL/min presents to the hospital with AKI. Her admission S[Cr] is 6.7 mg/dL. She states she has had severe back pain for the past month and recently started taking over the counter pain medication. Over the past week, she developed gastroenteritis with poor oral intake. Which of the following medications most likely contributed to the AKI?

A. Duloxetine
B. Tramadol
C. Ibuprofen
D. Acetaminophen

Answer: C

This patient presented to the hospital with AKI in the setting of volume depletion. Ibuprofen is a cause of AKI, especially in the setting of volume depletion and preexisting CKD. The other answer choices listed are not associated with AKI.[45–47,75]

CHAPTER

Abstract

Patients with chronic kidney disease (CKD) are at higher risk for mortality and adverse outcomes in the perioperative setting. Although surgical procedures in CKD patients are commonly performed, a paucity of research exists on the adequate evaluation and minimization of perioperative risk. Most data are tangential and explore the surgical risk of conditions that are associated with CKD, such as cardiovascular disease or anemia. Some strategies that have been adopted in the management of perioperative CKD patients include avoidance of nephrotoxic medications, analysis, and adjustment of electrolyte and glucose abnormalities, correction of anemia, and careful attention to types and amount of resuscitative fluids. Intraoperatively, the proper use of anesthetics, analgesics, and neuromuscular blocking agents, which exhibit altered pharmacodynamics and pharmacokinetics in CKD patients, can minimize unwanted side effects. Proper attention should be paid to postoperative planning and management, with specific attention paid to reinitiation of home medications, as well as adequate nutrition, mobilization, and discharge strategies.

INTRODUCTION

The perioperative management of the patient with chronic kidney disease (CKD) can be complex and challenging for the surgeon and the intensivist. Surgical risk is higher in CKD patients due in part to difficulties managing vascular access, electrolytes, volume status, and dosing adjustments for commonly used perioperative drugs. More importantly, cardiovascular comorbidities place CKD patients at a higher risk for perioperative mortality. In the preoperative period, proper patient selection, risk assessment, and strategies for risk abatement are vital for optimizing patient survival. Intraoperative management of blood pressure, electrolytes, fluids, and blood products warrants particular attention. Postoperative dosing of analgesia, reinitiation of home medications, and monitoring can minimize hospital length of stay (LOS) and adverse outcomes.

EPIDEMIOLOGY AND RISK ASSESSMENT

CKD is defined as long-term (≥3 months) structural or functional abnormality of the kidney associated with a decrease in glomerular filtration rate (GFR).[1] CKD is common in the US, with a prevalence in adults approaching 11% for stages 1 through 5. The prevalence for CKD stages 3 through 5, corresponding to a GFR of <60 mL/min/1.73 m^2, is 4.6%.[1] CKD is associated with higher rates of mortality, with hazard ratios of 1.03, 1.38, and 3.11 for estimated glomerular filtration rates (eGFRs) of 60, 45, and 15 mL/min/1.73 m^2, respectively.[2] Moreover, patients with CKD are at particular risk for development of acute kidney injury (AKI). A systematic review by Novis et al. of over ten thousand surgical patients found that increased serum creatinine (S[Cr]), increased BUN, and preoperative renal dysfunction were the three most common risk factors for the development of postoperative renal dysfunction.[3] AKI is also associated with increased risk of adverse outcomes. In a series of over

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00079-6

9000 hospitalized patients, AKI, as defined by an increase in S[Cr] of ≥0.5 mg/dL, was associated with a 6.5-fold increase in the odds of death, a 3.5-day increase of LOS, and $7500 in excess hospital costs.[4]

Surgical procedures are commonly performed in the US. According to the National Institutes of Health, 15 million people in the US each year undergo a surgical procedure.[5] Overall surgical perioperative mortality is estimated to be 1.85%, based on a large Dutch study of 3.7 million surgical procedures,[6] although mortality rates have recently been reported as high as 3.6%–4%.[7,8]

CKD is encountered commonly in the perioperative setting. As an example, an estimated 600,000 patients undergo coronary artery bypass grafting (CABG) each year in the US; of these, 10%–20% have a baseline S[Cr] of over 1.5 mg/dL.[9] Mortality rises considerably in these patients. In fact, in the perioperative setting, both CKD and AKI are associated with adverse outcomes. Postoperative AKI in the cardiac surgery population, for example, occurs in 1%–30% of patients, with a mortality of approximately 15%–30%.[10,11] A preoperative elevation of S[Cr] (and corresponding reduction in eGFR) was shown to be associated with mortality in a retrospective case-control study of 80 patients undergoing femoral neck fracture operative repair.[12] eGFR was further predictive of mortality in a retrospective analysis of almost 400 endovascular aortic aneurysm repair patients.[13] In a recent analysis by Jacob et al., patients with CKD who underwent cardiac surgery experienced a higher rate of renal replacement therapy and death than their counterparts without CKD (27.1% vs. 11.4%, $p < 0.001$).[14] A retrospective Veterans Administration database review of almost 4000 CABG patients showed that a S[Cr] level between 1.5 mg/dL and 3.0 mg/dL was associated with a more than doubled mortality rate (7% vs. 3%, $p < 0.001$).[9] Cooper et al. analyzed renal dysfunction and patient outcome during CABG using data from the Society of Thoracic Surgeons National Adult Cardiac Database over a three and a half year period. They concluded that preexisting renal dysfunction, as measured by GFR, carried a sixfold increase in operative mortality and a threefold increase in complications (including sepsis, stroke, LOS, and length of time on ventilator).[15] Longer-term outcomes in patients with severe renal dysfunction (defined as eGFR 15–45 mL/min/1.73 m^2) who underwent CABG were significantly worse than those with moderate renal dysfunction (eGFR 45–60 mL/min/1.73 m^2) or eGFR greater than 60 mL/min/1.73 m^2. The patients with severe dysfunction experienced more cardiovascular events or deaths (hazard ratio 1.36 with 95% confidence interval of 1.22–1.53).[16] Numerous other studies have demonstrated an increase in perioperative morbidity and mortality in the CKD population in other noncardiac surgical settings, including vascular, orthopedic procedures, and urologic oncological surgery.[12,13,17–19]

Lee's index of cardiac risk assessment in noncardiac surgery includes preoperative S[Cr] >2.0 mg/dL as one of the six independent predictors of adverse outcome.[20] Based on the aforementioned and other data, the American College of Cardiologists/American Heart Association (ACC/AHA) considers CKD to be a perioperative risk factor equal to ischemic heart disease and stroke.[21] Surgical risk accumulates with the presence of active cardiac conditions, limitations in the patient's underlying functional capacity, type of surgery, and underlying comorbidities, of which CKD is one. Figure 79.1 illustrates the 2007 ACC/AHA guidelines for perioperative risk stratification for noncardiac surgery.

PREOPERATIVE ASSESSMENT

Preoperative assessment is essential in understanding the nature of the patient's renal impairment, as well as the likelihood of adverse outcome. Figure 79.2 depicts some of the expected physiological and hormonal effects on the kidney in the operative setting, which can become dysregulated when kidney disease is present.

KDOQI guidelines suggest the following assessments as part of a comprehensive evaluation of all CKD patients.[1]

- Diagnosis of the type of kidney disease
- Comorbid conditions
- Severity of kidney disease
- Complications related to level of kidney function
- Risk for loss of kidney function
- Risk for cardiovascular disease

These factors are also of particular importance in the perioperative period, as an understanding of renal dysfunction can assist the surgeon and intensivist in managing essential tasks, such as minimizing metabolic and pharmacological sequelae, maintaining electrolyte homeostasis, managing acid–base levels, and mitigating fluid shifts. For example, a surgeon may avoid administering excess blood products or causing muscle trauma (both of which can increase S[K] levels) in patients with CKD who have an inability to regulate electrolytes.[22] Patients with CKD frequently have several comorbid conditions, including hypertension and diabetes, which are themselves associated with myocardial dysfunction, coronary artery disease, and peripheral vascular disease.[23] The presence of these conditions is associated with increased cardiovascular risk and may influence a surgeon's opinion on the necessity, timing, and duration of surgery. Additional factors, such as anemia, uremia, protein malnutrition, and bone disease

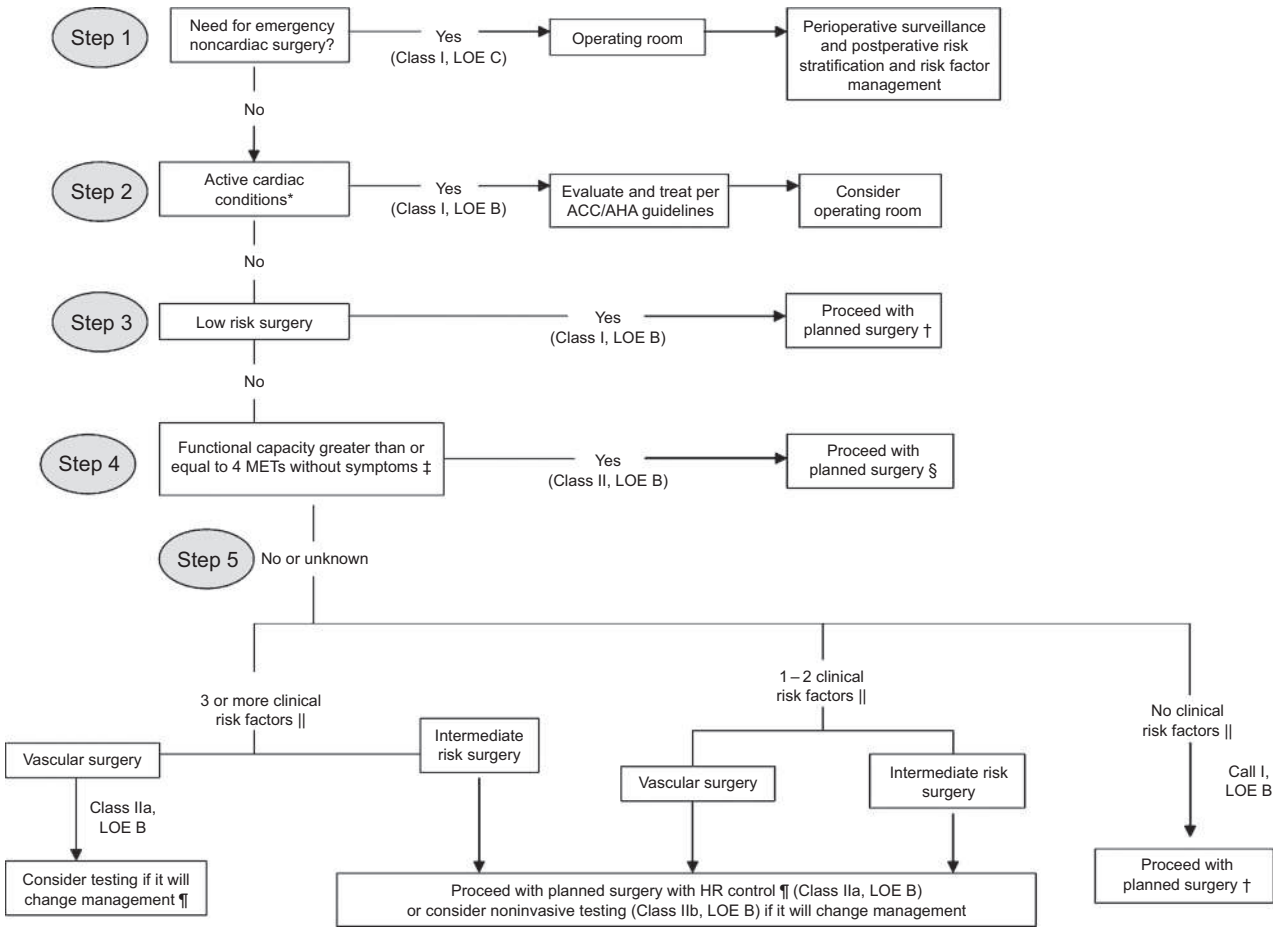

FIGURE 79.1 Stepwise algorithm for determining perioperative risk in noncardiac surgery. Active cardiac conditions include unstable coronary syndromes, decompensated heart failure, significant arrhythmia, or significant valvular conditions. Clinical risk factors include ischemic heart disease, compensated or prior heart failure, diabetes mellitus, renal insufficiency, or cerebrovascular disease. *Reproduced with permission from Fleisher et al. (2007).*[21]

(calcium−phosphorus metabolism), are also potential issues in CKD patients and can make it difficult in the operative setting to address blood loss, endocrine function, and wound healing. Infection can be more common in CKD patients due to a relatively immunocompromised state.[23] In addition, patients with CKD may develop neuropathy, which can affect postoperative pain management.[1] Moreover, because the magnitude of azotemia correlates with increasing levels of mortality, it behooves the surgeon and intensivist to understand the stage of CKD and the rate of decline in GFR, as well as to avoid interventions that may worsen kidney function (such as nephrotoxic medications or radiocontrast agents).

Medications in the Perioperative Period

Abnormalities in drug metabolism occur in patients with CKD related to alterations in volume of distribution and protein binding, changes in bioavailability, and prolongation of half-lives of both the drug and any metabolites.[24] Additionally, patients with CKD are more prone to adverse drug reactions, including neurological, psychiatric, integumentary, gastrointestinal, and cardiovascular events.[25] Accordingly, careful attention should be paid to the preoperative (i.e. home) medications that many CKD patients routinely take. Dose adjustment or discontinuation of certain agents may avoid unnecessary renal injury in the perioperative period. The American College of Physicians and the American Society of Internal Medicine have both published guidelines for prescribing drugs in the setting of diminished renal function.[24] Common drugs used in the CKD population are angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), beta blockers, calcium channel blockers, diuretics, antiarrhythmics, and analgesics.

Prior administration of ACEIs and ARBs is commonly associated with hypotension in the operating room, particularly on induction of anesthesia.[26,27] In a retrospective study of 267 patients on chronic ACEI or ARB therapy, those who took their home medication within

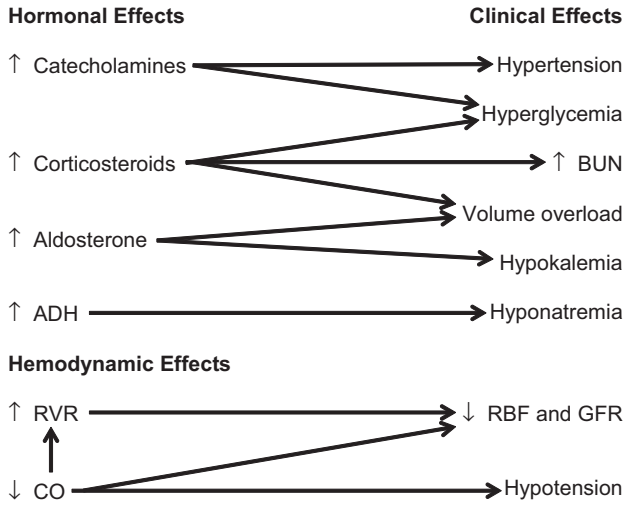

FIGURE 79.2 Physiologic and hormonal responses to surgery affecting the kidney. *ADH*, antidiuretic hormone; *BUN*, serum urea nitrogen; *CO*, cardiac output; *RVR*, renal vascular resistance.

10 hours of the onset of surgery were more likely to have moderate hypotension (systolic blood pressure ≤85 mm Hg) during the first 30 minutes after induction of anesthesia.[27] Currently, there is no consensus on management of preoperative ACEI/ARB administration. However, discontinuation of ACEI/ARB therapy and management of blood pressure with other short-acting and titratable agents may be prudent and should be considered in CKD patients before surgery.[28] The management of operative hypotension in the setting of preoperative ACEI or ARB use may be accomplished through conventional methods, such as fluid resuscitation and vasopressor therapy. Choice of vasopressor may have implications for kidney health and is addressed below, in addition to other novel therapies. On the other hand, ACEI/ARB therapy may provide the additional benefit of inhibiting the renin–angiotensin–aldosterone system (RAAS), which can affect the progression of renal disease.[29] Perioperative RAAS inactivation may be accomplished through the use of ACEI/ARB therapy, as well as alternative pathways. A randomized controlled trial studied the effects of human atrial natriuretic peptide (hANP) infusion intraoperatively and the ARB olmesartan in the immediate postoperative period in patients undergoing CABG. Those treated with hemodialysis and taking ACEI preoperatively were excluded. There was no significant difference in baseline variables including CKD stage, use of circulatory assist devices, or perioperative catecholamine use. Compared with placebo, the groups that received hANP alone and hANP in combination with ARB had lower 30-day mortality (6% for placebo vs. 0% for the other two groups) and lower need for dialysis (12% for placebo vs. 1.7% for hANP and 1.8% for hANP plus ARB).[30]

Beta blockers are safe in the perioperative period and have been shown in numerous studies to confer protection against perioperative myocardial ischemia, mostly due to avoidance of beta blocker withdrawal.[31] The ACC/AHA guidelines state that beta blockers should be continued in patients undergoing surgery who are receiving beta blockers to treat angina, symptomatic arrhythmia, or hypertension.[32] Data on other vasoactive drugs, such as calcium channel blockers, amiodarone, and alpha 2 blockers, are lacking.

Diuretics are also commonly used in CKD patients. In addition to altering volume status, diuretics can potentiate abnormalities in electrolyte levels.[33] For example hypokalemia (a common effect of most diuretics) has been shown in a prospective, observational, case-control study of over 2400 cardiac surgery patients to predict serious perioperative or intraoperative arrhythmia, postoperative atrial fibrillation/flutter, or the need for cardiopulmonary resuscitation.[34] Volume status can be difficult to manage perioperatively, as it is governed as much by free water as by total body sodium levels, serum and urine osmolality, and antidiuretic hormone levels.[35] Consensus opinion based in part on early observational studies is that diuretics be held before surgery.[31,36]

Other classes of drugs should be used judiciously, taking into consideration expected side effects, and how these may manifest in the perioperative period, especially with the possibility of worsening renal function. For example, the clinician should acknowledge the possibility of hypertension with the administration of erythropoietin, cyclosporine, and corticosteroids, or the lowering of the seizure threshold with certain antibiotics or meperidine.[23,37] Nephrotoxic agents, such as aminoglycosides and NSAIDs, should be avoided, as these are thought to contribute to the incidence of AKI.[38] Essential medications for other comorbid conditions, such as aspirin or clopidogrel for stents in the setting of coronary artery disease or peripheral vascular disease, should be evaluated on a case-by-case basis and continued if possible. The cardiac surgery literature suggests that aspirin may be continued, but that it is reasonable to hold clopidogrel 5–7 days before cardiac surgery.[39,40]

Perioperative Laboratory Evaluation/Tests

Routine preoperative laboratory evaluation is warranted, as a patient with CKD is at higher risk for anemia, electrolyte instability, coagulopathy, and abnormal levels of calcium, phosphate, and magnesium. These abnormalities have been associated with worse outcomes. Prompt attention to these abnormalities may mitigate perioperative risk.

eGFR

A basic metabolic panel and patient demographic data can be used to calculate the eGFR. eGFR can be determined using the widely accepted Modification of Diet in Renal Disease (MDRD) equation. Some clinicians still use the outdated Cockroft–Gault equation. This practice should be updated with MDRD or CKD-EPI equations. The results of this analysis can assist in medication adjustment, CKD staging, and identification of the presence of AKI. AKI is associated with adverse outcomes, and depending on etiology, its presence should be addressed perioperatively.

Some attempts have been made pharmacologically to address and correct a reduced eGFR. Dopamine and the dopaminergic analogue fenoldopam have been used in an attempt to prevent deterioration of renal function in CKD patients undergoing surgery. "Low" or "renal" dose dopamine infusion has been shown to increase urine output, but has not resulted in any renal protective effects and has, in fact, been associated with harmful side effects.[41–43] Dopamine is not recommended for the prevention or treatment of AKI in the critical care or perioperative setting. Fenoldopam, a pure dopamine type-1 agonist, has been studied in the prevention of AKI in high-risk surgery patients as well as in the critical care setting. A recent meta-analysis of 440 patients from six studies concluded that fenoldopam consistently and significantly reduced the incidence of AKI (odds ratio—0.41) but had no effect on the need for renal replacement therapy, survival, or LOS.[44] Other studies have found equivocal and inconsistent results.[45] Currently, fenoldopam is not recommended in the perioperative setting to prevent the development of AKI.[46] Other therapies aimed at mitigating kidney injury have been evaluated in various settings, including perioperatively.[47] The antioxidant alpha-lipoic acid (ALA) has been studied in renal ischemia-reperfusion injury, with adequate results.[48] Propofol, a common anesthetic, has proven to be superior to volatile anesthetics for renal protection in multiple studies.[49–51] Both ALA and propofol are known antioxidants, which may be beneficial in reducing the deleterious oxidative effects associated with AKI.

Glucose

Serum glucose should be routinely evaluated in the perioperative setting for hyperglycemia, especially in those CKD patients who have concomitant diabetes mellitus. Hyperglycemia (glucose values >200 mg/dL) has been found to be very common in the perioperative setting, occurring in 21%–41% of diabetic surgical patients, and is associated with perioperative morbidity and mortality in this population.[52,53] There are no data on perioperative outcomes of CKD patients with hyperglycemia. However, a cohort study found that chronic hyperglycemia (defined as HbA1c greater than or equal to 6.0%) was independently associated with AKI in patients undergoing CABG.[54] In addition, CKD was associated with worse outcomes in diabetic patients undergoing percutaneous coronary intervention in a retrospective analysis by Nikolsky et al.[55] Moreover, it has been shown that poor glucose control in diabetic CKD patients is associated with increased mortality.[56,57] Elevations in serum glucose can be corrected with parenteral insulin. Current guidelines recommend moderate glucose control, based on a preponderance of evidence.[58,59]

Minerals

Calcium and phosphate abnormalities in CKD patients have been associated with increased all-cause mortality, although studies evaluating mineral abnormalities in the perioperative setting are lacking.[60] Mechanisms of morbidity are thought to be related to vascular calcification, abnormalities in the microcirculation, decreased myocardial contractility, nutritional deficits, and respiratory insufficiency. Abnormalities in mineral metabolism in CKD patients before surgery can be addressed through the use of phosphate binders, vitamin D supplementation, and calcium altering medications, such as bisphosphonates and calcitriol. While calcitriol and other vitamin D analogues have been shown to reduce mortality in CKD patients, there are no data on perioperative outcomes with the use of these drugs specifically.[61,62] The use of bisphosphonates in CKD patients is controversial, as this population has typically been excluded from analysis.[63]

Hemoglobin

As kidney disease progresses, anemia can result from deficiency of erythropoietin, with commensurate diminished aerobic capacity and quality of life, as well as the potential for myocardial dysfunction.[64] Mild to moderate anemia has been associated with progression of renal injury, stroke, and death in surgical patients.[65] The degree of hemodilution during cardiopulmonary bypass was shown to be associated with worsening renal function necessitating renal replacement therapy in 9080 cardiac surgery patients, of whom 1818 had preexisting renal disease.[66] Additionally, incidences of myocardial infarction, shock, bleeding, multiple organ failure, and death were all increased in the setting of anemia (hematocrit <22%) in 5000 cardiac surgery patients, only 171 of whom had renal failure.[67] However, data on perioperative anemia in the CKD population are scant. A retrospective study of CKD patients undergoing hip and knee arthroplasty found that CKD patients, when compared with controls matched for age, gender, and type of orthopedic procedure, received significantly

more blood transfusions intraoperatively and during hospitalization.[68] The presence of CKD was independently associated with need for blood transfusion. Another prospective observational study analyzed preoperative hemoglobin and cardiac surgery outcomes in patients with CKD stages 3 to 5.[69] With every 1 g/dL decrease in preoperative hemoglobin, there was a higher risk of mortality, sepsis, cerebrovascular incident, and postoperative hemodialysis. Preoperative hemoglobin concentration below 12 g/dL was also an independent postoperative mortality risk factor. Therefore, blood transfusion, or alternatively treatment with erythropoietin-stimulating medications, may be appropriate perioperatively in the anemic CKD patient, but this practice is not data-driven and no randomized controlled trials exist to evaluate optimization of preoperative hemoglobin concentration in CKD patients.[23] Erythropoietin-stimulating medications have been used in the perioperative setting to reduce the need for blood transfusion, but these medications are associated with adverse cardiovascular, cerebrovascular, and thrombotic events.[70] Additional studies are needed to address the timing, dose, duration, and safety of erythropoietin-stimulating medications in the perioperative period.[71] Guidelines currently recommend transfusion of CKD patients to a hemoglobin level of 11–12 g/dL, although this recommendation is not specific to surgical populations.[72]

BUN

Patients with CKD are considered to have higher risk of bleeding from uremic platelet dysfunction, which can occur even though a coagulation evaluation is normal.[73] Some studies, however, suggest that blood from CKD patients is prothrombotic, and that concomitant anemia is responsible for perioperative bleeding. Red blood cell transfusion to a hematocrit of 26% has been shown to shorten bleeding time.[74] Correction of the effects of uremia, either by lowering BUN with dialysis or reversing the antiplatelet effects of uremia with deamino-8-D-arginine vasopressin (DDAVP), cryoprecipitate, or intravenous conjugated estrogens can address the risk of perioperative bleeding.[75] Dialysis acts to remove uremic toxins which are associated with coagulopathy, including urea, creatinine, phenol, phenolic acids, and guanidinosuccinic acid.[76–78] DDAVP is administered intravenously at a dose of 0.3 μg/kg and causes the release of von Willebrand factor from the vascular endothelium, which in turn enhances platelet aggregation.[78] DDAVP is effective within 30 minutes and lasts for four hours.[79] Estrogens do not become effective until 6 hours after administration, but effects last for 2–3 weeks.[75] The mechanism of action is thought to be related to interference with the nitric oxide synthetic pathway.[78] Importantly, aspirin-mediated platelet dysfunction in CKD patients with concomitant cardiovascular disease may be desired, and reversal of this effect with DDAVP, platelet transfusion, or estrogen therapy may increase the risk of perioperative acute coronary syndrome. Studies assessing the cost benefit of reversal of platelet dysfunction are lacking. Platelet mapping studies with thromboelastography (TEG) may assist the clinician in quantifying the level of platelet dysfunction and are more informative than the standard coagulation studies and platelet count.

Potassium

No specific recommendation exists regarding a safe potassium level before surgery. Historically, hyperkalemia has been associated with increased hospital mortality.[80,81] In CKD patients, hyperkalemia is likewise associated with increased mortality, although the presence and severity of CKD was associated with a lower odds ratio of potassium-related mortality compared with non-CKD patients.[82] Hyperkalemia is thought to be associated with up to 5% of all deaths among ESRD patients.[83] Studies on surgical mortality directly related to hyperkalemia, however, are lacking.[84–86] Singh Mangat et al. evaluated serum potassium (S[K]) levels perioperatively as a secondary endpoint and found no correlation between potassium levels and mortality.[12] Hyperkalemia is thought to predispose to ventricular arrhythmia, and sudden increases in S[K], such as encountered occasionally with the use of certain anesthetics or depolarizing agents, are generally best avoided. Consensus opinion is that most anesthesiologists avoid depolarizing anesthetic agents when S[K] is above 5.5 mEq/L. However, a number of studies report no adverse events with depolarizing agents, despite S[K] above this level.[87,88] Hypokalemia has likewise been evaluated in the perioperative setting and is associated with serious perioperative arrhythmias and the need for cardiopulmonary resuscitation.[34] Furthermore, low S[K] is associated with worsening renal function in the CKD population.[33] Evaluation of hyperkalemia or hypokalemia in the perioperative setting should be corroborated with evidence of myocardial instability by electrocardiography or rhythm monitoring.

Sodium

The loss of sodium regulation is a recognized risk factor for development of ESRD.[89,90] Hyponatremia may lead to worse surgical outcomes in patients with CKD. A retrospective study showed increased mortality and LOS in the ICU among patients with S[Na] <135 mEq/L compared with patients with S[Na] ≥135 mEq/L.[91] Logistic regression showed that hyponatremia was an independent risk factor for mortality and need for dialysis. Of note, although rates of congestive heart failure were similar in both groups, left ventricular dysfunction

was more prevalent in the hyponatremia group and may explain some of the risk seen with hyponatremia. A large retrospective cohort study by Leung et al. found that preoperative hyponatremia was associated with a higher risk of 30-day mortality (5.2% vs. 1.3%; adjusted odds ratio [aOR], 1.44; 95% CI, 1.38−1.50).[92] In subgroup analysis, dialysis-dependent patients exhibited a smaller but still significant increased risk of perioperative mortality.

Electrocardiography

Given the increased cardiac risk in CKD patients, an electrocardiogram (ECG) should be performed as part of the preoperative evaluation. Left ventricular hypertrophy (LVH) can signal long-standing or difficult-to-control hypertension. In ESRD patients, LVH on ECG was associated with cardiovascular mortality.[93] Evidence of myocardial electrical abnormality, such as peaked T waves in hyperkalemia or prolonged PR or QT segments as seen in hypokalemia can suggest electrolyte instability, although such ECG findings are unreliable.[94,95] ST segment changes and the presence of Q waves can signify current or prior myocardial infarction and the presence of coronary artery disease and may prompt an additional preoperative evaluation, such as echocardiogram or myocardial stress testing according to the ACC/AHA guidelines.[21]

Intraoperative Volume and Blood Pressure Management

The perioperative maintenance of euvolemia and adequate renal perfusion pressure is important in preventing postoperative AKI. At baseline, only 10−20% of the total renal blood flow of 1−1.5 L/min is filtered through the glomeruli, which still delivers adequate oxygen to the renal medullary parenchyma.[38] However, because of renal autoregulation and tubuloglomerular feedback mechanisms, reduced renal blood flow has a disproportionately large effect on GFR.[38] Hence, a drop in systolic blood pressure, either because of hypovolemia or vasodilation, can cause kidney hypoxia and ischemia, as well as render the kidney susceptible to further insult. On the other hand, fluid overload in the setting of CKD may be associated with progression of renal disease, as well as altered gut permeability and a maladaptive inflammatory response.[96] Patients with CKD have an impaired ability to excrete sodium, as well as dilute and concentrate urine in response to alterations in sodium and water intake.[97] As such, they are predisposed to the development of volume overload related to the dysregulation of free water distribution on receiving a sodium load.[37] Administration of saline solutions, as is common in the operative setting, can lead to the development of metabolic acidosis in patients with CKD.[98] In general, perioperative fluid administration has been associated with deleterious effects on cardiac, pulmonary, renal, and gastrointestinal function.[99] Therefore, it behooves the clinician to avoid *both* hypovolemia and hypervolemia in the perioperative setting. This is not always easy to do, as traditional signals of volume status may be misinterpreted in CKD patients. Intraoperative urine output repeatedly has been shown to poorly predict postoperative renal function.[100,101] Moreover, many of the anesthetics and analgesics as well as beta blockers may mask some of the features of hypovolemia, such as tachycardia.[40]

Determination of volume responsiveness (i.e. whether the patient's hemodynamic profile would improve with the administration of a volume challenge) can be made using a number of different dynamic tools, including the pulmonary artery catheter, pulse contour analysis, esophageal Doppler, or inferior vena cava diameter.[102] These tools have largely replaced the static measurements of volume status, such as central venous pressure and pulmonary artery occlusion pressure, which have been shown in numerous studies to poorly correlate with volume responsiveness.[103,104] There are a number of excellent review articles which explore volume management in the critical care environment.[102,105,106] The method of determining volume responsiveness is patient-, clinician-, and institution-specific.

Traditionally, perioperative fluid management has consisted of providing "maintenance" fluid with bolus administration in patients with hypotension or reduced urine output.[107] However, based on a number of studies that associate positive fluid balance with worse outcomes, emerging opinion is such that relative hypovolemia (i.e. a restrictive fluid balance) is a superior strategy in the perioperative setting.[108−112] A restricted crystalloid fluid strategy in thoracic surgery patients was not associated with development of AKI even in patients with decreased preoperative renal function.[113] Furthermore, a meta-analysis of patients undergoing colonic resection found that perioperative fluid restriction did not affect postoperative mortality, although this study was not conducted solely in CKD patients.[114] Commonly, the Enhanced Recovery After Surgery pathway may be used for fluid management during abdominal surgery.[115] This pathway facilitates euvolemia during surgery *via* a fluid replacement rate of 0.5 mL/kg/h, which is thought to be the insensible loss during abdominal surgery. Moreover, intraoperative dynamic measures of fluid responsiveness such as stroke volume variation are increasingly being used,[115] although these fluid management strategies have not been studied in randomized controlled trials in CKD patients. Nonetheless, it is reasonable to adopt a protocolized approach based on

frequently obtained objective measures in CKD patients undergoing major surgery.

In instances of hypovolemia and inadequate renal perfusion when fluid administration is needed, generally crystalloid or blood products are given. The choice of crystalloid is subject to debate, as recent data have emerged linking chloride-rich fluids to a higher incidence of AKI and renal replacement therapy.[116] Administration of balanced solutions, such as lactated ringers or Plasma-Lyte® 148 (Baxter Healthcare), may be associated with superior renal hemodynamics compared with administration of normal saline.[117] Administration of lactated ringers solution was compared with normal saline in patients undergoing renal transplantation and found to be associated with fewer incidents of hyperkalemia and metabolic acidosis.[98] Normal saline was compared with Plasma-Lyte® in an observational study of patients undergoing open abdominal surgery and found to be associated with higher mortality and perioperative complications.[118] Numerous studies have evaluated sodium bicarbonate solution as a resuscitative fluid strategy for the prevention or mitigation of AKI.[119–122] None of these, however, specifically focus on the CKD population.

Colloidal solutions may be preferred when the clinician desires to minimize extravascular volume, such as in cases of worsening pulmonary edema or abdominal compartment syndrome. The choice of colloids is also debatable. Starch solutions have been found to be associated with adverse outcomes (including bleeding, renal failure, and death).[123,124] In contrast, the SAFE Investigators evaluated normal saline vs. a 4% albumin solution and found no differences in death, organ failure, LOS, or days of renal replacement therapy.[125] Specialty solutions, such as mannitol or hypertonic saline, have been examined in CKD patients. Occasionally, mannitol is used in CABG patients to increase renal blood flow and appears to be effective.[126] In the authors' opinion, blood transfusion may be an appropriate colloidal resuscitative strategy in anemic CKD patients, in light of the impact of a low hematocrit on perioperative outcomes. Importantly, there is a paucity of research comparing clinical outcomes related with perioperative resuscitation with crystalloids compared with blood products. Moreover, the optimal fluid strategy in CKD patients has never been elucidated, and additional research is required on this topic.

Operative hypotension has been shown in multiple studies to be associated with the development of AKI.[127,128] Walsh et al. examined perioperative data for 33,330 patients undergoing noncardiac surgery and found that the probability of AKI increased with low MAP during surgery, an effect that was time sensitive.[127] Vasopressor therapy is frequently used in the perioperative setting, especially when fluid resuscitation is unable to achieve desired MAP goals or when a restrictive fluid resuscitation strategy may be desired. The choice of vasopressor agent may have clinical implications in the CKD population. Evidence is beginning to support the use of noncatecholamine therapy (vasopressin and angiotensin II) in patients at risk for AKI.[129–131] Subgroup and *post hoc* analyses of both the vasopressin vs. norepinephrine infusion in patients with septic shock (VASST) and the Angiotensin II for the Treatment of High Output Shock (ATHOS-3) trials both found improved kidney outcomes in septic shock patients treated with noncatecholamine pressors.[129,132] The Vasopressin vs. Norepinephrine in Patients with Vasoplegic Shock after Cardiac Surgery (VANCS) randomized controlled trial found that postoperative cardiac surgery patients with vasoplegic shock treated with vasopressin exhibited significantly lower incidence of AKI (10.3% vs. 35.8%, OR 0.26 (0.15–0.46), $p < 0.0001$).[133] Importantly, there are no studies specifically evaluating the choice of vasopressor in the CKD population. However, the effects of intrinsic vasopressin and angiotensin II on kidney function are well described.[134,135]

The drug levosimendan, a calcium sensitizer, has shown some ability to mitigate AKI in an operative setting. A *post hoc* study evaluated renal outcomes in patients with circulatory shock or heart failure (preoperative LVEF <25% and/or perioperative hemodynamic support with intraaortic ballon pump or inotropes) who underwent mitral valve surgery.[136] A significant decrease in the incidence of AKI (30% vs. 52 %, $p = 0.035$) and major complications (39% vs. 66%, $p = 0.011$) was seen in the levosimendan group compared with the placebo group. Two other randomized controlled trials have evaluated levosimendan in the postoperative setting and found no major differences in renal biomarkers or renal outcomes.[137,138] As of the publication of this chapter, levosimendan is not approved by the US Food and Drug Administration for clinical use.

Intraoperative hypertension is common (up to 80% of the cardiac surgery population and up to 25% of the noncardiac surgery population) and can contribute to complications such as myocardial ischemia, stroke, neurocognitive dysfunction, and surgical bleeding.[139] Intraoperative stressors such as endotracheal intubation and surgical incision are associated with increased sympathetic tone and consequent hemodynamic responses. The intravenous beta blockers esmolol and labetalol are short acting, easily titrated, and well-tolerated in the operating theater and can attenuate the hemodynamic responses of these stimuli.[140] Nicardipine, a dihydropyridine calcium channel blocker, is an appropriate alternative when beta blockade is contraindicated (such as in patients with asthma or bradycardia). Little

data exist, however, comparing intraoperative antihypertensive strategies in the CKD population. An optimal intraoperative blood pressure is determined in part by the observed blood pressure in the preoperative setting and by the type of surgery contemplated.[141] Notably, a mean arterial pressure of 65–75 mm Hg may result in underperfusion of the kidneys in the chronically hypertensive patient.[40,73] A randomized trial evaluated outcomes after major abdominal surgery in elderly hypertensive patients who were stratified by different MAP goals (65–79 mm Hg, 80–95 mm Hg, or 96–110 mm Hg).[142] The group with the intermediate MAP goal experienced less AKI, a lower rate of ICU admission, shorter length of ICU stay, and a lower incidence of hospital acquired pneumonia compared with those randomized to other MAP goals. Although this study did not specifically evaluate CKD patients, the results may nonetheless support higher blood pressure goals in patients likely to suffer from CKD (the elderly and those with high AKI risk). The Intraoperative Norepinephrine to Control Arterial Pressure trial tested two intraoperative blood pressure strategies in patients with a high risk of AKI: an "individualized" approach (targeted systolic BP within 10% of the patients' resting systolic BP) or a "standard" approach (systolic BP above 80 mm Hg or within 40% of the patients' resting systolic BP).[143] At enrollment, renal impairment was present in 11.7% of the standard therapy group, and 19.1% of the individualized therapy group. At 30 days, organ dysfunction was lower in the individualized strategy group, and there was no difference in 30-day mortality. However, renal-specific organ dysfunction was not different between groups.

TABLE 79.1 Drugs With Active or Toxic Metabolites Dependent on Renal Excretion[144]

Drug	Metabolites	Activity
Morphine	Morphine-3-glucuronide	Antanalgesic
	Morphine-6-glucuronide	Analgesic (40 x morphine)
Meperidine	Normeperidine	Neuroexcitatory
Diazepam	Oxazepam	Sedative
Midazolam	1-Hydroxy-midazolam	Sedative
Sodium nitroprusside	Thiocyanate	Neurotoxic
Enflurane	Fluoride	Nephrotoxic
Vecuronium	Desacetyl-vecuronium	Relaxant
Pancuronium	3-Hydroxy-pancuronium	Relaxant
Procainamide	n-Acetyl-procainamide (NAPA)	Neurotoxic

ANESTHESIA, ANALGESIA, AND NEUROMUSCULAR BLOCKING AGENTS

Induction Agents

Patients with CKD are at risk for adverse drug responses related to abnormalities in drug metabolism and elimination. Lipid insoluble drugs may be partially or completely dependent on renal function for adequate elimination. Lipid insoluble metabolites of lipid soluble drugs normally metabolized hepatically may also accumulate in patients with diminished renal function.[144] Table 79.1 lists commonly used medications with impaired clearance in renal failure.

Induction of anesthesia must be tailored appropriately to avoid these complications. Propofol is commonly used for induction and maintenance of anesthesia and has been found to be safe in patients with ESRD as well as CKD.[145,146] However, a higher dose of propofol may be required to reach the desired level of hypnosis as a result of altered plasma volume.[147] Propofol-related infusion syndrome (PRIS) is a rare complication of propofol administration, with several toxic metabolic effects including anion gap metabolic acidosis, rhabdomyolysis, and hyperkalemia and is of special concern and consideration in advanced CKD and ESRD patients, due to impaired potassium management.[148] The risk of PRIS is increased with duration of propofol administration, as well as with bolus dosing as part of rapid sequence intubation. Etomidate is safe in CKD patients.[147] Ketamine, too, is considered safe, but physicians must be aware of the side effects of hypertension and tachycardia when using ketamine.[149] Benzodiazepines are extensively protein-bound, and their effect is potentiated in CKD patients (where uremia alters protein binding activity). Moreover, many benzodiazepines are excreted by the kidneys, and repeated doses can accumulate, causing respiratory and cardiac depression.[149] For example, midazolam is metabolized to a renally excreted active metabolite, which is slow to clear in patients with diminished GFR.[150] Diazepam, compared with other benzodiazepines, is more extensively unbound to proteins, and doses should be adjusted downward in patients with CKD.[144]

The choice of induction agent may be patient-specific, given underlying morbidities. A retrospective study of patients with ST-elevation myocardial infarction showed that during rapid sequence intubation after

revascularization, midazolam was associated with more hypotension than ketamine,[151] which may be of particular concern to normotensive patients with CKD who might otherwise be served well *via* induction with ketamine.

Volatile Anesthetics

Inhalational anesthetics, such as halothane, desflurane, sevoflurane, isoflurane, and nitrous oxide, are eliminated by the lungs and are generally considered safe for use in CKD patients.[144] Initial concerns regarding elevated fluoride levels with the use of sevoflurane have abated, as studies have not demonstrated any evidence of adverse outcomes in the clinical setting.[152] Both sevoflurane and enflurane biodegrade into inorganiic fluoride, which can be nephrotoxic at a concentration of 50 μmol/L. This far exceeds measured fluoride levels after anesthetic doses of isoflurane and halothane, which cause an increase of 3−5 μmol/L and 1−2 μmol/L, respectively.[147] Conzen et al. found that neither sevoflurane nor isoflurane caused worsening of renal function in patients with preexisting CKD.[153] Litz et al. compared desflurane and isoflurane in a population of patients with preexisting renal disease and also found no deterioration in renal parameters such as creatinine clearance, S[Cr], and BUN level.[154] However, enflurane is best avoided, as it can cause a concentration defect in kidneys of healthy volunteers and has been associated in case reports with renal failure in CKD patients.[155,156]

Neuromuscular Blocking Agents

Administration of the depolarizing neuromuscular blocking agent succinylcholine is associated with the development of hyperkalemia, and this drug should be used with caution in CKD patients. Historically, succinylcholine has been considered safe for induction of anesthesia in patients with CKD who have normal preoperative potassium levels.[157] In these patients, S[K] levels were observed to increase by approximately 0.5 mEq/L for 10−15 minutes without the occurrence of arrhythmia.[158] Large or prolonged doses of succinylcholine should be avoided, as the active metabolite succinylmonocholine is renally excreted.[149] Nondepolarizing agents are not associated with hyperkalemia, but still must be used with caution due to altered pharmacokinetics and decreased elimination in renal failure. Vecuronium and rocuronium are primarily excreted in the bile, but partially eliminated through the kidney, and can exhibit a prolonged effect due to reduced renal clearance.[159−161] They are, however, fairly safe and predictable in renal failure.[160] Atracurium and the derivative cisatracurium are both metabolized by spontaneous nonenzymatic (Hoffmann) degradation and ester hydrolysis, a process completely independent of kidney function. These muscle relaxants are considered safe in patients with renal failure, with the caveat that laudanosine (a metabolite of atracurium and to a lesser extent cisatracurium) has been shown to cause seizures in laboratory animals.[162]

Analgesics

Opioids are extensively used both for induction of anesthesia and analgesia and must be administered with caution in patients with CKD. Morphine is catabolized by the liver into several metabolites, including morphine-6-glucuronide, which has an analgesic potency 40 times that of the parent drug. Morphine-6-glucuronide is eliminated renally and may have a prolonged half-life of up to 27 hours in patients with renal failure.[163] Morphine-6-gluconoride can accumulate in renal dysfunction and can potentially lead to severe, life-threatening side effects including respiratory depression, altered mental status, and myoclonus.[164] Consequently, morphine doses should be reduced in the CKD patient. Fentanyl is metabolized extensively in the liver and does not have active metabolites. A small percentage of fentanyl is excreted in the urine and clearance is reduced in patients with CKD.[165,166] One potentially appealing opioid for use in CKD patients is remifentanil, which undergoes degradation by ester hydrolysis, independent of renal function.[149]

Other analgesics which are not used for induction of anesthesia but rather for perioperative pain control include other opioid derivatives, nonsteroidal antiinflammatory drugs (NSAIDs), and acetaminophen. Hydromorphone is an opioid which is extensively metabolized by the liver to several renally excreted metabolites including hydromorphone-3-glucuronide, which has been associated with cognitive dysfunction and myoclonus.[167] Meperidine is metabolized to an active metabolite normeperidine, which has been associated with seizure activity in CKD patients and hence should be avoided in kidney failure.[168] NSAIDs affect renal function and can precipitate AKI *via* inhibition of prostaglandin-mediated renal blood flow. As such, they may be unsafe in patients with CKD, especially after surgery.[22,23,37,38,40,73] NSAIDs have been associated with adverse cardiovascular events and are known to exacerbate hypertension, hyperkalemia, and progression of AKI.[37,169] Acetaminophen is considered safe in the CKD population and can be used as an adjunct in pain management or as monotherapy.[170]

POSTOPERATIVE MANAGEMENT

There is little research guiding postoperative management of the CKD patient. Rather, the intensivist should use sound clinical judgment and common sense. Extubation should not be contemplated before a complete assessment of vital signs and airway reflexes, due to the possibility of reduced clearance of anesthetics and paralytics. Volume status should be carefully determined, as diuresis may be challenging in the setting of reduced renal blood flow, and early extubation may be associated with pulmonary edema. Analgesia in the postoperative setting can be difficult to manage, owing to altered pharmacokinetics of many of the commonly used analgesics. Blood pressure, fluid status, and mineral metabolism are dysregulated in the CKD population, and outpatient medications should be resumed when possible. It is prudent to involve the nephrologist postoperatively in the event that the patient may require renal replacement therapy.[38] Nephrotoxic medications should be avoided, and radiocontrast dye exposure should be minimized in postoperative CKD patients. Immunosuppressive therapy, if needed, should be dose-adjusted and monitored by serum level in patients with CKD who experience change in renal function after surgery. These drugs can cause side effects, including hypertension, hyperlipidemia, hyperkalemia, diabetes mellitus, neurotoxicity, and worsening of renal function.[37] Other aspects of postoperative care, such as nutrition, early mobility, and transition to home and should be considered an important aspect of any postsurgical care plan.[171–173]

CONCLUSION

The perioperative management of CKD patients continues to provide a challenge to their physicians. Close consideration must be given to the fluid and electrolyte disturbances associated with the underlying renal insufficiency as well as altered drug clearance and metabolism. In addition, the presence of several comorbid conditions such as diabetes mellitus, systemic hypertension, and cardiovascular disease are associated with worse outcomes and must be factored into a perioperative risk assessment. The avoidance of AKI, the correction of electrolyte, mineral and volume abnormalities, and the improvement of perioperative anemia can mitigate an adverse postoperative course. A multidisciplinary approach, consisting of the nephrologist, primary care physician, surgeon, anesthesiologist, and intensivist is required to optimize surgical success in the CKD patient.

QUESTIONS AND ANSWERS

Question 1

A 54-year old man is admitted with ischemic colitis and is scheduled for a right hemicolectomy. The patient has a history of diabetes mellitus, hypertension, and stage 4 CKD. Urinary protein excretion is less than 500 mg protein per day. On physical examination, his blood pressure is 190/80 mm Hg and pulse is 80 beats per minute. His jugular venous pressure is 10 cm, lungs are clear, heart sounds are normal, and abdomen is soft with slightly tender right lower quadrant. There is 1+ peripheral edema. The following labs are obtained:

S[Na] 129 mEq/L
S[K] 5.2 mEq/L
S[Cl] 105 mEq/L
tCO2 18 mEq/L
BUN 38 mg/dL
S[Cr] 2.7 mg/dL
Glucose 82 mg/dL

Which of the following intravenous fluids should be used during the operative case?

A. 3% hypertonic saline
B. The patient should not be given any fluid unless signs of hypotension become apparent
C. Normal saline
D. Lactated Ringer's solution
E. Balanced isotonic salt solution (e.g. Plasmalyte or Isolyte)

Answer: E

Chloride-rich solutions cause acidemia, and in this patient are likely to exacerbate the patient's hyperkalemia. Therefore, A and C are wrong. Maintenance fluid during exploratory laporatomy is standard of care. Waiting for hypotension to occur before intervening is not appropriate perioperative care. Therefore, B is wrong. Lactated Ringer's solution is not an optimal choice because the solution is hypotonic and the patient is already hyponatremic. Therefore, Answer D is wrong.

Question 2

Which of the following platelet function tests predicts bleeding in CKD patients?

A. Bleeding time
B. Thrombin time
C. TEG
D. Blood smear

Answer: C

Bleeding time is an invasive test characterized by high interoperator variability. In addition, it does not predict bleeding. Thrombin time is not a platelet assessment. The blood smear is qualitative and does not predict bleeding. The answer is C, TEG, which can elucidate platelet dysfunction and other bleeding diatheses.[174,175]

Question 3

Which of the following antihypertensive agents can be safely administered to CKD patients before surgery?

A. ACEIs
B. Beta blockers
C. ARBs
D. Nifedipine

Answer: B

Beta blockers can be safely prescribed to CKD patients before surgery. Both ACEI and ARB have been associated with AKI during the perioperative period and their continued use throughout the perioperative period is controversial. There are no data on the use of nifedipine in CKD patients in the perioperative setting.

Question 4

Which of the following paralytic agents should be avoided in a patient with stage 4 CKD who is about to undergo burn debridement surgery?

A. Pancuronium
B. Cisatracurium
C. Succinylcholine
D. Vecuronium

Answer: C

Succinylcholine is a depolarizing paralytic and is associated with hyperkalemia. In general, avoidance of this drug in a patient population that has a tendency to develop acidemia and hyperkalemia is warranted. In burn injuries, in particular, the development of hyperkalemia should be anticipated, due to extensive tissue damage.

Question 5

A 64-year-old woman is admitted with wet gangrene of the lower left extremity and is being taken to the operating room for debridement and possible amputation. The patient has a history of diabetes mellitus, hypertension, obstructive sleep apnea, and stage 3 CKD. Urine protein excretion is less that 100 mg/day. On physical examination, her blood pressure is 90/60 mm Hg and pulse is 130 beats per minute. The patient's lungs are clear, heart sounds are normal, tachycardic, and abdomen is soft. Left lower extremity from the ankle

down is dark, cool, and edematous with purulence and crepitus. The following labs are obtained:

Serum electrolytes:

S[Na] 139 mEq/L
S[K] 6.2 mEq/L
S[Cl] 105 mEq/L
tCO2 12 mEq/L
BUN 38 mg/dL
S[Cr] 3.5 mg/dL
Glucose 82 mg/dL
S[Cr] 2 months ago was 2.2 mg/dL.

The anesthesiologist indicates that he prefers colloid to crystalloid and but wants to preserve kidney function and avoid adverse events during and after surgery. The most appropriate treatment strategy is

A. There are no data to indicate benefit or harm for any colloidal solution compared with any crystalloid solution, so avoid hypotension, dose the medications appropriately, and avoid aminoglycosides
B. Use renal dose dopamine along with a balanced salt solution
C. Noncatecholamine vasopressor agents should be avoided, and resuscitation should be accomplished with blood products
D. While perioperative starch solutions have been shown to improve perioperative outcomes in surgical patients, for this patient any form of starch should be avoided due to the risk of nephrotoxicity

Answer: D

Answer A is wrong because the use of many colloids (i.e. startch solutions) has been shown to be potentially harmful. Answer B is wrong, as there is no role for renal dose dopamine in the preservation of renal function in CKD patients. Noncatecholmine vasopressor agents may confer benefit over catecholamines so Answer C is wrong. The answer is D, as multiple colloidal solutions compared with crystalloids have been preferentially used in the perioperative period with improved outcomes; however, starch is a known nephrotoxic agent and should be avoided in a patient with AKI superimposed on CKD.

Question 6

A 77-year-old man is admitted with worsening heart failure from ischemic cardiomyopathy. He has noticed increasing shortness of breath with exertion, orthopnea, and swelling of his lower extremities. On physical examination, his blood pressure is 90/60 mm Hg and pulse is 110 beats per minute. His jugular venous pressure is 18 cm, rales are heard bilaterally, S1, S2, and an S3 gallop are present, abdomen is soft and nontender but his liver is enlarged, and there is 4+ peripheral edema. Cardiac catheterization shows multivessel disease, and the patient is scheduled for bypass surgery.

The following laboratory tests are obtained:

Serum electrolytes:

S[Na] 142 mEq/L
S[K] 3.4 mEq/L
S[Cl] 107 mEq/L
tCO2 18 mEq/L
BUN 38 mg/dL
S[Cr] 1.7 mg/dL
Glucose 82 mg/dL
Hemoglobin: 7.5 g/dL
Platelets: 150,000 mm^3

Which **one** of the following is the most appropriate recommendation?

A. As the patient is volume overloaded, the patient should have a catheter placed intraoperatively and be started on ultrafiltration postoperatively
B. The patient is severely anemic and should be started on erythropoietin
C. The patient is volume overloaded and should be immediately diuresed before undergoing surgery
D. The patient should be placed on fenoldopam during the perioperative period
E. The patient has CKD and has been exposed to radiocontrast, thus the perioperative management should avoid NSAIDs if possible.

Answer: E

Administration of erythropoietin is not indicated and has been associated with thrombotic events; thus, Answer B is wrong. The management of fluid overload remains controversial, but preoperative dialysis has not been shown to be superior to standard expectant management, so Answers A and C are wrong. D is incorrect because fenoldopam has not been shown to alter outcomes in patients undergoing CABG.

CHAPTER

Ethical Issues in Chronic Kidney Disease Patients

Alvin H. Moss

Center for Health Ethics and Law, Robert C. Byrd Health Sciences Center, West Virginia University, Morgantown, WV, United States

Abstract

Patients with stage 3–5 chronic kidney disease (CKD) have increased rates of cardiovascular mortality and cognitive impairment and are more likely to die than progress to end-stage renal disease. Because of their distinctly worse prognosis compared with age-matched patients in the general population, treatment of these patients raises ethical issues which require special consideration. These include matters pertaining to informed consent, shared decision-making, advance care planning with the completion of advance directives and Physician Orders for Life-Sustaining Treatment (POLST) forms as appropriate, the "biomedicalization" of aging, conflicts of interest in clinical practice guideline development for patients with CKD, and the ethical responsibility for particularly careful management of patients with CKD. Shared decision-making is the model for advance care planning and emphasizes an individualized patient-centered approach focusing on the patient's goals of care vs. a disease-oriented approach to treatment of CKD patients. Informed consent is especially important for older stage 5 CKD patients with multiple comorbidities because they may not benefit from dialysis. The "biomedicalization" of aging as it relates to the use of dialysis in older Americans is a key concern. Palliative care is appropriate for CKD patients with a poor prognosis and for whom the nephrologist would not be surprised if the patient died in the next year. Palliative care should be instituted early in their course so that they experience an optimal quality of life.

A critical population for nephrologists is stage 3–5 chronic kidney disease (CKD) patients who would not be considered candidates for kidney transplantation. There is a maxim in ethics, "Good ethics starts with good facts." The starting point for an ethical discussion of CKD is that the CKD population is distinctly different from age-matched patients in the general population, and this difference forms the basis for an approach to their treatment that is ethically directed and takes into account the unique nature of CKD. This uniquely different approach is justified by a foundational principle in medical ethics, the principle of formal justice, which states that people who are equal in relevant respects should be treated equally, and that people who are unequal in relevant respects should be treated differently.[1] In three large studies of CKD populations, death is a more common outcome than end-stage renal disease (ESRD).[2–4] Compared with the age-matched population without CKD, patients at all stages of CKD have increased rates of all-cause mortality and cardiovascular mortality that progress with advancing CKD.[5] Cognitive impairment is also highly prevalent in CKD patients. Epidemiologic data suggest that individuals at all stages of CKD have a higher risk of developing cognitive disorders and dementia.[6] Consequently, the ethical questions of "Who should decide?" and "What should be decided?" as they relate to decisions about initiating or forgoing dialysis are particularly germane.

Key ethical tasks exist in the treatment of patients with CKD. CKD is a life-limiting illness which should trigger an informed consent process and advance care planning long before the initiation of dialysis. Shared decision-making is the model for advance care planning which emphasizes an individualized patient-centered approach focusing on the patient's goals of care rather than using a disease-oriented approach to treatment of CKD patients. The communication of decisions reached as a result of shared decision-making to family and loved ones and their implementation by completion of advance directives and Physician Orders for Life-Sustaining Treatment (POLST) Paradigm forms is appropriate. The influence of our culture, in which there has been a "biomedicalization" of aging as it relates to the use of "life-extending" dialysis in older Americans, needs to be recognized and explicitly addressed in decision-making. Conflicts of interest in the treatment of CKD, including in the creation of the Kidney Disease Outcomes

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00080-2

Quality Initiative (KDOQI) clinical practice guidelines, need to be appreciated, and the ethical concerns raised by industry funding of clinical practice guideline development need to be factored into decisions regarding whether to comply with the guidelines for all patients. Considerations regarding conflicts of interest must be taken into account in the creation of kidney-specific clinical practice guidelines in the future. Because of the range of choices, there is an ethical obligation to include patients in decision-making about the treatment for their kidney disease and to offer the options of active medical management without dialysis and palliative care for CKD patients who decide to forgo dialysis.[7,8]

ILLUSTRATIVE CASES

The following cases require the ethical tasks identified above to be implemented into the patients' treatment for them to receive the best care possible.

The first case is that of Mr. A, a 90-year-old man who has hypertensive nephrosclerosis as a cause of stage 4 CKD with an estimated glomerular filtration rate (eGFR) of 20 mL/min/1.73 m^2. He is referred from his primary care physician for predialysis planning when his S[Cr] reaches 3.0 mg/dL. According to the accompanying medical records, his S[Cr] has been rising very slowly over the last few years. His hemoglobin is 10.5 g/dL, and he is not iron deficient. Aside from hypertension and anemia, he has no other comorbidities, and he is fully functional. He still drives and is the primary caregiver for his 87-year-old wife who has moderate to severe Alzheimer disease. They have no children, and there are no other family who live nearby. When asked if he would want dialysis in the future if he were to progress to ESRD, he says "Yes" because he wants to continue to be able to care for his wife. He was a member of the National Kidney Foundation for a few years and read a newsletter some time back about the KDOQI guidelines. He asks if he should be referred for placement of an arteriovenous fistula to prepare him for dialysis and if he should be started on erythropoietin injections to raise his hemoglobin level and improve his quality of life.

The second case is that of Ms. B, a 76-year-old woman with diabetic nephropathy, retinopathy, and peripheral neuropathy. She has stage 3 CKD with an eGFR of 34 mL/min/1.73 m^2. One year ago, she had a right above-the-knee amputation for peripheral arterial disease. After rehabilitation therapy, she has been residing in an assisted living facility. At the time of the vascular surgery, she had a myocardial infarction. She had three coronary artery stents placed during that admission. In the last 18 months, she has had increasing periods of confusion and memory loss. An MRI of the brain shows cortical volume loss greater than would be expected for her age, with changes of chronic microvascular disease. She was recently hospitalized for sepsis from pneumonia and required a prolonged period of mechanical ventilation in the intensive care unit. Her CKD progressed to near ESRD and has not recovered. Her eGFR is now 9 mL/min/1.73 m^2 and is progressively decreasing. She was discharged to a skilled nursing facility because she is more confused, deconditioned, and malnourished (S [Alb] 2.7 g/dL). She is no longer able to care for herself. She has a Karnofsky Performance Score of 40.

In her younger life, she was a school teacher and very independent. Ms. B never married or had children. She did not like people making a fuss over her. As her diabetes took more and more of a toll on her, she repeatedly said she did not want to be a burden on others. Ms. B has good days and bad days with her vascular dementia, but she lacks sufficient decision-making capacity to decide about dialysis initiation.

Her closest living relative is a niece, her sister's daughter. The niece was appointed the patient's healthcare surrogate. The nephrologist has recommended insertion of an arteriovenous graft to prepare Ms. B for dialysis, but at the same time he admits that her prognosis for long-term survival is not good. The niece is not sure what she should decide about starting dialysis for her aunt.

INFORMED CONSENT FOR TREATMENT OF CKD

Informed consent is the accepted medical practice for reaching decisions with patients about treatment. It is based on the well-established ethical principle of respect for patient autonomy and the legal doctrine of patient self-determination.[1] Informed consent is to be obtained from the patient if he/she has decision-making capacity or else from the person designated in the patient's advance directive to be the patient's designated decision-maker in the event the patient loses decision-making capacity. If the patient has not completed an advance directive naming a substitute decision-maker (called a healthcare proxy, medical power of attorney, durable power of attorney for healthcare, or healthcare agent, depending on the state), most state laws specify that a healthcare surrogate should be appointed to participate with the physician in an informed consent process to make decisions for the patient according to the patient's expressed wishes or best interest.

The elements of informed consent have been clearly articulated.[1] The elements include the following:

1. A patient with decision-making capacity (or his/her substitute decision-maker),
2. Voluntary nature of the decision,

3. Disclosure of the benefits and risks of the proposed and alternative treatments including no treatment,
4. Recommendations by the physician based on the patient's overall condition and values,
5. Assuring patient understanding of the recommendations and the reasons for supporting the recommendations,
6. The patient makes an informed decision, and
7. The patient authorizes the chosen plan (often including signing a consent form)

Informed consent for predialysis CKD patients needs to acknowledge that most dialysis patients have a poor prognosis. *The Shared Decision-Making in the Appropriate Initiation of and Withdrawal from Dialysis* clinical practice guideline recommends that in the informed consent process each patient should be given a patient-specific estimate of prognosis.[7] Based on the US Renal Data System (USRDS) report, age-adjusted all-cause mortality is 6–8 times higher for dialysis patients than for individuals in the general population. Among dialysis patients 65 years of age and older, mortality is twice as high as for patients in the general population who have diabetes, cancer, congestive heart failure, stroke, or acute myocardial infarction.[9] According to the 2018 USRDS Annual Data Report for 2013 incident patients, only 60% are still alive three years after the start of dialysis.[10]

The informed consent process for Mr. A would include a review of the patient's overall condition and the likelihood that he is much more likely to die from a nonrenal cause than to progress to the need for dialysis.[4] The physician would need to explain that more recent evidence since the KDOQI guidelines indicates that placement of an arteriovenous fistula is unnecessary because of the slow rate of CKD progression in the elderly[4] and that for the patient's degree of anemia treatment with erythropoietin is not beneficial.[11] Control of the patient's hypertension, monitoring his CKD and anemia, and treatment of other problems as they develop would constitute a reasonable treatment plan for which the physician should obtain verbal consent.

Studies have identified a population of CKD patients for whom the prognosis is particularly poor and for whom informed consent needs to be more detailed. This population has been found to include patients with two or more of the following characteristics: (1) elderly (defined by research studies identifying poor outcomes in patients who are 75 years and older); (2) patients with high comorbidity scores (modified Charlson Comorbidity Index score of 8 or greater); (3) marked functional impairment (Karnofsky Performance Status Scale score less than 40); and (4) severe chronic malnutrition (S[Alb] less than 2.5 g/dL using the bromcresol green method).[7]

Elderly patients, aged 75 years and older, with stage 4 or 5 CKD constitute a group for whom the informed consent process regarding initiation of dialysis requires special consideration of the risk:benefit ratio. Because of the severe comorbidities, functional impairment, and malnutrition of some elderly CKD patients, nephrologists should not take an "age-neutral" approach to the management of CKD patients. On the other hand, age alone should not constitute a contraindication to starting dialysis because comorbidity is an important determinant of outcome in dialysis patients. Age and comorbidity are additive in predicting dialysis patient survival.

Ms. B is a patient who has a particularly poor prognosis, and for whom informed consent needs to be more detailed. She has a number of factors that predict poor prognosis for long-term survival on dialysis, including comorbidities such as coronary artery disease, peripheral arterial disease, and dementia, her functional status, and her nutritional status with a low S[Alb]. Using an integrated prognostic model developed for patients with stage 4 and 5 CKD, she is calculated to have a 6-month predicted survival of 53.5% and a 1-year survival of 41.4% (https://qxmd.com/calculate/calculator_446/Predicting-12-Month-Mortality-in-CKD-patients). Given this predicted limited survival, her nephrologist should engage the niece in a discussion of whether dialysis is something Ms. B would want based on her prior expressed wishes.

As recommended by the American Society of Nephrology in the Choosing Wisely Campaign, before placement of an arteriovenous access or peritoneal dialysis (PD) catheter, elderly patients with stage 4 or 5 CKD and severe comorbidities should have a shared decision-making conversation about the benefits and burdens of dialysis for a patient in their particular condition.[12] Ms. B's case is a perfect example of a patient for whom this recommendation is appropriate. Adapted from the surgical literature, researchers have suggested using the "Best Case/Worst Case" approach to discussing renal replacement therapy options, including medical management without dialysis with older advanced CKD patients.[13] The "Best Case" for such patients on dialysis has been described as patients being tired but having some good days in between dialysis treatment days and experiencing more complications over time with an estimated survival of one to three years.[13] The purpose of the shared decision-making conversation is for nephrologists to learn their patients' values, preferences, and goals and to make treatment recommendations in alignment with them. Some older patients, especially those with a good support system who place a high value on life extension, may find PD at home an attractive renal replacement therapy option.

As part of the discussion, nephrologists should inform patients of the following information:

- Dialysis may not confer a survival advantage.
- Patients with their level of illness who are not already uremic are more likely to die than live long enough to progress to ESRD.[4]
- Life on dialysis may entail significant burdens that may detract from their quality of life, and many dialysis patients experience a deterioration of their quality of life once dialysis is started.[14]
- They may not experience functional improvement with dialysis and may undergo significant functional decline during the first year after dialysis initiation.[15]
- The burdens of dialysis include surgery for vascular or PD access placement and complications from the vascular access or PD catheter.
- They may experience adverse physical symptoms on dialysis such as dizziness, fatigue, and cramping, and a feeling of "unwellness" after dialysis.
- There will be travel time and expense to and from dialysis, long hours spent on dialysis, and a reduction in the time available for physical activity.
- Dialysis may entail an "unnecessary medicalization of death" resulting in invasive tests, procedures, and hospitalizations.[7]

SHARED DECISION-MAKING IN THE PROCESS OF ADVANCE CARE PLANNING

Shared decision-making is the recognized preferred model for medical decision-making because it addresses the ethical need to fully inform patients about the risks and benefits of treatments, as well as the need to ensure that patients' values and preferences play a prominent role. It is the recommended process by which healthcare professionals and patients come to agreement on a specific course of action based on a common understanding of the goals of treatment and the risks and benefits of the chosen course compared with any reasonable alternative.[7] Shared decision-making has been referred to as the pinnacle of patient-centered care.[16]

In shared decision-making, the healthcare provider is the expert in diagnosis, prognosis, and treatment alternatives, and the patient is the expert in his or her own history, values, preferences, and goals. Physicians and patients work together to reach decisions that are individualized to the patient's particular circumstances and preferences (see also Figure 80.1).

Advance care planning represents one way in which shared decision-making is implemented. Advance care planning is inherently patient-centered rather than disease-oriented because its purpose is to identify and respect an individual patient's future medical treatment wishes (Table 80.1). The purpose of advance care planning is to help patients understand their condition, identify their goals for care, and prepare them for the decisions that may have to be made as the condition progresses over time. Because complex comorbid conditions, impaired functional status, and limited life expectancy are more common among older patients with CKD, older CKD patients especially are less likely to benefit from a disease-oriented approach.[17] A disease-oriented approach would lead to automatic referral of older stage 5 CKD patients with comorbid conditions for dialysis evaluation and access placement. This present default with regard to CKD care leads to poor outcomes of CKD patients 75 years of age or older. They have a five-year survival on dialysis of about 15%, and their deaths are often characterized by very aggressive treatment including hospitalization, frequent intensive care unit admissions, and late referral, if at all, to hospice.[18]

The proposed goal of advance care planning for CKD patients is to align the treatment they receive with their preferences and to begin the process long before end-of-life treatment decisions are necessary. Commentators have proposed that advance care planning be a required portion of the kidney disease education benefit.[19] Another has suggested that for older CKD patients with a heavy burden of comorbid illness, active medical management without dialysis or what has been called "planned conservative management" be the default choice rather than HD or even a 90-day time-limited trial of HD. It is during the 90-day time-limited trial that such patients experience the highest morbidity and mortality risk from vascular access complications, infection, and other hospital-acquired disease.[20]

COMPLETION OF ADVANCE DIRECTIVES AND MEDICAL ORDER FORMS TO IMPLEMENT ADVANCE CARE PLANNING DECISIONS

Advance care planning may vary with the patient's clinical situation and level of involvement of family as well as intrafamily communication dynamics. Gillick has proposed four components of advance care planning:

1. Patient and family understanding of the patient's current overall medical condition.
2. Elicitation of the patient's goals of care based on an understanding of the patient's condition and obtainable goals.
3. Identification of the patient's preferred decision-maker in the event of incapacity and completion of an advance directive naming that person.

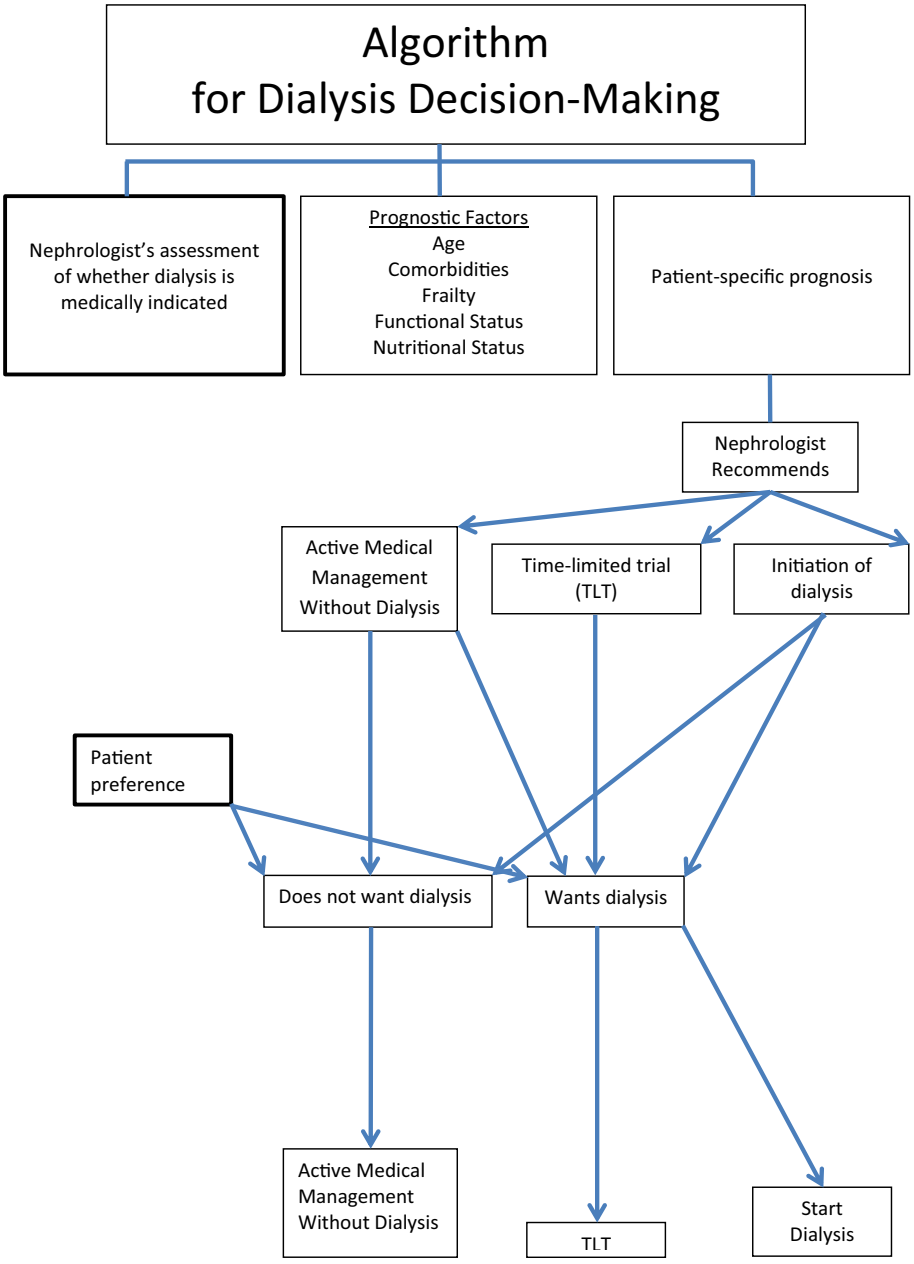

FIGURE 80.1 Implementation of the process of shared decision-making in deciding whether to initiate dialysis.

4. Completion of a POLST Paradigm form for seriously ill patients to translate the patient's wishes into medical orders that are respected throughout the healthcare system.[21]

POLST has been adopted by multiple states and regions (www.POLST.org) in response to inadequacies in general written advance directives.[22] Unlike living wills (instruction directives) or documents naming legal agents (proxy directives), POLST forms are signed physician orders directing treatments based on patient choice. In some states, nurse practitioners or physician assistants are authorized to sign POLST forms. POLST forms are especially appropriate for patients for whom the nephrologist would not be surprised if the patient died in the next year. The "surprise" question has been validated in primary care, CKD, and dialysis populations.[23,24] POLST forms have been shown to be effective in honoring patients' end-of-life treatment preferences, in part because they ensure continuity of orders for the patient across treatment settings. Where available, such documents are particularly applicable to many CKD patients and help to ensure that patients receive the treatment they want (Table 80.2).[25,26]

TABLE 80.1 Suggested Steps for Implementing Advance Care Planning in CKD Patients

- Recommend advance care planning at the initiation of overall treatment for patients with stage 3 or higher CKD
- Use a "No" response to the "surprise" question[24] as a trigger for advance care planning for CKD patients for whom it has not yet been conducted
- Assess decision-making capacity to determine if patient can complete an advance directive. Appoint a healthcare surrogate according to state law for patients who lack capacity
- Encourage patient-centered advance care planning among patients and families with completion of an advance directive as appropriate. Revisit advance care planning with each patient hospitalization and/or significant change in medical status
- Discuss advance care planning by asking:
  - What are your most important goals if your health gets worse?
  - What are your biggest fears and worries with regard to medical treatment?
  - If you become unable to make decisions for yourself, whom do you want to make decisions for you?
  - If you had to choose between being kept alive as long as possible regardless of personal suffering or living a shorter time to avoid suffering which would you choose?
  - In your condition, what is your understanding of the benefits and burdens of dialysis for you?
  - What are your current thoughts with regard to starting dialysis?
  - If you choose to start dialysis, under what circumstances, if any, would you want to stop it?
  - If your heart stops beating or you stop breathing, would you want to allow a natural death?
  - Under what circumstances, if any, would you not want to be kept alive with medical means such as cardiopulmonary resuscitation, a feeding tube, or mechanical ventilation?
  - Where do you prefer to die and who do you wish to be with you when you die?
- Document provider's discussion and understanding of patient's preferences in the medical record in a form in which it can be found on subsequent visits
- Where available, for seriously ill patients for whom the surprise question answer is "No" complete a Physician Orders for Life-Sustaining Treatment (POLST) or similar form to translate patients' wishes into medical orders (see www.polst.org)
- Place a copy of advance directives, DNR order card, and/or POLST form in multiple medical records as appropriate, including electronic medical record, statewide electronic advance directive and medical order registry, commonly attended clinics, hospital, nursing home, and home
- Encourage the patient, family, and/or legal agent to carry a current copy of the patient's advance directive, do not resuscitate order card, and/or POLST form whenever traveling or being admitted for overnight medical care

TABLE 80.2 Desired Outcomes of Advance Care Planning for CKD Patients[22]

- Enhance patient and family understanding about the patient's illness and end-of-life issues, including prognosis and likely outcomes of alternative plans of care
- Define the particular patient's key priorities in end-of-life care and develop a care plan that addresses these issues and identifies the patient's overall goals of care
- Enhance patient autonomy by shaping future clinical care to fit the patient's preferences and values
- Improve the process of healthcare decision-making generally, including (1) patient and family satisfaction with the advance care planning process; (2) healthcare provider understanding of advance care planning and advance directives; and (3) provider comfort in participating in advance care planning
- Help patients find hope and meaning in life and achieve a sense of spiritual peace
- Explore ways to ease the emotional and financial burdens borne by patients and families
- Strengthen relationships with loved ones
- Complete written advance directives, particularly those identifying a legal agent, do not resuscitate documents, and POLST documents where available
- Honor advance directives, do not resuscitate orders, and POLST orders at the end of life

THE "BIOMEDICALIZATION" OF AGING AND CONSEQUENCES FOR DIALYSIS DECISION-MAKING IN ELDERLY STAGE 5 CKD PATIENTS

Older patients are more likely to have CKD.[27] Of the estimated 29.7 million US residents with stage 3 and 4 CKD in 2011–2012, 31.5% of the 65- to 79-year olds and 65% of the 80 and older patients had CKD. Guidelines typically do not stratify their recommendations for older patients compared with younger adults, or consider the burden of comorbid illness. Older adults tend to have more comorbidities, increased mortality risk, and an increased risk of treatment-related adverse events. These factors are likely to alter guideline-projected benefits and harms of treatment for a single disease such as CKD. Simply said, most guidelines for CKD and ESRD patients underestimate the risk and overestimate the benefit for older patients.[28]

In this context, the processes of informed consent, shared decision-making, and advance care planning are particularly important to individualize decision-making and not take an "age-neutral" approach for older CKD patients.[4] Unfortunately, the US culture is moving in the opposite direction, and medical interventions such as dialysis are being normalized as necessary and appropriate to treat the problem of ESRD.[29] Old age is being transformed through clinical practices and medical innovations that lie at the heart of biomedicalization in the US.[30]

Effective clinical treatments for ever-older persons have led to an interesting turn in the biomedicalization of aging. There are said to no longer be technological or biological limits to what can be done, medically or surgically, for older persons. Biomedicalization has

resulted in an aged body being seen as a diseased entity in need of restoration and improvement. Medical anthropologists have described an incremental creep upward in the acceptable "normal" age range for aggressive, invasive medical interventions. The technological imperative—"If it can be done, it must be done"—has become a moral imperative for patients, families, and physicians. A diagnostic test confirms the "need" for an intervention. The performance of the intervention becomes routinized based on its clinical indication. Reasoned choice is said to be obfuscated by the need to treat, the routinization of the intervention, and the specter of future risk if the intervention is not undertaken. The aggressive dialysis treatment for an older stage 5 CKD patient with multiple severe comorbidities becomes standard practice. Commentators have described a new ethical field in our social fabric, the difficulty or impossibility of saying "no" to life-extending medical interventions. This new "field" has resulted in a blurring of the focus in medicine between cure, life enhancement, and life prolongation on the one hand and reducing the burden of disease and promoting comfort on the other. There is a new "ethics of normalcy" in which expectations about long lives and routine medical treatments have come together. It is no longer acceptable to die at age 91 if there is a medical treatment that might be able to prevent death regardless of what suffering might be entailed in the continued life.

Observers of the application of the technological imperative to implantable cardioverter-defibrillators (ICDs), another life-sustaining technology like dialysis, note that in the US two cultural moves—from new technique to standard technique, and then, from standard technique to ethical necessity—are evident in the growing trend to use aggressive interventions like dialysis and ICDs for older or sicker patients. The irony is that such interventions prolong debilitation, suffering, and the dying process, something which patients report they want to avoid.[31]

CONFLICTS OF INTEREST IN THE TREATMENT OF CKD

The National Kidney Foundation KDOQI clinical practice guidelines published in 2002 and updated in 2006[32] shifted the concept of kidney disease from that of an uncommon life-threatening condition requiring care by nephrologists to that of a common condition with a range of severity meriting attention by general internists. The guidelines not only had a major effect on clinical practice, research, and public health but also generated substantial controversy.[33,34]

There were four significantly controversial guideline recommendations. First, the extension of the diagnosis of CKD to a large percentage of the US population (10% at the time). Second, a recommendation for early preparation for arteriovenous fistula placement at 30 mL/min/1.73 m^2 eGFR, which resulted in many older CKD patients prematurely receiving surgery for access placement. Third, the recommendation of the upper range of the target for erythropoietin of 13 g/dL, which subsequently was shown to be not beneficial and possibly harmful.[11] Finally, the recommendation that patients be started on dialysis when their eGFR dropped to 10.5 mL/min/1.73 m^2, which subsequently was unsubstantiated by further research.[35]

Where there was insufficient evidence on which to base a recommendation, the National Kidney Foundation KDOQI workgroups used consensus opinion. Amgen, Inc. was the founding and principal sponsor of KDOQI. Additional support was provided by Baxter Healthcare Corporation, Fresenius USA, Inc., Genentech, Inc., and Watson Pharmaceuticals, Inc. There were disclosures provided for each workgroup member, but it was not possible to tell from the disclosures the extent of the relationships between the KDOQI guideline workgroup members and Amgen, Baxter, Fresenius, Genentech, and Watson.

The concern with regard to the development of KDOQI is that recommendations in the absence of solid evidence require subjective judgments. Such judgments naturally leave room for error and bias.[36] The process of the KDOQI guideline development has been criticized for its failure to adequately account for the influence of conflicts of interest and bias in the recommendations.[37,38] In their report on physician financial conflicts of interest in clinical care, the Association of American Medical Colleges cited the results of psychological research on how financial interests can distort medical decision-making.[39] They noted that when physicians stand to gain by reaching a particular conclusion, they tend to unconsciously and unintentionally weigh evidence in a biased fashion that favors that conclusion. Such weighing of the evidence can happen beneath the individual's level of awareness, such that a biased individual will sincerely claim objectivity. These studies explain how well-intentioned physicians can succumb to conflicts of interest and why the effects of such conflicts are so insidious and difficult to combat.[39]

In a study of the relationship between clinical practice guideline developers and the pharmaceutical industry, the majority of authors were found to have financial conflicts of interest, and 38% had served as employees or consultants for pharmaceutical companies.[40] The authors concluded that there was a high degree of interaction between authors of clinical practice guidelines and the pharmaceutical industry and that these interactions may influence the practice of a very large number of

physicians. They recommended a formal process for discussing the conflicts of interest before clinical practice guideline development.

The concern about trustworthiness of clinical practice guidelines prompted the Institute of Medicine at the request of the US Congress to develop eight standards for objective, scientifically valid, and consistent approaches to the establishment of guidelines.[41] A subsequent study of 114 guidelines demonstrated poor adherence to the Institute of Medicine standards, but the Institute of Medicine standards themselves have been criticized as being too inflexible and impractical to achieve.[42] The bottom line on clinical practice guideline development has yet to be found, but the need for an explicit, transparent process seems to be clear.[40]

The National Kidney Foundation KDOQI guidelines were created before there were standards for guideline development. It is not possible to assess to what extent, if any, KDOQI recommendations were biased by financial conflicts of interest. Subsequent continuing work by the Kidney Disease: Improving Global Outcomes effort, the successor to the KDOQI process, can take advantage of the scientific and ethical scrutiny that has occurred in the first decade of the 21st century with regard to guideline development.

THE ETHICAL RESPONSIBILITY FOR CAREFUL MANAGEMENT OF CKD PATIENTS

Because compared with the age-matched population without CKD, patients with all stages of CKD have increased rates of all-cause mortality, cardiovascular mortality, cognitive impairment, and dementia that progress with advancing CKD, physicians treating these patients are ethically obligated to do everything they can to identify and treat the risk factors for CKD, cardiovascular mortality, and cognitive impairment. This task is more difficult than it appears because in at least one study CKD was strongly associated with the incidence of dementia independent of age, sex, education, and other vascular risk factors.[43] Controlling hypertension to the recommended MDRD level of less than 130/80 mm Hg,[44] and treating hyperlipidemia and diabetes to achieve the target ranges to reduce the risk of atherosclerosis, are a good start, but may not be adequate to prevent the progression of CKD. Nephrologists and others treating CKD patients will need to keep abreast of the research to determine how best to slow the progression of CKD.

For patients with stage 5 CKD who choose to forgo dialysis, nephrologists will need to provide generalist palliative care and consult specialist palliative care as needed for refractory pain and symptom management; management of more complex depression, anxiety, grief, and existential despair; and assistance with conflict resolution regarding goals or methods of treatment.[45] Palliative and end-of-life care for CKD patients including systematic screening for symptoms provides them with the most optimal care (Table 80.3).[46]

TABLE 80.3 Recommendations for Palliative and End-of-Life Care in Chronic Kidney Disease

1. Identify patients who would benefit from palliative care interventions.
   a. Those with significant pain and symptoms. Screen with a simple tool such as the Edmonton Symptom Assessment Scale (ESAS)[46] which has been validated in ESRD.
   b. High risk of death within the next year. Consider using the "surprise" question, "Would I be surprised if this patient died in the next year?"[24]
2. Screen for and manage emotional, psychosocial, and spiritual distress; refer to allied health professionals as appropriate.
   a. The ESAS-Renal is also appropriate for screening for anxiety and depression. The PHQ-4 has also been validated and is brief.[45,47]
   b. A simple question such as "Do you have any spiritual needs or concerns that your healthcare providers may help address?" may be appropriate for screening for spiritual distress.
3. Assess patients' desire for prognostic information.
4. Enhance predialysis education.
   a. Educate regarding active medical management without dialysis option as appropriate
   b. Describe available palliative care and hospice services.
5. Provide routine advance care planning as described in Table 80.1.
   a. Ensure patients and families are aware of the relevance of these discussions (i.e. have an understanding of their overall health state and prognosis).
   b. Consider initiating advance care planning at the time that patients are being educated with respect to renal replacement options if not done already.
   c. Include discussions of patients' goals of care, health states for which the patient would not want or no longer want dialysis, and preferred location of death.
   d. Establish a substitute decision-maker in an advance directive.
   e. Ensure that family and other important people (as identified by the patient) are present for these discussions, especially the substitute decision-maker.
6. Increase access to specialist palliative care, including hospice.
7. Develop relationships with hospice providers that focus on sharing of care in active medical management without dialysis and transition of care from dialysis to hospice, bridging patients into hospice by decreasing frequency of dialysis treatments, and having the patient be in control of when they are ready to stop palliative dialysis.
8. Provide bereavement support to patients' families directly or through hospice services.

CONCLUSION

For patients with advanced CKD with progressive loss of kidney function, particularly those who are not candidates for kidney transplantation, nephrology professional societies and the medical literature recommend a shared decision-making discussion before the initiation of dialysis with a discussion of all renal replacement therapy options, including medical management without dialysis. In this discussion, particular attention needs to be devoted to the likelihood of benefits and burdens of dialysis for the patient based on the patient's prognosis and values, preferences, and goals. For older patients with significant comorbidities, a decision to initiate dialysis should not be automatic, because dialysis may not offer a survival benefit. Whether the patient chooses to start dialysis or not, a palliative care approach not only to the goals of care discussion but to meticulous pain and symptom management can improve patients' quality of life and satisfaction with care.

QUESTIONS AND ANSWERS

Question 1

Which one of the following is an advantage of the POLST form compared with an advance directive?

A. It is legal in all fifty states
B. It is an immediately actionable medical order
C. Checklist format prevents contradictory orders from being issued
D. It is appropriate for patients in all stages of CKD

Answer: B

The POLST form or a variant is legal in 15 states at present. Contradictory orders could be written between Sections A and B such that the patient is to receive CPR in Section A and comfort measures in Section B of the form. The form is only appropriate for patients who are seriously ill and for whom the physician would not be surprised if the patient died in the next year. B is the correct answer.[25]

Question 2

Which one of the following is true regarding the creation of clinical practice guidelines such as the Kidney Disease Outcomes Quality Initiative?

A. The exhaustive literature review minimizes the effect of financial conflicts of interests
B. Disclosure of financial conflicts of interests prevents subjectivity in guideline recommendations
C. Studies on clinical practice guidelines have found that most authors have financial relationships to pharmaceutical industries
D. The clinical practice guideline process guards against bias in the resulting recommendations

Answer: C

An exhaustive literature review does not guard against subjectivity and bias in the interpretation of the literature. Disclosure also has not been found to limit subjectivity in guideline recommendations. Most authors involved in clinical practice guideline development have financial conflicts of interest. C is the correct answer.[36,40]

Question 3

Which one of the following statements best summarizes the role of shared decision-making for patients with CKD?

A. Shared decision-making is an outmoded concept from the 1980s
B. Shared decision-making fits well with a disease-oriented approach to CKD patient treatment
C. Shared decision-making for CKD patients defaults to dialysis modality choices
D. Shared decision-making is the recognized preferred model for medical decision-making

Answer: D

Shared decision-making was introduced in the 1980s as a process to promote informed consent and decisions which adequately take account of patients' preferences. It fits well with an individualized, patient-centered approach to decision-making, not a disease-oriented approach. Shared decision-making for CKD patients encompasses decisions about whether to start or stop dialysis, not just dialysis modality. D is the correct answer.[7,16]

Question 4

An 87-year-old woman is approaching the need for dialysis. She has dementia and is no longer capable of making her own decisions. Her family would like her to start dialysis because they point out that she is healthy apart from the dementia which is progressing slowly and the kidney disease which she has known about for a number of years. The family is hopeful that she will be able to live to her 90th birthday as her mother did before her. Which one of the following is true with regard to informed consent for dialysis for an older stage 5 CKD patient with significant comorbid conditions?

A. An "age-neutral" approach is appropriate to avoid discrimination
B. Informed consent should include disclosure that dialysis may not confer a survival advantage
C. Consent for dialysis may only be obtained from the patient
D. Physicians are to provide information, not make a recommendation

Answer: B

Age is a major effect modifier in patients with CKD. Older CKD patients have higher rates of death and lower rates of dialysis initiation. For this reason, an age-neutral approach has not been recommended for decision-making with CKD patients. If patients lack decision-making capacity, consent for dialysis may be obtained from the patient's designated healthcare proxy on an advance directive or a healthcare surrogate appointed according to state law. The physician recommendation with regard to treatment is one of the seven elements of informed consent. Older CKD patients with significant comorbidities may not live any longer with dialysis than without. B is the correct answer.[1,4,7]

Question 5

An 86-year-old stage 5 CKD patient has mild vascular dementia and has had several TIAs and one myocardial infarction in the past 5 years. He has experienced a decline in eGFR from 20 to 17 mL/min/1.73 m^2 since being referred for nephrology evaluation three years ago. He has expressed an interest in HD as his preferred dialysis modality. What recommendation with regard to dialysis access should his nephrologist make?

A. Placement of an access now is indicated to ensure that it has time to mature before use
B. Access placement should be scheduled for six months from now
C. The nephrologist should not recommend access placement as the patient is unlikely to progress to ESRD*
D. The nephrologist should recommend placement of an arteriovenous graft as an arteriovenous fistula is unlikely to mature in an elderly patient in time for use

Answer: C

In one large study not one of the CKD patients over the age of 85 progressed to ESRD. They all died of other causes, most commonly cardiovascular, first. Placement of a working arterivenous fistula is challenging in many older CKD patients. There is an association between greater age and failure of fistula maturation.[4,48,49]

Question 6

A 78-year-old woman with stage 5 CKD is approaching the need for dialysis. She has hypertensive nephrosclerosis, a long smoking history, and severe COPD requiring oxygen 24 hours per day. She also has peripheral arterial disease with a below-the-knee amputation in the left leg. Which one of the following has been found to be the single best predictor of survival in such CKD patients?

A. Comorbid conditions
B. Age
C. Functional status
D. Nutritional status

Answer: A

All four answers are statistically significant independent predictors of poor prognosis in CKD and ESRD patients. Based on an extensive review of the literature, of the four, comorbid conditions have been found to be the single best predictor. A is the correct answer.[7]

CHAPTER

81

Imaging the Chronic Kidney Disease Patient

David C. Wymer[a], *David T.G. Wymer*[b]

[a]University of Florida, Malcom Randall VAMC, Gainesville, FL, United States; [b]Mount Sinai Medical Center, Miami Beach, FL, United States

Abstract

Imaging plays an increasingly vital role in measuring both renal function and structure in patients with chronic kidney disease. Diagnosis, disease status, disease progression, and development of complications of renal failure are monitored clinically as well as with laboratory studies and radiologic imaging. Although ultrasound and nuclear medicine have historically played a vital first role, newer magnetic resonance imaging (MRI) technologies promise to provide safe advanced functional renal analysis. With the sophisticated new MRI sequences, we are on the verge of major change in the evaluation and follow-up of patients with renal disease. The indications for evaluating the kidneys include evaluating for treatable cause of failure (such as hydronephrosis), documenting renal size, identifying renal position (for example, for biopsy), monitoring progression of disease, and identifying or confirming a specific disease entity (such as renal vascular or polycystic kidney disease).

INTRODUCTION

Other than to document renal size and some complications of chronic disease such as kidney stones, imaging has historically had a limited role in chronic kidney disease (CKD) patients, with most evaluation based on laboratory tests and renal biopsies. However, with newer modalities, imaging plays an increasingly vital role in assessing both renal function and structure in CKD. Diagnosis, disease status, disease progression, and development of complications of CKD are monitored clinically as well as with laboratory studies and radiologic imaging. While ultrasound and nuclear medicine have historically played a vital first role, newer magnetic resonance imaging (MRI) technologies promise to provide safe advanced functional renal analysis. With sophisticated new MRI sequences and techniques, we are on the verge of major changes in the evaluation and follow-up of patients with renal disease.

Patients with CKD can be broadly separated into those with chronic but potentially controllable bilateral or unilateral disease processes, such as arteriosclerotic vascular disease, infections, and stone disease, and those who have a systemic, progressive, and bilateral process such as diabetes, hypertension, and collagen vascular diseases.

The indications for evaluating the kidneys include assessments of treatable causes of kidney disease (such as hydronephrosis), documentation of renal size, identification of the position of the kidneys (for biopsy), monitoring progression of disease, or identification or confirmation of a specific disease entity (such as polycystic kidney disease or renal vascular disease).

UTILITY OF IMAGING MODALITIES

Modality Selection

There are many clinical scenarios which bring a CKD patient in for radiologic evaluation. The testing is specific for patient complaints. Guidelines for imaging are available online through the American College of Radiology. These are regularly updated (http://www.acr.org/Quality-Safety/Appropriateness-Criteria). The website is organized by signs and symptoms and suggests the most useful modality as well as contraindications, relative contraindications, and caveats for each modality.

Ultrasound

Ultrasound is often the first imaging modality used in evaluating the kidneys, especially in patients with decreased renal function because it is inexpensive, quick, safe, and easily accessible. In chronic renal infections and stone disease, ultrasound shows findings

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00081-4

referable to the disease process—such as abscesses, calculi, and hydronephrosis.[1]

Early in the course of systemic renal failure, the ultrasound exam is often normal. Depending on the underlying disease state, later imaging shows variable changes. Obstruction causing renal failure is readily identified by demonstration of hydronephrosis. Ultrasound allows measurements of kidney size and cortical thickness. Both are important measures in CKD. Plain films (KUB) and intravenous urography overestimate renal size, because X-ray procedures have an inherent magnification of approximately 25%. Because of operator dependence, it is generally felt that computed tomography (CT) and MRI give more accurate overall renal measurements than ultrasound. Nevertheless, ultrasound is readily available, rapid, and accurate enough for screening and following renal size. Although there are size differences related to age, gender, and body mass index, in the average adult the kidneys should measure about 11−12 cm in greatest length. Width measurements are variable and are not generally considered clinically useful. The cortex from renal margin to calyx should be about 1.5 cm in the mid-kidney and 3 cm at the poles. Lower measurements represent atrophy.

The ultrasound appearance of normal kidneys typically shows well-marginated kidneys with a uniform cortex which is less echogenic than adjacent liver. The renal hilus is of increased echogenicity due to the presence of renal sinus fat and fibrous tissue (Figure 81.1).

In most cases of CKD, ultrasound of the kidneys shows nonspecific small and echogenic kidneys (Figure 81.2). However, the ultrasound in patients with chronic polycystic kidney disease shows enlarged kidneys which are nearly completely replaced with cysts (Figure 81.3). Most patients with CKD are middle aged and older. It is estimated that approximately 50% of adults have an incidental renal lesion. The most common incidental renal lesion is a cyst. Renal cysts are common and seen in otherwise normal patients. These are readily demonstrated and evaluated with ultrasound. Benign cysts are sharply circumscribed and may have thin internal septations (Figure 81.4).[2]

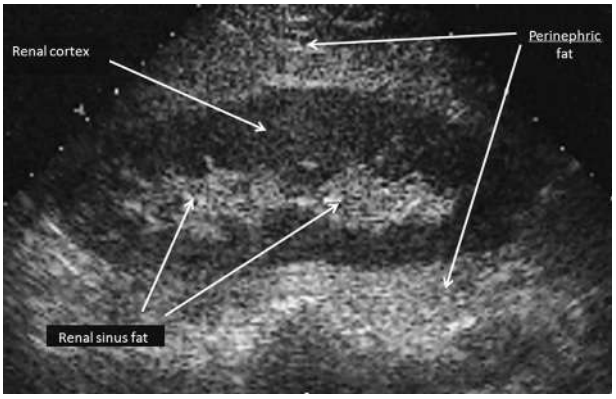

FIGURE 81.1 Normal renal ultrasound.

Contrast-enhanced ultrasound of the kidney with microbubbles is being used in other parts of the world, but it is an off-label use in the US at this time. Contrast-enhanced ultrasound with microbubbles is useful in evaluating renal blood flow (such as for the evaluation for renal artery stenosis) and more especially the degree of vascularity of complex real cysts and masses, allowing classification for malignant potential without the use of iodinated or gadolinium-based contrast agents and cost of CT or MRI.[3−5]

Nuclear Medicine

Nuclear scintigraphy techniques evaluate renal function and to a lesser extent anatomy. Because of the extremely small quantities injected and the benign nature of the radionuclides, these scans can be safely performed even in the face of markedly reduced renal function. Radioactive tracers are used which accumulate in renal tissues based on the underlying physiologic functions of the differing renal structures. For example, glomerular filtration rate (GFR) is evaluated with ^{99m}Tc-DTPA, tubular secretion with ^{99m}Tc-MAG3, general cortical integrity with ^{99m}Tc-DMSA, and renal parenchymal inflammation with ^{67}Ga-citrate.

One of the historic strengths of nuclear imaging is that, unlike the relative contraindications for contrast-enhanced CT and MRI, it can be used even in the face of declining renal function. Because of the relative preservation of tubular function and increased extraction efficiency compared with ^{99m}Tc-DTPA, ^{99m}Tc-MAG3 continues to provide information in the face of declining renal function. ^{67}Gallium-citrate has been used to diagnose interstitial nephritis as well as chronic infection of the kidneys.[6,7]

The usual functional renal scan is performed with ^{99m}Tc-MAG3 and can be studied in three phases of scanning. Following bolus intravenous injection of the nuclide, rapid sequential images are obtained to evaluate blood flow, which may be unilaterally or bilaterally compromised. Subsequent continued static imaging provides information on renal cortical function, both of the individual kidneys and the differential function between the kidneys. On subsequent delayed imaging, the excretion through the collecting system to the urinary bladder is displayed to evaluate the presence of obstructive uropathy. The renogram curve reflects abnormalities of vascular flow, renal function, and the presence of urinary tract obstruction. A normal curve of renal activity obtained during scanning is seen in Figure 81.5.

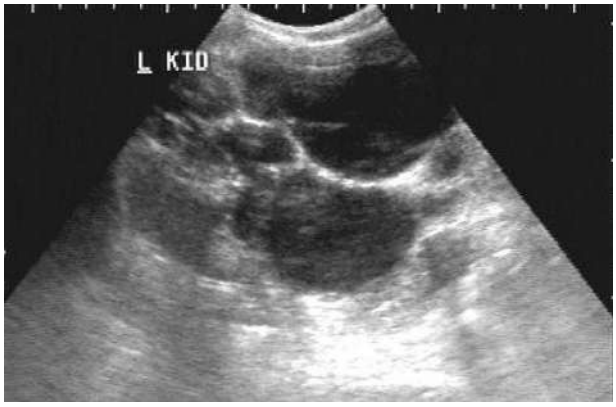

FIGURE 81.3 Numerous simple cysts replacing the renal parenchyma.

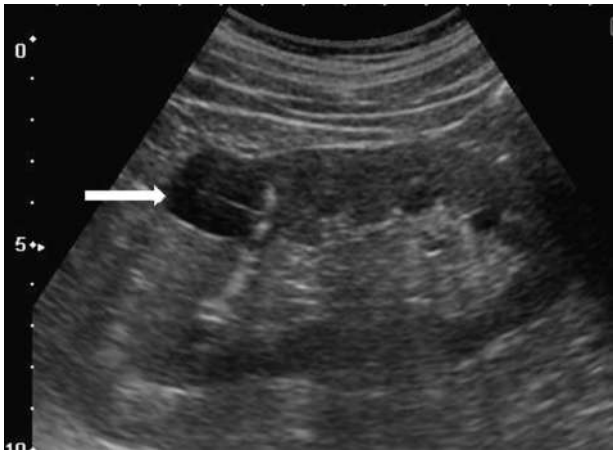

FIGURE 81.4 Benign renal cortical cyst with single thin internal septation.

Computed Tomography

CT has historically had a limited role in patients in the later stages of CKD. This has become more controversial recently, as research has demonstrated that intravenous administration of newer iso-osmolar or low osmolar iodinated contrast agents has no significant negative effect on CKD patients' short- or long-term renal function.[8] However, it is still standard of care that if the estimated GFR (eGFR) is below 30 mL/min/1.73 m^2, contrast material should be avoided if adequate diagnostic information can be obtained by other means. Contrast can be used judiciously and safely if the eGFR is 30–60 mL/min/1.73 m^2. If contrast is administered, patients should be hydrated before, during, and after contrast with intravenous saline and/or bicarbonate solution to reduce the risk of contrast-induced nephropathy (CIN). The use of other agents has shown questionable benefit in multiple studies, particularly N-acetylcysteine, which has shown to simply decrease S[Cr] even in normal volunteers without changing cystatin-C.[9–12] The recent 2018 Preserve Trial of 5177 patients failed to show any benefit on primary or secondary endpoints (renal or nonrenal adverse events) of any interventions beyond simple intravenous sodium chloride infusion.[12] The American College of Radiology manual on contrast media, which is regularly updated online (https://www.acr.org/Clinical-Resources/Contrast-Manual), recommends against routine use of N-acetylcysteine for prophylaxis or premedication.

Another disadvantage of CT scanning which is increasingly recognized as important is the associated radiation dose. Protocols are being changed to reduce dose exposure and new data reconstruction software is now available which has significantly reduced the

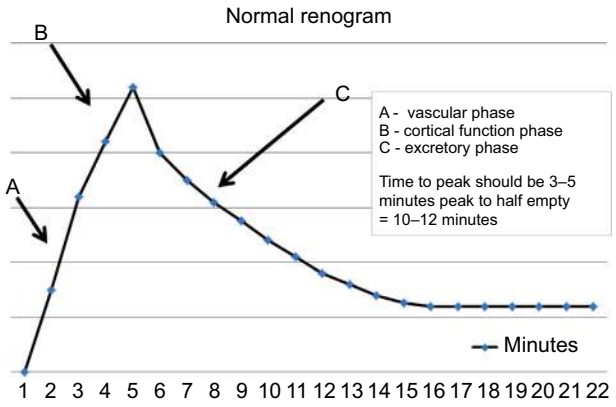

FIGURE 81.5 Normal renogram diagram showing different phases of renal nuclide clearance.

overall radiation exposures, but imaging with ultrasound and MRI which do not involve ionizing radiation is preferred whenever possible.

In earlier stages of chronic infectious kidney disease, such as in patients with xanthogranulomatous pyelonephritis, noncontrast CT can aid in determining extent of disease and for preoperative planning. Noncontrast CT is also used in evaluating, diagnosing, and following renal stone disease and nephrocalcinosis, and in guiding procedures such as renal biopsy and percutaneous nephrostomies.

Newer CT equipment has dual-energy scanning capability. This refers to simultaneous scanning using two distinct CT X-ray energies. Using the differential energy absorption of various renal stones, the mineral content of the stone can be noninvasively determined and appropriate therapy instituted, without having to physically remove and test the stone.

Magnetic Resonance Imaging

While it is not the usual first test in evaluation of the chronically diseased kidney, MRI is undergoing rapid technological change which is making it attractive as a renal imaging agent even in patients with CKD.[13,14] The ability to directly image in multiple planes allows excellent morphologic analysis. Imaging is based on the magnetic spin of hydrogen atoms, which are abundant in water-based tissues. Different sequences are used to highlight different structures such as cysts (water), fat, or other soft tissues.

Magnetic resonance angiography (MRA) visualizes flowing blood and can even quantitate the velocity and flow rate in vessels.[15–17] MRA can be performed with or without the intravenous administration of contrast material, although use of contrast usually provides better images. However, some of the new noncontrast sequences provide excellent vascular definition without the risk of contrast toxicity. By varying contrast injection timing and type of sequences, the abdominal venous structures can be visualized in addition to arteries. MRA is performed to evaluate the renal arteries for stenosis. MRA is less invasive than catheter angiography. With newer equipment and software, MRA now gives sensitivity of 97% and specificity of 93%, compared with digital subtraction angiography for contrast-enhanced MRA in the detection of renal artery stenosis. MRA without gadolinium historically has had a lower sensitivity (53%–100%) and specificity (65%–97%) for detection of renal artery stenosis, but this difference is becoming less with development of new noncontrast sequences. This makes MRA without gadolinium one of the best available tests for evaluating the renal vasculature in patients with hypertension, poor renal function, or allergies to intravenous contrast. With the appropriate timing of dialysis, CT angiography using contrast material can be performed in patients with severe decrements in renal function for surgical planning. However, MR imaging is often preferred before renal transplantation to evaluate the arteries (number and location), veins (number and location), and ureters (possible duplicated systems).

Multiple other sophisticated sequences have been developed and are being studied. While functional analysis used to require intravenous gadolinium, which is relatively contraindicated in severe renal failure, there are new sequences and contrast agents which do not have these drawbacks.

One sequence called diffusion-weighted imaging (DWI) displays the relative rate of diffusion of hydrogen atoms (mainly as water) through tissue. Various tissues have different diffusibility characteristics, which give different imaging appearances. Diffusion imaging has historically been most extensively studied in the brain and has been shown to be sensitive to both cellular edema and cellular atrophy, and hence to the tissue damage typically induced by acute or chronic hypoxia. Many causes of CKD have relationships with relative hypoxia, such as that seen in diabetes. This relationship is being studied with the idea of using DWI MRI to evaluate and follow disease processes in the kidney. Several studies have already shown DWI abnormalities in the renal cortex and medulla in patients with CKD as well as in states of obstructive uropathy.[18,19] Abnormalities are also seen in renal allografts, suggesting its use in transplant follow-up without the need for contrast.

Research is ongoing to assess how this technique can be used clinically to differentiate various benign and malignant processes, as well as to potentially evaluate systemic disease states of the renal parenchyma.

Another developing tool in MRI is blood oxygen level–dependent (BOLD) imaging. BOLD contrast

imaging sequences can noninvasively demonstrate the level of intrarenal oxygen tension. Because oxygen delivery correlates with reserve capacity of the kidney and renal tubular workload capacity, BOLD imaging provides further analysis of underlying renal parenchymal function in normal and disease states.[20,21] The clinical utility of BOLD imaging awaits further experimental validation.

Magnetic resonance elastography (MRE) is a technique that images the propagation of shear waves through tissue. Tissue motion is mechanically induced by an external source (such as a pneumatically driven pad) and the resultant tissue displacement is measured by the MR scanner. The degree of displacement is proportional to the elastic properties of the imaged tissue. An MRI parametric image map can be displayed which correlates with organ "stiffness." Ultrasound elastography is analogous and is also being investigated for evaluation of CKD patients. In CKD, one of the common final pathogenic pathways is interstitial fibrosis, which can be semiquantitatively analyzed with MRE. Elastography with MR and ultrasound is not in common use for kidney studies and are still being studied experimentally.[22]

One final developing tool is used in evaluating intrarenal inflammation. In current clinical practice, the degree of inflammatory response in the kidney can be demonstrated only by renal biopsy. Infiltration of the glomeruli and interstitium by inflammatory cells is a common finding in both glomerulosclerosis and tubulointerstitial nephritis. Diffuse interstitial macrophage infiltration of the parenchyma is well documented in many chronic renal diseases and has good correlation with renal transplant graft rejection. There are developing methods of imaging the inflammatory response with MRI by taking advantage of the fact that macrophages take up particles, such as ultrasmall particles of iron oxide (USPIO). Being paramagnetic, these particles result in fairly pronounced decreased signal intensity on MRI in any tissues in which they accumulate. Delayed imaging following USPIO intravenous injection with MR imaging in cases of intrarenal inflammation demonstrates a diffuse but significant decrease of signal intensity throughout the kidney, slightly more pronounced in the cortex. To date, the majority of studies have been in animal models, but some human trials are ongoing.[23]

Imaging to Diagnose Disease States

The normal aging kidney does not demonstrate significant pathologic changes other than a very minor decrease in size. Therefore, any variation from the normal appearance seen on imaging reflects some disease state. The challenge is to diagnose disease or at least to exclude some differential considerations. There are a few classic renal appearances seen, such as the large echogenic kidneys of HIV nephropathy[24,25] (Figure 81.6), the large cystic kidneys of polycystic kidney disease (Figure 81.3), and the renal vascular stenosis of renal artery hypertension.

The majority of renal disease states, however, have similar end results, such as parenchymal abnormalities which give similar imaging findings of small kidneys, increased ultrasound echogenicity, intrarenal arterial flow restriction due to interstitial processes, and general decreased functional clearance of contrast or radionuclides.

Renal angiography typically plays a limited role in CKD except in the evaluation and treatment of renal vascular disease—especially stenosis which may cause hypertension or even eventual renal failure from decreased blood flow. Other than the finding of renovascular stenosis, long-standing renal failure is angiographically seen as pruned and tortuous intrarenal vessels, diminished overall flow, and thinned cortex. Certain systemic diseases which lead to CKD have characteristic microaneurysms, such as seen in Wegener's granulomatosis, polyarteritis nodosa, and systemic lupus erythematosus.

Imaging can also be helpful for monitoring disease progression, and in some cases to corroborate a diagnosis or differentiate between possible diagnoses. This involves imaging organs other than the kidney, which may demonstrate diagnostic changes in certain diseases. For example, in the cardiorenal syndrome, the chest X-ray, echocardiogram, chest CT, or cardiac MRI can show changes of congestive failure, dilated nonischemic cardiomyopathy, or dilated ischemic cardiomyopathy,

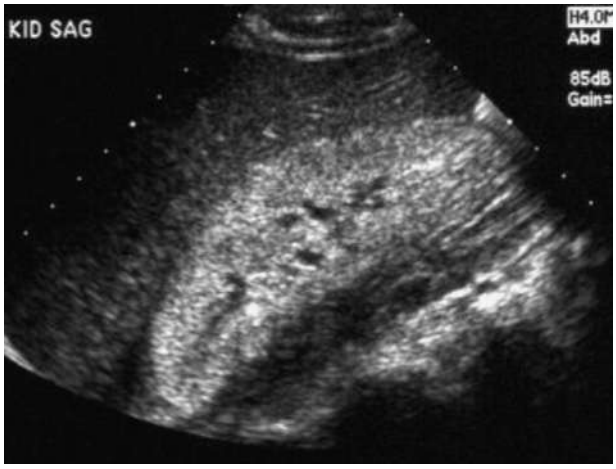

FIGURE 81.6 Large, intensely echogenic kidney with HIV nephropathy.

as well as specific causes of heart failure such as cardiac sarcoidosis or amyloidosis. In the hepatorenal syndrome, the liver is usually expected to show a small, irregular, dense, fibrotic cirrhotic appearance, with flow abnormalities in the portal system and portal venous hypertension. Patients with sickle cell disease, in its advanced stages, can show splenic and bone infarctions as well as other classic bone changes such as the "fish mouth" vertebral appearance. Many of the collagen vascular diseases have other organ involvement, especially lung parenchymal infiltrates or pulmonary fibrosis.

IMAGING CKD COMPLICATIONS

The most commonly associated complication of CKD discerned radiologically is renal calcifications. Calcifications can occur in the collecting systems as nephrolithiasis and in the renal parenchyma as nephrocalcinosis. Most renal calculi are calcium oxalate, calcium phosphate, urate, struvite, or cystine. The majority of stones contain calcium and are radioopaque. Ultrasound is relatively insensitive to stone detection, but when seen, the stones are very echogenic and classically demonstrate "shadowing" distal to the stone due to blocking of the ultrasound wave (Figure 81.7). Color Doppler can result in a characteristic turbulent signal called the "twinkle" artifact. Stones can be reasonably differentiated using CT scanning by dual-energy CT (DECT). Ultrasound is noninvasive without associated radiation and can be used in the initial evaluation of renal stones, especially in looking for hydronephrosis. Ultrasound, however, has a low sensitivity, particularly for small stones and ureteral stones. Noncontrast CT is the imaging method of choice for evaluating the location and size of renal calculi, as well as obstructive uropathy. These parameters affect treatment options.

FIGURE 81.7 Large upper pole renal stone with distal acoustical shadowing.

In differentiation from nephrolithiasis, nephrocalcinosis refers to more diffuse intrarenal calcium. This process is commonly bilateral and can be seen with medullary deposition in such states as hyperparathyroidism, renal tubular acidosis, medullary sponge kidney, and in some medication complications such as patients treated with acetazolamide. Cortical nephrocalcinosis is usually dystrophic in nature and is secondary to parenchymal tissue destruction, such as seen with infarction and infection. Common etiologies include chronic glomerulonephritis, cortical necrosis, and transplant rejection.

Osseous abnormalities are common in patients with CKD. These bone abnormalities can have various radiographic findings. Osteitis fibrosa is a manifestation of hyperparathyroidism from CKD and results in the formation of cyst-like areas of brown tumors. Other typical findings in hyperparathyroidism include osteosclerosis of the vertebra (giving an X-ray appearance of the so-called rugger jersey spine), subperiosteal bone resorption (seen especially in the digits and clavicles), and skull changes (with scattered lytic and ground glass appearance). Extraskeletal calcifications from abnormalities of calcium-phosphate metabolism result in vascular, lung, and periarticular calcium deposition. Osteomalacia results from abnormal mineralization. Osteomalacia can result in looser zones or pseudofractures, usually seen in the long bones of the extremities.

Osteopenia and osteoporosis with abnormal bone density is common in patients with CKD. Imaging with dual-energy X-ray absorptiometry is excellent at diagnosing demineralization, but it cannot differentiate the demineralization specific to CKD from other more common causes of osteoporosis. Bone biopsy is required for further differentiation and diagnosis.

There are multiple neurologic abnormalities associated with CKD, but imaging is of little help in the specific evaluation and diagnosis of CKD-induced changes. MRI of the brain can show white matter changes in some cases with uremic encephalopathy. Such changes can reverse following regular dialysis.

Cardiovascular abnormalities result from vascular inflammation as well as abnormal calcium metabolism, with accelerated progression of arteriosclerotic disease of vessels throughout the body as well as coronary vessels and cardiac valves. Screening for cardiac disease as well as risk stratification is possible with coronary calcium scoring with CT, cardiac CTA, stress echocardiography, and nuclear myocardial perfusion imaging. These studies have been validated as independent predictors of cardiac morbidity and/or mortality.

CONTRAST USE IN CKD

Caution should be exercised in the use of both the iodinated intravascular contrast used for CT and angiography and the gadolinium-based contrast used in MRI. While it is considered controversial, new data suggest that the concern over intravenous iodinated contrast agents is overexaggerated. Many experts suggest the risks of adverse events with iodinated contrast can be ameliorated with hydration and judicious use of dialysis as needed. However, the complications of nephrogenic systemic fibrosis (NSF), seen in patients following gadolinium contrast injection in patients with advanced renal insufficiency can be devastating. The first cases of NSF clinical findings were identified in 1997.[26] An international NSF registry was developed at Yale University which maintains records on over 215 patients with NSF worldwide.

NSF with pathological descriptions was reported in 2000. Evidence for a link between NSF and gadolinium was first described in a case series of 13 patients, all of whom developed NSF after being exposed to gadodiamide.[27] The background and history of NSF is nicely discussed in a review article from 2009.[28]

The reported incidence of NSF varies with individual gadolinium-based agents, primarily related to the degree of binding of the gadolinium chelate. Older, less stably bound agents are more directly implicated in the development of NSF.[29] Some of the newer agents are so tightly bound that it is suggested that they can be used safely in patients with advanced renal failure. Some large studies have demonstrated that certain newer agents have caused no cases of NSF even in patients treated with peritoneal and hemodialysis.[30]

The Contrast Media Safety Committee (CMSC) of the European Society of Urogenital Radiology (ESUR) updated their consensus guidelines in 2012. In summary, those guidelines suggest that gadolinium-based agents can be separated by risk of NSF, based on the molecular structure of the individual contrast agents. In contrast to NSF, there are concerns about the long-term retention of gadolinium in body tissues, especially the brain, even in patients with normal renal function. This is an ongoing area of investigation.[31]

Conservative strategies for administration of gadolinium-based contrast agents include contraindication in patients with stage 4 and 5 CKD (GFR<30 mL/min/1.73 m^2), acute renal injury, and pregnant women (gadolinium agents are pregnancy class C) and neonates, and use with caution in stage 3 CKD (GFR 30–60 mL/min/1.73 m^2) and children less than 1-year old. There should be at least 7 days between two injections. Lactating women should stop breastfeeding for 24 hours. The dose should not exceed 0.1 mmol/kg per examination.

The committee states that newer gadolinium agents which are more tightly bound in the molecular structure such as gadobutrol, gadoterate, and gadoteridol may be used with caution in patients with stage 4 and 5 CKD, because there are no well-documented unconfounded cases of NSF reported with these agents.

The 2011 ESUR guidelines for use of iodinated contrast identify patients as being at risk for CIN as those with eGFR below 60 mL/min/1.73 m^2, before intraarterial injections, and eGFR less than 45 mL/min/1.73 m^2 before intravenous injections.[32] There is additional concern when the patient has underlying diabetic nephropathy, dehydration, congestive heart failure, is over the age of 70, or has had concurrent use of nephrotoxic drugs.

In patients at risk, it is still recommended that alternative imaging methods be explored if reasonable. If contrast is to be used, low or iso-osmolar contrast at the lowest possible dose is recommended. Volume expansion has shown some protective effects. One general protocol suggests 1.0–1.5 mL/kg/h of intravenous saline for at least 6 hours before and after contrast administration. It is notable that to date prophylaxis with renal vasodilators, cytoprotective drugs, or other pharmacologic interventions has not proven efficacious against CIN. Early small studies suggested that the use of bicarbonate solutions helped to reduce the incidence of CIN. However, the largest trial to date showed no benefit of sodium bicarbonate nor acetylcysteine over normal saline.[12,33]

Specific guidelines have also been defined for contrast use in patients with reduced renal function taking metformin. This is because of the possibility of metformin-induced lactic acidosis. Because metformin is cleared by the kidneys, any reduction in renal function prolongs the biologic half-time of metformin and increases the subsequent risk of life-threatening acidosis. For these reasons, drug guidelines contraindicate the use of metformin in patients with eGFR less than 30 mL/min/1.73 m^2. The guidelines recommend that patients receiving IV contrast and with eGFR greater than 45 mL/min/1.73 m^2 can continue taking metformin normally. However, patients receiving intraarterial contrast and those with eGFR between 30 and 45 mL/min/1.73 m^2 should stop metformin before the study and not begin metformin again until 48 hours after the study, and then only after determining that renal function has not deteriorated.

Although it is still recommended to seek alternatives to imaging with intravenous iodinated contrast in patients with CKD, multiple recent studies and meta-analyses have demonstrated that the relative risk to these patients has been overestimated.[12,34–36] This should be taken into account in the decision process

for diagnostic imaging if there is significant potential benefit to using iodinated contrast in the patient's medical or surgical management, especially in emergent settings. For anuric end-stage renal disease patients without a functioning transplant treated with dialysis, the American College of Radiology manual on contrast media asserts that intravenous contrast material can be used safely without the risk of osmotic load. Low or iso-osmolar contrast media are recommended, and immediate postcontrast administration dialysis is not indicated.[37]

CONCLUSION

Imaging plays an increasingly vital role in measuring both renal function and structure in patients with CKD. Diagnosis, disease status, disease progression, and development of complications of renal failure are monitored clinically as well as with laboratory studies and radiologic imaging. Although ultrasound and nuclear medicine have historically played a vital first role, newer MRI technologies promise to provide safe advanced functional renal analysis. With sophisticated new MRI sequences, we are on the verge of major changes in the radiologic evaluation and follow-up of patients with CKD.

The indications for evaluating the kidneys include evaluation of treatable causes of renal failure (such as hydronephrosis), documentation of renal size, identification of the position of the kidneys, monitoring progression of disease, and identification or confirmation of a specific renal disease.

QUESTIONS AND ANSWERS

Question 1

What is the most common and classic ultrasound appearance of the kidneys in CKD?

A. Multiple cortical cysts
B. Hypoechoic cortex in large kidneys
C. Hyperechoic cortex in small kidneys
D. Lobulated margins with mixed hyperechoic and hypoechoic cortex
E. Normal cortex with medullary calcifications

Answer: C

The classic appearance is small echogenic kidneys (C) with thinned cortices as the end result in most renal processes leading to renal failure. Hyperechoic large kidneys are the classic appearance of HIV-associated nephropathy. While multiple renal cortical cysts are a common finding in normal kidneys, enlarged kidneys with innumerable cysts are typical of adult polycystic kidney disease. Various calcifications (renal stones, cortical calcifications of cortical necrosis, and medullary calcifications of medullary sponge kidney) are seen in CKD but are not the most common finding.

Question 2

Renal stone content can be differentiated with which imaging technique?

A. Diffusion-weighted MRI
B. Ultrasound with microbubbles
C. DECT
D. MRI with BOLD imaging
E. Standard intravenous urogram

Answer: C

Using the physics principles of differing X-ray absorption of different X-ray energies by materials of different chemical structure, DECT can differentiate stones into basic categories—the correct answer is (C). DWI measures ease of diffusion of water molecules in tissues. BOLD imaging uses MRI to measure relative blood oxygen level. Microbubbles evaluate perfusion and the urogram evaluates renal function.

Question 3

With an eGFR of 50 mL/min/1.73 m^2 which statement regarding metformin use in conjunction with iodinated contrast is most correct?

A. No restriction to metformin use with intravenous contrast
B. Stop metformin 48 hours before contrast
C. There is no difference in recommendations between intravenous and intraarterial injections
D. Metformin can be continued only if the patient is pretreated for 6 hours with normal saline
E. Metformin should be withheld for at least 72 hours after contrast administration

Answer: A

The latest consensus from the CMSC of the ESUR in 2012 states that metformin can be used normally during intravenous contrast administration as long as the eGFR is above 45 mL/min/1.73 m^2. Therefore, the correct answer is A. Patients with an eGFR between 30 and 45 mL/min/1.73 m^2 and those receiving intraarterial contrast should stop metformin for 48 hours before contrast administration to avoid possible lactic acidosis. Additionally, they should not restart metformin for 48 hours after contrast, and then, only after determining that renal function has not deteriorated. Pretreatment with normal saline is suggested as a renal protective agent against CIN but has no direct bearing on the use of metformin.

Question 4

Which statement regarding contrast use in CKD is most correct?

A. Nephropathy is only seen with iodinated contrast and not gadolinium agents
B. Use of gadolinium agents is contraindicated in patients with eGFR< 30 mL/min/1.73 m^2
C. There are no restrictions to breastfeeding following gadolinium administration
D. Prophylaxis with renal vasodilators is renal protective
E. Volume expansion with normal saline is not as effective as bicarbonate infusion

Answer: B

Contrast nephropathy has been reported with both iodinated and gadolinium-based agents; however, the incidence is much lower with gadolinium. While there are some cyclic gadolinium agents which to date have not been associated with NSF even in patients in renal failure, the incidence of NSF is significantly increased with the use of some gadolinium agents when the eGFR is less than 30 mL/min/1.73 m^2, so gadolinium agents should not routinely be used in these cases. (The correct answer is B.) Gadolinium is secreted in breast milk, so breastfeeding should be stopped for 24 hours after gadolinium contrast to avoid possible adverse effects in the immature newborn kidneys as well as possible persistent accumulation of gadolinium in other fetal tissues. There is evidence that volume expansion with normal saline has some renal protective

effect, and bicarbonate infusion has shown some efficacy; however, the effects with bicarbonate are not as clear as simple normal saline. There is no proven renal prophylactic protective effect with renal vasodilators, cytotoxic agents, or other pharmacologic interventions.

Question 5

Which imaging techniques can be used to measure relative renal hypoxia?

A. DECT
B. Diffusion-weighted MRI
C. BOLD MRI
D. Microbubble ultrasound
E. Nuclear medicine gallium scanning

Answer: C

BOLD imaging with MRI can be used to measure relative renal oxygen levels; however, BOLD imaging is not in regular clinical use, due to the sophistication of the equipment and protocol sequences. (The correct answer is C.) DECT is useful for evaluating the chemical make up of renal stones. DWI evaluates tissue structure by measuring the rate of water diffusion in tissues. Ultrasound microbubbles are used to measure relative blood flow.

Question 6

Secondary hyperparathyroidism seen in CKD can result in what classic X-ray finding?

A. Osseous brown tumors
B. Interstitial lung disease
C. Small shrunken liver with cirrhosis
D. "Fish mouth" vertebra
E. Echogenic liver of steatohepatitis

Answer: A

The osteitis fibrosa of hyperparathyroidism can result in focal bone replacement with development of "brown tumors" (A). "Fish mouth" vertebra are classic in sickle cell anemia. The other three possibilities have no relationship to hyperparathyroidism.
