QUESTIONS AND ANSWERS

Question 1

When differentiating between depression and uremia in a patient with CKD, which of the following symptoms would be most indicative of a diagnosis of depression?

A. Weight loss
B. Suicidal ideation
C. Sleep difficulty
D. Loss of energy
E. Decreased libido

Answer: B

Answers A, C, D, and E are incorrect because weight loss, sleep difficulty, loss of energy, and decreased libido are all symptoms that can overlap between depression and uremia. The correct answer is **B**, suicidal ideation, as it is the only symptom listed that is unique to the presentation of depression.

Question 2

It is important to diagnose and treat depression in CKD because:

A. Depression has been found to be associated with decline in eGFR
B. Patients with depression are more likely to experience adverse outcomes such as increased number of hospitalizations
C. Depression may be associated with greater cognitive decline in patients with CKD
D. Depression has been found to be a predictor of mortality in patients with CKD
E. All of the above

Answer: E

Depression can have a significant impact on the course of CKD progression. Research suggests that depression is a significant predictor of eGFR and adverse outcomes such as increased number of hospitalizations and mortality. Furthermore, research indicates that depression may be associated with greater cognitive decline. Therefore, the correct answer is **E,** all of the above.

Question 3

The most prominent psychiatric presentation in patients with CKD is:

A. Anxiety Disorders
B. Substance abuse disorders
C. Depression
D. Psychosis
E. Body Dysmorphic Disorder

Answer: C

The correct answer is **C**, Depression, with studies reporting prevalence rates between 20% and 30%. Answer A is incorrect because although there is growing evidence that anxiety disorders may have an impact on patients with CKD, early research suggests that these disorders are not more prevalent in patients with CKD compared to the general population. Answer B is incorrect because although comorbid substance abuse disorders can be very detrimental for patients with CKD, they have not been found to be as highly prevalent among this population. Answers D and E are incorrect in that there is no evidence that these conditions are prominent in patients with CKD.

Question 4

Which of the following has NOT been identified as a significant predictor of HRQOL in patients with CKD?

A. CRP
B. Sleep difficulty
C. CVD
D. Being male and under the age of 65
E. Pain

Answer: D

The correct answer is **D**, being male and under the age of 65. In a large-scale, longitudinal study data revealed that early-stage CKD patients who were female and/or over the age of 65 had worse perception of QOL. Answers A and C are incorrect as CRP and CVD have been identified as medical factors that predict HRQOL, along with GFR and diabetes. Answers B and E are incorrect as sleep difficulty and pain have been found to be associated with poor QOL in patients with CKD.

Question 5

During a visit with her nephrologist a 63-year-old woman with CKD reveals that she has not been taking her antihypertensive medication on a regular basis. During the physician's inquiry, the patient is tearful and appears frustrated as she describes her difficulties with learning how and when to take her various medications. This is an example of what kind of barrier to adherence?

A. Depression
B. Cost of medication
C. Health beliefs
D. Access to care
E. Regimen complexity

Answer: E

The correct answer is **E**, regimen complexity, as the patient has clearly indicated that she has difficulty

following specific instructions regarding the dosage and administration of her medications. Answer A is incorrect because even though the patient is tearful while talking about her problems, she has clearly communicated to the physician that her primary difficulty is due to learning her prescription regimen. Answers B and D are incorrect in that the patient has not indicated that the cost of medication or access to the pharmacy present a problem for her in adhering to her prescription. Answer C is incorrect because the patient does not appear to make decisions about adhering to her prescription based on beliefs about her condition or the efficacy of her medication.

Question 6

Which of the following is true regarding mental health disparities within CKD?

A. Prevalence of depression is greater in Blacks with CKD compared to Hispanics with CKD

B. Prevalence of depression is greater in Hispanics with CKD compared to Blacks with CKD

C. Utilization of depression treatment is low among Blacks and Hispanics with CKD

D. Utilization of depression treatment is high among Blacks and Hispanics with CKD

E. Women with CKD are less likely to use antidepressants

Answer: C

The correct answer is **C**. Research indicates that Black and Hispanic patients with CKD who present with elevated depressive affect are less likely to use antidepressant medication, compared to non-Hispanic White patients with CKD. Answer D is incorrect because utilization of depression treatment is lower among Blacks and Hispanics with CKD. Answers A and B are incorrect as there is no evidence of greater or lesser prevalence of depression within the Black or Hispanic CKD population. Answer E is incorrect as women are actually more likely to use antidepressants when presenting with depressive affect.

Abstract

There is a high prevalence of comorbid eye disease in patients with chronic kidney disease (CKD), end-stage renal disease (ESRD), and kidney transplant patients. The most common links are secondary from diabetes and hypertension. However, there are other disease states that link the kidneys and eyes, ranging from a host of systemic diseases such as sarcoidosis to ophthalmic complications of kidney transplantation. This chapter reviews the relationship between the kidneys and eyes in the setting of a variety of primary and secondary diseases. Early ophthalmic evaluation in the face of visual changes in these patients is of paramount importance. In addition, there may be a role for routine ophthalmology screening in any patient with stage 3 CKD or higher. Future studies focusing on the preventive benefit of such screening programs will benefit patients with kidney diseases.

INTRODUCTION

The association of kidney disease with eye pathology is well established. The most common links are secondary from diabetes and hypertension. However, there are other disease states that link the kidneys and eyes, ranging from a host of systemic diseases such as sarcoidosis to ophthalmic complications of kidney transplantation. This chapter reviews the relationship between the kidneys and eyes in the setting of a variety of primary and secondary diseases.

OPHTHALMIC FINDINGS IN HYPERTENSIVE NEPHROPATHY

Hypertension accounts for 30% of all kidney diseases, making it the second-leading cause after diabetes mellitus.[1] To date, there have been no population studies that have established an expected prevalence of hypertensive retinopathy in a cohort of patients with hypertensive nephropathy. Two cross-sectional studies have reported that in their group of hypertensive patients, 36% had microalbuminuria and 38% had hypertensive retinal changes. In addition, these two variables were strongly associated, suggesting a fairly high rate of nephropathy in those patients with hypertensive retinal pathology.[2,3]

Systemic hypertension causes diffuse and focal retinal arteriolar vasoconstrictions, which have been noted to be common in long-standing hypertension.[4] More significant pathology occurs when there is a breakdown of the inner blood–retinal barrier, leading to extravasation of red blood cells and plasma. This results in the classic findings of retinal hemorrhages, cotton-wool spots, intraretinal lipid accumulation, and macular stars.[4] However, these findings are not observed in most patients. Rather, the usual findings are arteriosclerotic changes in the retina, typically characterized by vascular thickening.[4] Despite several large population studies examining this link, it remains unclear if the retinal vascular changes are a cause of hypertension or a result of this disease.[5,6]

Severe or acute hypertension can cause additional pathology. With hypertensive emergency, occlusion of the retinal capillaries may occur. In addition, choroidal vessel hypertension can cause fibrinoid necrosis of choroidal arterioles and result in occlusion and ischemia of this blood supply, which can then lead to a breakdown of the outer blood–retinal barrier.[4] Finally, extreme accelerated hypertension can cause edema of the optic disk and swelling of the optic nerve.[4]

OPTHALMOLOGIC COMPLICATIONS IN CHRONIC KIDNEY DISEASE AND DIALYSIS PATIENTS

Retinopathy and Other Fundus Pathology

Retinopathy may be the best known ocular complication of chronic kidney disease (CKD). Recent population studies have examined the prevalence of retinopathy and other fundus pathology in patients with CKD.[7–9] A cross-sectional study found that 45% of all patients with CKD had retinal pathology that required follow-up with an ophthalmologist.[7] In addition, 25% of patients were diagnosed with retinopathy, typically secondary to hypertension and/or diabetes.[7] Furthermore, they found that those with an estimated glomerular filtration rate (eGFR) less than 30 mL/min/1.73 m^2 had a three times higher risk for being diagnosed with retinopathy. Similarly, retinopathy conferred a twice as great risk of developing CKD compared to those without.[8] Not only is the prevalence of retinopathy more common in CKD, but the severity has been shown to be inversely related to GFR.[9] In a study of 90 individuals with CKD on the transplant list, only 17% were found to have a normal ophthalmologic examination. The results also showed that 62% had hypertensive retinopathy, while 80% (8/10) with diabetes had diabetic retinopathy.[10]

Other fundus pathology also appears to be increased in prevalence in CKD patients. Microaneurysms, retinal hemorrhages, soft exudates, and arteriovenous nicking were all found to be risk factors for the development of CKD.[7,8]

Red Eyes and Corneal Inflammation

One of the most common complications involving the eye in patients treated with hemodialysis is inflammation and hyperemia of the episcleral tissue and conjunctivae. This inflammation seems to arise from several different mechanisms. Patients treated with dialysis can develop limbal epithelial erosions as a result of calcium deposits, resulting in focal inflammation and hyperemia.[11] (Figure 28.1).

A more diffuse form of hyperemia involving the cornea has also been linked to calcium deposits. Calcium salt deposition appears to be the inciting factor, with the main risk of this process linked to the precipitation product of S[Ca] and S[P].[12] Tokuyama et al. found that conjunctival and corneal calcifications were associated with longer dialysis times, higher calcium−phosphate product, higher PTH levels, and decreased bone mineral density. Interestingly, S[Ca] itself was not significantly associated with pathology.[13] Another study suggested a correlation of the ocular surface calcification with elevated blood urea nitrogen level.[14] Symptoms tend to improve on lowering the S[Ca] phosphate product, typically below 55. Additional treatment can be offered in the form of topical antihistamines, vasoconstrictors, or lubricants.[12,13]

Conjunctival and corneal calcifications should be of particular interest to nephrologists, given the predictive values of these findings for important outcomes in dialysis patients. A study of conjunctival and corneal calcifications and cardiovascular disease with carotid artery examinations showed that the intimal media thickness measurements, reflecting atherosclerosis of the carotid artery, was the best predictor of the development of ocular calcification.[15] The results suggested that perhaps ischemia played an important role in the development of calcification on the ocular surface of people treated with hemodialysis. Hsiao et al. examined the impact of mild, moderate, and severe conjunctival and corneal calcification scores on all cause 1-year mortality in 109 chronic dialysis patients.[16] They found that calcification was significantly associated with all-cause mortality. Those with the most severe conjunctival and corneal calcification had significantly lower survival at 1 year.[16] Figure 28.2 demonstrates band keratopathy, which can be seen in such patients.

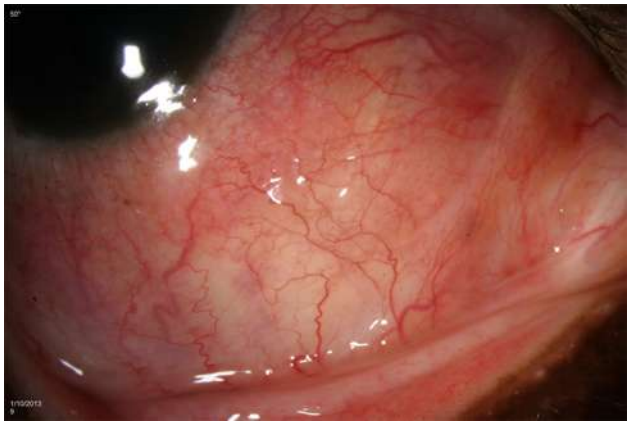

FIGURE 28.1 The conjunctiva of this eye demonstrates inflammation and hyperemia of the episcleral tissue.

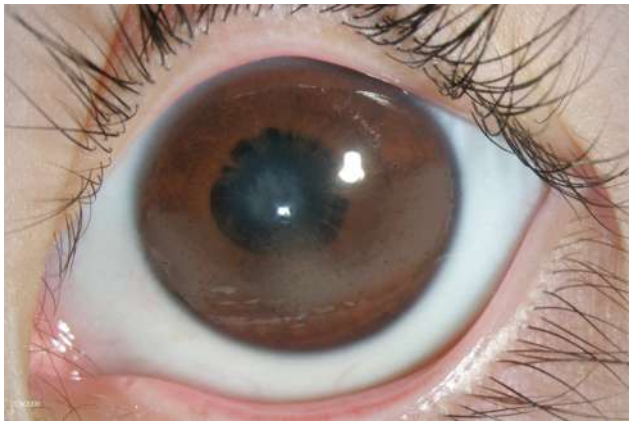

FIGURE 28.2 Band keratopathy is the horizontal band of calcific plaques across the interpalpebral zone of the cornea.

Intraocular Pressure

Many studies indicate intraocular pressure increases in those undergoing hemodialysis, although this has been somewhat of a controversial issue over the years.[17–20] The exact etiology remains unclear, but it has been hypothesized to be related to the underlying inherent hypervolemic and low oncotic pressure state of end-stage renal disease (ESRD) itself.[19,21] Others speculate that elevated intraocular pressure is related to a decrease in serum osmolality during hemodialysis, which results in an increase in fluid volume in the posterior chamber of the eye.[16,22] Dinc et al. set out to address whether or not dialysis treatments result in an increase in intraocular pressure.[20] This group found that changes in corneal thickness observed during hemodialysis may affect the accuracy of intraocular pressure measurements.[21] Increased oxidative stress related to kidney disease has been implicated as a potential cause of elevated intraocular pressure. Oxidative stress has been shown to impair the function of the trabecular meshwork that allows for normal drainage of aqueous humor through the anterior chamber.[18,20] Research in this area is ongoing.

Treatment of increased intraocular pressure in dialysis patients is similar to that in the general population, consisting of agents that decrease aqueous humor production (beta-blockers, alpha-2 adrenergic agonists, and acetazolamide), agents that increase humor filtration and drainage (prostaglandin agonists and miotic agents), or procedures such as surgical trabeculectomy in patients not sufficiently responsive to medical treatments.[21] Acetazolamide may not be the preferred agent in patients with kidney disease due to its propensity to worsen metabolic acidosis, hyperphosphatemia, and hypocalcemia. In dialysis patients, altering the dialysis prescription to decrease the rate of solute clearance and improve volume management may aid in preventing dialysis-associated elevation of intraocular pressure.[16,22]

Cataracts

There has been much speculation regarding whether kidney disease confers an increased risk for the development of cataracts. Much of the uncertainty stems from the fact that dialysis patients often have comorbidities that can contribute to cataract formation, including advanced age, diabetes, hypertension, corticosteroid use, ultraviolet light exposure, and hyperparathyroidism.[22–24] Although prior observational studies may suggest a connection between dialysis and cataracts, a more recent population-based study found that kidney function had no effect on the incidence of cataracts after adjusting for known risk factors.[23,24] One proposed mechanism for cataract formation in dialysis patients centers around urea trapping in the lens during the interdialytic interval, resulting in repeated osmotic shifts.[22–24] Surgical removal of cataracts is well tolerated by dialysis patients.

Retinal Detachment

Retinal detachment in dialysis patients is rare but has been the subject of case reports.[25,26,] As there were no hypertensive crises present at the time of retinal detachment, it was proposed that kidney failure and/or dialysis-related issues may have been responsible. The underlying mechanism is unclear but may be related to focal alterations of choriocapillary permeability and subsequent edema in the subretinal space.[25] A more recent case-control analysis of medical health records in Taiwan indicated an increased risk of serous retinal detachment in people with ESRD treated with dialysis (adjusted HR = 3.86, 95% CI = 1.15–12.96).[27] Prompt diagnosis is critical, as vision loss can be complete, resulting in blindness. Treatment is surgical and is often urgent or emergent.

Optic Neuropathy

Patients treated with hemodialysis are prone to developing anterior ischemic optic neuropathy owing to two risk factors in particular: intradialytic hypotension and anemia.[21] In addition, rapid ultrafiltration may increase blood viscosity and compromise retinal blood flow to the point where ischemia can occur.[28] Compromise of the retinal blood flow watershed area usually presents with loss of the inferior visual field.[22] One observational study noted that approximately 10% of patients suffered this malady over a 1-year follow-up period.[29] Prompt recognition of symptoms and diagnosis with subsequent restoration of adequate perfusion is key to allow maximal vision recovery.[22]

Patients with advanced CKD (but not on dialysis) have been reported to develop temporary blindness, classically known as uremic amaurosis.[30] Transient blindness can develop over minutes to hours and typically resolves over a period of days, sometimes after initiation of dialysis. The pathogenesis of this disorder is unknown, but it is speculated to involve dysfunction of the visual and/or paravisual cortices of the brain.[30] Others propose that the mechanism involves a defect in the optic nerve, with the pathogenesis secondary to uremia and chronic risk factors. The mainstay of treatment is initiation of dialysis, but there may also be a therapeutic role for corticosteroids.[22,31]

Optic neuropathy is also associated with medications used to treat kidney diseases. OKT3 (an immunomodulating drug) has been historically used in kidney transplantation and is associated with the development of optic neuropathy. Deferoxamine (an iron and aluminum

FIGURE 28.3 Age-related macular degeneration consists of drusen (round, yellow lesion located at the level of the retinal pigment epithelium). These can give way to the atrophic or neovascular form of late AMD.

chelator) is associated with both optic neuropathy and color blindness, although the underlying mechanisms are unclear.[22,32]

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) (Figure 28.3) may be related to the development of CKD.[33,34] A recent cohort study found that, after adjusting for multiple risk factors, those with a Cockcroft-Gault estimated GFR less than 60 mL/min/1.73 m^2 had three times greater odds of developing AMD compared to those with kidney function above this threshold.[33] Another study also found significant results for this comparison, as well as a greater than eleven times increased odds of having macular degeneration that was considered severe.[34] Evaluation of National Health and Examination (NHANES, 2005–2008) results found an association of early AMD, which currently has no effective therapy, with CKD.[35] Furthermore, a meta-analysis of 12 studies found a positive association of chronic renal disease with AMD, but there were many inconsistencies and limitations among the studies.[36] Early detection and treatment of CKD may be reasonable to help identify those at risk for AMD and prevent subsequent complications.

OPHTHALMIC FINDINGS IN DIABETES

Diabetes continues to be the leading cause of ESRD in the US.[37] In some studies, diabetic nephropathy, as ascertained by albuminuria, proteinuria, or kidney failure, is found to be a risk factor associated with progression of retinopathy.[38,39] Diabetic retinopathy is a leading cause of new cases of blindness in people aged 20–74 years in the US.[34,40] Diabetic retinopathy can be divided into two main categories: "nonproliferative" diabetic retinopathy (NPDR) and "proliferative" retinopathy (PDR). This retinopathy classification is based on an understanding of the influence of individual characteristics on the risk of progression from NPDR to proliferative stages. Macular edema is also an important etiology for vision loss and can occur at any stage. These changes can be detected with careful ophthalmologic examination and additional testing such as fluorescein angiography and optical coherence tomography.

Epidemiology of Diabetic Retinopathy

Data from population-based studies such as the Wisconsin Epidemiologic Study of Diabetic Retinopathy provide valuable information regarding the prevalence of diabetic retinopathy. In patients with onset of diabetes at 30 years of age or older (presumably type 2) with a duration of less than 5 years, 24%–40% have retinopathy.[41] These rates increase to 53%–84% with a duration of diabetes of 15–19 years. PDR develops in 25% of patients with a duration of 25 or more years of diabetes. In the younger onset group (presumably type 1 diabetes), either proliferative or nonproliferative changes were seen in 13% of patients with less than a 5-year duration of diabetes, and in 90% of patients with a duration of 10–15 years.[42] PDR was present in approximately 25% of patients with a 15-year duration of disease. The prevalence of diabetic macular edema does not vary as much by diabetes type and is approximately 18%–20%.

Risk Factors for Progression of Retinopathy

Medical management of risk factors for progression of retinopathy is essential. These include glucose, hypertension, and cholesterol control. Severity of diabetic retinopathy is associated with poorer glucose control. Although intensive therapy does not prevent retinopathy completely, it does reduce the risk of the development and progression of diabetic retinopathy.[43] A decreased risk of retinopathy was associated with intensive blood pressure control in comparison to less-intensive blood pressure control in a randomized study.[44] Finally, lowering elevated serum lipids may reduce visual loss as increased serum levels of cholesterol are associated with increased severity of hard exudates and development of PDR.[45,46]

Nonproliferative Diabetic Retinopathy

NPDR includes a wide variety of retinal abnormalities that occur well before neovascularization. These

changes include hemorrhages and microaneurysms, venous beading, intraretinal microvascular abnormalities (IRMA), cotton-wool spots, and hard exudates.

Microaneurysms are small saccular or fusiform capillary dilatations seen as small red dots with ophthalmoscopy. Microaneurysms alone (without hemorrhages) do not appear to contribute substantially to the risk of retinopathy progression. The presence of intraretinal hemorrhages, however, especially if present in all four midperipheral retinal quadrants, does predict risk of progression to proliferative retinopathy (Figure 28.4).[47]

Venous beading refers to irregular constriction and dilatation of venules in the retina. "Beading" is a nonspecific sign of retinal ischemia. Beading is a good predictor of risk for retinopathy progression if present in two of the four midperipheral retinal quadrants.[47]

IRMAs are shunt vessels that are enlarged hypercellular capillaries adjacent to or surrounding areas of occluded capillaries. They appear as dilated, telangiectatic capillaries within the retina. They strongly indicate the likelihood of retinopathy progression, even if present in only one midperipheral field.[47]

Cotton-wool spots (or soft exudates) are areas of nerve fiber ischemia or infarction with axonal swelling of the nerve fiber layer induced by areas of retinal capillary closure. They appear as opaque gray or white areas in the retina with "soft" or feathery edges. Although they are a sign of poor retinal perfusion and are easily seen, they have a poor predicative value for retinopathy progression.[47]

Hard exudates are lipid and lipoprotein deposits, usually found in the outer layers of the retina. They have a "waxy" appearance with sharply defined borders and result from leakage from abnormally permeable microaneurysms or capillaries in the retina. Therefore, these lesions are often accompanied by retinal edema and form circinate clusters surrounding areas of leaking microaneurysms. Elevated blood cholesterol is associated with increased severity and extent of hard exudates.[45,46]

Mild to moderate NPDR are related to decompensation of the retinal vasculature by years of diabetic damage. Early signs include small and less-extensive intraretinal hemorrhages, microaneurysms, and hard exudates. As NPDR progresses, increasing retinal ischemia develops and the risk of developing neovascularization increases. The triad of more extensive intraretinal hemorrhages, venous beading, and IRMAs comprises a more florid variety of NPDR, associated with a higher risk of progression to proliferative retinopathy. The Early Treatment Diabetic Retinopathy Study (ETDRS) "4-2-1" rule helps identify eyes in the severe or very severe NPDR groups.[47] The four midperipheral retinal quadrants are assessed for presence and severity of hemorrhages, venous beading, and IRMA.

Eyes with any one of these three features are considered to have severe NPDR: (1) hemorrhages in all four quadrants, (2) venous beading in two quadrants, or (3) IRMA in one quadrant (see Figure 28.5). Eyes with severe NPDR have a 26% chance of progressing to PDR in 1 year and a 48% chance in 3 years. Eyes with two or more of these features are considered to have very severe NPDR. They have a 50% chance of developing PDR in 1 year and a 71% chance in 3 years.

FIGURE 28.4 This montage of the right eye shows diffuse intraretinal hemorrhages in all four retinal quadrants, which indicates severe nonproliferative diabetic retinopathy.

FIGURE 28.5 This right eye has evidence of neovascularization of the disc and neovascularization elsewhere, representing proliferative diabetic retinopathy.

Proliferative Diabetic Retinopathy

In contrast to the changes in NPDR, those of PDR are no longer contained within the retina. PDR consists of neovascularization of the disc (NVD) and neovascularization elsewhere in the retina (NVE), which can lead to preretinal and vitreous hemorrhage (Figure 28.5). NVD comprises newly formed blood vessels, often associated with fibrous tissue, which grow from the optic nerve along the posterior surface of the vitreous and into the vitreous. NVD is associated with a high risk of hemorrhage and severe visual loss without laser photocoagulation. NVE refers to new vessels growing from the retina to proliferate on the posterior surface of the vitreous in a location away from the optic nerve, frequently along the temporal vascular arcades. Although NVE does not carry the same high risk for severe visual loss as does NVD, it may still require treatment or careful monitoring if not treated. NVD and NVE can hemorrhage behind the vitreous or into the vitreous space, decreasing vision. The subsequent contraction of fibrous proliferation can lead to retinal detachment with serious threat to vision.

Patients with proliferative retinopathy are at higher risk for developing severe visual loss (visual acuity less than 5/200). The Diabetic Retinopathy Study (DRS) identified four retinopathy factors associated with an increased risk of developing severe visual loss.[48] The risk factors are separate but cumulative: (1) presence of any new vessels in the eye, (2) presence of new vessels on or near the optic disc, (3) moderate or severe new vessels (greater than 1/4 disc area), and (4) vitreous hemorrhage. The presence of three or four risk factors places the eye in the "high-risk proliferative retinopathy" group. Without treatment, 50% develop severe visual loss in 5 years. Eyes with one or two risk factors are considered to have "early PDR" and are in a lower risk group.

Macular Edema

Diabetic macular edema is the most common cause of visual impairment from diabetes. It can occur in any stage of retinopathy; however, it is not usually present in the first 5–7 years of disease. Macular edema is edematous thickening of the macula (the area responsible for central vision) that can lead to blurring of vision by disturbing the architecture of the retina (Figure 28.6). Macular edema can be detected by ophthalmoscopy or optical coherence tomography. When thickening involves or threatens the center of the macula, it is considered to be "clinically significant" and carries a higher risk of visual loss. Eyes with "clinically significant macular edema" have a 32% chance of developing moderate visual loss (a decrease of 3 lines or more) in 3 years without treatment.[49]

FIGURE 28.6 The macula of this eye has edema, which is best seen clinically with stereoscopic viewing and the hard exudate is indicative of presence of macular edema.

Management

The treatment of diabetic retinopathy is based on the results of two major randomized clinical trials, the DRS and the ETDRS. Treatment for PDR is laser photocoagulation, involving applying multiple laser burns in the peripheral retina and posterior portion of the retina sparing the macula. The DRS results demonstrated a 50% reduction in severe visual loss (visual acuity of 5/200 or worse) in eyes with severe nonproliferative and proliferative retinopathy that received photocoagulation.[50] The rate of progression to neovascularization or to high-risk retinopathy stages was very low, and laser photocoagulation is not recommended for eyes with mild to moderate NPDR.[50] As the retinopathy advances to the severe or very severe nonproliferative or early proliferative stage, the risk–benefit ratio becomes more favorable, and it is reasonable to consider initiating photocoagulation before the development of high-risk proliferative retinopathy.[51]

Current treatments for diabetic macular edema include laser and intravitreal antivascular endothelial growth factor (anti-VEGF) injections. The mainstay of treatment for macular edema has been laser therapy, which involves small, mild-intensity laser burns targeted at areas of leakage in the macula[45,49] known as "focal macular photocoagulation." However, intravitreal injections of anti-VEGF are now also considered a first-line treatment and have been shown by several studies to be superior to laser therapy alone.[48–55]

Vision loss from diabetes can be reduced by appropriate diagnosis and proper treatment. However, patients are often asymptomatic until retinopathy has advanced beyond the stages in which treatment is most effective. Periodic detailed eye examinations are crucial for detecting and monitoring retinal changes before irreversible damage has occurred.

KIDNEY TRANSPLANT–RELATED OCULAR COMPLICATIONS

Those patients who have received a kidney transplant are not immune to the onset of ocular disease. The prevalence of ocular complications in kidney transplant patients has been described to be as high as 52% and often related to immunosuppression medications.[56] A common complication is posterior subcapsular cataract formation, typically thought to be a result of corticosteroid therapy. Other noninfectious complications include steroid-induced elevated intraocular pressure, as well as vascular complications that are typically associated with underlying disease. The remaining described complications after transplant are infectious in nature, with characteristic pathogens being cytomegalovirus, mucormycosis, cryptococcus, herpes simplex, and herpes zoster.[56] Prompt diagnosis, adjustment of immunosuppression, and prolonged antibiotic treatment are needed for ocular infections that carry a high risk of blindness and disseminated disease.

OCULORENAL SYSTEMIC DISEASES

There are a host of either acquired or genetic diseases that can result in pathologic findings in both the kidneys and the eyes. Understanding this relationship opens an opportunity to solidify an often elusive diagnosis in a noninvasive fashion.

Autoimmune Diseases

Systemic Lupus Erythematosus

Kidney involvement occurs in approximately 50% of those with systemic lupus erythematosus (SLE). Ophthalmic disease, however, is also common in patients with SLE. The range of these conditions is vast, though most are relatively rare. The most common symptom or finding is keratoconjunctivitis sicca, or dry eyes. The remaining findings range in severity from subtle skin findings to vision-threatening complications, including ischemic retinal vasculitis (Figure 28.7).[57] Complaints of the onset of blurry vision or double vision may be the result of cranial nerve palsies or optic neuropathy. Permanent vision loss may result from vascular complications, which may either be inflammatory or thrombotic in nature. Table 28.1 provides a comprehensive list of ocular findings in patients with SLE.

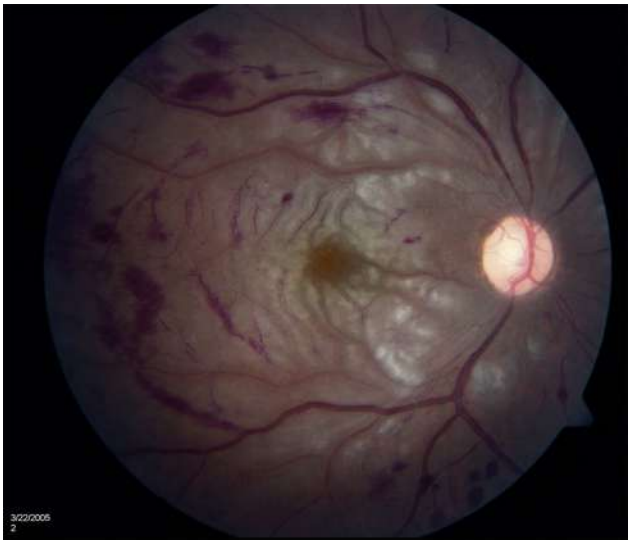

FIGURE 28.7 This right fundus shows marked retinal infarction from ischemic retinal vasculitis in systemic lupus erythematosus.

TABLE 28.1 A Comprehensive List of Ocular Findings in Systemic Lupus Erythematosus

Ocular Item	Finding
Sclera	Episcleritis Scleritis
Eyelid	Cutaneous manifestations
Retina	Retinal vasculitis Cotton-wool exudates Retinal hemorrhages Serous retinal detachment Retinal occlusive vasculitis Retinal venous thrombosis
Neurologic	Cranial nerve palsies Optic neuropathy Inflammatory pseudotumor of the orbit
Vascular	Transient ischemic attack (TIA) Amaurosis fugax Cerebrovascular accident (CVA)
Cornea	Keratoconjunctivitis sicca Secondary Sjögren's syndrome

See reference 48.

Hydroxychloroquine is often used as part of the treatment for SLE. Despite retinal toxicity being relatively rare, it is generally recommended that all patients started on hydroxychloroquine have a baseline ophthalmic examination.[58] In addition, all patients with kidney disease should be screened annually by an ophthalmologist.[58] The classic finding is known as a "bull's eye maculopathy." Bull's eye maculopathy is essentially a peripheral retinal lesion from which many

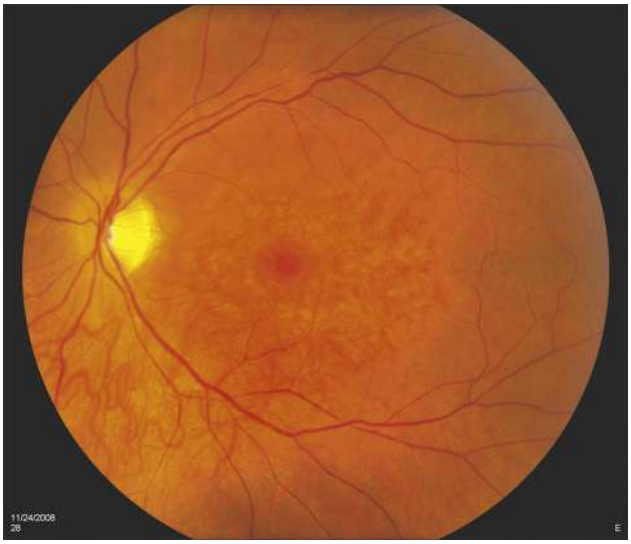

FIGURE 28.8 Plaquenil or hydroxychloroquine toxicity is manifested with atrophy of the retinal pigment epithelium with preservation of the center of the macula, consistent with "bull's eye maculopathy."

patients do not have symptoms until they develop advanced disease. This necessitates vigilant screening practices to detect early disease.[58] (Figure 28.8).

Granulomatosis with Polyangiitis and Microscopic Polyangiitis

Granulomatosis with polyangiitis (GPA) (formerly Wegener's Granulomatosis) and microscopic polyangiitis (MPA) are well known for their effects on both the lungs and kidneys. Less appreciated are the ocular complications of these diseases, which occur in 28–58% of patients.[57,59] Of these patients 15–20% have orbit disease. Proptosis is the usual symptom observed. Proptosis is the result of severe and long-term inflammation in the orbits. Not surprisingly, many of these patients have vision compromise either from compression of the optic nerve or vascular ischemia of this structure.[59] Up to 8% of patients suffer vision loss.[59]

Conjunctivitis in the setting of GPA has been associated with a higher incidence of subglottic stenosis, a life-threatening complication. Therefore, the finding of conjunctivitis in these patients must lead to an airway examination.[59,60]

Other important ocular findings in GPA and MPA include scleritis, episcleritis, peripheral ulcerative keratitis, and uveitis.[57]

Churg-Strauss Syndrome

Churg-Strauss syndrome is a condition that consists of eosinophilic and granulomatous inflammation capable of affecting multiple organs. Its most common manifestations are in the lungs and upper airways. Kidney involvement is also common, often presenting as focal interstitial eosinophilic nephritis or a focal segmental glomerulosclerosis-like pattern of injury. Ocular findings include conjunctival granulomas, scleritis, episcleritis, uveitis, cranial nerve palsies, and retinal arterial occlusion.[58]

Antiglomerular Basement Membrane Disease (Goodpasture's Syndrome)

Similar to the linear deposition of IgG on the basement membranes in lung and kidney tissue, this process can also occur on the basement membrane of the choroid (Bruch's membrane) and the basement membranes of the choroidal blood vessels. The resulting pathology includes retinal detachment, choroidal ischemia/infarction, and macular edema. Other possible pathologies include conjunctivitis, scleritis, retinal vasculitis, and occlusion of retinal vessels.[61]

Tubulointerstitial Nephritis and Uveitis Syndrome

Tubulointerstitial nephritis in conjunction with uveitis (TINU) is a clinical entity that classically affects young women. These patients commonly present with kidney dysfunction, but uveitis may be the presenting symptom in up to 36% of TINU cases.[57] Although the interstitial nephritis component of this syndrome often resolves completely, uveitis tends to be chronic or relapsing.[62] The uveitis is nongranulomatous, typically limited to the anterior segment, and responds well to topical or systemic antiinflammatory treatments.[63]

Sarcoidosis

Noncaseating granulomatous inflammation is the hallmark feature of this multisystem disease. Although classically involving the lung and mediastinal lymph nodes, both kidney and ocular involvement can occur. Kidney involvement is typically mild and is often the result of tubulointerstitial nephritis, hypercalcemia, granulomatous inflammation, and nephrocalcinosis, though glomerulonephritis has also been reported with sarcoidosis.[57] The classic ocular finding in sarcoidosis is granulomatous uveitis, though retinal periphlebitis, macular edema, retinal neovascularization, and granuloma formation can occur as well[57] (See Figure 28.9).

Treatment of uveitis typically involves corticosteroids. Milder cases are often amenable to topical corticosteroids, whereas more severe and chronic cases may necessitate intravitreal injections.[64] Other agents that have been used include methotrexate, azathioprine, mycophenolate, leflunomide, and anti-TNF agents.[64]

Others

There are other autoimmune diseases with oculorenal manifestations. These include giant cell arteritis, Takayasu's arteritis, polyarteritis nodosa, Behçet's disease, primary antiphospholipid antibody syndrome, Sjögren's

FIGURE 28.9 This patient has evidence of sarcoidosis-associated uveitis with evidence of periphlebitis and multiple granulomas along the retinal vessels.

syndrome, and cryoglobulinemia. The ocular and kidney findings associated with these diseases are summarized in Table 28.2.

Genetic Conditions

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common familial form of kidney disease. Ophthalmic disease is not a primary manifestation of ADPKD. A characteristic appearance of the eyelid, however, may be helpful in initial diagnosis. One study followed 75 families, with at least one member with ADPKD.[65] In 32% of these families at least one affected person had blepharochalasis, a condition that causes the upper eyelid to fold underneath the rest of the lid, obscuring the proximal portion of the eyelashes. This finding may be helpful in determining a cause of CKD in an undiagnosed person, particularly in cases that are sporadic in nature.

TABLE 28.2 The Ocular and Kidney Findings Associated with Autoimmune Diseases

Disease	Renal Findings	Ocular Findings
Behcet's disease	Rare—Nephrosclerosis, amyloidosis, glomerulonephritis	Common—Anterior uveitis, retinal vasculitis Rare—Neovascularization, strabismus, vitreous hemorrhage, cataracts, glaucoma
Cryoglobulinemia	Common—Membranoproliferative glomerulonephritis	Common—Inflammatory orbital pseudo tumor leading to acute orbital expansion Rare—Retrolental fibroplasias
Giant cell arteritis	Common—Minimal proteinuria, hematuria, red blood cell casts Rare—Intrarenal vasculitis, renal artery vasculitis, membranous glomerulopathy	Common—Anterior ischemic optic neuropathy Rare—Central retinal artery occlusion, chronic ocular ischemia, ophthalmoparesis
Polyarteritis nodosa	Common—Renal arteritis and ischemia	Common—Choroidal vasculitis
	Rare—Renal arterial aneurysm rupture with hematoma formation, renal vein thrombosis	Rare—Granulomatous scleritis, chronic nongranulomatous iridocyclitis, retinal detachment, retinal fusiform aneurysms, perivasculitis of several structures, stromal keratitis, cataract, posterior ischemic optic neuropathy, uveitis, hypertensive retinopathy
Primary antiphospholipid antibody syndrome	Common—Renal artery thrombosis, thrombotic microangiopathy	Common—Retinal vasculitis, vitritis, retinal detachment, central retinal artery occlusion
Sjögren's syndrome	Common—Tubulointerstitial nephritis	Common—Keratoconjunctivitis sicca
	Rare—Immune complex-mediated glomerulonephritis, mesangial nephropathy, renal pseudolymphoma, hemolytic uremic syndrome, amyloidosis, mixed cryoglobulinemia, obstructive nephropathy, renal artery vasculitis	Rare—Corneal melting
Takayasu's arteritis	Common—Renal artery stenosis, tubulointerstitial nephritis	Common—Retinal arteriovenous shunts, retinal artery occlusion, anterior ischemic optic neuropathy
	Rare—Glomerulonephritis, amyloidosis	

See Reference 48.

TABLE 28.3 Conditions in which Both Kidney Impairment and Ophthalmic Complications Occur

Disease	Renal Findings	Ocular Findings
Bardet–Biedl syndrome	Polycystic kidney disease, abnormal calyces, diffuse cortical loss	Retinal dystrophy, retinitis pigmentosa, blindness
Fabry disease	Polycystic disease	Cornea verticillata, tortuous conjunctival/retinal vessels, "Fabry cataract"
Inherited proximal renal tubular acidosis	Proximal renal tubular acidosis	Bilateral glaucoma, cataracts, band keratopathy
LCAT deficiency syndrome	Diffuse lipid accumulation, proteinuria, kidney failure	Arcus lipoides corneae, retinal hemorrhages, optic disc protrusion, Bruch's membrane rupture
Nail–patella syndrome	Glomerular basement membrane (GBM) abnormalities, fibrillar collagen deposition in GBM	Microcornea, sclerocornea, congenital cataract, abnormal iris pigmentation (Lester's sign), congenital glaucoma
Primary hyperoxaluria	Oxalate nephrocalcinosis, nephrolithiasis	Crystalline retinopathy, maculopathy
Sturge–Weber syndrome	Renal hemangiomas	Congenital glaucoma, choroidal hemangiomas, nevus of Ota, buphthalmos
Tuberous sclerosis	Renal angiomyolipomas, polycystic kidney disease, renal cell carcinoma	Retinal hamartomas, retinal depigmentation, angiofibromas of the eyelid
von-Hippel Lindau disease	Renal cell carcinoma, polycystic kidney disease	Retinal hemangioblastomas

See references 63–76.

Alport Syndrome

Although progressive hereditary nephritis and senorineural hearing loss are the hallmark manifestations of Alport Syndrome (AS), ocular signs have been reported. Most ocular abnormalities are associated with X-linked AS, which is by far the most common.[66] Dot-and-fleck retinopathy is found in up to 85% of AS patients, though the most common conditions causing decreased visual acuity are lenticular in nature. Anterior lenticonus occurs in approximately 25% of patients, whereas posterior lenticonus and posterior polymorphous corneal dystrophy occur much less frequently. The retinopathy usually becomes apparent around the time of kidney failure, whereas anterior lenticonus typically presents later in life. Dot-and-fleck retinopathy in combination with a family history of AS and kidney failure is diagnostic of an incident AS case, whereas the mere presence of anterior lenticonus or posterior polymorphous corneal dystrophy is highly suggestive of the disease without any other evidence.[67] Other reported ocular features of AS include microcornea, arcus, iris atrophy, cataracts, spontaneous lens rupture, spherophakia, recurrent corneal erosion, and retinal pigmentation.[67,68]

Cystinosis

This rare, autosomal recessive lysosomal storage disease affects primarily the kidneys but also the bone marrow, pancreas, skeletal muscles, brain, and eyes.[69] Eye disease manifests with crystal deposition in the cornea, conjunctiva, and iris, typically at very young ages. However, with the advent of kidney transplantation, patients are living much longer lives, and additional ophthalmic complications have been reported. In particular, superficial punctate keratopathy, severe peripheral neovascularization, various iris abnormalities, and band keratopathy range from 40% to 73% in prevalence in these patients.[70] Glaucoma has also been reported as a result of iris thickening and posterior synechiae.[69]

Others

Several other conditions exist in which both kidney impairment and ophthalmic complications occur (Table 28.3).[71–84]

CONCLUSION

It is clear that there is a high prevalence of comorbid eye disease in patients with CKD, ESRD, and kidney transplant patients. Early ophthalmic evaluation in the face of visual changes in these patients is of paramount importance. In addition, there may be a role for routine ophthalmology screening in any patient with stage 3 CKD or higher. Future studies focusing on the preventive benefit of such screening programs will certainly shed light on the potential benefits of this collaboration.

QUESTIONS AND ANSWERS

Question 1

A 46-year-old man presents for initial evaluation of CKD. S[Cr] is currently 1.5 mg/dL, corresponding to an eGFR of 50 mL/min/1.73 m^2. S[Cr] was normal 3 years ago. He has no history of diabetes mellitus. He has had hypertension for approximately 15 years. He does not have a family history of kidney disease. His urinalysis shows no RBCs or WBCs and has trace albumin on dipstick. His only complaint is increasing blurry vision, which he notes in both eyes. He states this has been slowly progressive for at least five years. You make the referral to ophthalmology, but as you are doing so you attempt to formulate a differential diagnosis of this visual problem. All of the following fundus pathologies are associated with increased risk of CKD **except**?

A. Microaneurysms
B. Retinal hemorrhages
C. Macular degeneration
D. Soft exudates
E. Arteriovenous nicking

Answer: C

Several fundus pathologies convey a risk for developing CKD according to some recent studies. The Chronic Renal Insufficiency Cohort study published a cross-sectional study in 2010 demonstrating an association between fundus pathology and the presence of CKD. Interestingly, this association also appeared to be stronger in males, non-whites, those with diabetes, and those under the age of 50.[7] This is consistent with an earlier prospective cohort study published in 2004 from the Atherosclerosis Risk in Communities database. Here, it was found that the presence of microaneurysms, retinal hemorrhages, soft exudates, and arteriovenous nicking was associated with a greater risk of later-developing CKD. They found no such risk with focal arteriolar narrowing or changes in arteriole-to-venule ratio.[8] Macular degeneration putting people at risk for CKD was not looked at in these studies, though there is some early evidence that the presence of CKD may increase the risk of later developing macular degeneration.[33,34]

Question 2

You see patients at the local dialysis unit as part of your monthly rounds. Your next patient is a 53-year-old man with ESRD secondary to focal segmental glomerulosclerosis who has been on dialysis for four years. Adequacy on dialysis has been acceptable and hemoglobin is at goal. There are no access issues and his electrolytes are acceptable. He complains of itchy, red eyes, which seems to be getting worse over the past couple of weeks. He wonders if he has developed allergies, though he denies rhinitis or cough. Examination demonstrates diffuse corneal erythema. Based on this appearance, you suspect corneal inflammation from calcium deposition. All of the following have been identified as risk factors in this process with the **exception** of:

A. Hypercalcemia
B. Longer dialysis times
C. Decreased bone mineral density
D. Hyperparathyroidism
E. Calcium x phosphorus product

Answer: A

Calcium deposition resulting in corneal inflammation is a problem stemming from calcium and phosphate mishandling and disturbances in the endocrine processes governing these ions. The most comprehensive study looking at this issue was a cross-sectional study from Japan published in 2002.[13] 44 men had corneal calcification scores detected by slit lamp examination. Several risk factors were evaluated. Longer dialysis times and decreased bone mineral density were associated with higher calcification scores but were more likely to represent background compliance factors. Higher PTH levels and calcium x phosphate product were strongly associated with higher corneal calcification scores, as were S[P] levels. However, interestingly, there was no significant association of hypercalcemia with this process.

Question 3

A 21-year-old woman comes to your office for initial evaluation of hematuria and proteinuria. A college sports examination included a urinalysis that demonstrated 2+ proteinuria, which then was followed by a protein:creatinine ratio of 1.8 g protein/g creatinine. She also had 20 RBC per high power field. S[Cr] is 1.2 mg/dL. She denies any current health problems. She has no history of hypertension or diabetes. She wears hearing aids for sensorineural hearing loss, which was diagnosed in childhood. Her father died when she was 5 years old, and she thinks he was treated with dialysis. She is unaware of anyone else in her family with kidney disease. She does not take nonsteroidal inflammatory drugs or any other medications. She has no history of kidney stones and history of frequent urinary tract infections. Review of systems was only notable for decreasing visual acuity over the past 6 months.

BP is 132/78 mm Hg with a pulse of 65 bpm. Physical examination is unremarkable other than the presence of hearing aids. In addition to collecting various serologies and planning a biopsy in the coming months (she would

like to wait until after the soccer season), you refer her to ophthalmology for decreasing visual acuity. Their findings included anterior lenticonus and dot-and-fleck retinopathy. The following criteria allow you to diagnose Alport's syndrome with the **exception** of:

A. Family history of Alport's syndrome
B. Sensorineural hearing loss
C. Evidence of kidney disease
D. Dot-and-fleck retinopathy

Answer: B

This young woman with the recent discovery of an elevated S[Cr], microscopic hematuria, and subnephrotic range proteinuria in the absence of known systemic disease raises concern regarding a primary glomerular disorder. The fact that she has sensorineural hearing loss and a probable family history of kidney disease raises the suspicion of Alport syndrome, but certainly other glomerular pathologies still need to be considered. Recent studies, however, have suggested that the presence of a family history of Alport's, evidence of kidney disease, and dot-and-fleck retinopathy is virtually diagnostic of Alport's syndrome.[67] Anterior lenticonus is seen in approximately 25% of cases. Posterior polymorphous corneal dystrophy is rare, but when present, is also nearly exclusive to Alport Syndrome.[66] Although characteristic of many types of Alport Syndrome, the presence or absence of hearing loss is not part of the clinical triad suggested by Colville et al.[67] It should be noted that many X-linked cases are not associated with hearing loss, causing many cases of Alport Syndrome to be missed by physicians expecting the presence of hearing problems.

Question 4

A 57-year-old man with CKD is referred for initial evaluation. He has a history of diabetes mellitus for 7 years and was recently diagnosed with hypertension and hypercholesterolemia, for which he was started on medication. He denies any systemic complaints and reports his last hemoglobin A1c was at goal. The patient recently underwent his first diabetic eye screening examination with ophthalmology and brought a copy of the report to you. It states he has moderate nonproliferative diabetic retinopathy without macular edema in both eyes. The patient is concerned about his ocular findings and the effect it will have on his vision if it progresses. All of the following have been identified as risk factors for progression of diabetic retinopathy **except**

A. Venous beading
B. Cotton-wool spots
C. Intraretinal hemorrhages
D. Poorly controlled cholesterol
E. Poorly controlled hypertension

Answer: B

Medical management of risk factors for progression of retinopathy is essential and includes glucose, hypertension, and cholesterol control. Severity of diabetic retinopathy is associated with poorer glucose control. Although intensive therapy does not prevent retinopathy completely, it does reduce the risk of the development and progression of diabetic retinopathy.[43] Intensive blood pressure control in comparison to less intensive blood pressure control is also associated with decreased retinopathy.[44] Additionally, increased serum cholesterol levels are associated with increased severity of hard exudates and development of proliferative diabetic retinopathy.[45,46] The Early Treatment Diabetic Retinopathy Study (ETDRS) "4-2-1" rule helps identify eyes in the severe or very severe NPDR groups.[47] Eyes with any one of these three features are considered to have severe NPDR: (1) hemorrhages in all four quadrants, (2) venous beading in two quadrants, or (3) IRMA in one quadrant, and have a 26% chance of progressing to proliferative diabetic retinopathy in 1 year and a 48% chance in 3 years. Although cotton-wool spots are a sign of poor retinal perfusion, they have poor predictive value for retinopathy progression.[47]

Question 5

A 62-year-old woman with CKD presents for routine follow-up. She has poorly controlled diabetes for the past 20 years. The patient was seen by ophthalmology yesterday for "floaters" in her right eye that appeared suddenly 3 days ago while she was watching television. The floaters obscure portions of her vision, but she denies any discomfort. The medical record from the ophthalmologist states the patient has proliferative diabetic retinopathy in both eyes with a vitreous hemorrhage in the right eye. The patient tells you she is scheduled to return to the ophthalmologist for treatment in a few days, but states the office is too far away and she would like to know if her vision will improve on its own. You tell her diabetic retinopathy is the leading cause of new cases of blindness in people aged 20–74 years in the US, and it is important to follow up for treatment. All of the following have been identified as risk factors for moderate or severe vision loss for which ocular treatment is recommended **except**

A. Vitreous hemorrhage
B. Intraretinal hemorrhages
C. Presence of new vessels on or near the optic disc
D. Moderate or severe new vessels (greater than 1/4 disc area)
E. Clinically significant macular edema

Answer: B

NPDR includes a wide variety of retinal abnormalities that occur well before neovascularization. These changes include intraretinal hemorrhages and microaneurysms, venous beading, IRMA, cotton-wool spots, and hard exudates. Although the presence of intraretinal hemorrhages, especially if present in all four retinal quadrants, predicts progression to PDR, intraretinal hemorrhages alone are not a risk factor for moderate or severe vision loss and do not require ocular treatment. In contrast, PDR consists of NVD and neovascularization elsewhere in the retina, which can lead to preretinal and vitreous hemorrhage. The Diabetic Retinopathy Study identified four retinopathy factors associated with an increased risk of developing severe visual loss without treatment.[48] The risk factors are separate but cumulative: (1) presence of any new vessels in the eye, (2) presence of new vessels on or near the optic disc, (3) moderate or severe new vessels (greater than 1/4 disc area), and (4) vitreous hemorrhage. Presence of three or four risk factors places the eye in the "high-risk proliferative retinopathy" group. Without treatment, 50% of such patients develop severe visual loss in 5 years. Another important cause of visual loss is macular edema. Eyes with clinically significant macular edema have a 32% chance of developing moderate visual loss in 3 years without treatment.[49]

Neurologic Complications of Chronic Kidney Disease

Stephen Seliger[a], *Salina P. Waddy*[b]

[a]Department of Medicine, Division of Nephrology, University of Maryland School of Medicine, Baltimore, MD, United States; [b]Atlanta Veterans Administration, Department of Neurology, Decatur, GA, United States

Abstract

Neurologic outcomes in chronic kidney disease (CKD) patients are pervasive. The most common are cognitive impairment, stroke, seizures, and peripheral neuropathies. Despite a strong graded association between measures of renal function and cognitive function, cognitive impairment in CKD patients is largely undiagnosed. Annual and predialysis cognitive screening is critical to avoid adverse outcomes of missed diagnoses of cognitive impairment: medication noncompliance and inability to make informed decisions regarding initiating dialysis. Cerebrovascular disease, neurodegenerative disease, and inflammation contribute to a CKD model of accelerated vascular cognitive impairment. Risk of stroke increases significantly in CKD and ESRD patients, up to sevenfold during the month of dialysis initiation. Aggressive treatment with erythropoiesis-stimulating agents increases stroke risk appreciably. For stroke prevention in atrial fibrillation, warfarin and dose-adjusted newer anticoagulants appear effective in stage 3 CKD patients but are unproven or contraindicated in CKD stage 4 or higher. Management of uremic polyneuropathy, mononeuropathies, and uremic pruritus is described in this chapter.

INTRODUCTION

Central and peripheral neurologic disorders in chronic kidney disease (CKD) patients are pervasive but are frequently underdiagnosed and their impact often underappreciated. The common neurologic complications in the CKD population are cognitive impairment, seizure, stroke, and peripheral neuropathies.[1]

COGNITIVE IMPAIRMENT IN CKD

Cognitive impairment is highly prevalent in CKD patients. Multiple studies have confirmed a graded association between renal function or albuminuria and cognitive impairment. Despite cognitive impairment being highly prevalent in the ESRD population, it is substantially underdiagnosed. In studies of HD patients,[2,3] only 4% of patients with cognitive impairment had received a medical record diagnosis. As early stage CKD patients on average have much less frequent healthcare contact than HD patients, the likelihood of underdetection in earlier stage CKD patients is probably greater.

Definitions of Cognitive Impairment (in the Non-CKD and CKD Populations)

Most studies describe the frequency of global cognitive impairment, measured on a test of overall cognitive function such as the Mini-Mental State Exam,[4] or of impairment in individual cognitive domains, including memory, attention, language, visual–spatial, calculations, and executive function. Executive function encompasses judgment and planning, including the ability to make informed healthcare decisions. Some studies measure diagnosed dementia, usually according to Diagnostic and Statistical Manual of Mental Disorders (DSM) IV criteria.

Mild cognitive impairment (MCI) is impairment that is no longer consistent with normal aging but has not progressed to dementia. MCI most often involves early short-term memory loss (amnestic MCI) or impairment in one or more other cognitive domains such as language or executive function (nonamnestic MCI). MCI is often defined as performing 1.5–1.99 standard deviations below standardized norms on a given cognitive test,[5,6] but the definition varies. The conversion rate from MCI to dementia is approximately 15% per year in elderly patients without CKD[6] and is higher in those

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00029-2

who carry the apolipoprotein E4 (APOE4) allele.[7] APOE4 is a genetic factor that confers increased risk of Alzheimer disease (AD).

Dementia is defined by DSM IV criteria as chronic persistent and usually progressive cognitive impairment in two or more cognitive domains (usually including memory) that substantially affects daily function, represents a decline in premorbid function, and is not due to concomitant acute delirium.[8] Dementia is often defined in research studies as performing two or more standard deviations below population-defined norms in at least two cognitive domains.

Dementia is the umbrella term for moderate to severe chronic cognitive impairment. AD is the most common type of dementia in the general US population and the most common neurodegenerative dementia. Hippocampal and cerebral atrophy are eventual prominent features of AD. Vascular dementia, due to both large- and small-vessel pathology and often accompanying white matter disease, is the second most common type, alone or in combination with AD. Dementia associated with Parkinson's disease (sometimes called Lewy body disease), frontal–temporal dementia, and other dementia syndromes account for the remaining approximately 20% of dementias in patients without CKD.[9]

Delirium is a syndrome of acute cognitive impairment characterized by acute onset, inattention, disorganized thinking, and an altered state of consciousness, including sleep–wake cycle disturbance. Other common symptoms include psychomotor agitation or retardation, memory loss, and disorientation. Delirium is defined by abrupt onset and fluctuating course, in contrast to the chronic insidious progressive nature of dementia. Delirium was previously believed to be transient. It is now established, however, that delirium often leads to sustained cognitive decline, especially in patients with preexisting dementia, and to a loss of on average one activity of daily living over 6 months of follow-up in non-CKD patients.[10–12] Delirium is often due to an acute intercurrent medical condition such as a urinary tract infection, a medication side effect, or electrolyte imbalance. Interventions that result in bed-restriction or decreased mobility such as physical restraints, urinary catheters, or intravenous lines also increase the risk of delirium. Delirium is often multifactorial, so the actual cause may be difficult to ascertain. The presence of dementia increases the risk of delirium, and they often coexist. As delirium occurs three times as often in patients with dementia[13] as in those without, the development of delirium should trigger suspicion of an underlying dementia. However, because the symptoms of delirium are difficult to distinguish from those of dementia, for patients with no previous diagnosis of cognitive impairment who develop delirium, it is recommended to wait for a period of approximately a month after the delirium episode to conduct a full dementia assessment.

The Confusion Assessment Method is the most commonly used instrument to assess the presence of delirium. The Confusion Assessment Method is a brief standardized validated instrument with questions regarding four features: (1) acute onset or fluctuating course, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness (such as hypervigilance, lethargy, or stupor). The diagnosis of delirium requires the presence of features 1 and 2, and either 3 or 4. Other symptoms may be present such as disorientation, psychomotor agitation or retardation, hallucinations, sleep–wake cycle disturbance, and memory loss.[14]

Epidemiology of Cognitive Impairment in CKD

The true population prevalence and incidence of cognitive impairment in CKD are difficult to estimate because most studies were not population based but conducted in clinic or referral populations. Among 80 stage 3–4 CKD clinic patients, 23% had severely impaired executive function and 28% scored poorly on delayed memory test.[15] In the 2006 US Renal Data System Annual Data Report using Medicare claims data, the prevalence of dementia was 7.6% in the CKD cohort, increasing to 16.8% among patients aged 85 years or older.[16] However, these rates are substantially underestimated because Medicare claims are an insensitive measure of dementia in populations in whom cognitive function is infrequently assessed.

Multiple reports describe a graded cross-sectional relationship between estimated glomerular filtration rate (eGFR) and cognitive impairment. As renal function declines, so does cognitive function.[17–20] In the Reasons for Geographic and Racial Differences in Stroke study, the prevalence of cognitive impairment increased with declining eGFR starting at eGFR<60 mL/min/1.73 m^2 and paralleled the prevalence of cerebrovascular disease (Figure 29.1).[18–20] In the Heart, Estrogen/Progesterone Study among menopausal women, each 10 mL/min/1.73 m^2 decrement in eGFR corresponded to an approximately 15–25% increase in risk of impairment in executive function, language, and memory.[19] Using a cognitive battery, the Chronic Renal Insufficiency Cohort study found that eGFR<30 compared with 45–59 mL/min/1.73 m^2 was associated with greater impairment in most cognitive domains.[20]

The Systolic Blood Pressure Intervention Trial (SPRINT) was a study of intensive compared with standard blood pressure goals. Patients with diabetes and those with a history of stroke were excluded. Of the more than 9000 SPRINT participants, 2707 had complete

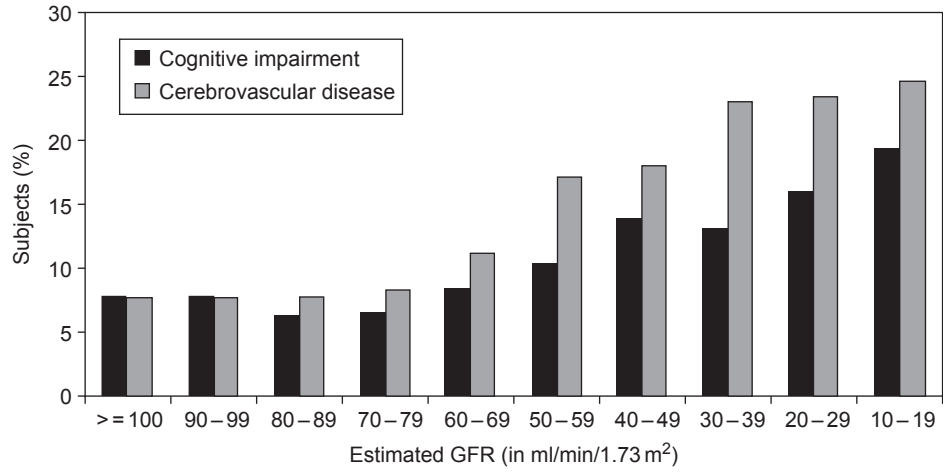

FIGURE 29.1 Unadjusted prevalence of cognitive impairment and cerebrovascular disease by estimated glomerular filtration rate (eGFR). *Reference 18, Copyright 2008 Elsevier Inc, reproduced with permission.*

assessments of cognitive function. A subset of 637 participants underwent brain imaging. Mean age was 68 years, more than a third were women, and almost a third were Black. Mean eGFR was 70.8 ± 20.9 mL/min/1.73 m^2. Median urine albumin:creatinine ratio (UACR) was 9.7 mg/g. In this cross-sectional assessment, higher UACR was associated with worse global cognitive function, executive function, memory, and attention, in adjusted analyses. Increased urinary albumin excretion was associated with cognitive performance typical of older people. Lower eGFR was independently associated with worse global cognitive function and memory. In adjusted models, higher urinary albumin excretion was associated with larger abnormal white matter volume. There was no relationship detected between this parameter and eGFR. The findings suggested vascular disease may be associated with abnormal cognitive function in this population.[21]

A longitudinal relation between baseline eGFR and declines in global cognitive function and cognitive domains has also been reported.[18,22–28] In the Cardiovascular Health Study, serum creatinine concentration (S[Cr]) >1.5 mg/dL in men and >1.3 mg/dL in women was associated with a 37% increased risk of incident dementia over 6 years.[27] In the Health, Aging, and Body Composition (Health ABC) Study, adjusted odds ratios for cognitive decline were 1.32 for baseline eGFR 45–59 mL/min/1.73 m^2 and 2.43 for <45 mL/min/1.73 m^2 (stage 3b CKD). In the Rush Memory and Aging Project, the effect on global cognitive function of 15 mL/min/1.73 m^2 lower eGFR at baseline was similar to 3 years of aging and equivalent to about 75% of the effect of the APOE-4 allele, which confers up to twofold increased risk of AD.[29] Baseline eGFR also predicted cognitive decline in the specific cognitive domains of memory and verbal fluency. Decline in eGFR over 5 years was associated with decline in global cognition, verbal episodic memory, and abstract reasoning in the Maine-Syracuse Longitudinal Study of 590 community-dwelling individuals with mean age of 62 years, and mean baseline eGFR of 78.4 mL/min/1.73 m^2. In that study, a decline in eGFR of 30 mL/min/1.73 m^2 over 5 years was equivalent to a decline in global cognitive function of approximately 7 years of aging.[28]

Serum cystatin C concentration is another parameter used to measure renal function that has been studied in relation to cognitive impairment. Cystatin C colocalizes with amyloid in the brains of AD patients, and elevated serum cystatin C concentrations in the Health ABC study were shown to be associated with increased risk of baseline cognitive impairment and cognitive decline.[30] Studies in animal models suggest that higher concentrations of cystatin C may have a protective effect against AD.[31]

Albuminuria may be a more sensitive biomarker for cognitive impairment than eGFR both cross-sectionally and longitudinally, because it is a measure of microvascular endothelial function and more likely to reflect similar vascular integrity in the cerebrovascular system.[32–34] In the Action to Control Cardiovascular Risk in Diabetes-Memory in Diabetes (ACCORD-MIND) trial,[32] urinary albumin excretion, measured as albumin:creatinine ratio (ACR) >30 μg/mg, was associated with performance in the lowest tertile on a verbal memory test and was equivalent to 3.6 years of aging on the Digit Symbol Substitution Test of processing speed/executive function. In contrast, eGFR was not associated with any cognitive measure in that study. In the Nurses' Health Study, ACR levels as low as 5 μg/mg were associated with cognitive decline equivalent to 2–7 years of aging in global cognitive function, verbal memory, and verbal fluency.[33]

Pathophysiology of Cognitive Impairment in CKD: the Brain–Kidney Connection

The pathophysiology of cognitive impairment in CKD may be an accelerated model of vascular cognitive impairment, superimposed on and parallel with mechanisms leading to neurodegenerative disease such as AD. Cognitive impairment in CKD is nonlinear and multifaceted. Ischemic cerebrovascular disease, including small-vessel arteriolar disease, is central to the model as both a common intermediary outcome and a major contributor to chronic cognitive impairment. Chronic inflammation and underlying vascular endothelial pathology also appear to play substantial roles.

The brain and kidneys can be considered end organs on parallel trajectories subject to shared cardiovascular risk factors and microvascular pathologic processes mediated by inflammatory[35] and oxidative processes, occurring in similar low-resistance vascular beds and endothelial structures.[36] Impaired endothelial function in the brain manifests as blood–brain barrier defects,[37,38] and increased susceptibility to microinfarcts, lacunar infarcts, and white matter changes.[39] Similarly, impaired endothelial function in the kidney manifests as impaired glomerular filtration with secondary increased glomerular permeability, or proteinuria. Independently, the effects of uremic toxins, disrupted calcium–phosphate metabolism, other metabolic disturbances, and a potential genetic predisposition to exaggerated inflammatory response may accelerate the rate of cognitive decline in CKD patients.[40] At the cellular and molecular level in the kidney, microvascular endothelial dysfunction in the glomerulus leads to abnormal glomerular permeability, which may trigger tubulointerstitial inflammation, secondary renal fibrosis, and progression of CKD.[41] Mitochondrial dysfunction that triggers inflammation may be prevalent in CKD.[42]

Uremic Encephalopathy

Uremic encephalopathy is a complication of both acute and chronic renal diseases. Uremic encephalopathy is characterized by a general sensorial clouding and may include other features such as headaches, dysarthria, gate instability, asterixis, action tremors, convulsions, and multifocal myoclonus.[43,44] If untreated, uremic encephalopathy can progress to coma. Uremic encephalopathy is generally attributed to the accumulation of uremic toxins, although there may be additional CKD-related contributions related to hormonal dysregulation, hypertension, fluid and electrolyte disturbances, and drug toxicity. Symptoms of uremic encephalopathy generally improve with dialysis or renal transplantation.

Model of Pathways Leading to Cognitive Impairment in CKD

Several models of the mechanisms of cognitive impairment in CKD patients have been proposed.[45–47] Figure 29.2 describes a modified version of a model previously proposed by Kurella and Yaffe.[47]

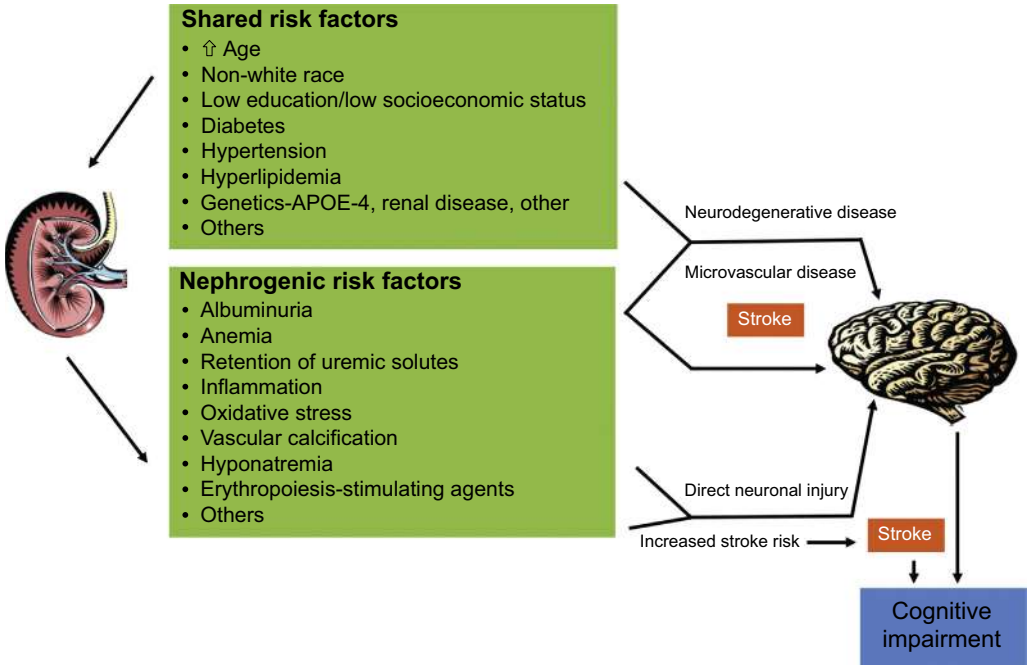

FIGURE 29.2 Mechanisms of cognitive impairment in chronic kidney disease patients. *Adapted from reference 47. Copyright 2011 Macmillan Publishers Ltd, reproduced with permission.*

Risk Factors for Cognitive Impairment in CKD

Shared risk factors that contribute to renal disease and low brain reserve appear in the top box (Figure 29.2). Risk factors for cognitive impairment in CKD patients are similar to those for dementia due to AD, vascular cognitive impairment, and combined types of dementia in the non-CKD population.[48–50] Lifestyle factors including the Mediterranean diet[51–53] and physical activity[54] appear to protect against cognitive impairment and incident cognitive decline in the general population. APOE-4, presenilin-1, other genetic variants, and Sortilin-related receptor 1 protein predispose to neurodegeneration. The gene ABCA7 (ATP-binding cassette transporter) is associated with almost double the risk of AD in African Americans, an effect similar to that of the APOE-4 gene in white patients.[55]

Nephrogenic factors appear in the middle box (Figure 29.2). Both shared and nephrogenic risk factors increase the risk of neurodegenerative disease, microvascular disease including white matter disease, and macrovascular disease or stroke. Each of these outcomes can contribute to cognitive impairment *via* direct neuronal injury. The role of erythropoiesis-stimulating agents (ESAs) in mediating cognitive impairment in CKD patients is controversial. Higher doses of ESAs increase risk of stroke in CKD patients as delineated in the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT) study,[56] but these agents may also decrease risk of neuronal apoptosis and secondary cognitive impairment.[57]

In CKD populations, aging and nonvascular factors are overshadowed by a 10–15% annual stroke incidence,[58] a high prevalence of cardiovascular risk factors including hypertension (80%) and diabetes (50–60%),[16] markedly elevated levels of inflammatory markers and homocysteine,[59] vascular endothelial dysfunction, cardiovascular events, and carotid atherosclerosis, all of which contribute to vascular dementia and neurodegenerative diseases such as AD[60] (Figure 29.2). The additional contributions of factors secondary to CKD, such as uremia, anemia, higher circulating levels of guanidine compounds,[61] endothelial dysfunction, and metabolic disturbances, are not well defined.[45] In the Health ABC study, CKD accounted for approximately 10% of the cognitive impairment risk that was unexplained by demographic factors and comorbid conditions.[26]

Importance of Making the Diagnosis of Cognitive Impairment: Avoiding Adverse Outcomes of a Missed Diagnosis

It is important for the clinician to become comfortable using brief cognitive screening instruments to make the diagnosis of cognitive impairment in CKD patients, to avoid multiple potential adverse outcomes of a missed diagnosis. Potential adverse outcomes related to missed diagnoses potentially include undetected medication and dietary noncompliance, secondary increased iatrogenic hospitalizations, and inability to make informed decisions regarding dialysis initiation. Dementia in CKD patients more than doubles the risk of death and is associated with a greater risk of death than in HD patients (hazard ratios [HRs] 2.26 and 1.86, respectively).[16] Advantages of early diagnosis of dementia in non-CKD patients also apply to CKD patients. These include substantial savings for the family and society due to decreased crisis-driven hospitalizations and delayed nursing home entry by up to 1.5 years.[62]

Other advantages of early diagnosis are that it potentially (a) identifies the most likely causes of cognitive impairment, including potentially treatable causes such as depression, delirium, or recent subdural hematoma; (b) enables early treatment to potentially delay progression; (c) allows enrollment in clinical trials; (d) helps families understand the symptoms of cognitive impairment and associated behaviors and obtain help from dementia specialists in managing them; (e) provides families with appropriate referrals to the Alzheimer's Association and dementia support groups; (f) enables improved management of comorbid conditions, decreases anxiety for patients and caregivers, and avoids crisis-driven acute and long-term care[62]; and (g) allows patients and families to plan together for future care and financial arrangements before dementia becomes advanced.

Cognitive Impairment Screening Instruments

Cognitive impairment screening instruments vary in sensitivity and length. Several instruments allow brief screening in the clinic setting. Most of these instruments can be administered by nonhealthcare professionals (Table 29.1).[47] The briefest test is the 3-minute Mini-Cog,[63] which is insensitive to MCI but identifies most dementia cases. The Mini-Cog consists of immediate recall of three words, followed by clock-drawing and then uncued recall of the same three words. The 8-minute Folstein's Mini-Mental State Exam is the most commonly used brief instrument, but it is copyrighted and does not measure executive functions.[4]

Two longer assessment tools (8–10 minutes) provide more information and are more sensitive for diagnosing MCI and measuring executive function.[64] The St. Louis Mental Status test (SLUMS) and the Montreal Cognitive Assessment (MOCA) are freely available. Both test the major cognitive domains of verbal memory, executive function, and visuospatial function.[65] The MOCA is

TABLE 29.1 Performance Characteristics of Selected Dementia Screening Instruments

Instrument	Administration Time (minutes)	Domains Evaluated	Sensitivity	Specificity	Positive Screen Cutpoint	Validation Reference Standard	Validated in CKD or ESRD	Comments
Clock-drawing task	1–3	Visuospatial executive function	85	85	Various	Clinical assessment for dementia	No	Less cultural bias. Evaluates executive function
Mini-Cog	3–4	Visuospatial executive function recall	76	89	2	Neuropsychological battery	No	Clock-drawing task plus uncued recall of three words
Mini-Mental State Exam (MMSE)	7–10	Orientation, recall attention visuospatial	71–92	56–96	23–25	Clinical assessment for dementia	No	Norms available. Copyrighted. Does not assess executive function well
St. Louis University Mental Status Exam (SLUMS)	7–10	Orientation, recall attention visuospatial executive function	98–100	91–100	21.5	Clinical assessment for dementia	No	Evaluates executive function
Montreal Cognitive Assessment (MoCA)	10	Orientation, recall attention visuospatial, verbal fluency executive function	100	87	25	Neuropsychological battery	No	Evaluates executive function

CKD, chronic kidney disease; *ESRD*, end-stage renal disease. Note: the sensitivity, specificity, and positive screen cutpoints listed above are for the general population, as most of the above tests have not been validated in patients with CKD.

now used as a global cognitive screening examination in ongoing and recently completed clinical trials, such as SPRINT, which has enrolled CKD participants.[66]

Because cognitive impairment is so common in CKD patients, annual cognitive screening is strongly recommended, especially before dialysis initiation to assess ability to make informed decisions.[47]

Diagnosis of Cognitive Impairment

The most important component in the diagnosis of cognitive impairment is an accurate history. The onset, duration, fluctuation, and nature and severity of cognitive impairment must be clarified, including behavioral symptoms, functional impairment, and coexistent symptoms of depression or sleep disorders. Elucidating a comprehensive history often requires interviewing caregivers and multiple family members. A physical examination and neurologic examination also need to be performed. For patients with previously undiagnosed cognitive impairment, brain imaging with computed tomography or magnetic resonance imaging is recommended to rule out potentially remediable causes such as subdural hematomas, brain tumors, and infection, and to detect stroke and severity and localization of brain atrophy and white matter disease. Brain imaging is critical if focal neurologic signs are present. Standard laboratory screening tests include complete blood count, chemistry panel, vitamin B_{12} level, and thyroid-stimulating hormone level to exclude common reversible hematologic or metabolic causes of cognitive dysfunction. For patients with high premorbid intelligence or for whom assessment of ability to make informed decisions is needed, a referral for detailed neuropsychologic testing is recommended. Depression commonly coexists with early dementia, and treatment with selective serotonin reuptake inhibitors is usually well tolerated. Delirium must be ruled out as a cause of acute cognitive impairment using the Confusion Assessment Method.[14]

Treatment of Cognitive Impairment in CKD Patients

There have been no clinical trials in CKD patients of dementia medications that are currently used in the general population. Several treatment options are available,

but their efficacy is controversial. These medications may be effective for 6–24 months in delaying the progression of cognitive impairment.[7] Any reversal of symptoms is minimal.

The two primary classes of dementia medications are cholinesterase inhibitors and *N*-methyl D-aspartate receptor antagonists. The cholinesterase inhibitors include donepezil, rivastigmine[67] (available in oral form and as a patch), and galantamine.[68] Their primary side effects are gastrointestinal disturbances. These include nausea and loose stools for approximately the first week, which usually resolve, mild anorexia and weight loss, dizziness, and, less frequently, insomnia. The medication should be withdrawn if severe nightmares occur, as they usually do not resolve. For CKD patients, a lower maximum dose of galanatime is recommended. Galantamine is contraindicated in end-stage renal disease (ESRD) patients. Memantine,[69] the *N*-methyl D-aspartate receptor antagonist, causes fewer gastrointestinal side effects except constipation but can occasionally cause acute delirium after initial doses. The drug should be discontinued if this occurs. Dose reduction is recommended for patients with eGFR<30 mL/min/1.73 m^2.

Behavioral disturbances such as increased agitation or paranoia, associated with moderate to severe dementia, are common and very stressful for patients and their caregivers. To evaluate new behavioral symptoms, a full clinical assessment should be conducted to rule out pain or delirium secondary to an acute medical illness, especially urinary tract infections or medication changes. Behavioral disturbances can also be due to environmental triggers such as changes in location or caregivers, or to nursing shift changes in the chronic care setting. Only after behavioral management trials and treatment of acute medical conditions have been employed should pharmacologic treatment be considered under guidance from a dementia expert because medication effectiveness is not well established and side effects can be substantial.[70] Atypical antipsychotics specifically are associated with modestly increased risk of cardiovascular disease and death.[71]

In the SPRINT MIND study, completed after the main study was stopped by the Data Safety Monitoring Board, the primary cognitive outcome was occurrence of probable dementia. Secondary cognitive outcomes included development of MCI and a composite outcome of MCI or probable dementia.[72] Among the 9361 randomized participants, 91.5% completed at least one follow-up cognitive assessment after a median intervention period of approximately 3.3 years. After a median follow-up of a little more than 5 years, probable dementia developed in a lower proportion of participants in the intensive treatment group compared to the standard treatment group (HR, 0.83; 95% CI, 0.67–1.04). Intensive BP control was associated with reduced risk of MCI (HR, 0.81; 95% CI, 0.69–0.95) and the combined rate of MCI or probable dementia (HR, 0.85; 95% CI, 0.74–0.97). The intervention did not result in a detectable significant reduction in the risk of developing probable dementia, perhaps because of reduced power due to early termination of the study, and fewer than expected cases of dementia. In subsequent analyses, the effects were determined to be similar in subgroups. The study therefore holds great promise for prevention of dementia in the CKD population, but further work will be necessary to establish definitive conclusions and treatment recommendations.[73]

Health Policy Implications

Currently, neither a cognitive history nor an assessment is required for CKD patients before, at, or any time after dialysis initiation. Given the rate of cognitive impairment in advanced CKD, many patients may lack adequate judgment to weigh the benefits and risks of initiating dialysis, or to withdraw from dialysis once initiated. Therefore there is a need to screen for cognitive impairment before dialysis initiation. The prognosis for HD patients with dementia is poor. In one study of nursing home ESRD patients, most experienced a rapid decline in physical function and more than half died 6 months after initiation.[74] The 2010 Renal Physicians' Association guidelines suggest that foregoing dialysis or withdrawing it from patients with advanced dementia is appropriate. Each case requires individual consideration and careful shared decision-making with patients and families.

Conclusion

Several studies have confirmed a graded association between renal function and cognitive function. Symptomatic and subclinical ischemic cerebrovascular disease, neurodegenerative disease, and inflammation appear to play large roles in a proposed model of accelerated vascular cognitive impairment in CKD patients. Annual and predialysis cognitive screening in CKD patients is critical to confirm a diagnosis of cognitive impairment, avoid adverse outcomes of missed diagnoses, and improve clinician awareness of the potential effects of cognitive impairment on medication, fluid, and dietary compliance, and on the ability to make informed decisions regarding dialysis initiation. While much remains to be learned regarding the pathophysiology of cognitive impairment in patients with CKD, the public health implications of its substantial burden are immediate. The role and timing of intensive blood pressure control in CKD patients at risk of developing dementia requires further study.

STROKE IN CHRONIC KIDNEY DISEASE

Cerebrovascular disease including stroke is a common, serious, and disabling disease within the CKD population. An update to the definition of stroke by the American Heart Association and affirmed by the American Academy of Neurology states that stroke includes the following: central nervous system (CNS) infarction including silent CNS infarction, ischemic stroke, intracerebral hemorrhage (ICH) including silent cerebral hemorrhage, stroke caused by ICH, subarachnoid hemorrhage (SAH), stroke caused by SAH, stroke caused by cerebral venous thrombosis, and stroke not otherwise specified.[75] Even though the definition of stroke is complex, studies in patients with CKD often focus on broadly defined stroke criteria, such as ischemic stroke, or ICH. Studies also include emerging data regarding CNS infarction (including silent CNS infarction). Both conditions can lead to cognitive impairment and cognitive deficits.

Stroke is common in all stages of CKD but increases significantly as kidney function worsens. The incident stroke rate is 1.9–3.6 times higher (depending on age, eGFR, and race) for those with incident CKD compared to those without CKD, and the risk of stroke in stage 5 CKD is double that of stage 3. A critical period, studied in patients who were at least 67 years old and had Medicare as the primary payor, is the time before and after the initiation of dialysis. A year before initiation, the baseline stroke rate in CKD patients was 0.15%–0.20% of patients per month. Stroke rates began rising approximately 3 months before initiation of dialysis and increased two- to threefold during the month before initiation, peaking during the month after the start of dialysis. The findings suggest the transition from CKD care to ESRD therapy may be fraught and that care must be taken to decrease the incidence of stroke during this period.[76]

The rate of incident stroke in incident CKD Medicare patients ages 67–85 years as reported in the 2009 USRDS Annual Data Report is estimated at 9.0/100 patient-years (pt-yrs) (Figure 29.3). The incident stroke rate in prevalent CKD patients is about two-thirds of the rate in incident CKD patients, or about 5–6.0/100 pt-yrs overall. The effect of CKD on stroke risk is even greater in younger individuals. Using the Ingenix i3 database of community-dwelling individuals aged 50–64 years, stroke is 4.6–7.6 times more frequent in incident CKD patients than in non-CKD patients. The absolute incidence is lower in this younger cohort, ranging from approximately 1.6–2.2/100 pt-yrs, or about one quarter the rate of the older Medicare cohort. In both the incident and prevalent CKD cohorts, the risk of stroke increases substantially with age and CKD stage. In CKD, the risk of incident stroke is also 50% higher for African Americans compared to white Medicare beneficiaries, similar to reports in non-CKD populations.[58]

Silent stroke describes lesions found incidentally on brain imaging in asymptomatic patients. Silent stroke increases the risk of subsequent stroke by over 10-fold (2.79/year compared to 0.21%/year) compared to those without previous silent stroke in the general population.[77]

Stroke Risk in CKD

Results from several observational studies suggest that CKD patients are at significantly increased risk of acute stroke compared with those without CKD.[74–79] This excess risk is not explained by common comorbid conditions or traditional vascular risk factors.

In a meta-analysis of 21 published reports, CKD, defined as eGFR less than 60 mL/min/1.73 m^2, was associated with a 43% greater risk of stroke (95% confidence interval [CI], 1.31–1.57).[79] As GFR decreases the rate of stroke increases. A dose–response relationship was observed. Risk was increased 22% for patients with eGFR 40–59 and 77% for those with eGFR less than 40 mL/min/1.73 m^2. Associations did not differ for hemorrhagic vs. ischemic stroke but were significantly greater for fatal stroke (relative risk [RR] 1.97) than for a combined outcome of fatal and nonfatal stroke (RR 1.37). However, overall heterogeneity was substantial across individual studies in a magnitude of reported associations and in types of patients studied (e.g., atrial fibrillation, postmenopausal women with coronary disease), methods of estimating renal function, and adjustment covariates included in statistical models.

Albuminuria is an independent risk factor for stroke even after accounting for reduced GFR. For example, among community-dwelling older adults, microalbuminuria was associated with nearly doubled risk of incident stroke among those with and without decreased eGFR.[80] These results were confirmed by a meta-analysis of 12 observational studies including 48,596 participants. Albuminuria was associated with a 92% greater RR of stroke compared to those without albuminuria. This association was significant in studies conducted in the general population, in diabetic and hypertensive patients, and in patients with prior stroke.[81]

Risk Factors and Mediators of Stroke

Few studies have specifically examined the factors that predict stroke in CKD patients, or that may potentially mediate the relationship between CKD and stroke

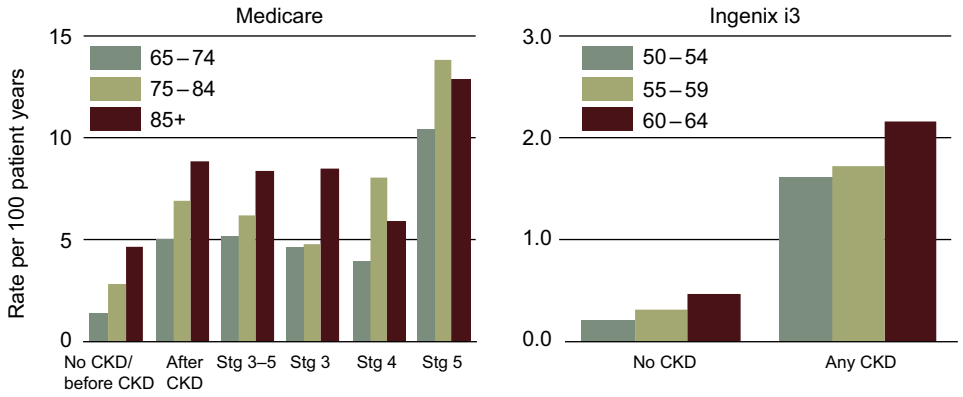

FIGURE 29.3 Rate of incident of stroke in incident chronic kidney disease (CKD) and non-CKD patients, by age and CKD status. *Reference 58. The data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the US government.*

(Figure 29.4). In general, estimated associations between CKD and stroke are attenuated after adjustment for multiple vascular risk factors and prevalent cardiac disease, raising the possibility that these associations represent the effect of unmeasured or residual confounding by other vascular risk factors or comorbidity severity. Alternatively, shared susceptibility to adverse end-organ effects in the brain and kidneys from vascular disease could identify individuals vulnerable to both stroke and renal disease.[36] This seems a plausible explanation for the increased stroke risk in patients with microalbuminuria and intact GFR, for whom low-level elevations in albuminuria may identify systemic vasculopathy with increased risk of major vascular events.

For patients with more impaired renal function, a direct causal effect of CKD on stroke risk is plausible, with potential mediators including retained uremic toxins, and metabolic consequences of decreased renal function including hyperhomocysteinemia and altered mineral metabolism, increased oxidative stress and inflammation, and anemia. The role of these factors in the pathogenesis of stroke in CKD patients has not been examined in detail in epidemiologic studies, although evidence indicates that hyperphosphatemia is associated with greater cardiovascular mortality in CKD, and greater serum phosphate concentration is associated with increased stroke risk in the general population.[82,83]

Evidence indicates that CKD may interact synergistically with anemia to contribute to stroke risk. Among 3015 adult diabetic participants in a combined sample of four general population cohorts, anemia in CKD was associated with an 81% greater risk of stroke compared to those without anemia. In contrast, anemia

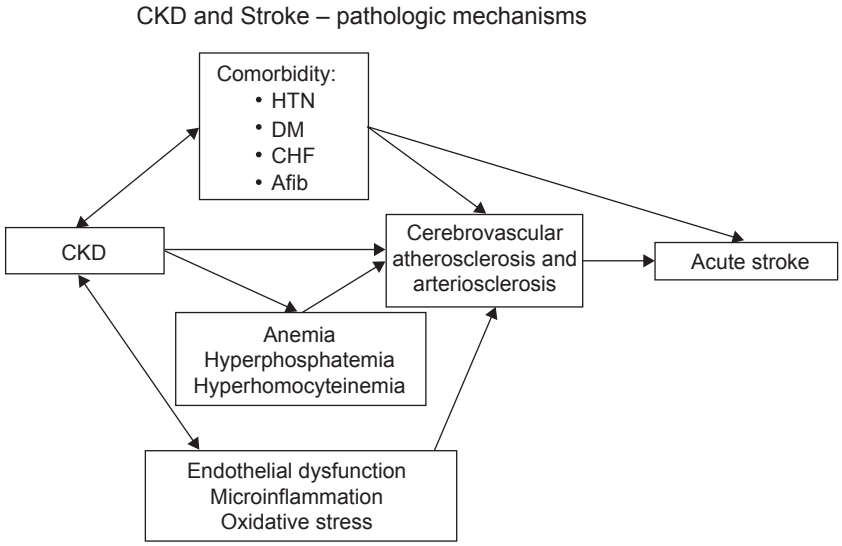

FIGURE 29.4 Pathologic mechanisms of chronic kidney disease (CKD) and stroke. *Afib*, atrial fibrillation; *CHF*, congestive heart failure; *DM*, diabetes mellitus; *HTN*, hypertension.

did not predict incident stroke among participants without CKD.[84] Physiological studies suggest that chronic anemia can cause adverse remodeling of the left ventricle and the peripheral arteries, leading to maladaptive cardiac hypertrophy and arteriosclerosis.[85] The resulting vascular stiffening may contribute to end-organ damage including cerebral ischemic injury such as acute stroke.

Erythropoiesis-Stimulating Agents and Stroke Risk

Given the epidemiological and physiologic data linking anemia to excess stroke risk in CKD, pharmacological correction of anemia with ESAs might be expected to be an effective preventive therapy. In addition to stimulating erythropoiesis, ESAs show direct neuroprotective effects in experimental models of cerebral ischemia.[86] Conversely, ESAs may have direct and indirect effects that could plausibly increase the risk of stroke, including increased blood pressure, acute endothelial dysfunction, platelet activation, and decreased cerebral blood flow due to rapid changes in red cell mass.

Results of large randomized clinical trials and observational studies conducted among CKD patients suggest that ESAs, especially when dosed to target high hemoglobin levels, increase the risk of stroke to a clinically significant degree. In the TREAT study, diabetic non–dialysis-dependent CKD patients with anemia were randomized to weekly darbepoetin with a goal hemoglobin of 13 g/dL or to placebo. During follow-up, the RR of fatal or nonfatal stroke (a secondary trial endpoint) was 92% greater in the active than in the control group.[56] In a *post hoc* multivariate analysis, this effect of treatment on stroke risk was similar to the effect of prior stroke. This analysis failed to find an effect of on-treatment changes in blood pressure, hemoglobin, or platelet count with risk of stroke.[87] In contrast, no excess stroke risk was identified among 1432 anemic CKD patients in the Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) trial randomized to epoetin alfa with high (13.5 g/dL) vs. normal (11 g/dL) hemoglobin targets.[88] However, this trial was terminated early for futility, and the number of observed stroke events was too small to allow conclusions regarding the cerebrovascular safety of the intervention.

In an observational case-control study among Veterans Administration outpatients with non-dialysis-dependent CKD and anemia, those with prior ESA treatment were 30% more likely to be stroke cases, after adjustment for potential confounders.[89] The association between ESA use and stroke was particularly strong (odds ratio 1.85) among CKD patients with evidence of cancer under active oncology care, whereas no significant association was observed among CKD patients without cancer (odds ratio 1.07). ESA-treated CKD patients with active cancer received initial ESA doses 2.5–4 times higher than those without cancer, despite similar pretreatment hemoglobin concentrations. Whether their greater stroke risk compared to ESA-treated patients without cancer is explained by the higher ESA dosing they received, or by other stroke risk factors concurrent in cancer patients—such as greater inflammation or increased thrombotic potential—is unclear. Patients with active cancer were specifically excluded from both the TREAT and the CHOIR studies.

Primary and Secondary Stroke Prevention

No RCTs have been designed specifically to test the efficacy of stroke prevention strategies in patients with non–dialysis-dependent CKD. However, limited data regarding treatment effects are derived from *post hoc* subgroup analyses of RCTs conducted in the general population, from RCTs in CKD populations of therapies designed to prevent all cardiovascular events (for which stroke was a secondary or tertiary outcome), and from observational cohort studies.

For patients with symptomatic severe (≥70% diameter reduction) carotid stenosis, carotid endarterectomy (CEA) has long been established as an effective intervention for secondary stroke prevention.[90] However, observational studies have suggested that non–dialysis-dependent CKD patients have a much higher risk of perioperative mortality and other complications after CEA,[91,92] raising questions about the risk–benefit tradeoff in these patients. In a *post hoc* subgroup analysis of data from the North American Symptomatic Carotid Endarterectomy Trial (NASCET), patients with stage 3 CKD (mean eGFR 49 mL/min/1.73 m^2) had a fourfold higher risk of cardiac complications than those with normal renal function, but no excess risk of mortality.[93] However, they also experienced a markedly greater benefit from CEA than from standard medical therapy, with an 82% RR reduction of recurrent stroke. In contrast, CKD patients with moderate carotid stenosis (50–69% diameter reduction) experienced no significant benefit in stroke reduction.

Atrial fibrillation is an important risk factor for stroke in the general population, and risk of stroke is 40% greater among atrial fibrillation patients who also have CKD stage 3B or higher.[94] Warfarin therapy has been the mainstay of stroke prevention among atrial fibrillation patients estimated to be at high stroke risk. However, reports have suggested that warfarin use in

maintenance dialysis patients may be associated with a paradoxically increased risk of stroke,[95] especially hemorrhagic stroke,[96] raising concerns about its safety in non−dialysis-dependent CKD patients. Hart et al. performed a *post hoc* subgroup analysis of the Stroke Prevention in Atrial Fibrillation (SPAF) 3 trial, which compared adjusted-dose warfarin with combination aspirin plus fixed low-dose warfarin among high-risk atrial fibrillation patients.[97] Among the 805 participants with stage 3 CKD (42%) (mean eGFR 49 mL/min/1.73 m^2), adjusted-dose warfarin reduced the risk of ischemic stroke or systemic thromboembolism by 76%, an effect size similar to that among participants with normal eGFR. No excess risk of major hemorrhage was observed with adjusted-dose warfarin in the CKD participants. As the renal impairment was relatively modest, whether the same risk−benefit ratio favoring warfarin also applies to more advanced CKD is unclear. Somewhat discrepant results were reported from an observational cohort study among patients with nonvalvular atrial fibrillation, using Danish national patient registry data.[98] CKD not requiring renal replacement therapy was identified by diagnosis codes, not by renal function measurement, likely resulting in significant underascertainment. Warfarin use was associated with a 16% lower risk of stroke or systemic thromboembolism (RR 0.84), but this association did not meet the conventional threshold of significance ($p = 0.07$). However, warfarin-treated participants were at a 36% greater risk for major bleeding after other risk factors were accounted for.

Warfarin has been a mainstay of oral anticoagulation, but the new oral anticoagulants (NOACs) such as dabigatran,[99] rivaroxaban,[100] and apixaban[101] are increasingly being used, as they have been shown to be efficacious for non-CKD patients. In addition, the NOACs provide increased simplicity for healthcare management because they do not require laboratory monitoring, have fewer drug−drug interactions, and necessitate fewer dietary restrictions (compared to vitamin K in warfarin use). However, NOAC use can be complex in CKD patients because NOACs rely at least partly on renal excretion for elimination. Use of NOACs has not been studied in clinical trials specifically designed with CKD patients. Importantly, the major trials that demonstrated efficacy for SPAF excluded patients with advanced (typically stage 4 or higher CKD) renal impairment.[102] Eikelboom et al. conducted a *post hoc* subgroup analysis of the Apixaban *Versus* Acetylsalicylic Acid to Prevent Stroke in Atrial Fibrillation Patients Who Have Failed or are Unsuitable for Vitamin K Antagonist Treatment trial, which compared apixaban with aspirin among chronic atrial fibrillation patients who were not candidates for warfarin.[103] Apixaban was dose-reduced among patients with S[Cr] greater than 1.5 mg/dL. Results suggested a similar treatment advantage of apixaban over aspirin among patients with stage 3 CKD (mean eGFR 49 mL/min/1.73 m^2) compared with non-CKD patients, with a RR reduction of 68%. There was no excess risk of major bleeding with apixaban among CKD patients. In the Apixaban for Reduction In Stroke and Other Thromboembolic Events in Atrial Fibrillation trial comparing apixaban to warfarin, the effect of apixaban also did not differ significantly by renal function.[104] (Patients with creatinine clearance less than 30 mL/min were excluded.) Apixaban, compared with warfarin, reduced the risk of hemorrhage among participants with eGFR less than 50 mL/min/1.73 m^2 (HR 0.48; 95% CI 0.37−0.64) to a greater extent than among those with intact renal function. Additional studies regarding the safety and efficacy of apixaban in various levels of renal disease have demonstrated the net benefit of apixaban over warfarin.[105]

Similar evidence for a favorable risk−benefit ratio in CKD patients was reported for rivaroxaban vs. warfarin in a *post hoc* subgroup analysis of the Rivaroxaban Once-Daily, Oral, Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF) trial.[106,107]

Dabigatran—a direct thrombin inhibitor—is contraindicated in those with eGFR less than 30 mL/min/1.73 m^2. A subgroup analysis did not find any difference in the effect of dabigatran compared to warfarin for the prevention of stroke or thromboembolism among those with eGFR 30−50 mL/min/1.73 m^2 compared to $\geq$80 mL/min/1.73 m^2.[108] However, the relative benefit and risk of dabigatran in stroke prevention in CKD stage 3 patients is a topic of ongoing uncertainty and debate.[109] There is no readily available method for monitoring drug concentrations or anticoagulant effects of dabigatran.

Unlike warfarin, for which there is extensive experience in reversing, monitoring, and fine-tuning the degree of anticoagulation, the NOACs have emerging methods for reversing anticoagulant effects, which include the development of new medications and development of NOAC-specific strategies. Idarucizumab is a Food and Drug Administration−approved monoclonal antibody fragment to reverse dabigatran. Other types of pro-coagulant clotting agents, known as bypass agents, are being studied and used by some to reverse numerous types of NOACs.[110] Use of these newer reversal agents need additional study in patients with CKD as concerns about the safety of NOACs in those with renal impairment exist. In addition to the safety concerns in CKD, there are challenges to reversal agent availability, due to lack of widespread stocking of the newer agents and the high price of the reversal agents.

HMG CoA-reductase inhibitors have been demonstrated to reduce the risk of both initial and recurrent stroke in the general population. However, two large multicenter trials in maintenance HD patients showed no reduction in total stroke with rosuvastatin or atorvastatin vs. placebo, and a doubling of fatal stroke with atorvastatin in the Deutsche Diabetes Dialyze Study (4D) trial.[111,112] The Study of Heart and Renal Protection (SHARP) trial examined the effects of simvastatin 20 mg plus ezetimibe 10 mg daily vs. placebo on atherosclerotic events among CKD patients, including those requiring RRT (roughly one-third of the total sample).[113] The risk of nonhemorrhagic stroke was reduced by 25% in the active treatment group (RR 0.75; 95% CI, 0.60–0.94). The effects of stroke risk were not reported separately for study participants with non–dialysis-dependent CKD, although there was a significant effect on all atherosclerotic events in this subgroup (RR 0.78). Additional evidence for the effect of statins is provided by subgroup analyses of general population clinical trials. A meta-analysis estimated a summary RR reduction of 39% for fatal and nonfatal strokes (RR 0.61; 95% CI, 0.38–0.98) with statin therapy compared to placebo. However, most included clinical trials constituting this meta-analysis intentionally excluded patients with advanced CKD. Statin therapy did not result in excess risk of major adverse effects, including myalgias, cancer, or abnormal liver or muscle enzyme concentrations.

Antiplatelet agents such as glycoprotein IIb/IIIa inhibitors or clopidogrel are recommended for primary and secondary prevention of stroke among patients at high vascular risk.[114] However, no clinical trials have specifically examined their effectiveness or safety in CKD patients. There are only limited data from secondary subgroup analyses of clinical trials. A meta-analysis found an "uncertain effect" of these agents on risk of stroke in CKD patients (RR 0.66; CI, 0.16–2.78).[115] The risk of minor bleeding was increased by 70% in CKD patients randomized to antiplatelet drugs.

Thrombolytic Therapy

Since the late 1990s, tissue plasminogen activator (tPA, or specifically alteplase) has been an important and increasingly utilized treatment for acute stroke, in the general population.[116] Guidelines by the American Heart Association and American Stroke Association regarding the treatment of acute ischemic stroke have informed the field regarding the use of alteplase.[117] There are several recent outcomes that are important to patients with kidney dysfunction in terms of both efficacy and safety. Participants with a lower eGFR (less than 60 mL/min/1.73 m^2) received less benefit from the administration of alteplase, compared to participants with normal eGFR at 24 hours (coefficient −2.3, 95% CI −3.7 to −0.9; $p = 0.002$) and at 7 days (coefficient −3.5, 95% CI −5.3 to −1.7; $p < 0.001$). With modeling, each 10 mL/min/1.73 m^2 decline in eGFR was associated with a 0.4 decrease in NIHSS improvement in the setting of alteplase use.[118]

There are concerns regarding the potential for bleeding and hemorrhage risk that occurs in CKD patients with use of tPA. The safety of tPA in CKD was recently studied by Ovbiagele et al. through the retrospective Get With the Guidelines-Stroke Program (GWTG-Stroke).[119] The CKD patients had a higher unadjusted odd of symptomatic intracranial hemorrhage or serious systemic hemorrhage, while also being more likely to die in the hospital (adjusted odds ratio, 1.22; 95% CI: 1.14–1.32) or have an unfavorable functional status at discharge (adjusted odds ratio, 1.13; 95% CI: 1.07–1.19), compared to patients with normal kidney function. This was further studied and confirmed through a meta-analysis of seven studies, which included 7168 CKD patients with IS and treated with tPA to show that there was a higher risk of symptomatic ICH and mortality, while also having an increased risk of poor outcome at 3 months.[120]

SPRINT

The SPRINT trial results showed that the intensive target resulted in a significantly lower rate of major cardiovascular events and death from any cause.[66] CKD patients comprised 28% of study participants.[121] A SPRINT-CKD subgroup analysis showed that the intensive treatment target had a lower rate of cardiovascular events (HR, 0.81; 95% CI, 0.63–1.05) and all-cause death (HR, 0.72; 95% CI, 0.53–0.99) than the standard treatment group.

Conclusion

Patients with non–dialysis-dependent CKD (whether defined by reduced eGFR or albuminuria cutoffs) are at a significantly increased risk of acute stroke compared with individuals without evidence of renal disease. This may represent a direct causal relationship of renal disease on stroke risk, or shared susceptibilities to end-organ damage in both the brain and the kidneys among patients with vascular risk factors or established vascular diseases. Although anemia is associated with a marked increase in stroke risk in CKD patients, and is a plausible mediator for the CKD/stroke association, aggressive correction of anemia with ESAs increases the risk of stroke appreciably. However, the precise mechanisms that mediate this risk, and the relative contributions of ESA dose vs. achieved or targeted

hemoglobin levels in increasing risk, remain unclear. A *post hoc* subgroup analysis suggests a large benefit in secondary prevention of stroke with CEA in selected patients with stage 3 CKD, although at the cost of greater perioperative complications. Statins, warfarin, and dose-adjusted oral anticoagulants in patients with atrial fibrillation appear at least as effective among stage 3 CKD patients as among non-CKD patients for stroke prevention. However, no clinical trial data support the use of warfarin or newer anticoagulants among patients with CKD stage 4 or higher. Use of newer anticoagulants is contraindicated for patients with stage 5 CKD. There is emerging evidence regarding the use of these newer NOAC and DOAC agents in addition to strategies to optimize efficacy, while providing the drug safely in addition to the recent introduction of reversal agents. Data are insufficient to indicate a benefit in stroke prevention of glycoprotein IIb/IIIa inhibitors or clopidogrel as antiplatelet therapy.

NEUROLOGICAL AND MUSCULAR DISEASE

Peripheral neuropathies and myopathies are common complications of renal dysfunction and contribute significantly to disability and reduced quality of life. While these conditions are typically more prevalent and more severe in ESRD, it is important to recognize that they often become clinically relevant during the latter stages of CKD. Data on the prevalence of these conditions in CKD are very limited, and it is likely that many of these conditions are either underdiagnosed or misdiagnosed.

Uremic Somatic Polyneuropathy

Somatic polyneuropathy is a highly prevalent and potentially disabling complication of advanced CKD.[43,44,122] Somatic polyneuropathy is characterized by mixed sensory and motor dysfunction in a symmetrical, length-dependent distribution and typically presents with lower extremity pain, hypoesthesia, and/or paresthesias. Sensory dysfunction expands proximally as the disease progresses and is eventually complicated by weakness and muscle wasting. Estimates of the prevalence of uremic somatic polyneuropathy vary greatly.[16,123] This likely relates, in part, to the relatively high prevalence of nonuremic polyneuropathies in CKD populations, which confound diagnosis. Diabetes mellitus is the most common nonuremic etiology of polyneuropathy in CKD populations, although contributions from other nonuremic sources such as alcohol use, amyloidosis, and systemic vasculitides should always be considered in the evaluation of such patients.[44]

The pathogenesis of somatic polyneuropathy in CKD patients remains incompletely understood and may be multifactorial. Advanced stage disease nerve biopsies typically demonstrate axonal degeneration and secondary segmental demyelination.[124] Accordingly, nerve conduction studies characteristically show significant reductions in sensory and motor amplitudes, with more moderate reductions in conduction velocities.[125] Early theories attributed uremic axonal damage to CKD-related accumulation of "middle molecules," i.e., renally cleared mid-range molecular weight substances such as β_2-microglobulin and parathyroid hormone.[126] However, this hypothesis remains unproven, and parathyroid hormone is the only middle molecule for which some evidence of neurotoxicity exists.[127,128] More recent work indicates that hyperkalemia may play an important role in pathogenesis.[129,130]

Management of uremic somatic polyneuropathy includes dialysis and supportive medical therapy. Adequate dialysis generally prevents neuropathic progression, but complete clinical reversibility is uncommon.[131] Accordingly, rapid symptom progression remains an important indicator of dialysis insufficiency. Medical management includes nutritional supplementation (with drugs such as biotin, pyridoxine, cobalamin, thiamine), routine foot care, and pain management with tricyclic antidepressants (such as amitriptyline) and anticonvulsants (such as pregabalin).[43,44,122] The potential role of hyperkalemia in neurotoxicity has also led to efforts to reduce interdialytic potassium concentrations by dietary therapy.[130] Proper management of uremic somatic polyneuropathy also includes diagnosis and treatment of other conditions, which may contribute to polyneuropathy, such as diabetes mellitus and alcohol use.

Renal transplantation remains the only treatment that consistently reverses uremic somatic polyneuropathy. Neurological recovery after renal transplantation is often dramatic and rapid, with measurable improvements in nerve conduction velocities days after surgery.[132] Clinical recovery is often achieved within several months of transplantation in mild cases but may take longer in more severe cases.[133]

Uremic Autonomic Neuropathy

Dysfunction of autonomic nerves can also occur in patients with advanced CKD.[43,44,122] Common autonomic manifestations include postural and interdialytic hypotension, cardiac arrhythmias, impaired sweating, gastrointestinal dysmotility, and sexual dysfunction. Because CKD-related autonomic neuropathies do not

always coexist with somatic polyneuropathies, it is not clear if they are manifestations of the same or separate processes.[134] Parasympathatic dysfunction tends to predominate in CKD-related autonomic neuropathy, whereas sympathetic dysfunction tends to be more common in diabetes-related disease.[43] While the true burden and clinical significance of CKD-related autonomic neuropathy is unknown, it is important to note that studies in dialysis patients associate autonomic dysfunction with sudden cardiac death.[135,136]

Diagnosis of autonomic neuropathy in CKD patients can be challenging, due to the nonspecific nature of clinical symptoms and an incomplete correlation between symptoms and common clinical diagnostics, such as resting R−R interval variation and blood pressure responses to sustained handgrip.[134] For example, diagnosis of gastrointestinal dysfunction due to autonomic neuropathy in CKD patients can be particularly challenging because CKD-related uremic toxins, ischemia, and decreased clearance of gastrointestinal hormones may produce similar symptoms. Similarly, diagnosis of sexual dysfunction related to autonomic neuropathy in male and female CKD patients requires exclusion of other factors commonly associated with CKD, including vascular disease, hormonal dysregulation, nutritional deficiencies, depression, and medications.[137−139] As with uremic somatic polyneuropathy, renal transplantation provides the most effective treatment for uremic autonomic neuropathy.[122] Specific medical therapies include sildenafil for erectile dysfunction, midodrine for hypotension, and renally dosed metoclopramide for impaired gastrointestinal mobility.[140]

Uremic Mononeuropathies

Carpal tunnel syndrome (CTS) is the most common mononeuropathy related to CKD.[43,44,122] CTS results from median nerve compression in the carpal tunnel of the wrist and typically presents as weakness or paresthesias in the hand, and dull, aching discomfort in the hand, forearm, or upper arm.[141] These symptoms are often exacerbated by repetitive actions, sustained hand positions, and sleep and are mitigated by position changes and hand shaking. Initial sensory symptoms may progress to weakness and atrophy as axonal loss occurs. Diagnosis of CTS is typically clinical, with confirmation provided by electrophysiologic testing when needed.[141] Nerve conduction studies characteristically show reductions in distal median conduction velocities due to axonal compression. Conduction amplitudes are typically preserved in the early stages of CTS but may be reduced in later stages if axonal loss occurs.

CTS is a long-term complication of renal insufficiency and typically presents after dialysis initiation. The prevalence of CTS increases with dialysis duration, affecting up to 30% of patients treated with dialysis for more than 10 years.[142] The increased prevalence of CTS in CKD and ESRD populations is primarily attributed to amyloidosis from β_2-microglobulin accumulation,[143,144] although uremic tumoral calcinosis and complications of arteriovenous fistula creation are also implicated.[145,146]

Treatment of mild CTS involves conservative strategies, such as activity modification and nocturnal splinting.[141] Corticosteroid injections may improve symptoms, although relapse is common and procedure-related median nerve injury is a risk. Surgical decompression of the carpal tunnel is indicated for patients with severe symptoms. Renal transplantation remains the only definitive preventive therapy.[144]

Uremic Pruritus

Pruritus is a common complication of advanced CKD.[147,148] While uremic pruritus (UP) is often associated with dialysis, most patients develop symptoms before dialysis initiation. UP is usually episodic and more intense at night. Pruritic sensation can be generalized or localized, and patients typically present with skin excoriations. Aside from being an obvious threat to quality of life, UP may have greater implications. The recent large DOPPS II study associated UP with sleep disorders and increased mortality.[149]

The pathogenesis of UP is incompletely understood and likely multifactorial. Potential contributing factors include calcium and phosphorus metabolic abnormalities, uremic toxin accumulation, cytokine dysregulation and systemic inflammation, cutaneous xerosis, damage and dysregulation of peripheral and somatic nerves, intrinsic opioid system dysregulation, and common comorbid conditions such as advanced age, diabetes mellitus, iron deficiency anemia, and viral hepatitis.[147,148] The management of UP remains challenging. To date, there are no definitive therapies for UP short of renal transplant. General treatment strategies include skin emollients, mineral metabolism regulation, and dialysis optimization.[147,148] Gabapentin, ultraviolet phototherapy, and nalfurafine, a κ-opioid receptor agonist, have also been shown to be effective and well tolerated.[150−152] Erythropoietin and previously common therapies such as antihistamines and serotonin receptor antagonists have not been proven effective.[147]

Uremic Myopathy

Uremic myopathy is a general term used to describe the constellation of functional and structural muscle abnormalities commonly associated with chronic

uremia.[153] Uremic myopathy is characterized by proximal weakness, muscle atrophy, limited exercise tolerance, and rapid fatigability.[154] Symptoms typically appear when GFR is below 25 mL/min/1.73 m^2, and disease progression tends to parallel the decline in renal function.[153] Patients affected by uremic myopathy generally have normal creatine kinase levels, and electromyography studies and tissue biopsies only occasionally show muscle fiber atrophy.[153,155] The pathogenesis of uremic myopathy is not completely understood but has been linked to factors such as uremic toxins, insulin resistance, carnitine deficiency, and hyperparathyroidism.[153] Care must be taken to rule out contributions from simple water and electrolyte disturbances, which can underlie similar presentations. Management of uremic myopathy includes provision of adequate HD, correction of anemia, exercise therapy, nutritional supplementation, and treatment of secondary hyperparathyroidism.[153] While both CKD and dialysis therapy lead to disorders in carnitine metabolism that may contribute to muscular dysfunction, the benefits of carnitine supplementation in these conditions remain incompletely established.[156,157] However, given the favorable safety profile of carnitine and the potentially debilitating nature of muscular dysfunction, carnitine supplementation on a trial basis may be recommended for patients who do not respond to standard therapy.[156,157]

Conclusion

CKD is associated with several forms of neuromuscular disease that can significantly diminish quality of life. Many of these conditions first become clinically significant in patients with advanced or long-standing CKD. Proper diagnosis and treatment of these conditions is challenging but is an important component in the comprehensive care of CKD patients. Additional work is needed to further characterize the prevalence and clinical course of these conditions in CKD populations.

SUMMARY

Neurologic outcomes in CKD patients are prevalent. The most common neurologic complications in CKD patients are cognitive impairment, stroke, and peripheral neuropathies. Despite a strong graded association between measures of renal function and cognitive function, cognitive impairment in CKD patients is largely undiagnosed. Annual and predialysis cognitive screening is critical to avoid adverse outcomes of missed diagnoses of cognitive impairment, such as medication noncompliance and inability to make informed decisions regarding initiating dialysis. Early dementia diagnosis decreases anxiety for patients and caregivers, avoids crisis-driven acute and long-term care, and allows patients and families to plan for future care and financial arrangements. Cerebrovascular disease, uremic encephalopathy, neurodegenerative disease, and inflammation contribute to a model of accelerated vascular cognitive impairment in patients with CKD. Aggressive treatment with ESAs increases stroke risk appreciably. Warfarin and dose-adjusted newer anticoagulants appear effective for stroke prevention in stage 3 CKD patients with atrial fibrillation, but such therapy is unproven or contraindicated in higher CKD stages. Neuromuscular disease in advanced CKD patients, such as uremic peripheral neuropathies, uremic myopathy, and pruritucan significantly diminish patient perception of quality of life. Proper diagnosis and treatment of these conditions is a challenging but important component in the comprehensive care of CKD patients.

QUESTIONS AND ANSWERS

Question 1

You are seeing a 75-year-old woman with stage 4 CKD in clinic for the first time for a scheduled follow-up. She is living with her husband in assisted living. He reports that she became more agitated yesterday and was up most of the night. Today she seems more confused and initially refused to get dressed, which is unusual for her. She has no fever but her appetite is poor. There has been no recent change in her medications. On examination, she is uncooperative, has difficulty tracking, and is easily distracted. The remainder of her exam is normal. What would be your next step?

A. Use the Mini-Cog to assess cognitive function
B. Obtain a urine culture and serum electrolytes
C. Use the Confusion Assessment Method to assess cognitive function
D. B and C
E. Refer to a neurologist, psychiatrist, or geriatrician

Answer: D

This patient is presenting with classic symptoms of delirium: acute onset confusion, decreased attention, disrupted sleep–wake cycle, and agitation. As she is living in assisted living, she may also have underlying dementia but has never been diagnosed with cognitive impairment. It is not possible to differentiate delirium from dementia on an initial evaluation. The best steps are to use the Confusion Assessment Method to confirm the diagnosis of delirium and obtain a urine culture and electrolytes. Urinary tract infection and serum electrolyte disturbance are two very common causes of delirium in the elderly, the latter being especially common in CKD. Medication change is another common cause, but her medications have not changed.

Question 2

Which of these statements is true?

A. Dementia in CKD patients more than doubles the risk of death
B. Brain imaging is recommended for most new cases of cognitive impairment
C. High cystatin C, albuminuria, and eGFR <45 mL/min/1.73.m^2 are associated with an increased risk of cognitive impairment
D. Delirium in the hospitalized elderly usually results in long-term cognitive and functional decline
E. All are true

Answer: E

All of these statements are true. Of note delirium in the hospitalized elderly rarely complete reverses, especially in those with underlying dementia.

Question 3

A 65-year-old man with stage 3 CKD (eGFR 45 mL/min/1.73 m^2) has an ischemic stroke affecting the right middle cerebral artery territory. A duplex ultrasound study demonstrates high-grade (>70%) stenosis in the right internal carotid artery. Which of the following statements is correct regarding the role of CEA in this patient?

A. This patient is at no greater risk for postoperative complications than a patient with similar comorbidity but without CKD
B. The benefit in ipsilateral stroke recurrence from CEA is similar to the benefit in patients with CKD and moderate-grade (50%–69%) carotid stenosis
C. CEA compared with standard medical therapy reduces the risk of ipsilateral stroke by approximately 80%
D. The benefit in prevention of recurrent stroke from CEA is similar to the benefit in patients with stage 5 CKD

Answer: C

A subgroup analysis from the NASCET clinical trial suggests that patients with stage 3 CKD and symptomatic high-grade internal carotid artery stenosis have an 82% lower risk of recurrent ipsilateral stroke with CEA compared with standard medical therapy. In contrast, no significant difference in stroke risk was observed with CEA among patients with moderate stenosis. This same analysis, and additional observational cohort studies, suggests an increased risk of postoperative cardiac complications (myocardial infarction, congestive heart failure, arrhythmia, and potentially death) in CKD patients undergoing CEA compared with patients with eGFR > 60 mL/min/1.73m^2. There are no data from clinical trials regarding effects of CEA vs. medical therapy in patients with stage 5 CKD.

Question 4

Which of the following statements about stroke risk in patients with non–dialysis-dependent CKD is true:

A. Lower eGFR but not greater albuminuria is associated with an increased risk of acute stroke
B. Patients with non–dialysis-dependent CKD and anemia are at greater risk for acute stroke than those with CKD but no anemia
C. ESAs reduce the risk of acute stroke in non–dialysis-dependent CKD patients with anemia

D. HMG CoA-reductase inhibitors (statins) are not effective in stroke prevention among patients with non−dialysis-dependent CKD
E. In patients with stage 3 CKD and atrial fibrillation, oral factor Xa inhibitors (e.g., apixaban) are less effective for stroke prevention than in patients without CKD

Answer: B

Meta-analyses of observational studies suggest that both albuminuria and lower eGFR are risk factors for acute stroke, independent of traditional vascular risk factors. Data from observational studies suggest that anemia is associated with greater risk of stroke among patients with non−dialysis-dependent CKD. However, the results of interventional and observational studies suggest that ESAs, especially when administered at high doses and/or targeting high hemoglobin concentrations, increase rather than reduce stroke risk. A summary of *post hoc* subgroup analyses of clinical trials involving statins suggest that statins reduce the risk of fatal and nonfatal strokes among patients with non−dialysis-dependent (primarily stage 3) CKD; these results are supported by the SHARP study, which found a 25% lower risk of nonhemorrhagic stroke among non−dialysis-dependent and dialysis-dependent CKD patients treated with simvastatin combined with ezetimibe. *Post hoc* subgroup analyses of clinical trials of oral factor Xa inhibitors suggest patients with stage 3 CKD have the same reduction in risk of stroke as those with preserved renal function, at least when reduced doses for lower renal function are used. These medications are contraindicated in patients with more advanced CKD.

Question 5

A 70-year-old man with long-standing CKD due to hypertension presents with 3 weeks of tingling and dull pain in the distal portions of both feet. His GFR is approximately 10−15 mL/min/1.73 m^2 and has declined only minimally over the past year. His exam is significant for decreased sensation to monofilament and vibration. He has repeatedly said that he is not interested in initiating dialysis. He does not have diabetes mellitus and does not drink alcohol. Which one of the following is the best initial treatment for his symptoms?

A. Ibuprofen
B. Amitriptyline
C. Oxycodone
D. Sertraline
E. Tramadol

Answer: B

The patient's presentation is consistent with uremic polyneuropathy. Amitriptyline, a tricyclic antidepressant, is regarded as a first-line agent for treatment of painful uremic polyneuropathy. Anticonvulsants such as pregabalin and valproate are also regarded as effective. While opioids such as tramadol and oxycodone may provide effective pain relief, potential problems with addiction, abuse, and overdose generally preclude their use as initial therapy. NSAIDs such as ibuprofen are contraindicated in CKD due to adverse effects on renal function. There are also theoretical concerns that NSAID-induced prostacyclin inhibition may impair nerve circulation and worsen nerve injury.

Question 6

A 52-year-old woman with advanced CKD due to diabetes mellitus has been experiencing daily episodes of itching for the past 2 weeks. The itching has been most intense at night and is interrupting sleep. Her GFR has declined significantly over the past 12 months and is now approximately 15 mL/min/1.73 m^2. Her exam is significant for dry, flaking skin with patches of erythema and excoriation on her arms and abdomen. She is scheduled for vascular access placement in the coming week in anticipation of hemodialysis initiation in the coming months. Which one of the following is the best initial treatment for her symptoms?

A. Odansetron
B. Oxycodone
C. Diphenhydramine
D. Topical emollient
E. Cetirizine

Answer: D

The patient's presentation is consistent with UP. Topical emollients are safe and inexpensive and have been shown to be very effective in reducing pruritic symptoms. Other potentially effective treatments include gabapentin, UVB phototherapy, and nalfurafine, a κ-opioid receptor agonist. Antihistamines such as diphenhydramine and cetirizine are widely used in the treatment of uremic pruritus, but their effectiveness is controversial. 5-HT_3 receptor agonists such as odansetron have not been proven effective. Opiates such as oxycodone are frequently associated with pruritic side effects and are not effective treatments for uremic pruritus.

CHAPTER

30

Hematologic Complications of Chronic Kidney Disease—Anemia and Platelet Disorders

Sarah J. Schrauben, Jeffrey S. Berns

Renal-Electrolyte and Hypertension Division, Department of Medicine, Perelman School of Medicine of the University of Pennsylvania School of Medicine, Philadelphia, PA, United States

Abstract

Anemia is a common complication of chronic kidney disease (CKD), particularly among patients whose glomerular filtration rate (GFR) is less than 30–40 mL/min. The pathogenesis of anemia in CKD is complex, but the central etiological factor is the relative deficiency of erythropoietin. Erythropoietin is produced in the kidneys by cortical peritubular interstitial fibroblast-like cells. The production of erythropoietin decreases as the functioning renal mass declines. Iron deficiency also commonly contributes to anemia in CKD. Iron metabolism is normally tightly regulated by hepcidin. Inflammation induces changes in hepcidin that reduces the availability of iron for erythropoiesis, which contributes to anemia in CKD patients. Erythrocytosis is a much less common occurrence in patients with CKD and is mostly seen in patients with polycystic kidney disease or following kidney transplantation. Defective platelet function with a bleeding tendency is well known to occur in patients with advanced CKD and uremia. The CKD stage at which platelet dysfunction becomes clinically relevant is not known. Therapies aimed at improving this acquired platelet dysfunction include initiation of dialysis, desmopressin (1-deamino-8-d-arginine vasopressin), cryoprecipitate, improvement in anemia, and estrogens.

ANEMIA OF CHRONIC KIDNEY DISEASE

Anemia is common among patients with chronic kidney disease (CKD), increasing in prevalence with progressively reduced kidney function (i.e. lower levels of glomerular filtration rate [GFR] or creatinine clearance).[1–3] The dominant factor controlling red blood cell (RBC) production in the bone marrow is the regulatory hormone, erythropoietin, which stimulates maturation and release of RBCs into the circulation. The primary basis for anemia in those with CKD is a relative deficiency of erythropoietin, although other factors may also contribute (Table 30.1). The anemia of CKD is hypoproliferative in nature, with a low circulating reticulocyte count and without increased bone marrow RBC progenitor cells. The RBCs in circulation in patients with CKD and anemia are typically normochromic and normocytic unless there is also superimposed iron, folate, or vitamin B12 deficiency.

The anemia of CKD is a major contributor to impaired quality of life and decreased functional capacity and is also associated with hospitalization risk, adverse cardiovascular disease outcomes, cognitive dysfunction, and death.[4,5] Clinical practice guidelines developed for the care of patients with CKD recommend the evaluation of anemia in those with CKD should begin when the hemoglobin [Hb] concentration is less than 13.0 g/dL in men (<130 g/L) and 12.0 g/dL (<120 g/L) in women (approximately equivalent to hematocrit levels of 39% and 36%, respectively).[6,7] Patients may have anemia related to CKD, but they are also at risk for all the other causes of anemia that can occur in the general population. Common factors associated with causing anemia in CKD are listed in Table 30.1. Recommended testing to evaluate anemia in patients with CKD includes a complete blood count, measuring the Hb concentration, red cell indices, white blood cell count and differential, and platelet count, absolute reticulocyte count, and serum ferritin level, transferrin saturation (TSAT), serum vitamin B12, and folate levels.[2,6] Other testing should be performed as clinically indicated. Abnormalities of white blood cell numbers and distribution and platelet count are not typically seen in CKD patients, so their presence should suggest other causes of anemia not related to CKD.

A Hb concentration less than 13.0 g/dL is seen in approximately 20% of CKD patients with GFR

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00030-9

TABLE 30.1 Factors Involved in the Anemia of Chronic Kidney Disease

Most Important, Common
Decreased erythropoietin synthesis
Relative erythropoietin deficiency
Important, Common
Iron deficiency (absolute)
Chronic blood loss, including from phlebotomy
Infection/inflammation—"anemia of chronic disease"
Less Important, Less Common, or of Uncertain Significance
Vitamin B12 and/or folate deficiency
"Uremic toxins"
Reduced red blood cell life span
Increased red blood cell fragility
Carnitine deficiency
Aluminum toxicity
Severe hyperparathyroidism
ACEIs/ARBs

45–60 mL/min and approximately 90% of patients with GFR below 15 mL/min.[1,3,8,9] Anemia associated with CKD is unusual when the GFR is over 60 mL/min (Figure 30.1), and therefore other causes of anemia should be considered in these patients. Severe anemia (Hb less than 10.0 g/dL) due to CKD alone is uncommon unless the GFR is less than 20–30 mL/min. At any given GFR level, anemia tends to be more common and severe among women compared to men, particularly below the age of 65 years, African Americans compared to whites, and those with diabetes compared to those without.[10–14] Anemia also tends to develop earlier in the course of CKD in those with diabetes compared to those without diabetes.[13]

Erythropoiesis and Erythropoietin

The erythopoietic system maintains homeostasis of the blood supply to achieve adequate tissue oxygen delivery. The dominant factor controlling RBC production in the bone marrow is the regulatory glycoprotein hormone, erythropoietin, which is produced mainly in the liver prenatally, but then predominantly by the kidneys shortly after birth. Synthesis of erythropoietin is stimulated by hypoxia in cortical peritubular interstitial fibroblast-like cells of the kidney. Erythropoietin interacts with receptors on RBC progenitor cells in the bone marrow to release mature RBCs into the bloodstream.[15–19]

Erythropoietin is a 165 amino acid, 30.5 kDa glycoprotein containing carbohydrate chains with variable sialic acid content. Various circulating erythropoietin isoforms contain different numbers of sialic acid residues, which stabilize the molecule in the circulation and are necessary for its biological activity.[20–22] Regulation of erythropoietin synthesis by peritubular fibroblasts is mediated primarily through binding of the hypoxia-inducible factor (HIF), a transcription factor comprised of HIFα and HIFβ subunits, to a hypoxia response element in the erythropoietin gene and other related hypoxia-responsive genes to increase their transcription.[23,24] In the presence of oxygen, HIFα subunits are hydroxylated and undergo ubiquination by the von Hippel-Lindau complex, leading to proteosomal degradation and reduced erythropoietin levels. In the presence of hypoxia, HIF degradation is impaired and the HIF transcription complex enhances transcription of the erythropoietin gene with subsequent translation and secretion of the hormone directly into the bloodstream.[25–27] Under normal, basal conditions, the

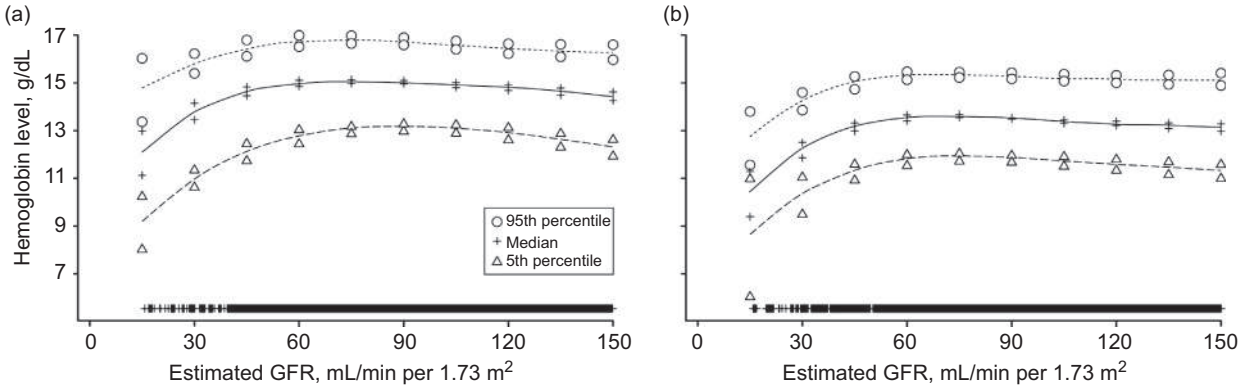

FIGURE 30.1 Median, 5th, and 95th percentiles of Hb levels among adult men (a) and women (b) 20 who participated in the Third National Health and Nutrition Examination Survey (1988–1994). All values are adjusted to the age of 60 years. *From reference 3.*

serum erythropoietin concentration is in the range of 0.01−0.03 U/mL. In response to anemia and hypoxia, circulating erythropoietin levels typically increase 100- to 1000-fold in individuals without kidney disease.[28]

The action of erythropoietin occurs after its interaction with the erythropoietin receptor, present in the highest quantities on the cell membranes of bone marrow erythroid precursor cells. Binding of erythropoietin to the erythropoietin receptor of erythroid progenitor cells induces a conformational change, leading to activation of a Janus tyrosine kinase-2 intracellular signaling cascade that increases the number of erythroid precursors.[29−31] In the absence of erythropoietin, erythroid precursors are rapidly lost due to apoptosis. In the presence of erythropoietin, there is reduced apoptosis and these cells develop into mature erythrocytes.[32−34]

In patients with relatively mild CKD and anemia, serum erythropoietin concentrations, although possibly within or even above the "normal range," are inappropriately low for the degree of anemia but remain correlated with the severity of anemia. As functioning nephron mass and GFR decline, generally below about 40 mL/min, serum erythropoietin levels fall, become clearly low, and no longer correlate with the degree of anemia. To what extent the impaired synthesis of erythropoietin is due to reduced numbers of erythropoietin-secreting peritubular fibroblasts or impairment in the hypoxia-sensing regulatory process controlling erythropoiesis has not been definitively established, but there is some evidence to suggest both may play a role.[35−37] Even in the presence of advanced CKD, erythropoietin synthesis increases with stimuli from acute hemorrhage and hypoxia, albeit to a lesser degree than in the absence of CKD. Measurement of serum or plasma erythropoietin levels is not recommended in the evaluation of patients with CKD and anemia.

Iron and Anemia of CKD

Effective erythropoiesis is dependent on adequate availability of both iron and erythropoietin. Iron balance, which includes the absorption of iron from the gastrointestinal (GI) tract, storage in the liver and other reticuloendothelial storage sites, and circulation throughout the body, is normally tightly regulated to maintain an adequate iron supply for effective erythropoiesis while avoiding iron overload and potential organ toxicity.[38] Iron deficiency is common in patients with CKD.

Iron deficiency can be "true," with insufficient body stores and characterized by markedly reduced or absent iron in the bone marrow, or "functional," in which total body iron stores are adequate, but the stored iron is prevented from being made available in the circulation to adequately support erythropoiesis. Functional iron deficiency can be due to administration of erythropoiesis stimulating agents (ESAs) or to what is often referred to as "anemia of chronic disease." Anemia of chronic disease appears to be mediated largely by inflammation *via* upregulation of the iron regulatory protein hepcidin that causes sequestration of iron.[38,39] Hepcidin is produced by the liver and cleared from the circulation by the kidneys and plays a key role in systemic iron homeostasis.[40] Hepcidin reduces intestinal iron absorption and inhibits release of iron from the reticuloendothelial macrophages and hepatocytes into plasma by inducing internalization and degradation of a cell membrane iron channel, ferroportin.[41−44] In animal models and humans with absent or reduced hepcidin synthesis, iron overload ensues, and in settings of increased hepcidin synthesis, severe iron deficiency is found. Hepcidin expression is increased in response to iron administration and systemic inflammation,[45,46] whereas it is decreased in response to anemia and hypoxemia.[47] Each of the mediators of changes in hepcidin synthesis acts through complex signaling pathways. For instance, the hemochromatosis protein, transferrin receptors 1 and 2, hemojuvelin, bone morphogenic protein 6, and several SMAD proteins, among others, are involved in iron-signal pathways, while inflammation also involves IL-6, Janus kinase, and STAT3 as well as other mediators. ESAs also directly inhibit hepcidin expression.[38,39,48,49] Hypoxic regulation of hepcidin synthesis appears to be mediated at least in part by the HIF pathway, whereas iron deficiency appears to modulate hepcidin expression *via* HIF and other pathways.

True, or absolute, iron deficiency is less common among CKD patients who are not treated with dialysis than those treated with dialysis. The exact prevalence, however, has not been well studied and likely varies among different populations as it does in the general population (for example, menstruating women compared to men and postmenopausal women). Patients with CKD not on dialysis are thought to have normal intestinal absorption of iron in the absence of elevated ferritin levels (which would suggest the presence of iron overload or systemic inflammation).[50,51] Oral iron supplements should be taken separately from calcium-containing phosphate binders, which can bind iron and reduce its availability. CKD patients on dialysis (CKD-HD) may have impaired iron absorption, as it has been shown that oral iron supplementation is no better than placebo for correction of iron deficiency. The gold standard for the diagnosis of iron deficiency is measurement of iron stores in bone marrow obtained on biopsy, but this is not used routinely, given the invasiveness of the procedure and evidence that determination of bone marrow iron does not accurately

predict responsiveness to intravenous iron supplementation.[52] Instead, iron stores are more commonly estimated by measuring serum iron, total iron-binding capacity, ferritin, and calculation of the percent TSAT. Other markers of iron status such as serum transferrin receptor, percent hypochromic RBCs, and reticulocyte Hb content have been studied but are not in widespread clinical use in the US. Although measurement of blood hepcidin levels is available, studies have not found that hepcidin testing is consistently predictive of response to iron supplementation or ESA therapy or of greater diagnostic value than ferritin level testing in CKD patients, and hepcidin is not used in routine clinical practice.[53,54]

True iron deficiency is diagnosed in patients with CKD when the TSAT is less than 20% and the serum ferritin concentration is less than 100 ng/dL.[2,52] These tests, however, have limited sensitivity, specificity, and predictive value. Patients with TSAT and ferritin levels above these limits will often respond to iron supplementation with an increase in Hb level, even when bone marrow iron staining does not indicate absolute iron deficiency.[55–57] The likelihood of responding to intravenous iron supplementation with a significant increase in Hb concentration is low among patients with serum ferritin concentrations above 500 ng/mL. Clinical practice guidelines for anemia management in patients with CKD suggest iron supplementation with intravenous iron or a short trial of oral iron when the TSAT is 30% or less and the serum ferritin concentration is 500 ng/mL or less.[7] Prior guidelines recommended that supplemental iron be provided to CKD patients with anemia when the serum ferritin was 100 ng/mL or less and the TSAT was 20% or lower.[6]

Other factors besides impaired erythropoietin synthesis and iron deficiency can contribute variably to anemia in CKD patients (Table 30.1).[58,59] Shortened RBC survival in uremic patients has been attributed to increased erythrophagocytosis, increased RBC osmotic fragility, decreased RBC deformability in the circulation, carnitine deficiency, RBC complement deposition and activation, and reduced RBC tolerance to oxidative stress.[60–64] These factors have for the most part been studied primarily in CKD-HD patients. It is very unlikely that any are clinically important contributors to the anemia of CKD in patients who are not treated with dialysis or have very advanced uremia. Angiotensin converting enzyme inhibitors (ACEIs), and to a lesser extent angiotensin receptor blockers (ARBs), have been suggested to exacerbate anemia in CKD patients due to increased synthesis of erythropoiesis inhibitors and alterations in renal blood flow and oxygen supply,[65–67] although this finding is controversial.[68] In addition to the supply of iron and erythropoietin, normal basal erythropoiesis and the ability to increase RBC production in response to hypoxia and anemia require adequate supplies of vitamin B12 and folate. Erythropoiesis can also be inhibited directly, as well as indirectly through effects on iron metabolism, by negative influences of inflammatory cytokines such as tumor necrosis factor-α (TNF-α), interferon-γ, interleukin-6 (IL-6), and transforming growth factor-β (TGF-β).[69–75]

ERYTHROCYTOSIS IN PATIENTS WITH CKD

Patients with autosomal dominant polycystic kidney disease (ADPKD) often have anemia that is less severe than expected for their level of GFR, and some ADPKD patients have normal or even elevated Hb levels. Serum erythropoietin levels tend to be higher in patients with ADPKD compared to patients with other causes of CKD.[76,77] The kidneys are the source of this relatively increased erythropoietin synthesis, at least in part from interstitial cells in the vicinity of proximal tubule cysts. It is thought that local hypoxia, due to physical effects of enlarged cysts, leads to HIF activation and erythropoietin synthesis. A similar phenomenon has been described in patients with acquired renal cystic disease associated with long-standing HD treatment.[78]

Erythrocytosis is also seen in up to 20% of patients following kidney transplantation, usually within the first 1–2 years after transplantation.[79,80] The increase in plasma erythropoietin levels in this setting is due, at least in part, to increased erythropoietin production by the native kidneys, which do not respond to the usual feedback regulation, although the exact etiology of this phenomenon is not known.[81] This type of erythrocytosis may remit spontaneously or persist for years. Angiotensin II may also play a role in increasing erythropoietin, as the treatment with an ACEI or ARB is effective in reducing posttransplant erythrocytosis in most patients.[82–85] In extreme cases, phlebotomy may be necessary to reduce the risk of microvascular and thrombotic complications.

DISORDERS OF PLATELETS AND COAGULATION

An increased propensity to bleeding is present in patients with advanced CKD. Easy bruising and excessive bleeding from the skin, oral or nasal mucosa, respiratory, GI and urinary tracts, or following invasive procedures are well-known complications of advanced CKD, most notably in patients with advanced uremia and ESRD who have not been dialyzed or who are severely underdialyzed.[86,87] The bleeding tendency

seen with advanced CKD occurs despite usual normal platelet counts and normal or elevated levels of circulating clotting factors, von Willebrand factor (vWF), and fibrinogen, with normal partial thromboplastin time, prothrombin time, and International Normalized Ratio.[88] *In vivo* and *in vitro* measures of platelet function, such as the bleeding time[89] and tests of platelet aggregation or agglutination in response to epinephrine, adenosine diphosphate (ADP), or ristocetin consistently point to platelet dysfunction as a primary underlying defect for this bleeding tendency.[90–92] The specific factors in patients with advanced CKD that lead to impaired platelet function remains to be definitively identified but likely include factors intrinsic to and extrinsic to platelets. Contributing factors intrinsic to platelet dysfunction include abnormal expression of platelet glycoproteins, reduced release of ADP and serotonin from platelet granules, depressed prostaglandin metabolism, decreased platelet thromboxane A2 generation, impaired adhesion of platelet glycoprotein receptors (GPIIb/IIIa and GPIb/IX) to endothelial vWF, and abnormal platelet cytoskeletal assembly and intracellular singling pathways.[93–97] Contributing factors extrinsic to platelets include the action of "uremic toxins," anemia, increased NO, and cyclic guanosine monophosphate production, functional vWF abnormalities, decreased platelet production, and abnormal interactions between the platelet and the endothelium of the vessel wall.

The observation that uremic platelets mixed with normal plasma function normally has suggested a plasma factor as the culprit. It is also observed that mixing uremic plasma with normal platelets impairs platelet function.[98,99] Urea itself does not appear to impair platelet function or contribute to the uremic bleeding tendency seen in patients with uremia. Uremic toxins, such as guanidinosuccinic acid and phenolic compounds have been implicated in the impaired interaction between platelets and endothelial vWF multimers, thereby inhibiting ADP-mediate platelet aggregation.[100–102]

In addition to plasma abnormalities, there are also likely to be concomitant abnormalities of the vascular endothelium, at least with advanced uremia.[103] Abnormalities of the vascular endothelium appear to contribute to the impairment of platelet function in advanced CKD by impairing platelet adhesion and aggregation. Nitric oxide (NO) is an inhibitor of platelet function that is produced by endothelial cells. NO synthesis is increased in uremic patients, perhaps related to elevated levels of guanidinosuccinic acid.[104,105] Increased endothelial synthesis of platelet-inhibitory prostaglandins may also contribute.[106] Anemia contributes to platelet dysfunction by altering the flow pattern of circulating platelets to be directed more centrally within the blood vessel, instead of the normal peripheral flow, and thus, platelets are less likely to be in close contact with the endothelial surface.[107,108] Anemia may also impair platelet aggregation and plug formation by reducing availability of ADP and thromboxane, which are released by RBCs, and inhibit platelet function by reducing the availability of NO, which is bound by Hb.[109] Increased platelet surface expression of various receptors that might lead to enhanced platelet activation has also been described in patients with mild to moderate CKD. The clinical consequences of this are uncertain.

There is also some evidence to suggest that CKD is associated with an increased risk of venous thromboembolism. The etiology of this is unclear, but severity of proteinuria, underlying kidney disease, and elevated levels of fibrinogen and factor VIII may be involved.[110–114]

Treatment of Uremic Bleeding

It is unfortunately not known at what level of GFR platelet dysfunction becomes a significant clinical problem. Blood urea nitrogen and creatinine levels do not correlate well with bleeding in patients with advanced CKD.[90] Traditionally, the bleeding time has been the most common test used to assess bleeding tendency in uremia.[89] However, assessing the bleeding time in CKD patients has fallen out of favor due to its lack of sensitivity and specificity. As a result, in the absence of readily available and reliable tests of platelet function, clinical judgment must dictate decision-making regarding which patients are likely to respond to initiation of dialysis or other therapies to reverse platelet dysfunction (Table 30.2, Figure 30.2).

In undialyzed (or severely underdialyzed) patients with advanced uremia and uncontrolled bleeding, initiation of dialysis should be undertaken (if hemodialysis, not with anticoagulation), even though its effectiveness is variable and unreliable. The extent to which dialysis actually improves clinically significant bleeding remains uncertain, because most studies have examined effects on bleeding time or *in vitro* tests of platelet function that may or may not correlate with clinical bleeding, rather than evaluating active, clinical bleeding directly.[115–119] Bleeding time and some *in vitro* measures of platelet function improve in some but not all patients with initiation of dialysis. One study suggested that *in vitro* tests of platelet function improved with peritoneal dialysis but not hemodialysis.[119]

Besides initiation of dialysis, options for reversal of the platelet defect associated with kidney dysfunction include treatment with desmopressin (1-deamino-8-d-arginine vasopressin; DDAVP), cryoprecipitate, estrogens, recombinant human erythropoietin (or similar agents), tranexamic acid, and RBC transfusion. DDAVP,

TABLE 30.2 Treatments for Hemostasis Abnormalities of Chronic Kidney Disease

For acute/active bleeding

Initiation or intensification of dialysis (without anticoagulation if hemodialysis) Desmopressin (DDAVP)
Dose: 0.3–0.4 μg/kg IV or 3 ug/kg intranasally

Transfusion of packed red blood cells
Goal: Hemoglobin ~10 g/dL

Cryoprecipitate
Dose: 10 units IV (American Red Cross prepared) every 12 to 24 hr

For chronic bleeding or in preparation for invasive procedure

ESA to improve anemia
Goal: Hemoglobin ~10 g/dL

Conjugated estrogens
Dose: 0.6 mg/kg IV for 5 days; oral 50 mg daily; transdermal 17β-estradiol 50–100 μg/24 hr

To consider if above options are ineffective

Tranexamic acid
Dose: 10 mg/kg IV with infusion of 0.5–1.5 mg/kg/hr

Factor VII

a synthetic form of vasopressin, improves platelet function at least in part by stimulating release of large vWF multimers from endothelial cells.[120,121] DDAVP may also have direct effects on platelet aggregation and increase platelet surface GP Ib/IX and some circulating clotting factor concentrations such as factor VIII. DDAVP may be given intravenously or subcutaneously with reduction in the bleeding time within 1–2 hours, an effect lasting up to 8 hours. Tachyphylaxis, presumably due to depletion of endothelial stores of vWF multimers, limits the effectiveness of DDAVP after the first or second dose.[122] The short duration of action of DDAVP and the development of tachyphylaxis limit its use to attempt to prevent bleeding with invasive procedures (e.g. kidney biopsy, surgery) or use in the initial efforts to control active bleeding while also administering other therapies that have more prolonged effects. Many, but not all, patients treated with DDAVP have improvement in bleeding time.[123–126] Reduction in actual bleeding or reduction in bleeding risk with invasive procedures has never been documented with the use of DDAVP. The currently available studies on DDAVP have been

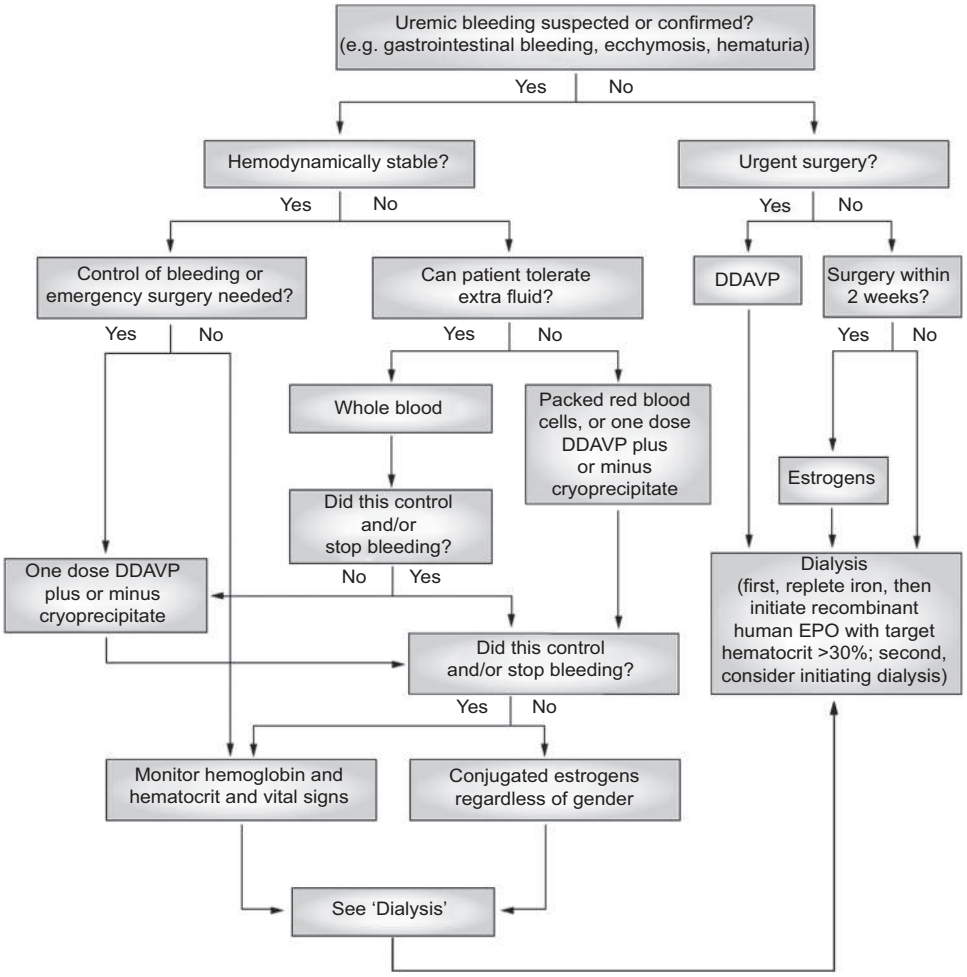

FIGURE 30.2 Suggested algorithm for management of patients with uremic platelet dysfunction and bleeding. *From reference 90.*

limited to assessments of its use with bleeding time or have been uncontrolled clinical observations.

Transfusion of RBCs to an Hb level of about 10 g/dL may also improve platelet dysfunction in patients with advanced CKD. It is thought that increasing the overall RBC supply in circulation will force platelets from the central location in the blood vessel to a more peripheral location, closer to the endothelium.[108] For chronic bleeding, an increase in the RBC supply can also be obtained with the use of ESAs.[127,128] ESAs also have direct effects on platelet number and platelet signaling, adhesion, and aggregation.[129,130] The elevated Hb concentration may also improve platelet function through enhanced binding of NO.[109]

Administration of cryoprecipitate may also have a role in the treatment of CKD patients with active bleeding who do not respond to local measures, DDVAP, and blood transfusions, or who are undergoing surgery.[131–133] Cryoprecipitate is enriched with vWF, factor VIII, and fibrinogen. Limited experience suggests that cryoprecipitate infusion can reduce the bleeding time in some patients and perhaps reduce operative blood loss. When effective in reducing the bleeding time, cryoprecipitate infusion does so within about an hour. Risks of cryoprecipitate administration include transmission of infectious agents and allergic reactions, including anaphylaxis.

Tranexamic acid is an inhibitor of fibrinolysis that reduces bleeding time and improves impaired platelet function in patients with advanced CKD.[134,135] Recombinant activated factor VII has also been reported to stop bleeding following a kidney biopsy that did not respond to DDAVP.[136] Further study will be needed to assess the role of both of these interventions.

For chronic bleeding, treatment with estrogens should be considered as conjugated estrogens reduce bleeding time. Effects on clinical bleeding or evidence that estrogens reduce bleeding risk following invasive procedures remains to be fully demonstrated, although estrogens have been reported to be useful in control of GI tract bleeding in patients with both acute and chronic renal failure.[107,137–143] Treatment with intravenous, oral, or transdermal estrogens reduces bleeding time within a day or two in some patients, with a lasting effect persisting for as long as 10–14 days after treatment is stopped. The mechanism of action is unknown, although effects of estrogen on NO have been postulated.[144] Estrogen-related side effects may limit its long-term use.

CONCLUSIONS

Anemia is a relatively common complication of CKD, particularly when the GFR declines to less than 30–40 mL/min. The most important factor contributing to this anemia is the relative deficiency of erythropoietin. Iron deficiency is also a common contributing factor. Erythrocytosis is a much less common occurrence in patients with CKD and is mostly seen in patients with polycystic kidney disease or following kidney transplantation. Defective platelet function occurs in some patients with advanced CKD but is not a common problem in those with mild to moderate CKD. Several treatments for platelet dysfunction in patients with CKD at risk for bleeding are available, but knowledge regarding their clinical efficacy is limited in the absence of appropriate well-designed randomized controlled clinical trials.

QUESTIONS AND ANSWERS

Question 1

A 51-year-old woman is referred to the nephrology clinic for management of CKD secondary to diabetic nephropathy. Serum creatinine (S[Cr]) is 2.1 mg/dL (eGFR 25 mL/min/1.73 m^2). She is taking lisinopril 40 mg daily and hydrochlorothiazide 25 mg daily. Her review of systems is completely negative. On examination, her blood pressure is 135/75 mm Hg. Her hemoglobin concentration is 11 g/dL, MCV 85 fL, serum ferritin 110 ng/mL, percent saturation of iron is 25%.

Which ONE of the following is NOT correct regarding her anemia?

A. Anemia is hypoproliferative with a low reticulocyte count
B. Anemia is associated with hospitalization risk, cognitive dysfunction and death
C. Anemia tends to develop at a higher level of GFR in diabetics vs. nondiabetics
D. She does not have anemia since her hemoglobin is greater than 10 g/dL

Answer: D

Answers A, B, C, are correct and answer D is not correct and therefore the answer to this question. **Answer D** is not correct because anemia is diagnosed when hemoglobin concentration is <13.0–13.5 g/dL in men and <12.0 g/dL in women.[6] **Answer A** is accurate as the anemia of CKD is hypoproliferative and associated with a low reticulocyte count. The primary cause is deficiency of erythropoietin. **Answer B** is accurate as evidenced by observational studies demonstrating an association between anemia in CKD and a higher risk of hospitalization, cognitive dysfunction, and death.[4,5] **Answer C** is accurate because anemia tends to develop at a higher level of GFR in diabetics than nondiabetics.[10–12] The exact reasons for this observation are not clear.

Question 2

A 67-year-old woman with membranous glomerulonephritis and an eGFR of 23 mL/min/1.73 m^2 presents with a hemoglobin of 11.5 g/dL.

Which of the following is NOT true regarding control of erythropoiesis in this patient:

A. The transcription factor HIF binds to a hypoxia response element in the erythropoietin gene to increase transcription of erythropoietin
B. An erythropoietin receptor is present on colony-forming units-erythroid (CFU-E) and other erythroid progenitor cells
C. In the presence of erythropoietin CFU-E develop into mature erythrocytes due to reduced apoptosis
D. Inflammatory cytokines such as TNF-α stimulate erythropoiesis

Answer: D

Answer D is the one answer that is NOT true. In CKD patients inflammatory cytokines such as TNF-α, interferon-γ, IL-6, and TGF-β inhibit erythropoiesis and contribute to anemia and erythropoietin resistance.[36–42] **Answer A** is accurate as the transcription factor HIF, a dimer comprised of HIFα and HIFβ subunits, binds to a hypoxia response element in the erythropoietin gene and other related hypoxia-responsive genes, increasing their transcription.[23,24] **Answer B** is accurate as an erythropoietin receptor is present on colony-forming units-erythroid (CFU-E) and other erythroid progenitor cells.[30] Binding of erythropoietin to its receptor results in a signaling cascade leading to increased numbers of CFU-E and other erythroid precursors. **Answer C** is correct because erythroid precursors, CFU-E in particular but others up to the stage of basophilic erythroblasts, are rapidly lost due to apoptosis in the absence of erythropoietin. In the presence of erythropoietin these cells develop into mature erythrocytes due to reduced apoptosis.[32,33]

Question 3

A 45-year-old man presents with hematemesis, a BP of 105/75 mm Hg, and a hemoglobin of 9 g/dL. He has a history of membranoproliferative glomerulonephritis secondary to hepatitis C virus infection and a baseline S[Cr] of 4.7 mg/dL and eGFR of 14 mL/min/1.73 m^2.

Which one of the following is TRUE regarding treatment directed at the uremic platelet defect?

A. No specific treatment for uremic bleeding is needed since patient is not yet on dialysis
B. The patient should be emergently started on hemodialysis
C. Desmopressin (DDAVP) should be started
D. Cryoprecipitate should not be used since it has been ineffective in correcting bleeding and carries the risk of transmission of infective agents

Answer: C

Answer C, use of DDAVP, is correct. DDAVP, a synthetic form of vasopressin, improves platelet function at least in part by stimulating release of large vWF multimers from endothelial cells.[115,116] DDAVP may also have direct effects on platelet aggregation and increase platelet surface GP Ib/IX and some circulating clotting factor concentrations such as factor VIII. DDAVP may be given intravenously or subcutaneously with

reduction in the bleeding time within 1−2 hours, an effect lasting up to 8 hours. Tachyphylaxis, presumably due to depletion of endothelial stores of vWF multimers, limits the effectiveness of DDAVP after the first or second dose.[117] **Answer A** is incorrect because DDAVP may be effective in this situation of active bleeding. **Answer B** is incorrect and will likely distract from the primary goal of diagnosing the source of bleeding. The extent to which dialysis actually improves clinically significant bleeding remains uncertain, because most studies have examined effects on bleeding time or *in vitro* tests of platelet function that may or may not correlate with clinical bleeding, rather than active, clinical bleeding directly.[110−114] **Answer D** is incorrect as cryoprecipitate is enriched with vWF, factor VIII, and fibrinogen and can reduce the bleeding time. Cryoprecipitate may have a role in patients with active bleeding that does not respond to local measures, DDAVP, and transfusion or who are undergoing surgery.[126−128] When effective in reducing the bleeding time, cryoprecipitate infusion does so within about an hour. Risks include transmission of infectious agents and allergic reactions, but in the correct situation should not preclude its use.

Question 4

A 37-yr-old man has CKD from IgA nephropathy. S[Cr] is 3.4 mg/dL and estimated GFR 20 mL/min/1.73 m^2. Hemoglobin concentration is 11.2 g/dL, MCV 86 fL, serum iron 148 μg/dL, percent saturation of iron is 29%, and serum ferritin 140 ng/dL.

Which ONE of the following contributes to the anemia of this patient?

A. Increased circulating hepcidin levels
B. Chronic ongoing blood loss
C. Iron deficiency
D. Vitamin B12 deficiency

Answer: A

Answer A is correct. Hepcidin is produced by the liver and plays an important role in systemic iron homeostasis. Hepcidin reduces intestinal iron absorption and hepatocyte and reticuloendothelial cell iron release by inducing internalization and degradation of an iron channel, ferroportin, which is present on the cell surface of duodenal enterocytes, hepatocytes, and macrophages.[41−43] Hepcidin levels are increased with inflammation and contribute to the functional iron deficiency seen in CKD patients. **Answer B,** ongoing blood loss, does not appear likely as there is no clinical reason for blood loss and iron deficiency would be expected to develop, which has not occurred. **Answer C**, iron deficiency, is incorrect because in the presence of true iron deficiency the percent saturation of iron is less than 20% and serum ferritin concentration is less than 100 ng/mL. **Answer D** is incorrect as vitamin B12 deficiency should lead to an increased MCV.

Question 5

Erythrocytosis can be seen in which ONE of the following conditions:

A. Diabetic nephropathy
B. Polycystic kidney disease
C. Focal and segmental glomerulosclerosis
D. Membranous glomerulonephritis

Answer: B

Answer B is correct as patients with ADPKD often have anemia that is less severe than expected for their level of GFR. Some ADPKD patients will have normal or even elevated Hb levels. Serum erythropoietin levels tend to be higher in patients with ADPKD compared to patients with other causes of CKD.[76,77] None of the other conditions is associated with erythrocytosis

Question 6

Which ONE of the following is true about the bleeding tendency seen in patients with advanced CKD?

A. Increased partial thromboplastin time is seen due to accumulation of uremic toxins
B. Primary defect is platelet dysfunction
C. Treatment with Factor V can decrease bleeding
D. Increased circulating levels of vWF interferes with endotheial function

Answer: B

Answer B is the correct answer. Levels of vWF are normal or at most minimally reduced in CKD. However, the functional interaction between platelets and vWF multimers is impaired, leading to platelet dysfunction.[88−90] **Answer A** is incorrect because partial thromboplastin time is normal in CKD patients. **Answer C** is incorrect because factor V levels are normal and treatment with factor V does not improve the uremic platelet defect. **Answer D** is incorrect because levels of vWF are normal, and it is the vWF−platelet interaction and not endothelial interaction that impairs platelet function.

CHAPTER

Hematologic and Infectious Complications of Chronic Kidney Disease

Jay I. Lakkis[a], *Matthew R. Weir*[b]

[a]University of Hawaii John A. Burns School of Medicine, Wailuku, HI, United States; [b]Division of Nephrology, University of Maryland School of Medicine, Baltimore, MD, United States

Abstract

Chronic kidney disease (CKD) is associated with an array of secondary abnormalities of blood cell lines: red blood cells, white blood cells, and platelets. Anemia in CKD becomes more common as CKD progresses and is associated with significant all-cause as well as cardiovascular morbidity and mortality. CKD also results in progressive platelet dysfunction and impaired primary hemostasis. Furthermore, CKD is associated with impaired immune homeostasis, with abnormalities in both innate and adaptive immunity, and their effector cells as well as humoral components, promoting infection and a state of chronic sterile inflammation. The latter is associated with increased risk of cardiovascular disease. We review the hematological and infectious complications of CKD, and their interconnectedness with cardiovascular disease and infection, the two major causes of mortality and morbidity in this patient population.

INTRODUCTION

Chronic kidney disease (CKD) affects 14.8% of the adult general population in the US and around 10% of adults worldwide.[1,2] The prevalence of CKD seems to have stabilized over the last decade after a persistent rise in the preceding two decades.[3]

CKD, whether a reduced estimated glomerular filtration rate (eGFR) and/or an increased urinary albumin excretion rate (UAER), carries an independent risk of cardiovascular and all-cause mortality.[4–10] The mortality rate more than doubles for Medicare patients with CKD aged 66 years or older,[1] and increases by a factor of 12 for CKD patients aged 50–64 and by a factor of 36 for CKD patients aged 16–49 years, when each subgroup is compared to age-matched subjects without CKD.[11] Seen in a different light, when comparing the life expectancy of an end-stage renal disease (ESRD) patient on renal replacement therapy (RRT) to that of a matched individual without ESRD, life expectancy is less than one-third for a person aged 80 years or less and around half for a patient aged 85 years or older.[1]

The two most common causes of mortality in the CKD population are cardiovascular disease (CVD) and infection.[1] Both burdens have strong links and associations rooted in dysregulation of immune homeostasis and chronic inflammation.

Furthermore, CKD results in significant morbidity. This chapter reviews the hematologic and infectious complications of CKD, focusing on the effects of CKD on erythrocytes and platelets, as well as its effects on leukocytes and immune homeostasis.

HEMATOLOGIC COMPLICATIONS OF CKD: RED BLOOD CELLS

Anemia in CKD: Introduction

Anemia is a relatively common complication of CKD that carries an increased risk of morbidity and mortality.[12,13] Analyses of adult (age >18 years) participant data from The National Health and Nutrition Examination Survey (NHANES) 2007–2008 and 2009–2010[14] estimate the prevalence of CKD at 14.0%, and the prevalence of anemia in patients with non–dialysis-dependent CKD (NDD-CKD) at 15.4%.

The prevalence of anemia increases in proportion with the National Kidney Foundation/Kidney Disease Outcomes Quality Initiative stage of CKD, with 17.4% of individuals with stage 3 CKD, 50.3% with stage 4 CKD, and 53.4% with stage 5 CKD having anemia. Similarly, a retrospective analysis of combined data from

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00031-0

non-Medicare patients aged 18–63 years and from Medicare patients aged 66–85 years estimated the prevalence of anemia at 28% in patients with stage 3–5 NDD-CKD,[15] with a prevalence of 22.4% in stage 3 CKD, 41.3% in stage 4 CKD, and 53.9% stage 5 CKD. In the older Medicare population, the prevalence of anemia in CKD (ACKD) was 50.1%, with a prevalence of 43.9% in stage 3 CKD, 64.0% in stage 4 CKD, and 72.8% stage 5 CKD. In patients with ESRD treated with hemodialysis (HD) for a period of 90 or more days, 80–83% had ACKD, which required erythropoiesis-stimulating agent (ESA) therapy.[1]

Anemia in CKD: Pathophysiology

CKD results in relative erythropoietin (Epo) deficiency, at times concomitant with Epo resistance, with a secondary decrease in red blood cell (RBC) production in the bone marrow. Up to 90% of human Epo is synthesized by renal interstitial fibroblasts,[16] with the remaining 10% in extra-renal tissues, mainly the liver. Hypoxia is the most potent stimulus for Epo production. Its effects are mediated by the inhibition of prolyl hydroxylase domain (PHD) proteins, which are responsible for the degradation of the alpha subunit of hypoxia-inducible factor (HIF) under normal oxygen conditions. The end result is an increase in HIF proteins with enhanced expression of hypoxia-induced genes (e.g. Epo).[17] Despite the chronic reduction in tissue oxygen tension linked to ACKD, Epo expression and production do not increase proportionately as expected, suggesting permanent loss of the fibroblasts' capacity to produce Epo. The relative Epo deficiency worsens with the severity of CKD, and no extra-renal compensatory corrective production has been described.

Dysregulation of iron homeostasis plays a pivotal role in the generation and maintenance of ACKD, as well as in resistance to ESA therapy,[18] especially in dialysis patients. Iron-restricted erythropoiesis is relatively common in patients with CKD. Iron-restricted erythropoiesis may have different phenotypes: iron deficiency, iron deficiency anemia, or functional iron deficiency (FID). Iron deficiency refers to diminished body iron stores with no anemia.[19] Iron deficiency anemia refers to depleted body iron stores with a secondary decrease in RBC mass. FID refers to iron-restricted erythropoiesis resulting from a failure to mobilize iron to the bone marrow for erythropoiesis despite apparent normal or increased iron body stores.[20]

In a normal steady state, oxygen is transported in humans by hemoglobin (Hb), a tetramer with two pairs of globin chains (α and β), with each chain bound to a heme group made of a porphyrin ring and an iron atom, which carries the oxygen. Thus, iron homeostasis (reduction, absorption, storage, transfer) is under strict control. The majority of iron in the human body is recycled from senescent cells (old RBCs phagocytized by macrophages or hepatocytes). A much smaller portion is absorbed daily to replace losses. Gastrointestinal dietary iron (Fe^{3+}) must be first reduced (Fe^{2+}) to be absorbed. The reduction is mediated by duodenal cytochrome B, a duodenal brush border ferric reductase enzyme. Following reduction of dietary iron, absorption takes place *via* the duodenal enterocyte luminal/apical divalent metal transporter 1 (DMT1). Thereafter intracellular iron is stored as ferritin, with subsequent regulated transfer to the blood *via* the basolateral transporter ferroportin,[21] where it is reoxidized (Fe^{3+}) and loaded to its carrier transferrin (known as apotransferrin when not carrying any iron). Transferrin delivers the iron to its target tissues for use (mainly in the bone marrow) or for storage (mainly by the liver), where it binds to its cell surface transferrin receptor (TfR) and is internalized and binds to intracellular ferritin. Transferrin exists predominantly in the monoferric form in a normal steady state, and in the diferric form in iron overload states.[18]

Ferroportin also mediates cellular iron efflux from other storage cells, mainly macrophages and hepatocytes,[22] and is feedback-regulated by hepcidin. Hepcidin is a 25-amino acid negative iron-regulatory hormone at the center of iron metabolism. Hepcidin is synthesized exclusively in the liver and binds ferroportin in response to an iron load or to inflammation. Then the hepcidin–ferroportin complex is endocytosed and broken down by lysosomes,[23] thus blocking any further rise in iron bioavailability and enhancing iron sequestration.

Hepcidin plays a key role in iron-restricted erythropoiesis, FID, and resistance to ESA therapy. CKD patients have increased plasma hepcidin levels, due to chronic inflammation and reduced renal clearance. They also have low ferroportin levels,[24,25] a combination that downregulates duodenal iron absorption[26] and interferes with the availability of stored iron for erythropoiesis.

Abnormal bone and mineral metabolism has also been associated with Epo resistance and iron-restricted erythropoiesis. Vitamin D is a potent inhibitor of hepcidin.[27] Vitamin D deficiency is a common finding in patients with CKD. As such, low vitamin D levels are associated with an increase in circulating hepcidin levels and FID. Furthermore, iron seems to play an important role in the regulation of fibroblast growth factor 23 (FGF-23) through mechanisms not yet fully elucidated.[28] Iron deficiency increases levels of FGF-23, a regulatory hormone secreted by osteocytes and osteoblasts with a crucial role in the maintenance of phosphorus homeostasis. This seems to be one of the mechanisms that

may explain the elevated levels of FGF-23 in CKD patients, in whom it promotes urinary phosphate excretion.

Patients with CKD, especially patients on RRT,[29] have diminished duodenal iron absorption as well as chronic blood loss due to relatively frequent phlebotomy, platelet dysfunction, and (in the case of HD patients) blood loss in the dialysis membrane and tubing.

ACKD may also result from other pathophysiological pathways such as inhibition of erythropoiesis by uremic toxins, Epo resistance due to a multitude of causes (such as chronic inflammation or secondary hyperparathyroidism, hemolysis, vitamin B12 [cobalamin], or folate deficiency) or shortened erythrocyte life span.[30–32] Finally, angiotensin II may play a minor physiological role in stimulating Epo production in humans.[33–35] Angiotensin-converting–enzyme inhibitor (ACEI) therapy may reduce the response to ESAs and contribute to ESA hyporesponsiveness or resistance.[16,36–38]

Anemia in CKD: Diagnosis

The severity of ACKD is proportional to the degree of reduction in eGFR (in mL/min/1.73 m^2 body surface area).[1] Anemia may become clinically evident when the eGFR decreases below 60 mL/min/1.73 m^2 but is most common in individuals with eGFR <30 mL/min/1.73 m^2. The most reliable biochemical marker for ACKD is the Hb concentration, rather than the hematocrit (Hct), because the latter may vary with extracellular fluid volume, measuring methods, and sample storage time.

The 2012 KDIGO (Kidney Disease: Improving Global Outcomes) Clinical Practice Guideline for Anemia in CKD adopted the 1968 World Health Organization definition of anemia as a hemoglobin concentration less than 12 g/dL in women and less than 13 g/dL in men.[39]

All best practice guidelines for the management of ACKD recommend periodic monitoring of the serum Hb in patients with CKD with and without anemia.[39–42] The 2012 KDIGO anemia guideline recommends, in the absence of anemia, a minimal Hb testing frequency of once every three months in patients with ESRD on RRT, once every six months in stage 4–5 CKD, and once a year in patients with stage 3 CKD.[39] In patients diagnosed with anemia not treated with ESA, the minimal frequency was once a month in patients with ESRD on RRT with HD, and every three months in all other CKD populations. In patients with ACKD receiving ESA therapy, Hb should be monitored at least once a month during the initiation phase, at least once every three months in NDD-CKD patients, and at least every month in dialysis patients during the maintenance phase.

An initial diagnostic workup for ACKD entails a strategy aimed at the exclusion of other potential causes of anemia in this patient population.[39–42] Age-appropriate screening for occult gastrointestinal blood loss is recommended. On peripheral blood smear and complete blood count, RBCs are typically normochromic, with a normal mean corpuscular hemoglobin, normocytic with a normal mean corpuscular volume, and have a normal RBC distribution width. Echinocytes or burr cells may be seen. The absolute and the corrected reticulocyte count confirm the hypoproliferative nature of this anemia.

Iron, transferrin saturation (TSat), and ferritin are essential to exclude concomitant iron deficiency and iron-restricted erythropoiesis. Most clinical practice guidelines would accept a transferrin saturation at 30% or less and a ferritin at 500 ng/mL or less as cutoffs that indicate iron deficiency and that warrant iron replacement therapy. The challenge arises with FID, where the iron parameters are discordant, with a transferrin saturation at 20% or less and a ferritin at 500 ng/mL or more and the safety of iron replacement therapy becomes questionable. Iron parameters should be evaluated at least once every three months in patients with ACKD on maintenance ESA therapy, and more often (e.g. every month) when ESA therapy is being initiated or adjusted, or when response to iron therapy is being evaluated.[39] However, the interpretation of these tests is fraught with complexities and may not always be straightforward. Neither the ferritin nor the transferrin saturation should be used alone to diagnose iron deficiency or to measure response to intravenous (IV) iron therapy.

Ferritin, a surrogate measure of total body iron stores, is an acute phase reactant that may be increased in patients with chronic inflammation.[18] Although a serum level of less than 100 mcg/L in NDD-CKD or less than 200 mcg/L in dialysis patients is desirable to diagnose iron deficiency with certainty, there is no evidence-based upper-limit ferritin cutoff above which FID can be excluded.

Other less available diagnostic tools for the evaluation of FID include the percentage of hypochromic red cells and the reticulocyte hemoglobin content.[20] Assessment of hepcidin levels is not currently recommended to evaluate iron status.

Evaluation of vitamin B12 (cobalamin) and RBC-folate levels should be performed.[39–42] Epo levels should not be part of a routine workup. The interpretation of Epo level is fraught with technical limitations and rarely adds to the evaluation and management plan. Epo levels are usually normal or slightly elevated in absolute terms.[32] They are, however, much lower than what would be expected for the degree of anemia, reflecting profound relative deficiency of Epo.

Anemia in CKD: Prognosis

ACKD is associated with increased mortality and morbidity.[13,43] ACKD has been associated with more frequent hospitalizations[44] and its severity with an increased length of hospital stay.[45] ACKD is also associated with a higher risk of left ventricular mass index (LVMI) and left ventricular hypertrophy (LVH), an independent predictor of increased mortality risk[46] and heart failure, new-onset atrial fibrillation,[47] increased CVD and mortality, impaired cognitive function, reduced functional status and exercise tolerance, decreased quality of life, and increased RBC transfusion requirements.

ACKD therapy, however, has not been reproducibly associated with reversal of mortality risk.[48] Similarly, there is conflicting evidence about the effect of ACKD therapy on associated morbidities such as health-related quality of life (HRQOL).[49,50] All evidence, however, points to a significant reduction in erythrocyte transfusion requirements.[31]

Anemia in CKD: Treatment

Treatment of ACKD focuses on minimizing blood loss, iron replacement therapy, and use of ESAs. If a patient requires both iron replacement and ESA therapy, then iron stores must be replenished first. Such a strategy is associated with a significantly lower ESA dose and prevents ESA resistance.[51]

Iron replacement therapy is one of the tenets of pharmacological therapy in patients with ACKD. Oral iron must be taken between meals and should not be combined with calcium-based phosphate-binders or foods. Absorption may be enhanced with concomitant administration of vitamin C. However, iron absorption in CKD is diminished, especially in ESRD patients. The excess hepcidin and low ferroportin downregulate duodenal iron absorption mediating FID. For these reasons, anemia management guidelines[39–42] in patients with ESRD recommend IV rather than oral iron therapy. Clinical trials and meta-analyses comparing the efficacy of oral vs. IV iron in the treatment of ACKD in patients with stage 3–5 CKD reached a similar conclusion.[52,53]

In patients with ESRD on RRT, in whom iron deficiency anemia is virtually ubiquitous and recurrent, the monthly dose of IV iron that can be administered safely is not well established. Some evidence indicates that a safe monthly dose is 100–200 mg per month and should not exceed 300 mg per month.[54] A higher monthly dose exceeding 400 mg is associated with increased mortality rate in HD patients.[55] However a meta-analysis of data from seven randomized controlled trials showed that higher dose iron (defined as >400 mg/month) was not associated with a higher risk of infection or all-cause mortality. Similarly the same meta-analysis analyzed data from fifteen observational trials and again higher dose iron (defined as >200 mg/month) was not associated with an increased risk of all-cause mortality, infection, cardiovascular events, or hospitalizations.[56]

The traditional oral iron formulations (e.g. ferrous sulfate, ferrous gluconate, ferrous fumarate) are relatively safe. Adverse reactions to oral iron therapy are mostly gastrointestinal, such as dark discoloration of stools, dyspepsia, and constipation. More recent additions to the pharmacopoeia of phosphate-binders, namely sucroferric oxyhydroxide and ferric citrate, are iron-based and serve dual roles as phosphate-binders and iron supplements. Administration of IV iron formulations (e.g. iron sucrose, ferric gluconate, ferumoxytol, ferric carboxymaltose, and iron dextran) can result in hypersensitivity reactions, including anaphylactic as well as anaphylactoid reactions. The highest risk of anaphylaxis on initial exposure has been associated with iron dextran, and the lowest with iron sucrose.[57] Evidence regarding safety of IV iron compared to oral iron is not uniform. Some studies reported a similar risk for infectious or cardiovascular events with oral and IV iron in patients with NDD-CKD and ESRD,[52,53] whereas others have shown an increased risk of infectious or cardiovascular events with administration of IV iron in patients with NDD-CKD, compared to the group treated with oral iron.[58,59] The mode of dosing IV iron has also been studied. Maintenance IV dosing is associated with a lower risk of infection than loading IV dosing.[60] All iron formulations may result in short- and long-term secondary iron overload. Immediately after IV iron is administered, the supra-physiologic iron load exceeds the capacity of a saturated iron homeostasis system, resulting in the generation of circulating free iron, which has been associated with enhanced bacterial growth *in vitro*,[61] impaired immune effector cell function, endothelial dysfunction, and increased oxidative stress.[62] Magnetic resonance imaging revealed evidence of hepatic iron overload in HD patients receiving IV iron replacement therapy, but the clinical significance of such a finding remains to be established.[63] Finally, detection of iron deposits in the microvasculature of patients with calcific uremic arteriolopathy raises concern about the role of iron administration in the pathogenesis of this serious disease.[64,65]

The Food and Drug Administration (FDA) approval of the first ESA, recombinant human Epo (rHuEPO), in 1989 for treatment of ACKD in dialysis patients and in 1993 for NDD-CKD patients heralded a new era in the treatment of ACKD. Pharmacological therapy of anemia decreases the need for RBC transfusions,[66] may cause partial regression of LVH,[67] may reverse clinical manifestations and symptomatology, may improve functional status, and some even report improved survival.

The benefits of treatment of anemia remain a topic of debate. For example, a systematic review of the effect of ESA therapy on HRQOL in CKD patients did not reveal any significant improvement.[49]

Currently available ESAs approved by the US FDA include:

(a) recombinant human Epo was approved for use in patients with ESRD on June 1, 1989, and for use in NDD-CKD patients on April 1, 1993?[68]
(b) darbepoetin alpha was approved for use in both dialysis and NDD-CKD patients on September 17, 2001,[69] and
(c) methoxy polyethylene glycol-epoetin beta, a continuous erythropoiesis receptor activator (CERA), was approved for use in all CKD patients on November 14, 2007.[70]
(d) On May 15, 2018, the first epoetin alpha biosimilar, epoetin alfa-epbx was approved by the FDA for treatment ACKD.[71]

ESA therapy is initiated, in the majority of patients, when he or she manifests clinical symptoms of anemia, or when Hb levels decline below 9 g/dL. Therapy should target a goal Hb of 10–11 g/dL. Levels higher than 12 g/dL must be avoided. Higher goals have been associated with poorer blood pressure (BP) control and increased risk of stroke and mortality.[66,72]

Most starting ESA doses are weight based. For example, epoetin alpha is usually started at 50–100 units/kg three times a week. Darbepoetin alpha is usually started at a dose of 0.45 mcg/kg once a week or 0.75 mcg/kg once every 2 weeks in dialysis patients, or at a dose of 0.45 mcg/kg every 4 weeks in NDD-CKD (usually 60–200 mcg every 2–4 weeks). Methoxy polyethylene glycol-epoetin beta is usually started at a dose of 0.6 mcg/kg once every 2 weeks (usually 25–75 mcg every 2–4 weeks). All ESA doses are titrated to achieve a goal Hb level of 10–11 g/dL in patients with ESRD. ESAs must be held if Hb level exceeds 11–11.5 g/dL, and the dose reduced before resumption of therapy. Targeting higher or gender-normal hemoglobin goals must be avoided.[72–76] Although the use of ESA and iron therapy confer a survival benefit in patients with lower hemoglobin levels, the benefit dissipates and mortality risk increases when therapy is administered in patients with higher hemoglobin levels.[77] Patients with a blunted initial Hb response to ESA carry a higher risk for development of CVD.[78] A higher ESA dose also conveys an increased risk for all-cause mortality as well as cardiovascular mortality.[79]

There is no evidence that one ESA, e.g. CERA, is superior in efficacy or safety to another.[31,80] A systematic review showed higher doses of short-acting ESA (epoetin alpha) over a longer time frame are noninferior to lower doses with more frequent administration in NDD-CKD patients.[81] Subcutaneous administration of epoetin is less costly than use of the IV route.[82] ESA therapy does not slow progression of CKD.[83,84]

Adverse effects of ESAs include an increase in BP, mediated by a direct systemic vasoconstrictive effect of ESAs.[16,85,86] Other risks associated with ESA administration include pure red cell aplasia, seizure activity,[80,87] thrombotic events, including stroke[88] and enhanced arteriovenous dialysis access thrombosis, and promotion of tumor growth. In patients with ACKD and cancer, ESAs are relatively contraindicated due to evidence pointing to enhancement of tumor growth and increased mortality in the cancer patient population.[89,90] Risks and benefits of ESA therapy and alternative options must be discussed with the patient and care coordinated with an oncologist.

Novel therapies for ACKD include inhibitors of HIF-PHDs,[17,91–98] non-ESA therapies that simulate hypoxic conditions and are currently in phase 3 clinical trials. PHD inhibitors stop the degradation of the alpha subunit of HIF, levels of which are normally regulated by oxygen tension. This results in the increased concentration and stabilization of the heterodimer HIF (α and β subunits, the beta subunit of which is under constitutive expression). In turn, HIF upregulates the expression of hypoxia-induced genes, including Epo and DMT1. Phase 2a and 3 trials with four different agents (GSK-1278863/daprodustat, FG-4592/roxadustat, AKB-6548/vadadustat, and BAY-85-3934/molidustat) have shown that HIF–prolyl hydroxylase inhibitors offer an additional form of treatment in patients with ACKD and NDD-CKD as well as ESRD, through the induction of endogenous Epo production and promotion of more favorable iron homoeostasis (e.g. improved intestinal iron absorption and decreased circulating hepcidin levels). No serious adverse reactions have been reported so far, although theoretical concerns over promotion of tumor growth and pulmonary arterial hypertension remain.

Anemia in CKD: Conclusions

Anemia is a common complication of CKD and is associated with increased morbidity and mortality, including cardiovascular morbidity and mortality (Figure 31.1). ACKD is primarily mediated by relative Epo deficiency, Epo hyporesponsiveness or resistance, and iron-restricted erythropoiesis, which may take the form of true iron deficiency anemia or FID. Treatment of ACKD is focused on achieving a goal Hb that alleviates any existing symptoms, reverses the high mortality rate associated with very low Hb, minimizes transfusion-dependence, and avoids the thrombotic complications of correction to normal Hb levels. A level of 10 g/dL is

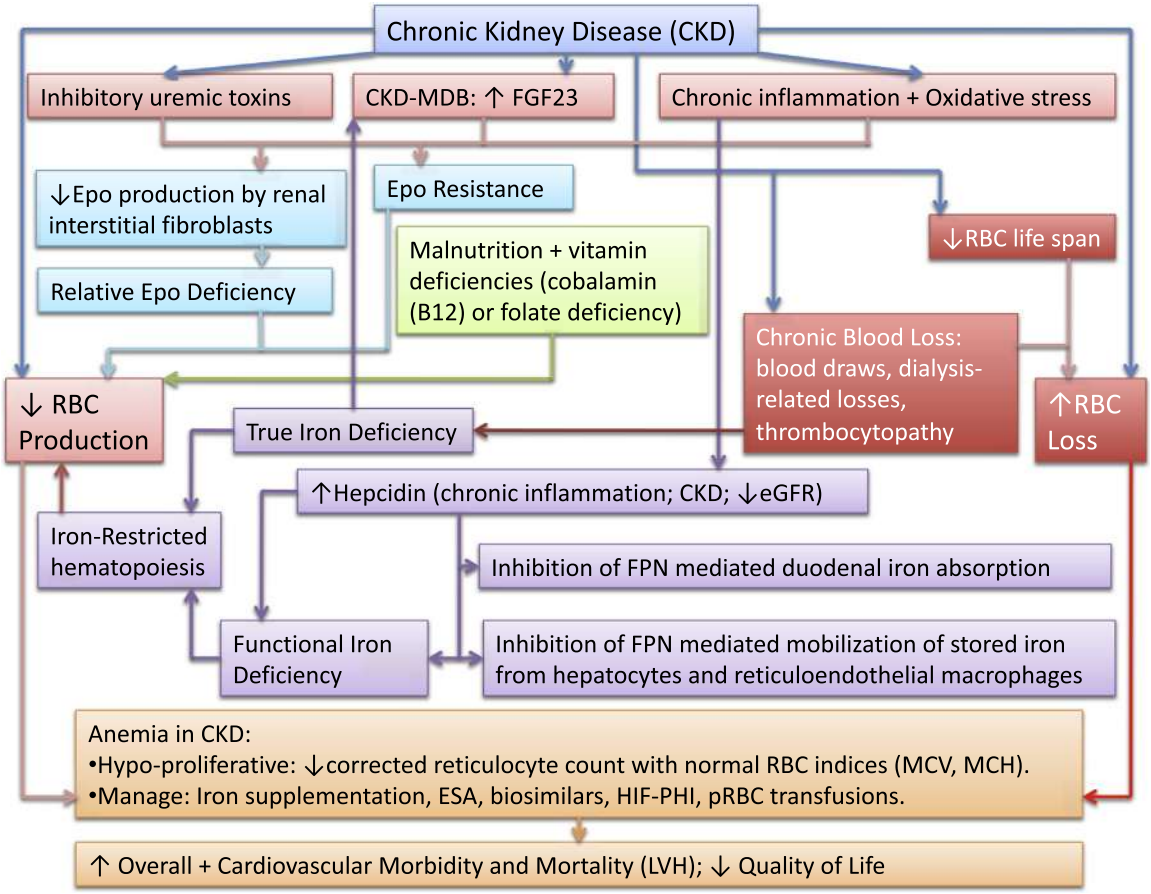

FIGURE 31.1 The pathophysiology and management of anemia in chronic kidney disease. Many processes increase the risk of cardiovascular disease in the patient with chronic kidney disease. *eGFR*, estimated glomerular filtration rate; *ESA*, erythropoiesis-stimulating agent.

acceptable for most CKD patient populations. Pharmacological therapy consists of ESAs and iron supplementation, but both therapies are associated with risks that must be weighed carefully against the benefits.

Erythrocytosis/Polycythemia

Erythrocytosis can be seen in patients with CKD in two settings: cystic kidney disease (mostly autosomal dominant polycystic kidney disease [ADPKD]), and following kidney transplantation. In ADPKD, erythrocytosis is thought to be due to pericystic local tissue hypoxia and dysregulated HIF proteins, with a secondary increase in Epo production.[99] In ESRD patients treated with HD and not on Epo therapy, an elevated Hb concentration was not associated with increased risk of mortality.[100] Erythrocytosis in this patient population may be associated with cystic kidney disease, chronic hypoxia due to pulmonary or CVD, and tobacco use.

Erythrocytosis after transplantation complicates around 8–15% of kidney transplants and occurs 8–24 months after transplantation with a spontaneous remission rate of 25% at 2 years.[101] This is clinically relevant because 10–30% of polycythemic patients develop arterial or venous thrombotic complications (including cerebrovascular accident and pulmonary embolism) with a 1–2% mortality rate.

Treatment with an ACEI or an angiotensin receptor blocker (ARB) is preferred.[101] Angiotensin II (AII) is a direct stimulus to Epo production. Increased AII production may be encountered in patients with renal hypoperfusion and tissue hypoxia, such as those with transplant renal artery stenosis or native renovascular disease, who develop erythrocytosis, which improves with ACEI or ARB therapy.[16]

HEMATOLOGIC COMPLICATIONS OF CKD: PLATELETS

Platelet Dysfunction: Introduction

Patients with CKD are at increased risk of hemorrhage[102–104] as well as thrombosis.[105] Both risks increase progressively with worsening CKD.

Abnormalities in either eGFR or UAER (urine albumin:creatinine ratio [UACR] in mg albumin per gram creatinine) have been associated with increased risk of hemorrhage.[106] For instance, a patient with an eGFR of <15 mL/min/1.73 m^2, and an UACR >300 mg/g has an adjusted relative risk of all-cause major hemorrhage of 5.5 compared to one with an eGFR ≥ 90 mL/min/1.73 m^2, and an UACR <30 mg/g. It is estimated that one in seven patients will develop a major hemorrhagic event for ESRD patients within three years after initiating dialysis.

Similar results are also seen in more specific CKD subpopulations. Patients with CKD and high CVD risk have a 1.5-fold increased risk of bleeding compared to matched subjects with no CKD.[107] This risk is increased with albuminuria as well as decreased eGFR, although the risk association is stronger with albuminuria. For example, the risk is 3.5-fold in a patient with an eGFR <45 mL/min/1.73 m^2 and albuminuria compared to a patient with eGFR above 45 mL/min/1.73 m^2 and no albuminuria. Similarly, in patients with non−ST-elevation myocardial infarction or unstable angina who had percutaneous coronary intervention and received anticoagulant therapy, CKD was associated with a higher risk of major and minor bleeding as well as restenosis at 30 days and 180 days. The risk increased progressively with the severity of CKD.[108] NDD-CKD adult patients aged 66 years or more who were treated with warfarin for atrial fibrillation had an increased risk of major hemorrhage.[109] The risk is also higher in dialysis patients. Finally, the risk of gastrointestinal hemorrhage was significantly higher in NDD-CKD patients depending on the eGFR. In a patient with eGFR <30 mL/min/1.73 m^2, the hazard ratio was 7.06 compared to a patient with eGFR ≥ 90 mL/min/1.73 m^2.[110] The risk of hemorrhage is also approximately five times higher in dialysis patients compared to patients without CKD.[111]

Acquired platelet dysfunction or uremic thrombocytopathy plays a key role in the increased risk of bleeding seen in the CKD population. Below, we will review normal platelet function and summarize alterations triggered by CKD.

Platelet Dysfunction: Pathophysiology

Platelets originate from bone marrow megakaryocytes and migrate to the circulation, where they are responsible for primary hemostasis during their seven day lifetime. Structurally, a platelet has heterogeneous components.[112] First, a peripheral zone composed of a plasma membrane glycocalyx that houses the surface glycoporteins (GPs), which are essential for platelet activation and adhesion and aggregation; a lipid bilayer, which contains tissue factor (coagulation factor III) that plays a key role in binding coagulation factors after platelet activation; and a submembrane area with a membrane contractile cytoskeleton made of actin filaments that determine platelet morphology and mediate receptor translocation to the surface and regulate platelet activation signal systems. Secondly, a sol−gel zone consists of an organized matrix of circumferential micrtotubules and microfilaments that make up the cytoplasmic contractile cytoskeleton, a system designed to contribute to platelet morphology and keep secretory organelles apart from each other and from other structures, and which on platelet activation constricts to reposition organelles in the platelet center, where they release their contents through a surface-connected canalicular system. Third, an Organelle Zone consists of alpha-granules where von Willebrand factor (VWF) can be found, dense granules that contain serotonin (5-hydroxytryptamine, 5HT) and adenosine diphosphate (ADP), and lysosomes.

In the event of endothelial injury, circulating platelets are mobilized to the site of injury, where platelet adhesion to the injured blood vessel takes place. Adhesion is mediated by the binding of exposed subendothelial extracellular matrix collagen to platelet surface GPVI and integrin $\alpha 2\beta 1$, and in conditions of high shear, the binding of GPIbα-IX-V complex to VWF.[113] Platelet activation occurs when platelet thrombin receptors, protease-activated receptors PAR1 and PAR4, interact with thrombin (byproduct of prothrombin, coagulation factor II).[114] An activation signal may be amplified *via* a positive feedback loop generated by the interaction of ADP and 5HT (released by platelet dense granules) with platelet receptors $P2Y_1$, $P2Y_{12}$, and $5HT_{2A}$, or by the interaction of thromboxane A2 (the product of arachidonic acid metabolism *via* the cyclooxygenase 1 pathway) with its thromboxane prostanoid receptor on the platelet surface. Platelet aggregation is mediated by fibrinogen (coagulation factor I) and by the binding of VWF to activated platelet surface GP integrin αIIbβ3 (previously known as GPIIb/IIIa).[115] The aggregation reaction may also be amplified by other mediators. Platelet adhesion, activation, and aggregation result in the formation of a platelet plug, which is solidified as a thrombus by secondary hemostasis and formation of a fibrin clot. On their natural end of life or on completion of their role in primary hemostasis, platelets are cleared from the circulation by phagocytes, and taken up by the spleen, where they are destroyed.

The mechanisms by which CKD promotes risk of bleeding are not completely understood. CKD impairs platelet adhesion, activation, and aggregation.[116] CKD has been associated with dysfunctional platelet interaction and adhesion to injured blood vessel walls, a paucity in the content of the dense granule including

decreased content of ADP and serotonin/5HT, defective release of the alpha granule, altered VWF function, abnormal cytoskeletal structures, impaired platelet intracellular signaling, increased platelet cyclic adenosine monophosphate and cyclic guanosine monophosphate (cGMP), abnormal vascular endothelium, and increased synthesis of nitric oxide (NO; endothelium-derived relaxing factor, EDRF), which exerts direct and indirect inhibitory effects on platelet aggregation. The latter are mediated by an NO-driven rise in cGMP and a secondary decline in ADP and thromboxane A2, both of which amplify the signal for platelet aggregation. Finally uremia is hypothesized to generate and retain incompletely identified circulating "uremic" toxins and inhibitors detrimental to platelet function (such as guanidino compounds).[117–119] These findings are best illustrated by experiments showing that the addition of normal plasma to a uremic milieu improves platelet function and *vice versa*.

Anemia also plays a role in the pathogenesis of thrombocytopathy in CKD patients.[120,121] Anemia alters the flow pattern of platelets in the blood vessels, shifting them into a central position and away from the endothelial surface. Hemoglobin binds NO. Therefore a decrease in hemoglobin results in increased bioavailability of NO and secondary direct and indirect inhibitory effects on platelet aggregation. Finally, a decrease in RBC mass is associated with a further decrease in availability of ADP and thromboxane A2, both of which are also produced by RBCs.

Platelet Dysfunction: Diagnosis

The diagnosis of platelet dysfunction is often made by the clinical presentation and rarely by specific diagnostic testing. Clinical manifestations of acquired platelet dysfunction may be minor or major and involve cutaneous, mucosal, and serosal tissues. Minor bleeding events involve the skin, with oozing from sites of previous venipunctures, easy bruising, ecchymoses or purpura, or the mucosa with epistaxis, gingival hemorrhage, menorrhagia, or hematuria.[122] Major bleeding events include intracranial, gastrointestinal, and retroperitoneal hemorrhage. Bleeding may be spontaneous, but more often is provoked (e.g. associated with procedures or trauma). Bleeding is more pronounced in patients with ESRD who are receiving inadequate or no dialysis.

Platelet count is usually normal, as are the prothrombin time (PT) and the activated partial thromboplastin time (aPTT).[103] Levels of coagulation factors are normal to increased. Neither serum blood urea nitrogen nor serum creatinine concentration (S[Cr]) levels accurately predict bleeding risk.

Bleeding time (BT) increases with declining eGFR or worsening UACR.[104] BT may play a role in the evaluation of platelet function before surgical or invasive procedures in patients with ESRD with inadequate or no dialysis.[123] The BT, however, is insensitive and nonspecific. Its interpretation is marred by severe technical and other limitations. Therefore the BT is rarely used clinically.

Platelet adhesion and aggregation are impaired in CKD patients. Ristocetin-induced platelet aggregation (RIPA), a diagnostic tool to assess platelet aggregation and the intact functionality of the interaction of GPIbα-IX-V with its ligand (VWF), is diminished in uremic patients.[124,125] Similarly, platelet VWF multimer pattern is abnormal and the mean platelet VWF antigen and activity are reduced, whereas the mean plasma VWF antigen and activity are increased. However, these diagnostic tools are not routinely available for clinicians and are mainly used in research settings.

Platelet Dysfunction: Prognosis

Acquired platelet dysfunction in CKD cannot be fully and permanently reversed. A thorough and preventive approach may decrease risks of bleeding and/or thrombosis. For example, in ESRD patients, it is essential to ensure prescription and delivery of adequate dialysis. Correcting ACKD may help decrease the degree of platelet dysfunction. Patients with CKD may have indications for anticoagulant therapy, and risks and benefits must be assessed carefully and discussed with the patient.

Platelet Dysfunction: Treatment

Several strategies have been evaluated in the management of uremic thrombocytopathy.[117] Initiation of RRT or ensuring the adequacy of dialysis in the ESRD patients improves platelet function, albeit not fully.[103,126–130] Provision of adequate dialysis without anticoagulation is specifically recommended before any invasive or surgical procedures.

Correction of anemia to goal hemoglobin of 10 g/dL in the CKD patient reduces BT and may improve platelet function and primary hemostasis.[120,121,131] Correction of anemia may be achieved by ESA and/or iron therapy or by red blood cell transfusions. ESA therapy may have a direct salutary effect on platelet function in ESRD patients.[132–134]

Desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP), whether used at 0.3 mcg per kg IV or subcutaneously, or at 3 mcg per kg intranasally, shortens BT and restores hemostasis temporarily, and slows or stops bleeding. Its effects last up to 4–8 hours.[135–138] DDAVP appears to replenish a large

VWF multimer pattern *via* endothelial cell stimulation and promote platelet glycocalyx glycoprotein expression. It is one of the safest pharmacological therapies available, but its drawbacks include short duration of action and tachyphylaxis.

Cryoprecipitate also improves BT and reduces or corrects major bleeding for a period lasting less than 24–36 hours.[139–141] Cryoprecipitate is rich in VWF, factor VIII, and fibrinogen. Its major drawbacks, infections, and transfusion reactions, limit its use to clinical scenarios where other measures have failed or in the perioperative setting. Conjugated estrogens, whether administered orally or intravenously, also reduce BT in uremic patients and improve hemorrhage during active bleeding.[142–144] The major drawbacks are estrogen-related side effects, including hot flashes. Low-dose transdermal estradiol at 50–100 mcg twice weekly provides a mode of sustained long-term estrogen therapy that is best suited for refractory uremic bleeding. Transdermal estradiol may have the additional benefit of a lower risk of thrombotic events compared to oral estrogen.[145,146] Tranexamic acid, a synthetic antifibrinolytic agent, has been used to treat uremic thrombocytopathy.[147,148]

Platelet Dysfunction: Conclusions

Platelet dysfunction and secondary abnormal primary hemostasis and bleeding diathesis are relatively common complications of CKD and carry an increased risk of mortality and morbidity (Figure 31.2). Such abnormalities become more prevalent with declining eGFR or worsening UACR and are most pronounced in patients with advanced CKD or ESRD. The mechanisms underlying platelet dysfunction have not been fully explained, but a multitude of abnormalities have been described. Therapy is usually reserved for patients with active bleeding or in the perioperative setting. Therapy is only successful at partial and temporary reversal of the bleeding problem and consists of

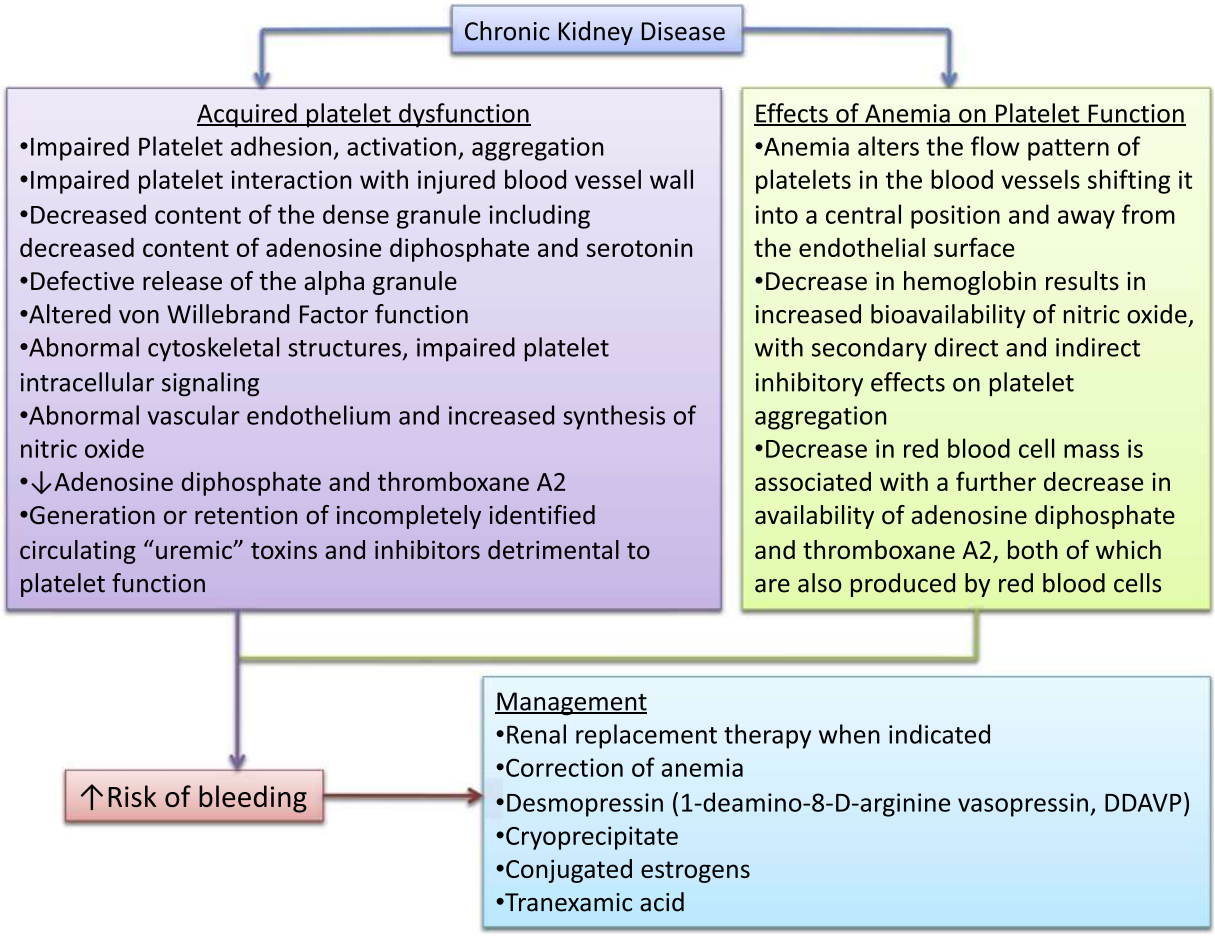

FIGURE 31.2 Platelet dysfunction in chronic kidney disease and its management.

emphasizing the adequacy of dialysis in the ESRD population, correction of anemia, and use of selected pharmacological agents. Evidence from randomized control trials to guide therapy is lacking.

INFECTIOUS COMPLICATIONS OF CKD: LEUKOCYTES AND IMMUNE HOMEOSTASIS

Introduction: Leukocyte and Immune Dysfunction in CKD

Kidney injury triggers injury in distant organs *via* organ cross-talk. CKD affects multiple organ systems, including the immune system. Immune dysfunction in this patient population may manifest as a higher rate of infections as well as a state of chronic sterile inflammation, lower rates of response to vaccinations, and a higher rate of neoplastic diseases.

Infection is the second most common cause of mortality (after CVD) in patients with ESRD on RRT,[1] with a mortality rate of 11%. Septicemia accounts for 8% and other infections for 3% of deaths. Similarly reduction in eGFR and/or albuminuria is associated with an increased risk of infection and infection-related mortality.[149,150] The increased risk of infection applies to community-acquired infections[151] as well as infection-related hospitalizations.[152] Furthermore, in NDD-CKD patients, an infectious event is independently associated with an increased rate of adverse cardiovascular outcomes, progression to ESRD and mortality.[153]

In addition to infection, CKD has been associated with a state of chronic sterile inflammation, which promotes atherosclerosis, cardiovascular morbidity, and mortality. CKD is also associated with increased rates of nonresponse to immunizations.

To understand the full complexity of the effects of CKD on leukocytes and their place in immune homeostasis, it is essential to highlight relevant components of the immune system and summarize the effects of CKD on these components.

The human immune system serves to recognize, defend against, and eliminate a potential source of danger (microbes, tumor cells) and to assist in recovery and tissue repair, all while maintaining a set of checks and balances to avoid mounting a response to self-antigens or to the ubiquitous human microbiome.[154,155] The immune system infrastructure is the sum total of the coordinated efforts of innate immunity and adaptive immunity, both of which have cellular and humoral components, as well as a complex network of cell-to-cell signaling and communication in different tissues and organ systems.

Pathophysiology: the Immune System in Health and in CKD

Types of Cellular Immunity

Cellular immunity, whether innate or adaptive, may be classified into three types[156]:

Type 1 immunity defends against intracellular infections. Its effector cells include the mononuclear phagocyte system (circulating monocytes and tissue-resident macrophages, as well as tissue dendritic cells [DCs]), natural killer (NK) cells, and other group 1 innate lymphoid cells (ILC1s). ILC groups[157] are lymphoid cell groups that do not express antigen-specific receptors and are either classified as cytotoxic or helper, cytotoxic (TC1), and helper (Th1) T lymphocytes.
Type 2 immunity defends against helminths and venoms. Its effector cells include basophils and mast cells, eosinophils, group 2 innate lymphoid cells (ILC2s), cytotoxic (TC2) and helper (Th2) T lymphocytes.
Type 3 immunity protects against extracellular bacterial and mycotic infections. Its effector cells include neutrophils and mononuclear phagocytes, group 3 innate lymphoid cells (e.g. ILC3s), cytotoxic (TC17) and helper (Th17) T lymphocytes, and epithelial cells.

Innate Cellular Immunity: An Overview

Innate immunity is elicited by several first line general defense mechanisms, written in one's genetic code, and may be cellular or humoral. Innate immunity entails a swift response within minutes of exposure to a threat, with nonspecific, general pathogen recognition, phagocytosis, and antigen presentation. Innate immunity has no immunologic memory. In the short-term, this defense strategy is desirable to contain and neutralize any potential threat. If innate nonspecific activity lasts for longer times, however, then responses can cause extensive damage to host tissue. Therefore, the innate immune system also works in tandem with, induces, and regulates elements of the slower and more specific adaptive immune system, which ultimately accomplishes the task of accurate and precise neutralization of the threat.

Cellular innate defenses include nonprofessional physical or anatomical barriers such as surface epithelia and mucous membranes (skin, respiratory, gastrointestinal and genitourinary systems), and secretions with soluble antimicrobial products such as tears and saliva.

Innate Cellular Immunity: Pattern Recognition Receptors

Innate cellular immunity includes multiple professional effector cells equipped with pattern recognition receptors (PRRs).[158] PRRs are instrumental in the recognition of characteristic conserved motifs found on the surface of various pathogens, known as pathogen-associated molecular patterns (PAMPs). PRRs also recognize and respond to damage-associated molecular patterns (DAMPs), molecules released by cells in distress. Functionally, PRR-mediated innate immune response activation may follow one of two pathways: signaling PRRs that activate immune effector cells, or endocytotic receptors and soluble PRRs that phagocytose and internalize pathogens.[159]

PRRs may be classified functionally into three categories: secreted (e.g. mannose-binding lectin family), endocytic (e.g. macrophage scavenger receptor), and signaling (e.g. toll-like receptors [TLRs]).[160] There are different families of PRRs. Four have been characterized, including two trans-membrane and two cytosolic families.[161,162]

Trans-membrane—TLRs

The TLR family includes 13 members.[163,164] TLRs are found either on the surface of the cell membrane (TLR1, TLR2, TLR2, TLR4, TLR5, TLR6) or in the membrane of endosomes and lysosomes (TLR3, TL7, TLR8, TLR9). One example is TLR4, a cell-membrane PRR, which recognizes and binds the gram-negative bacterial lipopolysaccharide (LPS).

Compared to controls, CKD patients have a higher level of TLR4 activity.[165] The activity level rises with declining eGFR. For example, there was higher TLR4 expression in neutrophils in HD patients and higher TLR4 expression in monocytes in stage 3−4 CKD patients compared to patients with eGFR greater than 60 mL/min/1.73 m^2.[166] This increase may play a proinflammatory role and promote muscle wasting in CKD, as well as progression of CKD and renal fibrosis.[167,168]

Trans-membrane—C-type Lectin Receptors

One example is DC-specific receptor-1, which is expressed in DCs, monocytes and macrophages, as well as polymorphonucelar cells (PMNs), and binds to carbohydrate-rich PAMPs in the fungal cell wall.[169]

Cytosolic—Retinoic acid-inducible gene I−like receptors).

Cytosolic retinoic acid-inducible gene I−like receptors identify intracellular viral RNA PAMPs and trigger an innate immune response including the release of type I interferons (IFNs).[170]

Cytosolic—Nucleotide-binding oligomerization domain-like receptors

Cytosolic nucleotide-binding oligomerization domain−like receptors serve as continuous patrols to recognize and respond to PAMPs or DAMPs.[171,172]

Innate Cellular Immunity: Effector Cells: An Overview

Innate effector cells initiate and regulate the inflammatory response, help contain and eliminate potential threats, and assist in the repair of tissue damage. Many are professional antigen-presenting cells (APCs) such as monocytes/macrophages and DCs. Neutrophils/granulocytes have also been described to acquire and play a role in antigen presentation to CD4+ memory T cells.[173,174]

Antigens are presented to T cells *via* cell a surface tetramer known as the major histocompatibility complex (MHC). MHC class I molecules (HLA-A, B, and C) are expressed on the surface of all nucleated cells and process endogenous or intracellular peptide antigens such as viral antigens. Expression of MHC class II molecules (HLA-DP, DQ, and DR) are unique to APCs only and process exogenous or extracellular peptide antigens. After an APC engulfs and degrades a pathogen, MHC class II binds with a pathogen-derived peptide and moves to the cell surface where it presents its antigen to T cells.

Innate Effector Cells Include Phagocytes, Granulocytes and Natural Killer Cells

Innate Cellular Immunity: Effector Cells: Phagocytes

Phagocytes function as continuous sensors and monitors for pathogens in the circulation as well as in tissues. Phagocytes include neutrophils (granulocytes [WBC]/PMNs), and cells of the mononuclear phagocyte system, including circulating monocytes and their derivative tissue-resident macrophages, as well as tissue-resident DCs. Their defining feature is phagocytosis. Phagocytosis may be a direct process of engulfing the pathogen, or an indirect process where the pathogen is premodified by antibodies or complement (opsonization) for more effective phagocyte identification and recognition, before phagocytosis.

Neutrophils are products of myeloid progenitor cells and are the most abundant granulocytes. Neutrophils are among the first cells to migrate to the site of infection in response to chemotactic stimuli produced by cells in distress or by tissue-resident immune cells. Responding neutrophils switch on nicotinamide adenine dinucleotide phosphate oxidase (NOX2) and produce superoxide, the precursor for reactive oxygen species (ROS) through the enzymatic activity of intracellular myeloperoxidase. Neutrophils may directly engulf,

phagocytose, and kill pathogens through PRR–PAMP interaction or may indirectly recognize a complement-opsonized or antibody-opsonized pathogen and internalize it into a phagosome and kill it. The phagosome then merges with the PMN granules, resulting in degranulation, with the release of preformed antimicrobial factors as well as toxic ROS, in addition to the formation of neutrophil extracellular traps (NETs) and ectosomes.[175,176] NETs consist of antimicrobial proteins and enzymes embedded in a matrix of chromatin fibers and histones released by neutrophils. NETs trap and destroy pathogens,[177,178] but in certain disease states, NETs promote chronic inflammation and atherosclerosis, and sometimes they play the role of an autoamplifying loop of cell death, a process known as necroinflammation.

CKD results in a spontaneous chronic activation[178] of the neutrophil and impairs its primary functions.[179] These dysregulated functions include its ability to respond to a stimulus due to impaired chemotaxis and adhesion, the magnitude and efficacy of its response with impaired production and release of ROS and cytokines and lytic enzymes, as well as its ability to ingest and kill a pathogen and to undergo apoptosis afterward, as well as its ability to recruit other immune cells to the site of an infection. For example, in ESRD patients, *in vitro* studies show altered neutrophil function, with diminished chemotactic response, as well as oxidative metabolic response to chemotactic stimuli, and downregulation of C5a receptors.[180] Similarly, in CKD patients, there is also downregulation of the expression of superoxide dismutase 2,[181] an enzyme crucial for the oxidative burst, as well as blunted or downregulated cytokine gene expression. Expression and activity of TLR-4 in neutrophils is increased in HD patients.[182] FGF-23 (increased in CKD to maintain phosphate homeostasis) impedes neutrophil activation, chemotaxis, and function.[183]

CKD is associated with enhanced neutrophil priming and activation, decreased responsiveness to stimuli, increased myeloperoxidase activity and increased oxidative stress, and an overall increase in PMN apoptosis.[184] These effects were related to the severity of CKD and most prominent in ESRD patients treated with dialysis. Uremic toxins enhance neutrophil activation, with a resultant increase in NET and ROS formation, and impair PMN programmed cell death and clearance at the conclusion of an immune response, promoting a state of chronic sterile inflammation,[178,184,185] which in turn increases the risk of atherosclerosis and CVD.

Circulating or peripheral monocytes are a heterogeneous cell population of the myeloid lineage. They migrate to different organs and differentiate into specialized tissue-resident macrophages. For example, in the kidneys there are kidney macrophages, in the liver Kupffer cells, in the brain microglia, and in the lungs alveolar macrophages. Macrophages serve patrolling functions, recognizing pathogens directly through PRR (e.g. TLR) or indirectly through opsonization. Macrophages phagocytize and destroy potential threats including microbes, recruit other immune cells to the site of infection, and release inflammatory cytokines and ROS. Macrophages also function as APCs to adaptive immune effector cells.

In vitro studies in ESRD patients show altered monocyte function, with diminished oxidative metabolic response to chemotactic stimuli, and downregulation of C5a receptors.[180] Other studies show impaired phagocytosis,[186] increased cytokine[187] and ROS production, and increased TLR-2 expression and TLR-4 expression and activity[182] in dialysis patients.

Some subsets of circulating or peripheral monocytes in CKD patients manifest a phenotype of persistent proinflammatory activation,[188–191] and these subsets increase in number as CKD stage progresses. One subset, $CD40^{+}$ monocytes, increases with severity of CKD, an increase mediated by hyperhomocysteinemia.[190,192] $CD40^{+}$ monocytes are associated with a proinflammatory state and CVD. These altered monocyte subsets, other examples of which include $CD14^{++}$ $CD16^{+}$ intermediate monocytes, promote the CKD chronic inflammatory state in various ways (e.g. secrete proinflammatory cytokines) and cause damage to host (self) tissues such as vascular endothelial cells, increasing risk of developing CVD and atherosclerosis.[190,193–195] Chronic inflammation has been associated with increased foam cell formation, atherosclerosis, and enhanced macrophage infiltration of radial artery samples collected from patients with ESRD undergoing surgery for arteriovenous access.[196] Tissues show increased expression of tumor necrosis factor alpha (TNFα) and monocyte chemotactic protein-1 (MCP-1). Elevated MCP1 plasma levels correlate with the severity of coronary in CKD patients.[197]

In vitro studies show patients with NDD-CKD have decreased monocyte TL4 expression and a blunted response of $CD14^{+}$ monocytes to LPS, with diminished production of cytokines TNFα, interleukin (IL) 1β, IL6 and IL8, compared to controls.[198,199]

A higher absolute blood monocyte count has been associated with a higher risk of incident CKD, as well as progression of CKD,[200] and a higher risk of the combined endpoint of ESRD and death.[201]

DCs are another heterogeneous subset of phagocytes derived from bone marrow myeloid leukocyte precursors. They move as immature cells to nonlymphoid tissues, such as the kidney (cortex, medulla, or

tubulointerstitium), where they continuously monitor for pathogens. When a DC-PRR identifies a PAMP, the DC begins migration to secondary lymphoid tissue (lymph nodes, spleen, mucosal lymphoid tissues), during which it matures *via* TLR-mediated expression of key surface markers, and plays a salient role as the most powerful APC to naïve T cells, resulting in T-lymphocyte activation as well as regulation.

In vitro studies show that normal DCs fail to differentiate and exhibit decreased ability to endocytose in a uremic milieu, while enhancing T-cell proliferation.[186]

In the CKD population, DC play a proinflammatory role in stimulation of T cells[202] *via* supply of costimulatory signaling molecules (e.g. CD80, CD86, B7) and release of proinflammatory cytokines, promoting fibrosis and progression of CKD. Furthermore, DCs may be implicated in the etiology of hypertension.[203] DCs also play role in the progression of several primary kidney diseases, such as T-cell mediated glomerular injury, antiphospholipid disease, and lupus nephritis.[202,204–206]

Differentiation lines are often blurred between tissue-resident macrophages and tissue-resident DCs. There is no consensus at this time, regarding which establishes unique identity or roles, between these two components of the mononuclear phagocyte system.[207]

Innate Cellular Immunity: Effector Cells: Natural Killer Cells

NK cells also have heterogeneous subsets of cells: regulatory NK cells, tolerant NK cells, and cytotoxic NK cells.[208] The latter subset of cells are cytotoxic group 1 ILCs, which have the ability to recognize infected cells or tumor cells, through loss of cell surface MHC class I. NK cells lyse target cells *via* cytotoxic granules (perforin, granzymes) on first encounter without any prerequisite activation. Cytotoxic NK cells may also perform their role *via* antibody-dependent cellular cytotoxicity. They also secrete cytokines (such as IFNγ, TNFα), which activate other effector cells, resulting in phagocytosis and destruction of the pathogen.

In CKD patients, activated NK cells are thought to play a role in progression of CKD and renal fibrosis.[209] In ESRD patients, the activity of NK cells is downregulated,[210] possibly as a result of the chronic inflammatory state and increased levels of proinflammatory mediators.

Innate Cellular Immunity: Effector Cells: Granulocytes (Other than Neutrophils)

Circulating basophils (granulocyte WBCs)[211] and tissue-resident mast cells[212] play a major role in eliciting immediate and late-phase hypersensitivity/allergic reactions, as well as in the defense against parasitic infections. Basophil activation may be IgE-dependent. In this case, IgE-dependent cross-linking results in cell degranulation, with release of preformed mediators (mainly histamine and leukotriene C4 [LT-C4]), and *de novo* synthesis and secretion of cytokines (IL-4 and IL-13). Basophil activation may also be IgE-independent in response to PAMPs recognition by TLR-2/TLR-4 ligands, interaction with complement component 5a receptor (C5aR) or helper T cells (TH2) cytokines. The end result is cytokine synthesis and release.

Similar to tissue-resident macrophages, mast cells function as quite effective sentinels for immediate detection of pathogen exposure. In addition to their role as effector cells, basophils and mast cells also play an immunomodulatory role.[212,213] In patients with ESRD, basophil function is impaired with impaired adhesion and degranulation.[214] CKD patients have an increased kidney mast cell population. Mast cells have been associated with chronic local inflammation, progression of CKD, and renal fibrosis.[215]

The activation of eosinophils (granulocyte WBCs),[216] with or without degranulation is essential in the defense against parasitic infections, leading to the release of preformed cytotoxic proteins, lyzoymes, cytokines, chemokines, and leukotrienes. Eosinophils also play a key role in immunoregulation. Patients with CKD tend to have a higher blood eosinophil count,[201] and a spike in blood eosinophil count is an independent predictor of increased risk of ESRD and death.

Innate Humoral Immunity

Humoral innate defenses include additional physiological barriers such as proteins with immune function, such as antimicrobial peptides and acute phase proteins and cytokines, as well as complement proteins from any of the three complement activation pathways: the classical pathway, the alternative pathway, and the mannose-binding lectin (MBL) pathway.

The complement system plays a major role in opsonization of pathogens. It incorporates a large number of circulating proteins, which on recognition of a pathogen component, trigger one of the three series of activation reactions. Antibody–antigen complexes bind C1 to activate the classical pathway, pathogen cell surface proteins bind C3b to activate the alternative pathway, and mannose residues on pathogen surfaces bind MBL, activating the MBL pathway. All three activated complement pathways converge to form C3-convertase, which activates C3 and the lytic pathway with the production of C5b-9 or the membrane attack complex (MAC), while producing byproducts. These byproducts include C3b, which serves the role of opsonin, C3a, which activates

mast cells, and C5a that also activates mast cells and in addition chemotactically recruits neutrophils and macrophages. The MAC binds the pathogen's cell surface, resulting in lytic cell death.

In CKD patients, the cytokine response to pathogen exposure is impaired, whereas basal proinflammatory cytokine levels are elevated.[160,166,217,218] The basal elevation may be due to primed effector cells as well as decreased renal clearance. The latter seems to affect the balance in favor of proinflammatory cytokines. For example, TNFα levels are elevated in uremic patients and promote oxidative stress and chronic inflammation.[219]

In patients with proteinuria, loss of proteins with immune functions may also increase risk of infection. A multiplex proteomics assay identified 28 proteins whose levels were associated with the annual change in eGFR. Eleven of these predicted the incidence of CKD. Proteins linked to inflammation included TNF-related apoptosis-inducing ligand receptor 2, TNF receptor 1, TNF receptor 2, CD40L receptor, FGF-23, macrophage colony-stimulating factor 1, and MCP-1.[220] ESRD patients have a significant increase in MBL levels. During an infection a low level predicts higher mortality rate.[160,221] Endotoxin tolerance has also been hypothesized.

Adaptive Cellular Immunity: an Overview

Adaptive immunity is antigen-specific and is elicited by T cells and B cells. Adaptive immunity is mounted over days by acquired cellular and humoral responses, with the development of lasting immunologic memory.

Adaptive Cellular Immunity: T Cells

The champion effectors of adaptive cellular immunity are the T lymphocytes, which mature in the thymus into naive T cells and eventually become either CD4+ helper T cells (subtypes include Th1, Th2, and Th17), CD8+ cytotoxic T cells, or natural regulatory T cells (Tregs: CD4+ CD25+) in secondary lymphoid tissues (lymph nodes, spleen, mucosa-associated lymphoid tissue [MALT]).

T cell activation and proliferation follows a three-signal model. The first signal to trigger T cell activation is specific, occurring when a T cell receptor (TCR) binds to a non-self antigen scavenged by an APC. For the antigen to be recognized by the T cell, it has to be loaded to the MHC class II receptor on the surface of APCs. The TCR-MHCII complex is further stabilized by the T cell CD4 or CD8 coreceptor. A second general (nonspecific) signal, mediated by the interaction of APC costimulatory receptors with T-cell ligands, is required to trigger full T-cell activation and proliferation. Exposure to a pathogen activates helper T cell CD28, which binds to APC surface molecule CD80 (B7.1) or CD86 (B7.2), triggering T cell proliferation as well as the production of CD152 (CTLA-4), which competes with CD28 for the binding of CD80/CD86, regulating the degree of T cell activation and proliferation. A third signal, in the form of cytokines, helps T cells differentiate and mature into what is needed in the tissue to conquer and degrade the pathogen.

When CD4+ helper T cells are activated *via* the MHC class II three-signal model, they induce and regulate the adaptive immune response. Th1 cells synthesize and release IL2 and IFNγ; recruit macrophages, neutrophils, and cytotoxic T cells; and play a major role in neutralizing intracellular pathogens (such as viruses and bacteria). Th2 cells synthesize and release IL4, IL5, IL6, IL10, and IL13; recruit eosinophils and mast cells; stimulate B-cell antibody production; and play a major role in neutralizing extracellular pathogens (such as helminths and bacteria). Th17 cells synthesize and release IL17, in response to APC secretion of IL23, and play a role in instigating an inflammatory response and recruiting Th2 and NK cells.

CD8+ cytotoxic T cells are serial killers. They may also be activated following recognition and binding of the TCR to antigenic peptides presented by MHC class I molecules and play a major role in destruction of cells infected with intracellular pathogens or invaded by tumor cells. Their cytotoxicty pathways may be cytokine mediated (IFNγ, TNFα), or involve targeted cytotoxic granules (such as perforin and granzymes), or *via* the binding of CD8+ T cell Fas ligand to fas receptor on the surface of the target cell, thus activating the caspase cascade, resulting in cell death. Because CD8+ T cells can express both Fas and Fas ligand, this last mechanism is used to shape and downregulate the immune response *via* CD8+ T cell fratricide.

Helper T-cell activation and proliferation in response to a pathogen is decreased in CKD.[222–225] This is characterized by a dysfunctional second signal (the APC-costimulation signal), which is believed to be due to decreased expression of costimulatory surface molecules on the APC surface. The chronic priming or activation of APCs and the hypercytokinemia also blunt T-cell activation. Finally, cytokines seem to shift helper T-cell differentiation in favor of Th1 rather than Th2, with a subsequent decline in B-cell activation and antibody production.

Furthermore, CKD patients have an abnormal ratio of CD4+/CD8+ cells in favor of an excess of cytotoxic T cells and manifest overexpression of CD8+ T cell Fas ligand. Their T-cell lines, including naïve and memory

T cells, have accelerated apoptosis.[223,226,227] The Treg population is also decreased in CKD[228–230] and manifests increased susceptibility to apoptosis, a process mediated by oxidized low-density lipoprotein.

Adaptive Humoral Immunity: B Cells

The proponent effectors of adaptive humoral immunity are the B lymphocytes, which mature in the bone marrow (the other primary lymphoid tissue) and produce immunoglobulins (Ig). B cell activation occurs on the binding of a B cell receptor to a circulating free or membrane-bound antigen, triggering a chain of bidirectional activation signals between B cells and Th2 Cells. B cells then can differentiate into short-lived plasma cells that secrete antibodies, providing a rapid response. Alternatively B cells can establish a germline center in secondary lymphoid tissue for B cell maturation and proliferation, resulting in memory B cells and long-lived plasma cells. These cells capable of Ig class switch recombination and can produce high-affinity antigen-specific antibodies.

CKD is associated with a reduction in B-cell activation, proliferation, immunoregulation, and antibody production.[231,232] In ESRD patients, all subpopulations of B cells were reduced resulting in B-cell lymphopenia.[187] This may be mediated by a diminished Th1 cell population and increased apoptosis.[233–235]

The Aftermath of an Immune Response to a Pathogen Exposure

After immune activation and containment of a pathogen, not only is it paramount for the immune response to be proportionate and measured, but it is also important for it to dissipate and be part of the healing and repair process to restore a healthy and steady-state immune homeostasis. An intact immune system is essential to "clean up" after infection, to avoid a residual chronic inflammatory state. Apoptosis (programmed cell death) is a physiologic process, which occurs in the maintenance of tissue homeostasis. Apoptotic cells express unique characteristics, which assist phagocytes to target and kill them with little if any immune reaction. Apoptosis of immune effector cells has to occur at the right moment in the timeline of an immune reaction to pathogen exposure. If the timeline occurs early, due to enhanced immune effector cell apoptosis, this will result in an attenuated immune response and inability to control infection. If timeline occurs late, due to delayed apoptosis or impaired clearance of apoptotic PMNs by macrophages, then a persistent inflammatory state may ensue. The most proapoptotic stimuli studied, which might be affected in CKD, are TNF-α and Fas ligand. Immunoglobulin light chains have been found to have antiapoptotic effects.

Chronic Inflammation and Immune Dysfunction in CKD

Chronic inflammation is a risk factor for cardiovascular mortality in patients with CKD. The relationship between CKD and chronic inflammation is complex, multifaceted, and not completely understood. Both eGFR reduction and glomerular podocyte injury manifested as microalbuminuria or macroalbuminuria promote a proinflammatory state and tubulointerstitial disease.[236,237]

The pathophysiology of the chronic inflammation is multifactorial. CKD is associated with chronic stimulation of the renin–angiotensin–aldosterone system (RAAS). Both angiotensin II and aldosterone promote oxidative stress and chronic inflammation. Acidosis and use of less biocompatible membranes or venous catheters for access in HD patients have also been shown to promote inflammation.[238]

In addition, there is growing evidence that CKD patients have altered gut microbiota (intestinal dysbiosis), and intestinal inflammation with significant disruptions in the functional integrity of the intestinal epithelial barrier,[239–241] resulting in a "leaky gut" and translocation of bacterial deoxyribonucleic acid (DNA) and endotoxins into the systemic circulation. The endotoxemia plays an important role in generating or maintaining the inflammatory state in CKD. Blood endotoxin levels correlate with severity of CKD, predict the severity of inflammation, and correlate with atherosclerosis risk.

Dietary restrictions imposed on patients with advanced CKD (especially low potassium and low phosphorus diets) dictate a low plant fiber intake. This diet results in a secondary change in the gut microbiome. Epidemiologic studies suggest that a high-fiber diet promotes the growth of endosymbiotic bacteria, preventing gram-negative bacterial overgrowth and the production of endotoxins and gut-derived uremic toxins, and thereby minimizing these triggers of systemic inflammation. Similarly, some observational studies suggest a beneficial role of prebiotics (ingested nondigestible compounds, which enhance bacterial growth and activity, e.g. chicory), and probiotics (ingested live organisms, such as yogurts). Finally, many CKD patients have comorbidities, such as diabetes mellitus, which are a significant source of inflammation and infection.

Diagnosis: Infectious Complications of CKD

CKD patients may have a blunted immune response to infection. The classical signs and symptoms of infection, such as fever or leukocytosis, therefore may not always be present. Patients with ESRD may present with nonspecific symptoms. Diagnosis is usually based on a focused history and physical examination. Additional

diagnostic tools, such as cultures and or imaging studies, may be ordered when indicated.

Prognosis: Infectious Complications of CKD

CKD patients have an increase in the rate and in the severity of infections, with a secondary increase in all-cause mortality as well as cardiovascular mortality. Infection is the second most common cause of death, after CVD, in the ESRD population.

The basal chronic inflammatory state not only potentiates but is sometimes also enhanced by other complications of CKD, such as atherogenesis and CVD,[242,243] ACKD,[32] mineral and bone disorder (MBD),[183,244–247] protein energy wasting (PEW) and protein-calorie malnutrition, and secondary muscle wasting and cachexia.[248–250] Thus, a thorough strategy to mitigate inflammation and potential sources of infection is essential.

Treatment: Infectious Complications of CKD

Infections should be treated with targeted empirical antimicrobial therapy, and in a timely fashion in CKD patients, due to their acquired immunodeficiency and concerns regarding potentially increased severity. Dosing of antimicrobial therapy must be adjusted to the eGFR as needed. At the conclusion of the diagnostic evaluation, the antimicrobial regimen may be modified based on pathogen identification and susceptibility.

Prevention may play a key role in decreasing infection and inflammation in CKD patients. Avoidance or expedited removal of venous catheters as accesses for dialysis is imperative. Treatment and correction of metabolic acidosis and MBD, regular foot examinations in diabetic patients, evidence-based use of renin–angiotensin–aldosterone blockers in patients with proteinuria (where therapy may minimize loss of proteins with immune functions), physical activity, and dietary interventions, which may help restore the gut microbiota and treat PEW may all prove helpful.

Suboptimal response to immunizations, due to acquired impairment in T-cell dependent immunity, has been well described in CKD patients.[232,251] The rate of nonresponders is relatively high especially with advanced CKD and ESRD. The response of tuberculosis skin testing is impaired in ESRD patients, reducing its utility to diagnose latent tuberculosis.

Both the CDC and the 2012 KDIGO clinical practice guideline recommend that all patients with CKD, regardless of stage, receive the annual age-appropriate inactivated influenza vaccine.[252] Pneumococcal vaccination, ideally pneumococcal conjugate vaccine (PCV13) followed by pneumococcal polysaccharide vaccine (PPSV23), and a booster offered every five years, is advised for patients aged 65 years or older, or with stage 4–5 CKD (eGFR $<30\,mL/min/1.73\,m^2$) and ESRD. Tetanus, diphtheria, and pertussis vaccination should be offered every ten years after initial dose. Zoster recombinant zoster vaccine is recommended in a series of two doses, two to six months apart, for CKD patients aged 50 years or older. Finally, hepatitis B vaccination series at 0, 1, and 6 months is advised for all patients with ESRD who are susceptible (especially the HD population, and preferably in stage 4–5 CKD) as this approach has been associated with a higher rate of responsiveness to the vaccine.

Conclusions: Infectious Complications of CKD

CKD is associated with a state of immune deficiency on exposure to pathogens, increasing the risk and severity of infections in this population, with secondary risk of morbidity and mortality (Figure 31.3). This state of immune incompetence is mediated by dysfunctional innate immunity in response to pathogens, with diminished PRR expression and blunted phagocyte function, affecting adhesion, chemotaxis, cytokine and ROS production, signaling, endocytosis, proteolytic activity, and antigen-presentation capacity. Adaptive immunity is also affected, with a decrease in T cell activation and proliferation, with disruption of the ratio of Th1/Th2 cells in favor of Th1 cells, and in the ratio of CD4+/CD8+ T cells in favor of CD8+ T cells, as well as increased susceptibility to early and accelerated apoptosis. Similarly B-cell activation and proliferation is decreased, as is immunoglobulin production, while apoptosis is increased.

On the other hand, CKD is associated with a state of basal immune activation, oxidative stress and chronic sterile inflammation, also associated with an increase in morbidity and mortality (Figure 31.3). This state of basal immune activation may be in response to a multitude of factors (such as altered gut microbiota and low level endotoxemia, acidosis, RAAS activation, dialysis membrane characteristics, and dialysis water quality). Immune activation is mainly mediated by primed or preactivated neutrophils and monocytes, increased levels of proinflammatory cytokines, and an aberrant complement system activity. Chronic inflammation and oxidative stress are interlinked with other undesirable outcomes such as enhanced atherosclerosis, PEW, MBD, obesity, and insulin resistance.

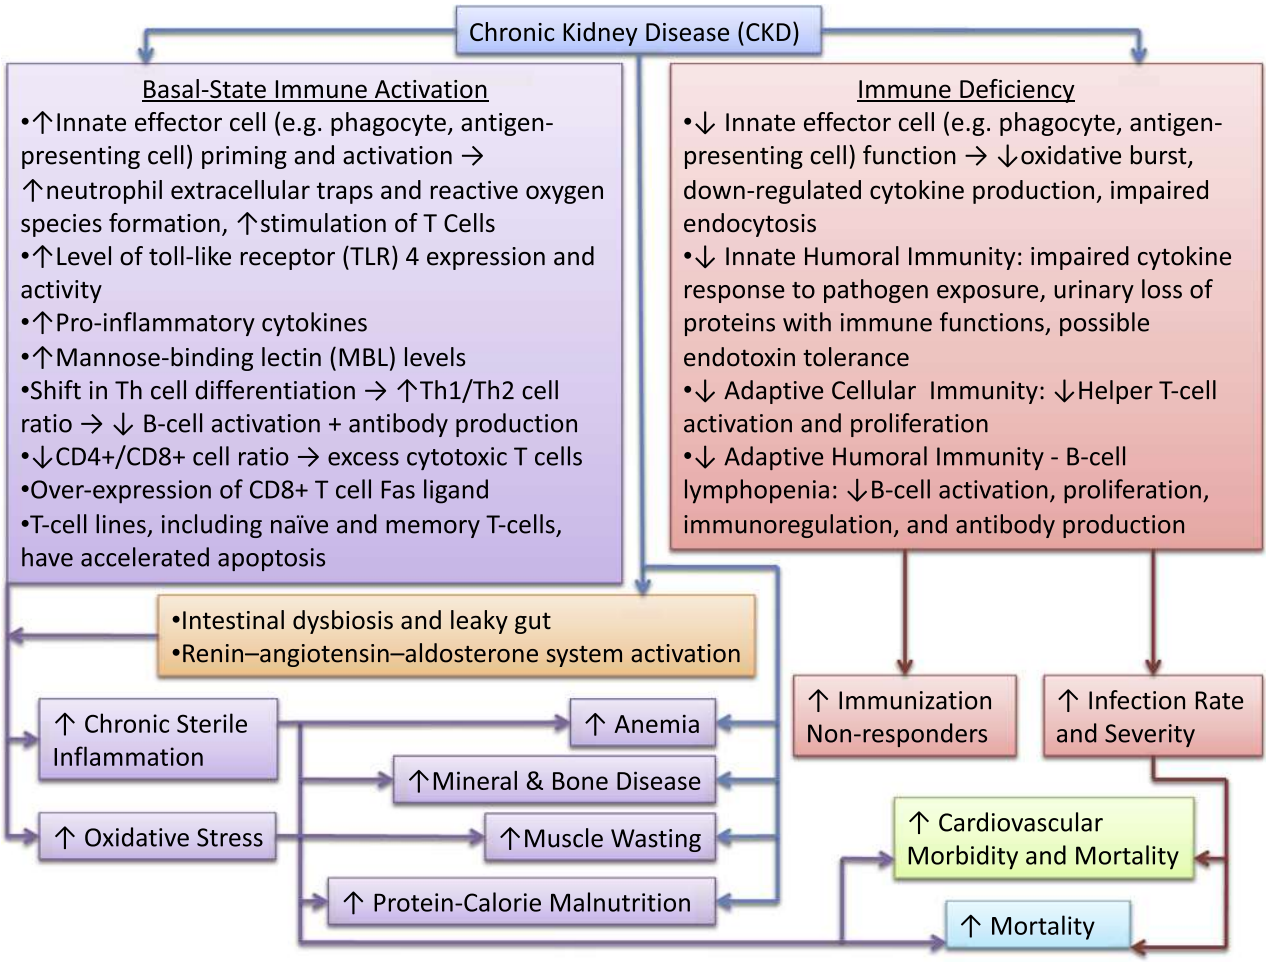

FIGURE 31.3 Immune dysfunction in chronic kidney disease, and how it may lead to increased risk for infection and cardiovascular disease.

QUESTIONS AND ANSWERS

Question 1

The anemia seen in patients with CKD is, in part, related to all of the following except:

A. Chronic inflammation
B. Relative erythropoietin deficiency
C. FID
D. Abnormal mineral and bone metabolism
E. Hepcidin deficiency

Answer: E

Hepcidin levels are increased in CKD and play a role in iron restricted erythropoiesis, FID, and resistance to erythropoietin therapy.

Question 2

The diagnostic workup for anemia in patients with CKD should include all of the following except:

A. Age appropriate screening for gastrointestinal blood loss
B. Evaluation of red blood cell morphology
C. Transferrin saturation and ferritin
D. Hepcidin level
E. Erythropoietin level

Answer: D and E

Neither measurement of hepcidin or erythropoietin levels are recommended as part of the evaluation. These tests may be less available and have substantial technical limitations and rarely add to the evaluation.

Question 3

The treatment of anemia in patients with dialysis-dependent or non−dialysis-dependent CKD with ESAs may be associated with all of the following except:

A. Diminished need for red blood cell transfusion
B. Increased BP
C. Increased risk of cardiovascular thrombotic events
D. Improved cardiovascular outcomes in patients with heart failure
E. Enhanced quality of life

Answer: D

There are no studies demonstrating improved cardiovascular outcomes with correction of anemia in patients with dialysis-dependent or nondialysis-dependent CKD.

Question 4

All of the following factors are mechanistically related to the thrombocytopathy seen in patients with CKD except:

A. Anemia
B. Dysfunctional platelet adhesion, activation, and aggregation
C. Increased content in the platelet dense granules of ADP and serotonin
D. Impaired intracellular signaling in the platelet
E. Increased vascular endothelial production of nitric oxide

Answer: C

There is a paucity in the content (ADP and serotonin) of platelet dense granules and their release in the patient with CKD.

Question 5

Which of the following statements are false about monitoring bleeding risk in patients with reduced kidney function:

A. Platelet count is usually normal
B. PT and aPTT are usually normal or increased
C. BT is reasonably accurate and commonly available
D. The RIPA is diminished
E. Serum blood urea nitrogen and creatinine levels may be used as an assessment tool to predict bleeding risk

Answer: C and E

Serum blood urea nitrogen and creatinine do not accurately predict bleeding risk. The BT is nonsensitive and nonspecific and fraught with technical and interpretation limitations.

Question 6

Which of the following statements are false about the effects of CKD on immune function:

A. CKD is associated with decreased baseline neutrophil and activation
B. FGF-23 has been shown to impede neutrophil activation, chemotaxis, and function
C. CKD is associated with an overall increase in neutrophil apoptosis

D. CKD is associated with decreased monocyte TL4 expression and a blunted response to LPS exposure, as well as a diminished production of TNFα, IL-1β, and IL-6

E. Cytokine responses to pathogen exposure is impaired

Answer: A

CKD is associated with spontaneous chronic activation of neutrophils, which impairs its primary functions of chemotaxis, adhesion, and production and release of ROS and cytokines as well as its ability to ingest and kill a pathogen.

CHAPTER

Immune Function in Chronic Kidney Disease

Madeleine V. Pahl, Nosratola D. Vaziri

Division of Nephrology and Hypertension, UCI Medical Center, Orange, CA, United States

Abstract

Chronic Kidney Disease (CKD) is simultaneously associated with immune activation, marked by systemic inflammation, and immune deficiency. Systemic inflammation contributes to the development of atherosclerosis, cardiovascular disease, cachexia, and anemia, while immune deficiency leads to impaired response to vaccination, and increased incidence and severity of microbial infections. CKD-associated inflammation and immune deficiency are associated with (a) general expansion of monocytes and elevations of their basal integrin, Toll-like receptor expression, cytokine production, and reactive oxygen species (ROS) generation and reduced phagocytic capacity, (b) depletion and impaired inhibitory activity of regulatory T cells, (c) spontaneous activation, degranulation, increased basal ROS production, decreased phagocytic capacity, and increased apoptosis of circulating polymorphonuclear leukocytes, (d) upregulation of ROS production machinery and chemokine expression in the cellular constituents of various tissues, highlighting participation of nonimmune cells in the prevailing inflammatory state, (e) depletion of the antigen-presenting dendritic cells, (f) reduced CD4/CD8 T cell ratio and depletion of naïve and central memory T cells, and (g) diffuse B cell lymphopenia leading to impaired humoral immunity. Thus, CKD-associated inflammation is due to activation of the innate immune system, orchestrated by monocytes, macrophages, granulocytes, and cellular constituents of other organs/tissues. This is coupled with immune deficiency caused by depletion of dendritic cells, naïve and central memory T cells and B cells, and impaired phagocytic function of polymorphonuclear leukocytes and monocytes.

EPIDEMIOLOGY AND BACKGROUND

Chronic kidney disease (CKD) is simultaneously associated with immune activation that is characterized by systemic inflammation and immune deficiency.[1,2] The systemic inflammation contributes to many comorbidities, including atherosclerosis, cardiovascular disease, cachexia, malnutrition, and anemia,[1] whereas the immune deficiency leads to impaired response to vaccination and increased incidence, severity, and poor outcome of microbial infections (Figure 32.1).[1–3] High failure rates for vaccinations against hepatitis B virus, influenza, *Clostridium tetani*, and *Corynebacterium diphtheriae* are well known.[4] Reports from the Hemodialysis (HEMO) study note annual infection rates as high as 35%.[5] Mortality rates are increased 10-fold for pneumonia and 100-fold for sepsis in hemodialysis (HD) patients, compared with the general population.[6]

Before describing CKD-associated immunological disorders, a brief overview of the structure and function of the immune system is provided.

STRUCTURE AND FUNCTION OF THE IMMUNE SYSTEM

The immune system comprises a complex set of interactions between soluble factors and cells designed to protect against various diseases, by detecting and destroying invading microbes and cancer cells, and identifying, removing, and helping to repair damaged tissues. Inflammation is the critical step in the immune response to infection and tissue damage.[7]

The body's immune defense is accomplished by the innate and adaptive immune systems. The innate immune system comprises cells and processes that culminate in a prompt and nonspecific response to infection and tissue injury. Activation of the innate immune system is orchestrated by neutrophils, monocytes, macrophages, platelets, natural killer cells (NK cells), innate lymphoid cells, and other cellular constituents such as epithelial and mast cells. These cells use pattern recognition receptors (PRRs), which recognize pathogen-associated molecular patterns (PAMPs) on microorganisms, and communicate through various cytokines. The PRRs exist as either secreted circulating proteins or membrane-bound receptors. The secreted proteins, which include defensin, cathelicidin (induced by vitamin D), collectins, lectins, and pentraxins

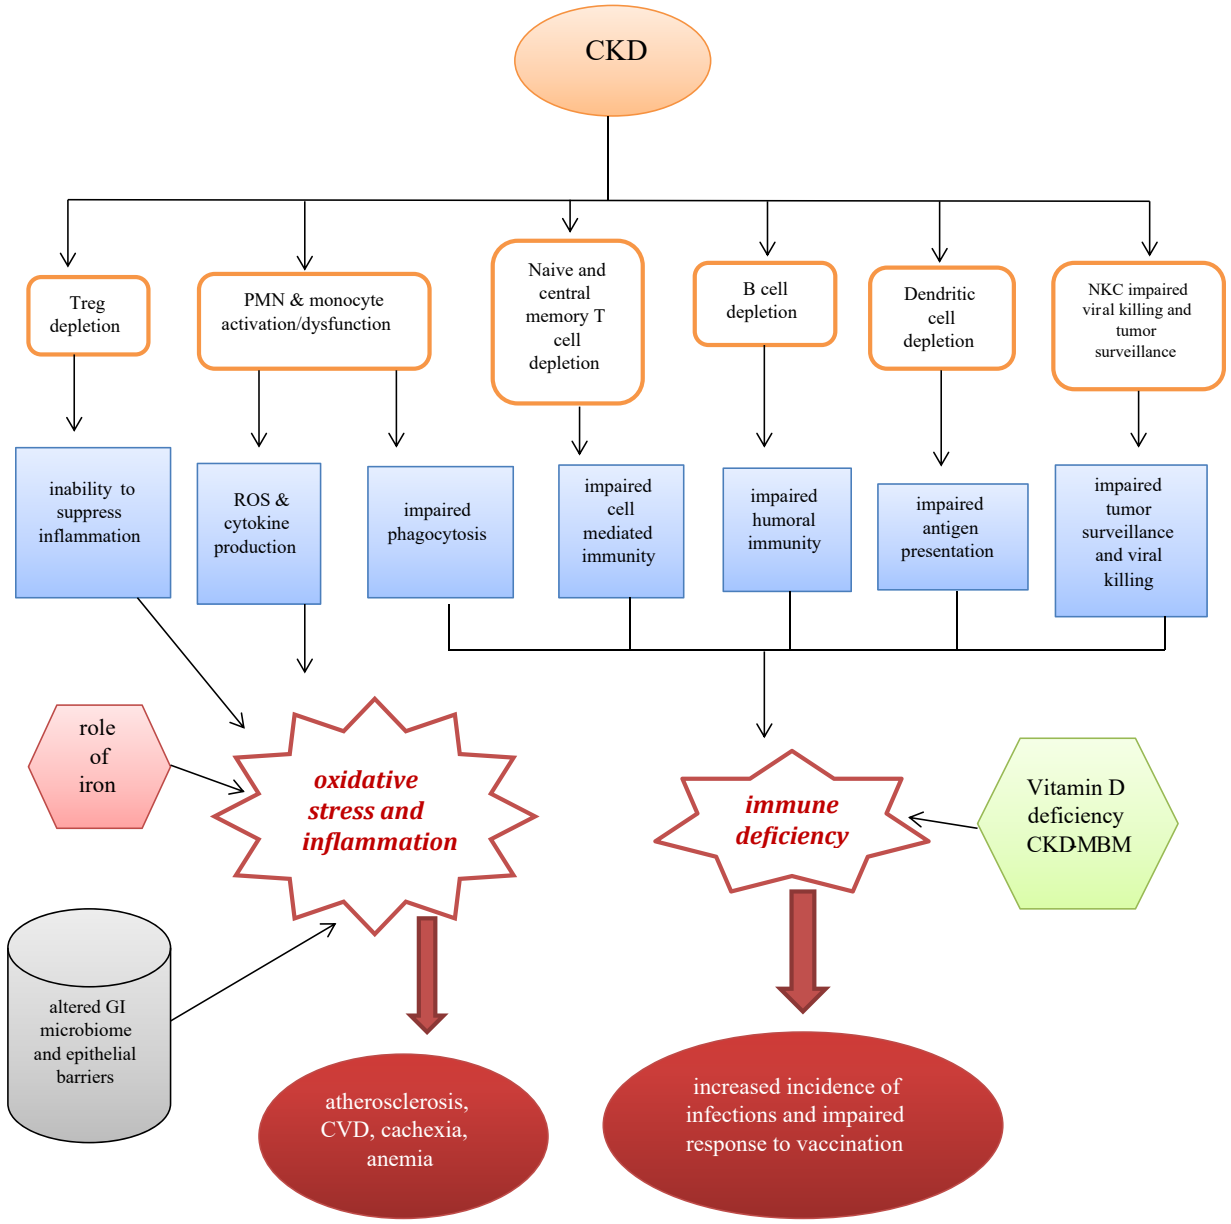

FIGURE 32.1 Summary of the impact of chronic kidney disease (CKD) on innate and adaptive immunity and their adverse consequences.

(including CRP) mediate direct microbial killing, act as helper proteins for transmembrane receptors, or opsonins. Membrane-bound PRRs are expressed constitutively on many innate immune cells and the antigen-presenting cells (APCs). They include the membrane-bound and intracellular Toll-like receptors (TLRs) and their associated detection-enhancing proteins (LPS-binding protein, CD14, and MD2), nucleotide-binding oligomerization domain–like receptors, RIG-1-like receptors, and C-type lectin receptors on macrophages and dendritic cells. Activation of the innate immune system begins with the resident cells at the site of infection or injury (macrophages, epithelial cells, mast cells) followed by recruitment of circulating neutrophils, NK cells, dendritic cells, monocytes, and platelets if needed.

The adaptive immune response enables the host to recognize, remember, and mount stronger attacks on reencounter with the same pathogen. Adaptive immune cells include T and B lymphocytes that express cell-specific receptors (T cell receptors [TCR] and B cell receptors [BCR]) with which they recognize their cognate antigens.

T cells recognize their cognate antigen in a processed form as a peptide in the context of a major histocompatibility complex (MHC) molecule. APCs take up,

degrade, and load antigens onto the MHC for presentation to T cells. Dendritc cells (DCs) are the predominant APC, but monocytes/macrophages also act as APC and can differentiate into DCs.[8] After exposure to antigen DCs migrate to lymphoid tissues where they come into contact with the naïve T cells. This interaction results in a complex cascade of membrane glycoprotein contacts, intracellular signaling, and cytokine secretion leading to activation of T cells. Activated T cells that express CD 4 (helper T cells) play a role in activation of cytotoxic effector T cells (CD8+ lymphocytes) and the differentiation of B cells. They are subdivided into distinct categories (i.e. Th1, Th2, Th17, and regulatory [Treg] T cells) based on their cytokine production profile.[9] After activation some naïve T cells become short-lived effector T cells, while others become long-lived memory T-cells to provide a more rapid and effective response to a recurrent insult.[10] Effector T cells migrate into the peripheral tissues to combat the injury or interact with other lymphocytes, such as B cells.

B lymphocytes are the precursors of plasma cells that produce antibodies. B cells are produced in the bone marrow. After an initial differentiation they migrate to the spleen as transitional B cells, where they differentiate into mature long-lived lymphocytes.[11] The diversity of the B lymphocyte pool determines the individual's capacity to mount a protective immune response. Innate B cells produce mainly IgM antibodies that have low-affinity and high cross-reactivity. They constitute a readily available immunoglobulin pool that fights various infections before high-affinity specific antibodies are produced by conventional B cells.[12] Primed B cells express a unique BCR made of an immobilized antibody that recognizes and binds only one particular antigen. Unlike T cells, which require processed antigen presentation, B cells recognize antigens in their native forms. Once encountering their cognate antigen and receiving signals from the helper T cells (predominately Th2 type), B cells differentiate into short-lived antibody-producing plasma cells and long-lived memory B cells. Memory cells lodge in lymph nodes and mucosal tissues, and on subsequent encounter with the antigen, rapidly proliferate and produce high affinity, antigen-specific immunoglobulins.[13] A brief overview of the immune system is depicted in Figure 32.2.

CKD-ASSOCIATED IMMUNE DEFICIENCY

Although bacterial infections have diminished as a cause of death in the general population, they remain a common cause of death in patients with advanced CKD, particularly those maintained on renal replacement therapy.[2,3] This is due to the impaired immune response in uremia[2] that is caused by: (a) decreased granulocyte and monocyte/macrophage phagocytic function[14,15]; (b) defective antigen-presenting capacity of APC[8,9]; (c) depletion of dendritic cells[16]; (d) reduced numbers and antibody-producing capacity of B lymphocytes[17,18]; (e) increased T cell apoptosis causing depletion of naïve and central memory CD 4+ and CD8+ T lymphocytes[19,20]; and (f) impaired cell-mediated immunity.[19] The exact mechanisms underlying these derangements are not fully understood, but signs of activation and/or loss of function have been found.

Patients with advanced CKD develop anemia, due to diminished erythropoietin production, erythropoietin resistance, shortened erythrocyte life span, and impaired intestinal absorption and defective release of iron from storage sites. Indiscriminate use of intravenous iron preparations to treat anemia has resulted in an epidemic of iron overload and elevated levels of non−transferrin bound iron in the dialysis population.[21−23] The poorly liganded iron compounds are taken up by lymphocytes whose capacity to safely store iron in catalytically inactive form is limited. This results in iron-catalyzed oxidative stress and death or dysfunction of lymphocytes, which can contribute to immune deficiency.[24,25] In addition, iron overload impairs microbial killing and phagocytic capacities of macrophages and neutrophilic granulocytes and simultaneously heightens proliferation and virulence of pathogenic microorganisms. Together these abnormalities increase the incidence, severity, and poor outcome of microbial infections in iron-overloaded CKD patients.[26]

CKD-ASSOCIATED INFLAMMATION

CKD is associated with systemic inflammation and oxidative stress, which contribute to progression of CKD, atherosclerosis, cardiovascular disease, cachexia, and anemia, among other comorbidities.[1,27] CKD-associated inflammation is due to the activation of the innate immune system, orchestrated by monocytes, macrophages, granulocytes, and nonimmune cells. It is associated with: (a) general expansion of monocytes and elevations of their basal integrin, Toll-like receptor (TLR)-2, and TLR-4 expression, cytokine production, and reactive oxygen species (ROS) generation[28,29]; (b) depletion and impaired inhibitory activity of Treg cells[30,31]; (c) polymorphonuclear leukocyte (PMN) activation, degranulation, and basal ROS production[28]; (d) upregulation of ROS production machinery and chemokine expression in the cellular constituents of various tissues, highlighting participation of nonimmune cells in the inflammatory state[32]; (e) increased proinflammatory activity of low density lipoprotein

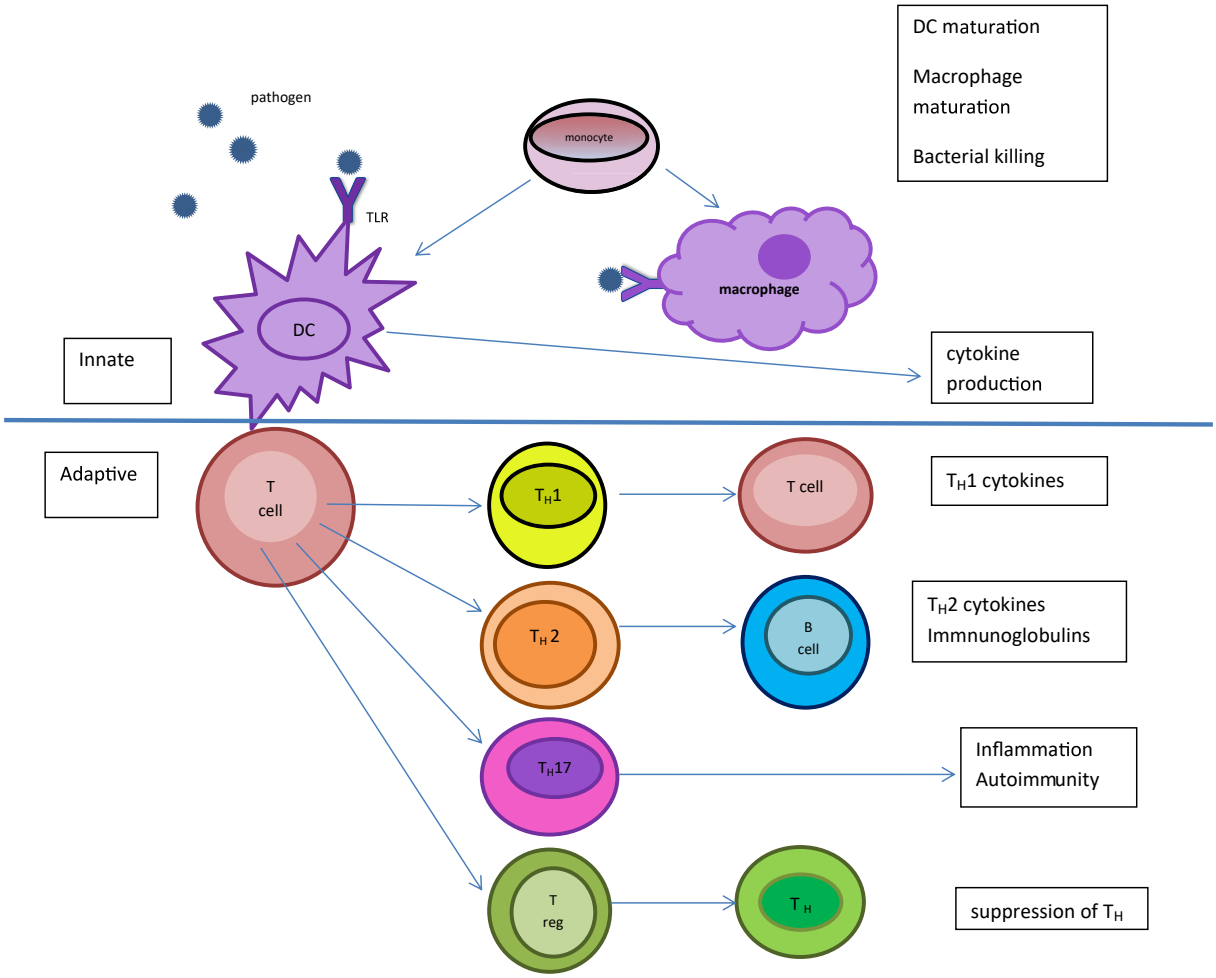

FIGURE 32.2 Overview of innate and adaptive immune system.

(LDL) and reduced antiinflammatory capacity of high density lipoprotein (HDL)[33,34]; (f) paralysis of the endogenous antioxidant, anti-inflammatory, and cytoprotective defense systems due to impaired activation of Nrf2, the master regulator of genes encoding numerous antioxidant and cytoprotective enzymes and related proteins[35–37]; (g) comorbid conditions such as diabetes and autoimmune disorders; (h) impaired intestinal epithelial barrier structure and function, which by enabling influx of endotoxin and other noxious luminal contents into the systemic circulation results in endotoxemia and systemic inflammation[38]; (i) uremic toxins; (j) blood exposure to dialyzer membranes and dialysate impurities; (k) hypervolemia and hypertension; (l) as well as other factors.

The majority of the available data on the effects of CKD on the immune system are derived from studies in patients with end-stage renal disease (ESRD) on renal replacement therapy. There are little available data from individuals with early stage CKD, but where available this information will be highlighted. Further studies are needed to explore the effects of mild to moderate CKD on the structure and function of the immune system in humans.

EFFECTS OF CKD ON COMPONENTS OF INNATE IMMUNITY

Monocyte and Macrophage Abnormalities in CKD

Monocytes are produced by the bone marrow, stored in the spleen, and distributed in all tissues as macrophages. Monocytes/macrophages play a key role in defense against microbial infections, participate in tissue healing, and contribute to the pathogenesis of inflammation and atherosclerosis. They engulf microbes, infected cells, and tissue debris directly or *via* intermediary proteins such as antibodies or complement components. These functions are essential in the

defense against microbial infections and healing of injured tissues. However, uptake of oxidized LDL *via* scavenger receptors by macrophages in the artery wall and glomerular mesangium results in the development and progression of atherosclerosis and glomerulosclerosis. Finally by producing cytokines and ROS, and releasing growth factors, metalloproteinases, and tissue factor, macrophages participate in the healing of damaged tissues, and the development of local and systemic inflammation, oxidative stress, and rupture of atheromatous plaques.[39]

Monocytes are classified based on expressions of CD14 (PRR) and CD16 (Fc gamma III receptor) into CD14++/CD16− (classical), CD14++/CD16+ (intermediate), and CD14+/CD16+ (proinflammatory) subtypes. CD14+CD16+ monocytes have a high capacity to produce inflammatory cytokines (TNF-α, IL-6, and IFN-α) and promote inflammation.[39] ESRD is associated with a general expansion of circulating monocytes, particularly of the proinflammatory CD14+CD16+ subtype.[29] The increase in circulating CD16+ monocytes has been reported in patients with CKD stage 2−5 and appears to be exacerbated by the initiation of HD.[40] Additionally, expression of purigenic receptors (P2X7)[41] and TLR-4 has been shown to be increased in circulating monocytes in those with early stage CKD, and to be associated with elevated levels of IL-6 and MCP-1.[42] In HD patients, monocytes show elevated basal toll-like receptor TLR-2 and TLR-4 expression, upregulation of cell surface integrin expression, increased basal cytokine and ROS production, and exaggerated response to lipopolysaccharide.[28,29,43] The modality of renal replacement therapy appears to play a role in the level of proinflammatory monocytes as patients treated with peritoneal dialysis have lower levels compared with those maintained on HD.[44] These abnormalities point to spontaneous activation of monocytes and their contribution to the prevailing oxidative stress, systemic inflammation, and atherosclerosis in CKD. Uremic plasma triggers production of osteoactivin by monocytes and macrophages, which can contribute to vascular calcification.[45] Moreover uremic plasma stimulates adhesion and infiltration of normal monocytes−macrophages in cultured human endothelial monolayers used to simulate an arterial wall *in vitro*[46] and to increase the expression of scavenger receptors, SR-A and CD36.[47,48] Epidemiologic studies have identified the association of increased intermediate monocytes (CD14++/CD16+) with adverse cardiovascular outcomes in nondialysis CKD stage 2−5 patients, as is the case in the general population,[39] and higher monocyte counts with increased incident kidney disease and progression of CKD.[49]

The mechanisms responsible for the increased numbers of proinflammatory monocytes in CKD are unknown. It has been speculated that oxidative stress, which increases generation of TLR ligands (such as oxidized phospholipids), may stimulate release of CD14+/CD16+ monocytes from the bone marrow.[50] Increased angiotensin converting enzyme (ACE) mRNA levels, decreased ACE2 levels, and upregulation of angiotensin II levels have recently been described in both subjects with CKD stage 2−5 and HD patients, and noted to be associated with increased monocyte−endothelial cell adhesion.[51] Additionally, both uremic serum with elevated levels of homocysteine and exogenous homocysteine have been shown to induce CD40 expression in CD14+/CD16− monocytes, suggesting homocysteine may play a role in the CKD-associated increase of proinflammatory monocytes.[52] Exposure to uremic toxins may also play a role. Exposure to p-cresyl sulfate has been shown to result in increased monocyte nitrous oxide (NO) production and macrophage activation.[53] Moderate increases of indoxyl sulfate result in promotion of monocyte-derived profibrotic macrophages that may contribute to maladaptive vascular remodeling and sustain a level of chronic inflammation.[54]

The spontaneous activation of monocytes in uremia is accompanied by impaired phagocytic capacity,[2,14,15] release of IL-6 and TNF-α, and an associated reduced response to vaccinations.[55] *In vitro* exposure to p-cresyl sulfate results in impaired phagocytosis and antigen presentation by monocyte-derived macrophages.[53] Tissue macrophages recovered from the peritoneal dialysis effluent of ESRD patients exhibit an immature phenotype and evidence of activation, features that may impair their ability to clear bacteria.[56,57] Together these monocyte−macrophage abnormalities contribute to the immune deficiency and increased incidence and severity of infections in the CKD population.

Polymorphonuclear Leukocyte Abnormalities in CKD

PMN are short-lived (5 days) professional phagocytes that avidly engulf antibody-coated and complement-coated microbes, damaged cells, and cellular debris. They have many intracellular granules that contain bacteriocidal proteins such as cationic proteins and defensins, proteolytic enzymes and cathepsin G (to degrade bacterial proteins), lysozyme (to lyse bacterial cell walls), NAD(P)H oxidase-II (to generate ROS), myeloperoxidase (to produce HOCl), and lactoferrin (to inhibit bacterial replication *via* iron deprivation). PMNs are the first line of defense against invading microbes and

important players in inflammation. In CKD patients the number of circulating PMNs progressively increases with declining renal function.[58] In ESRD patients PMNs demonstrate spontaneous activation. Circulating PMNs in HD patients exhibit upregulation of TLR-4, TLR-2, Cd11b, and CD18 expression, increased superoxide and hydrogen peroxide production, and marked degranulation, pointing to their spontaneous activation.[28,29] These abnormalities contribute to the prevailing systemic oxidative stress, inflammation, and tissue damage in this population. Increased numbers of circulating PMNs and high neutrophil-to-lymphocyte ratios have been associated with endothelial dysfunction, cardiovascular events,[59] CKD incidence,[60] and CKD progression.[61]

The spontaneous activation of PMNs is accompanied by their impaired migratory function,[62] decreased phagocytic and bactericidal capacity, and increased apoptosis.[14,15,63,64] The resultant CKD-associated impaired recruitment of neutrophils into inflamed tissue has been associated with increased fibroblast growth factor 23 (FGF-23) levels. *In vitro*, FGF-23 has been shown to directly inhibit PMN adhesion and transendothelial migration by binding to FGF2, blocking neutrophil integrin expression through activation of protein kinase A.[65] The increased apoptosis has been attributed to increased sensitivity of uremic PMNs to fas-fas-ligand–mediated apoptosis and to the effects of oxidative stress.[66–68] Collectively, these abnormalities contribute to the increased risk of infection in CKD. The PMN abnormalities are transiently intensified by HD,[28,29] most likely due to exposure to dialyzer membranes, cytoskeletal stresses from roller pumps, and influx of impurities from the dialysate compartment.[69] Kidney transplantation improves PMN function,[70] pointing to the role of uremia in the pathogenesis of these abnormalities.

Dendritic Cell Abnormalities in CKD

DCs, the major APCs, continuously survey the antigenic milieu of the body and act as sensors of microbial invasion and tissue damage. DCs prime and regulate immune responses in T cells, B cells, and NK cells and thereby play a critical part in tumor surveillance, defense against microbial pathogens, and tolerance to self antigens. Several sources of DC have been described, including Langerhans cells of the skin, monocytes that differentiate into DC, and circulating immature DCs.[50] Two types of circulating DCs have been identified. Plasmacytoid DCs (pDC) that possess intracellular TLRs (including TLR7 and TLR9), which sense viral or self-nucleic acids, and produce large amounts of type I interferons (such as IFNα) in response to viral infections, and myeloid DCs, which possess cell surface TLRs (including TLR3 and TLR4) and produce IL-12 and type I interferons in response to TLR3 and TLR4 agonists.

CKD stage 4 and 5 are associated with DC depletion and dysfunction.[16,71,72] Langerhans cell density is reduced in dialysis patients, compared with normal individuals.[73] Several studies have shown that DC derived from circulating monocytes of patients with CKD stage 4 and 5 are less effective in stimulating T cells[43,72,74], possibly due to uremia-induced reduction in expression of CD36 costimulatory molecule by DCs.[75] Circulating DCs are also significantly decreased in dialysis patients,[16,71] primarily due to the reduction of the pDC subset.[16] Circulating DC depletion in ESRD is transiently exacerbated by HD[16] and reversed by renal transplantation.[72] Given the critical role of DCs in regulation of innate and adaptive immunity, DC depletion contributes to impaired defense against infections and poor response to vaccination in patients with late-stage CKD. In an attempt to improve DC number and function, Verkade et al.[76] treated HD patients with granulocyte/macrophage colony stimulating factor. After treatment, DCs largely disappeared from the circulation, presumably due to their migration into lymphoid tissues, and response to hepatitis B vaccination improved.

Although DC numbers are reduced in HD patients, their basal and LPS-stimulated TNF production is increased.[16] These findings point to participation of DCs in the pathogenesis of systemic inflammation in CKD.

Natural Killer Cell Abnormalities in CKD

NK cells are cytotoxic lymphocytes that are critical to the innate immune system and can function as an interface to the adaptive immune response. NK cells rapidly respond to virally infected cells and tumor formation in the absence of antibodies.[77] NK cells are derived from the common lymphoid progenitor that generates B and T lymphocytes and differentiates and matures in the bone marrow, lymph node, spleen, tonsils, and thymus before entering the circulation. NK cells exist as classical and nonclassical subsets that commonly express CD16 and CD56 surface markers. Up to 80% of human NK cells also express CD8. A subset of NK cells, termed natural killer T cells, express TCR and BCR on their surface and differ phenotypically, by origin and respective effector functions. These NK cells also play a role in the adaptive immune response and can develop antigen-specific immunological memory.[78]

Studies of NK cells in CKD patients are limited and have yielded conflicting results.[79,80] In a study of 219 HD patients, Vacher-Coponat et al.[81] found reduced

numbers of NK cells associated with increased expression of activation markers (CD69 and NKp44 receptors) but normal NK function compared to healthy controls. In contrast, others have reported reduced expression of pivotal-activating receptor NKG2D on NK cells in HD patients.[82] Thus decreased number of NK cells in CKD patients may be associated with their impaired function and might contribute to reduced tumor surveillance and increased viral infections.

Role of Intestinal Epithelium and Other Nonimmune Cells

Studies in experimental animals with CKD have shown upregulation of ROS production machinery and chemokine expression in the cellular constituents of various tissues, highlighting their participation in the prevailing oxidative and inflammatory states.[32] The gastrointestinal epithelium serves as the barrier against entry of microbial toxins, antigens, and other harmful luminal contents into the intestinal wall and systemic circulation. The intestinal epithelial barrier consists of the epithelial cells and the paracellular junctional complex, which seals the gap between the adjacent epithelial cells. The epithelial tight junction is a major component of the junctional complex that plays a central role in preventing the influx of the noxious products into the circulation. By allowing the entry of microbial products and other noxious luminal contents into the body's internal milieu, disruption of the gastrointestinal epithelial barrier results in local and systemic inflammation. There is considerable evidence pointing to the dysfunction of the gastrointestinal epithelial barrier and its contribution to systemic inflammation in humans and animals with advanced CKD.[38] HD patients commonly exhibit endotoxemia in the absence of clinical infection[83] and histological evidence of inflammation throughout the gastrointestinal tract.[84] Heavy losses of the key protein constituents of colonic epithelial tight junction have been found in animals with CKD.[85] These findings explain the source of endotoxemia, which is commonly present and is a major cause of inflammation in the CKD population.[83] *In vivo* and *in vitro* studies identified urea (which enters the gastrointestinal tract of uremic humans and animals) and the byproducts of its hydrolysis by microbial urease (namely ammonia and ammonium hydroxide), as the main cause of disruption of intestinal barrier function and structure in uremia.[86–88] These findings explain the underlying mechanism of the previously demonstrated salutary effects of a low protein diet and longer/more frequent dialysis regimens, which help to lower the urea burden in the CKD/ESRD population.

COMPONENTS OF ADAPTIVE IMMUNITY AND THEIR ABNORMALITIES IN CKD

T Lymphocytes

T cells represent a major component of the adaptive immune system and play a central part in cell-mediated immunity. They are distinguished from other lymphocytes by the expression of the TCR. Exposure of naive T cells to antigen leads to clonal expansion and differentiation, and generation of memory and effector T cells. Effector T cells perform their effector function *via* secretion of cytokines and destruction of target cells. At the conclusion of a specific immune reaction, the population of the related effector T cells contracts. A small number of the memory T cells however remain indefinitely, enabling the host to mount a robust immune response on reexposure to the same pathogen. T cells are derived from bone marrow stem cells that populate the thymus as thymocytes and subsequently differentiate into functionally distinct subtypes.

Helper T Cells (CD4+ T Cells)

Helper T cells express CD4 protein on their surface. They play a key role in various immunologic processes, such as activation of cytotoxic T cells and macrophages, maturation of B cells into plasma cells and memory B cells, antibody production by B cells, recruitment of PMNs, eosinophils and basophils to the loci of infection/inflammation, amplification of microbiocidal activity of macrophages as well as development of tolerance or suppression of the inflammatory response, among others. When presented with the peptide fragments of the processed antigens by the APCs, CD4+ T cells rapidly proliferate and secrete cytokines to direct the immune response. Helper T cells can differentiate into several distinct subtypes, including Th1, Th2, Th3, Th17, or T follicular helper cells. Each of these subtypes secretes a different panel of cytokines that drive the immune response in specific manners. The CD4+ cell differentiation into the given subtypes is driven by the signaling patterns from the APCs.[7,50]

Cytotoxic T Lymphocytes (CD8+ T Cells)

These cells express CD8 protein on their surface. CD8+ T cells can destroy virally infected cells and tumor cells and participate in transplant rejection. CD8+ T cells recognize antigens associated with MHC class I, which is expressed by nearly all cells in the body. The regulatory T cells inactivate and transform CD8+ cells into an anergic state by secreting IL-10, adenosine, and other molecules, a process that is critical in preventing autoimmune diseases.[7,50]

Memory T Cells

Following acute infection a small fraction of the primed CD4+ or CD8+ cells persist indefinitely as central memory T cells and effector memory T cells, which typically express CD45RO. On reexposure to their cognate antigen, these cells undergo rapid proliferation to form large numbers of effector T cells. Memory T cells play a central part in adaptive immunity by providing the immune system with "memory" against past infections.[7,50]

Regulatory T Cells

Treg cells are derived from two distinct origins: (a) adapted regulatory T cells (also known as Tr1 cells or Th3 cells), which originate from alternative differentiation of naïve T cells, and (b) natural regulatory T cells (also known as CD4+ CD25+ FoxP3+ Treg cells), which mature in the thymus as a distinct lineage and comprise 5−10% of the circulating CD4+ T cells.

Treg cells, previously known as suppressor T cells, play a central role in maintaining immunological self-tolerance, limiting the inflammatory response to foreign antigens, ceasing T cell-mediated immunity on completion of the immune reaction, and suppressing autoreactive T cells that escape negative selection in the thymus. Activated Tregs suppress proliferation and blunt the effector functions of B cells, monocytes, and other T cells *via* cytokine-mediated or contact-dependent mechanisms. Through their actions Tregs protect the host by preventing the inflammatory response from becoming perpetual or disproportionately exuberant.[7,50]

CKD-Associated T Cell Abnormalities

Patients with advanced CKD and ESRD exhibit reduced numbers of total circulating T cells, accompanied by a profound difference in T cell composition. CKD patients have reduced CD4/CD8 ratio, increased Th1/Th2 ratio, and depletion of naïve and central memory CD4+ and CD8+ T cells.[19,20,89] The reduction in naïve and memory T cells is associated with reduced thymic output of naïve T cells[90] and increased expression of apoptotic markers and apoptosis of both naïve and central memory CD4+ and CD8+ T cells.[20] The magnitude of the naïve and central memory CD4+ and CD8+ T cell depletion is directly related to severity of azotemia, oxidative stress, secondary hyperparathyroidism, iron overload, and inflammation.[20] Given the critical role of naïve and central memory T-cells in orchestrating the immune response to the *de novo* exposure and reexposure to pathogens, their depletion must be, in part, responsible for increased incidence and poor outcome of various infections in the CKD population.

T cell dysfunction in CKD patients may also be associated with impaired response to vaccination. Using a highly sensitive multiparameter flow cytometry assay that permits the detection of antigen specific T-cells, Litjens et al.[91] demonstrated that the formation of hepatitis B surface antigen-specific CD4+ T cells was impaired in dialysis patients undergoing hepatitis B vaccination. The authors suggested that lack of adequate antigen-specific T cell differentiation was in part the cause for the observed poor response to vaccination.

T cell dysfunction may also play a role in CKD-associated chronic inflammation and increased cardiovascular risk. Patients with ESRD maintained on HD have an imbalance of Treg to Th17 cells. Compared with normal controls, they have reduced Treg cell frequency and lower Treg-related cytokine (IL-10, TGFβ1) levels, along with increased Th17 cell frequency and elevated Th17-related cytokine (IL-17, IL-6, IL-23) levels. These abnormalities were especially present in patients with a history of cardiovascular events.[92] Additionally, patients with CKD 5 have increased numbers of terminally differentiated CD4+ memory T cells that do not express CD28 (CD4+CD28-cells).[93] This T cell subpopulation, activated by human heat-shock protein (HSP) 60 and HSP70, is increased in patients with acute coronary syndrome and in CKD patients.[94] The initiation of HD appears to exacerbate these abnormalities.[95] These CD4+CD28-cells (previously categorized as Th1 helper cells) are highly proinflammatory, express large amounts of IFN-γ and TNF-α on activation, and are cytotoxic,[96] *via* the expression of activating killer cell-immunoglobulin-like receptor KIR2DS2, mainly in the absence of inhibitory KIR2DL3. Expression of KIR2DS2 is increased in HD patients compared to nondialysis-dependent CKD patients and is associated with reduced expression of the inhibitory KIR2DL3 expression.[97] These proinflammatory cells are thought to participate in the destabilization of atherosclerotic plaques. Their increased presence in CKD patients has been shown to be strongly associated with atherosclerotic changes[98] and a history of cardiovascular disease.[99]

Increased apoptosis has been reported in circulating lymphocytes of patients with early CKD and appeared to increase across stages 1−4.[100] Meier et al.[30] and Hendrikx et al.[31] have demonstrated increased apoptosis and marked reduction of the Treg cells (CD4+/CD25+) in dialysis-independent CKD 5 patients and ESRD patients maintained on peritoneal or HD. The observed depletion of the Treg cells was accompanied by their impaired ability to inhibit PHA-induced CD4+ cell proliferation, reflecting reduction in their anti-inflammatory capacity. The magnitude of Treg cell depletion and dysfunction was greatest in HD-treated patients followed by peritoneal dialysis-treated and dialysis-independent CKD5 patients. Incubation of

isolated Treg cells from normal subjects with uremic plasma lowered the number and reduced the suppressive capacity of these cells, pointing to the deleterious effect of the uremic milieu. This effect could be reproduced by addition of oxidized LDL, illustrating the interconnection between oxidative stress and lipid disorders with immunological abnormalities and the associated atherogenic diathesis in CKD.

Given the critical role of Treg cells in mitigating inflammation, Treg cell deficiency and dysfunction in the CKD/ESRD population may contribute to the prevailing systemic inflammation and cardiovascular and other complications. Use of recombinant erythropoietin (EPO) has been shown to have T-cell associated immunomodulating, anti-inflammatory effects. Through its effect on an EPO receptor and CD131 on APCs, EPO has been shown to increase TGFβ secretion, which results in conversion of naïve CD4+ T cells to functional Treg cells. Purroy et al. showed that in doses used to correct anemia in CKD patients, EPO inhibited conventional T cell proliferation, while facilitating Treg proliferation. Conventional T cell proliferation was inhibited *via* tyrosine phosphate SHP-1−dependent uncoupling of IL-2Rβ signaling, and Treg proliferation was achieved through increased IL-2Rγ and decreased IL-2Rβ signaling.[101]

B Lymphocytes

B lymphocytes are generated from hematopoietic stem cells in the bone marrow throughout life. They contribute to the immune system by producing antigen-specific antibodies. The pleotropic cytokine, IL-7, plays a major part in B-lymphopoiesis by promoting maturation of pre-B cells to B cells in the bone marrow.[102] After differentiation and selection in the bone marrow, newly emerging B lymphocytes (termed transitional B cells; CD19+ CD10+) migrate to the spleen. Further differentiation of transitional B cells into mature long-lived lymphocytes is driven by B cell activating factor of tumor necrosis family (BAFF).[103] B cells failing any maturation steps undergo clonal deletion by apoptosis, and those recognizing self-antigen during maturation become suppressed (anergy or negative selection). In the blood and lymphatic system B cells conduct immune surveillance *via* their BCR, which consists of a membrane-bound immunoglobulin molecule capable of binding a specific antigen. In adults, innate B1 cells (CD5+ B cells), which account for 25−27% of peripheral blood B lymphocytes, produce mainly IgM antibodies with high cross-reactivity but low affinity. These antibodies constitute a readily available pool of immunoglobulin for use against a variety of infections, before specific high-affinity antibodies are produced. In contrast, the conventional B cells (CD5− B cells, also known as B2 cells) produce more diverse and high-affinity antibodies and account for 75−80% of peripheral blood B lymphocytes. When the naive mature B lymphocytes recognize an antigen with their receptors and receive an additional signal from the T helper cells, they undergo proliferation and differentiation into long-lived memory B cells (CD27+) and short-lived plasma cells. Most activated B cells differentiate into plasma cells that secrete antibodies against the specific epitope of the inciting antigen. A small minority of these cells survive as memory cells that recognize the given antigen. However, with each reexposure, the number of surviving memory cells rises and specificity of immune response improves. Memory cells, which can survive decades, actively circulate from blood to lymph nodes and populate mucosal tissues. On subsequent encounter with the antigen, memory B cells rapidly produce immunoglobulin isotypes with high affinity for the given antigen. In adult humans, memory B cells constitute approximately 40% of all circulating B cells. The subpopulations of circulating B cells include innate B1 cells (CD19+,CD5+), conventional B2 cells (CD19+, CD5−), newly formed transitional B cells (CD19+, CD10+, CD27−), naïve B cells (CD19+, CD27−), and memory B cells (CD19+, CD27+).[7,18]

CKD-Associated B Cell Abnormalities

Several studies have demonstrated significant B lymphopenia in patients with CKD stage 5 with or without renal replacement therapy.[18,104] In addition, a diminished population of CD5+ innate B cells and CD27+ memory B cells has been demonstrated in children with CKD5.[104] Pahl et al.[18] demonstrated depletion of several other B cell subtypes in adult HD patients. The observed B cell lymphopenia was accompanied by elevated levels of IL-7 and BAFF, which are the key B cell differentiation and survival factors. The number of transitional B cells was not significantly reduced in the dialysis patients. These observations suggest that decreased output of B cells from bone marrow may not be the main cause of the B cell lymphopenia in CKD. This view is supported by the finding that plasma levels of IL-7, a cytokine that facilitates conversion of pre-B cells to B cells, was increased in the ESRD patients.

Two alternative mechanisms can account for B lymphopenia in CKD. First, the uremic milieu may increase susceptibility of B cells to apoptosis. This supposition is supported by the study of Fernández-Fresnedo et al. who reported increased apoptosis of B cells in predialysis CKD stage 5 and HD patients.[105] The second possibility is that the uremic environment may interfere with the maturation of transitional B cells to mature B cells

by promoting resistance to BAAF-mediated differentiation and survival signals. This supposition was supported by marked downregulation of BAAF receptor in HD patients reported by Pahl et al.[18] Thus B cell deficiency and dysfunction in advanced CKD can be simultaneously mediated by increased B cell apoptosis and impaired transitional B cell differentiation and maturation. In contrast to the observed reduction of BAFF receptor expression in transitional B cells, BAFF receptor expression was unchanged in circulating mature B cells (CD19+ CD10− cells). Because BAFF receptor expression and activity contributes to the survival of mature B lymphocytes,[106] the observed elevation of the circulating BAFF levels and the normality of BAFF receptor expression in mature B cells preclude the deficiency of either as the primary cause of the observed reduction of mature circulating B cells in advanced stages of CKD.

The studies of the effect of CKD/ESRD on B cell populations in humans have been restricted to the examination of cells found in blood samples. This is inadequate for a full understanding of the impact of the disease, due to lack of relevant studies of bone marrow and lymphoid tissues, critical sites in the maturation and functional development of these cells. Further studies are needed to explore the effects of uremia on B cell precursors in the bone marrow and downstream signal transduction pathways involved in B cell growth, differentiation, and survival. Regardless of the cause, uremia-induced naïve and memory B cell lymphopenia are, in part, responsible for the defective humoral response to infections, vaccination, and recall antigens and increased incidence of infection in CKD patients.

CLINICAL CONSIDERATIONS

Role of Vitamin D and CKD-Mineral Bone Disorders

CKD is associated with a progressive impairment of vitamin D metabolism, declining circulating $1,25(0H)D_3$ and resultant alterations in S[Ca], S[P], FGF-23, and parathyroid hormone (PTH) levels. In addition 25(OH)D levels are reduced in many CKD patients. These changes that result in secondary hyperparathyroidism and mineral-bone disorders have also been implicated in the pathogenesis of altered immune responses and chronic inflammation. In fact, altered vitamin D parameters and markers of mineral-bone disorders have been associated with increased infectious and cardiovascular mortality rates in CKD patients.[107]

Vitamin D possesses "classical" actions that affect mineral bone metabolism and "nonclassical" actions that include regulation of the innate and adaptive immune systems.[108] Activation of the TLR pathway in the human monocyte−macrophage by PAMPs shed by microbial agents such as mycobacterium tuberculosis results in increased expression of the vitamin D receptor (VDR), CYP27B1-hydroxylase, and local synthesis of $1,25(OH)_2D_3$, which stimulates production of cathelicidin and culminates in the killing of the ingested microbe.[108] Active vitamin D, $1,25(OH)_2D_3$, suppresses B lymphocyte proliferation and immunoglobulin production and inhibits the differentiation of B lymphocytes to plasma cells and memory B cells.[109] Active vitamin D can suppress proliferation of T lymphocytes and result in inhibition of Th1 cytokine production[110] while enhancing Th2 cytokine production, either directly or through its effects on APCs.[111,112] Vitamin D promotes the generation of Treg lymphocytes, likely mediated by suppression of myeloid DC maturation and enhancement of IL-10 production.[113]

Studies in CKD patients have implicated alterations of vitamin D levels and the hormones associated with mineral-bone metabolism in the dysfunction of both innate and adaptive immune cells. Increased circulating PTH levels in dialysis patients result in elevated cytosolic calcium concentrations, which reduce PMN-phagocytosis, B cell proliferation, and antibody production.[17] Parathyroidectomy or the use of calcium channel blockers improves PMN and B cell function,[17] suggesting these therapeutic interventions may result in reduced infections in CKD patients.

Elevated levels of FGF-23 have been shown to be independently associated with increases of proinflammatory cytokine levels in patients with CKD 2−4, although the underlying mechanism of action is unclear.[114] There are emerging data that FGF-23 can directly interact with PMNs and macrophages through the binding of FGFR/α-Klotho receptors.[115] Elevated FGF-23 levels result in reduced PMN recruitment and infection severity in CKD animal models with pneumonia.[65] However, PMNs lack the FGF-23 coreceptor α-Klotho. Although some have hypothesized that the effect can be modulated through the noncanonical FGFR2 pathway, this receptor has not been shown to be a target for FGF-23 in several functional studies.[115] There are however compelling data that FGF-23 directly effects macrophages. Macrophages express FGFR1, and exposure to inflammatory stimuli results in upregulation of α-Klotho expression. *In vitro* stimulation of macrophages with FGF-23 results in induction of TNF-mRNA and increased protein expression that can be blocked with FGFR inhibitors.[116,117] The effects of FGF-23 may be mediated by its effects of vitamin D metabolism. FGF-23, a regulator of CYP27B1 in the kidney, inhibits local CYP27B1 expression and synthesis of $1,25(OH)_2D_3$ in monocytes obtained from peritoneal

dialysis effluent as well as normal circulating monocytes.[118] The findings of low vitamin D and high FGF-23 serum levels have been recently reported to be associated with infectious and cardiac deaths in a large cohort of ESRD patients.[119] Correction of 25(OH) Vit D deficiency in HD patients resulted in increased monocyte VDR expression and expansion of proinflammatory, CD16+ monocytes associated with increased TLR2 and cathelicidin expression. These findings however were associated with a reduction of circulating levels of inflammatory cytokines.

These data point to the complex and diverse effects of vitamin D, PTH, and FGF-23 levels on immune cells and suggest that their CKD-associated alterations play a significant role in the pathogenesis of immune deficiency and chronic inflammation. More studies are needed to determine the role of vitamin D deficiency, hyperparathyroidism, and FGF-23 levels on immune dysfunction, to dissect the potential confounding paracrine and endocrine effects, and to ultimately guide future therapeutic strategies.

Role of Iron Deficiency and Iron Overload in CKD-Associated Immunological Disorders

Losses of blood in the HD circuit, routine blood samples drawn for laboratory testing, and impaired intestinal absorption of iron in dialysis patients frequently result in the development of iron deficiency in this population. Conversely administration of intravenous iron preparations commonly used to treat anemia often results in iron overload and the rise in poorly liganded catalytically active iron in the plasma and tissues in HD patients. The immune system is adversely affected by both iron depletion and iron overload. Iron deficiency results in thymus atrophy and T cell lymphopenia.[120] Iron overload causes CD4+ T cell depletion in transfusion-dependent thalassemic patients and expansion of CD8+CD28− T lymphocytes in patients with hemochromatosis.[24,25] Non−transferrin-bound iron increases iron uptake by lymphocytes and impairs their proliferation.[121] This phenomenon may, in part, account for immune dysfunction and impaired cellular and humoral immunity in patients with iron overload.[24,25] This is exemplified by the diminished antibody production in response to hepatitis B vaccination in HD patients treated with intravenous (IV) iron preparations.[122] Gupta et al.[123] found that exposure of peripheral blood mononuclear cells to relevant concentrations of sodium ferric gluconate, iron sucrose, or iron dextran for 24−72 hours induced a significant time-dependent intracellular oxidative stress and shortened cell survival, particularly in helper CD4+ T lymphocytes. They concluded that IV iron products exert deleterious effects on human CD4+ and CD16+ lymphocytes by increasing intracellular generation of ROS and causing apoptosis. This supposition is supported by experiments that showed that exposure of Jurkat cells (an immortalized T cell line) to hydrogen peroxide results in the release of iron from lysosomes leading to DNA damage, mitochondrial membrane potential instability, and apoptosis, events that could be prevented by the iron chelator, deferoxamine.[124] High doses of IV iron preparations impair phagocytic activity and microbial killing capability of polymorphonuclear leukocytes.[125,126] Pharmacologically relevant concentrations of iron sucrose impair phagocytic function and promote apoptosis of polymorphonuclear leukocytes.[127] Thus both iron deficiency and iron overload can contribute to immune deficiency and increase susceptibility to infection. These observations point to the importance of the judicious use of IV iron preparations in dialysis patients. Administration of IV iron products has been shown to result in increased ROS generation and cytokine production, and loss of mitochondrial membrane potential in the blood mononuclear cells of HD patients.[128] Sindrilaru et al.[129] showed *in vivo* iron-loading results in formation of proinflammatory M1 macrophages that sustain local inflammation and prevent healing. Accumulation of excess iron in macrophages in the artery wall, diseased kidney, and other tissues can, therefore, contribute to the pathogenesis of oxidative stress, inflammation, atherosclerosis, and CKD progression.

To address concerns regarding the effects of iron use in ESRD patients, a recent, prospective, open label study was conducted across multiple dialysis centers in the United Kingdom. HD patients with ferritin levels <400 mcg/L and transferrin saturation levels (TSAT) of <30% were randomized to receive high dose IV iron (400 mg/month) proactively or low-dose reactively administered IV iron. Treatment was withheld for serum ferritin of 700 mcg/L or TSAT of 40%. At the end of the study period, a median of 2.1 years, the high-dose group received a median of 264 mg/month (interquartile range of 200−336 mg), whereas the low-dose group received a median monthly dose of 145 mg (interquartile range of 100−190 mg). The blinded primary endpoint of a composite of nonfatal myocardial infarction, stroke, heart failure, or death was similar in both groups. Those treated with high dose iron required lower erythropoietin doses and fewer blood transfusions. Additionally, there was no evidence of increased infectious complications in the high-dose group. Thus, while available data provide convincing evidence for the role of iron overload in the pathogenesis of inflammation and impaired adaptive immunity, recent

clinical experience suggests that IV iron can be safely used at the doses tested in this study with the dosing restrictions described for the duration studied.[130]

CONCLUSIONS

CKD-associated inflammation is due to activation of the innate immune system orchestrated by monocytes, macrophages, granulocytes, and cellular constituents of nearly all organs and tissues in the body. CKD-associated inflammation is coupled with immune deficiency, which is caused by depletion of the antigen-presenting dendritic cells, naïve and central memory T cells and B cells, and impaired phagocytic ability of monocytes and PMNs.

QUESTIONS AND ANSWERS

Question 1

T cells represent a major component of the adaptive immune system and play a central role in cell-mediated immunity. Which T-cell abnormalities have been associated with CKD?

A. Patients with advanced CKD and ESRD have increased number of total circulating T cells
B. HD patients have depletion of naïve and central memory CD4+ and CD8+ T cells
C. CKD patients have increased apoptosis and marked reduction of Treg cells
D. None of the above
E. Both B and C

Answer: E

Patients with advanced CKD and ESRD exhibit reduced, rather than increased numbers of total circulating T cells, with a reduced CD4/CD8 ratio, increased Th1/Th2 ratio, and depletion of naïve and central memory CD4+ and CD8+ T cells. Additionally, increased apoptosis and marked reduction of the Treg cells (CD4+/CD25+) in dialysis-independent stage 5 CKD patients and ESRD patients maintained on dialysis have been reported. Thus both B and C are true, making E the correct response. Given the critical role of naïve and central memory T cells in orchestrating the immune response to the *de novo* exposure and reexposure to pathogens, and of Treg cells in mitigating inflammation, T-cell deficiency and dysfunction in CKD population may contribute to the prevailing immune dysfunction, increased risk of infection, and systemic inflammation.

Question 2

Vitamin D affects both the innate and the adaptive immune systems. Which one of the following statements is true?

A. Local conversion of 25(OH) vitamin D to active 1,25(OH) vitamin D by monocyte−macrophages stimulates production of cathelicidin and results in killing of ingested mycobacterium
B. Supplementation with ergocalciferol in 25(OH) deficient individuals can improve immune dysfunction in CKD patients
C. 1-25(OH) vitamin D can stimulate B proliferation and result in increased plasma cell transformation and increased immunoglobulin production
D. Elevations in PTH associated with late stages of CKD have been shown to improve neutrophil phagocytosis through alterations in intracellular calcium concentrations

Answer: A

Local conversion of 25(OH) vitamin D to active 1,25(OH) vitamin D by monocyte−macrophages stimulates production of cathelicidin and results in killing of ingested mycobacterium.

Vitamin D abnormalities and CKD-associated mineral bone disorders may alter the host's response to infection. Although supplementation with ergocalciferol results in improved 25(OH) vitamin D levels, no studies in CKD patients have shown improved immune function. Active vitamin D affects a variety of cell functions in the adaptive immune system, but active vitamin D suppresses rather than stimulates B proliferation and further results in reduced plasma cell transformation and immunoglobulin production in experimental settings. Elevations in PTH associated with late stages of CKD also affect the immune response to infection, but have not been shown to improve impaired neutrophil phagocytosis. The mechanism is thought however to be mediated through increases in intracellular calcium concentrations. Finally, activation of the TLR pathway in the human monocyte−macrophages by mycobacterium tuberculosis stimulates local synthesis of $1,25(OH)_2D_3$, which results in production of cathelicidin and killing of the ingested microbes, thus making A the only correct response.

Question 3

Intravenous iron preparations are commonly used in conjunction with erythropoietic agents to manage anemia in late stages of CKD. Which of these statements is true regarding the effect of parenteral iron preparations on the immune system?

A. Iron overload has not been implicated in immune disturbances
B. Intravenous iron has been shown to result in increased intracellular oxidative stress and shortened T-cell lymphocyte survival
C. Studies in CKD patients maintained on HD and treated with intravenous iron preparations have failed to show any effect of neutrophil function
D. None of the above

Answer: B

Intravenous iron has been shown to result in increased intracellular oxidative stress and shortened T-cell lymphocyte survival.

The immune system is adversely affected by iron overload. Intravenous iron preparations have been associated with increased inflammatory response and impaired cellular immunity and reduced antibody response to vaccinations. Studies of circulating neutrophils from stage 5 CKD patients maintained on HD

and treated with intravenous iron preparations have shown impaired phagocytic activity and microbial killing capacity. Finally, iron overload causes increased intracellular oxidative stress and reduced lymphocyte proliferation and CD4+ T cell depletion, making B the only correct answer.

Question 4

Advanced CKD is associated with increased incidence and heightened severity of microbial infections. Which of the following factors contribute to this abnormality?

A. The phagocytic capacity of PMNs and monocytes is impaired in patients with advanced CKD
B. Arteriovenous fistulas, grafts, and indwelling catheters or peritoneal catheters provide easy ports of entry for microorganisms in ESRD patients
C. Immunosuppressive medications used to prevent graft rejection in kidney transplant recipients or prescribed to treat the underlying autoimmune disorders in CKD patients impair host response to microbial infections
D. Impairment of the adaptive cellular and humoral immune systems in patients with advanced CKD results in poor response to vaccination and reexposure to pathogens
E. All the above

Answer: E

CKD-induced impairment of the phagocytic capacity as well as the adaptive cellular and humoral immune responses work in concert to comprise the host response to microbial infections. The defense against infectious pathogens is compromised by vascular access or peritoneal catheters in ESRD patients or use of immunosuppressive medications in transplant recipients or in those with autoimmune disorders. Thus all the statements are true, making E the correct response.

Question 5

Systemic inflammation plays a major role in the pathogenesis of CVD, cachexia, anemia, and numerous other morbidities in CKD patients. Which of the following factors contribute to the CKD-associated systemic inflammation?

A. Accumulation of uremic toxins and metabolites such as indoxyl sulfate
B. Impairment of the intestinal epithelial barrier structure and function, which enables the entry of microbial endotoxins and other luminal contents into the body's internal milieu
C. Accumulation of highly proinflammatory oxidized LDL particles and deficiency and impaired anti-inflammatory properties of HDL in CKD patients
D. Depletion and dysfunction of Treg lymphocytes
E. All of the above

Answer: E

CKD results in accumulation of proinflammatory uremic toxins and metabolites, formation of oxidized LDL, and activation of the innate immune system, all of which contribute to the pathogenesis of systemic inflammation. The gut epithelium provides a barrier to substances that may have deleterious effects on immune function, but this defense may be compromised in CKD patients. The high burden of the proinflammatory factors in CKD is compounded by impaired natural anti-inflammatory mechanisms, including abnormalities in lipid metabolism, as well as Treg cell depletion and dysfunction. Thus all the statements are true making E the correct response.

CHAPTER

Chronic Kidney Disease and Gastrointestinal Disorders

Susie Q. Lew[a], *Jai Radhakrishnan*[b]

[a]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States; [b]Division of Nephrology, Department of Medicine, Columbia University Irving Medical Center, New York, NY, United States

Abstract

The kidneys and the gastrointestinal (GI) tract share a bidirectional relationship. Patients with chronic kidney disease (CKD) commonly experience GI symptoms including dysgeusia, anorexia, dyspepsia, hiccups, nausea, and vomiting. GI hemorrhage occurs more frequently in CKD patients. Lower GI tract symptoms occurring in CKD patients include constipation and diarrhea. CKD also affects gastric motility, the pancreas, and the gall bladder. Disorders of the GI tract may result in renal injury. Inflammatory bowel disease may affect kidney function through development of acid/base disorders, hypovolemia, and kidney stones. Patients undergoing Roux-en-Y gastric bypass surgery may develop kidney stones and kidney injury. Amyloidosis may involve the GI tract and the kidney independently. This chapter reviews the nexus between the kidneys and the GI tract and explores the etiology, pathophysiology, and management of the relevant disorders.

INTRODUCTION

Patients with chronic kidney disease (CKD) frequently experience upper gastrointestinal (GI) symptoms including dysgeusia, anorexia, hiccups, stomatitis, nausea, vomiting, and gastroparesis. Constipation and diarrhea represent the main lower GI tract symptoms associated with CKD. GI hemorrhage may originate from lesions anywhere along the GI tract. Hemorrhage may be exacerbated by the coagulopathy of uremia, but usually has an underlying etiology.

Although many of these symptoms are nonspecific, they do occur in the setting of uremia in patients with acute kidney injury (AKI) and advanced CKD. These symptoms provide indications to initiate renal replacement therapy in these settings.[1–4]

Conversely, disorders of the GI tract such as inflammatory bowel disease (IBD) and interventions such as gastric bypass surgery may lead to renal injury. Alterations in acid–base and volume status, electrolyte imbalance, and kidney stone formation may lead to or contribute to subsequent CKD in such patients. Thus, a bidirectional relationship exists between the kidneys and the GI tract (Figure 33.1).

GASTROINTESTINAL MANIFESTATIONS OF KIDNEY DISEASE

The lack of standardized definitions and the presence of comorbid conditions in the CKD population make estimating the prevalence of GI symptoms in CKD patients difficult. For the most part, patients do not report GI symptoms due to their sporadic nature and the absence of a temporal relationship to kidney disease. However, patients may recall a noticeable increase in frequency or appearance of symptoms if questioned. Most GI symptoms and complications of CKD are found in the late stages of CKD. Although nonspecific, significant GI symptoms in the setting of a low estimated glomerular filtration rate (eGFR) signal the need for initiation of renal replacement therapy.

Dysgeusia

Uremic patients may complain of uriniferous odor of the breath, known as uremic fetor, and an unpleasant metallic or a foul taste in the mouth, known as

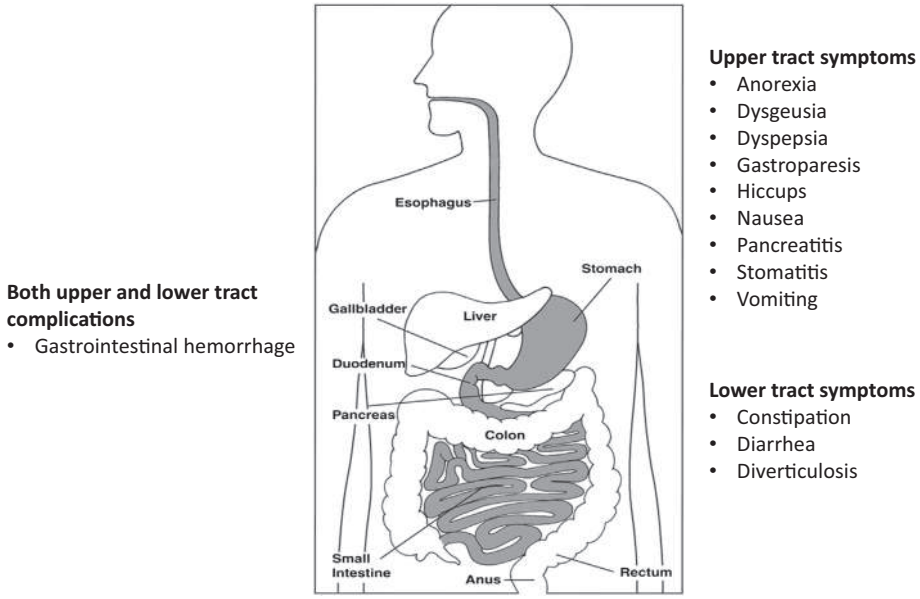

FIGURE 33.1 Gastrointestinal manifestations of chronic kidney disease.

dysgeusia.[5,6] Breakdown of large amounts of salivary urea to ammonia by bacterial urease in the mouth results in uremic fetor and dysgeusia.[5,6]

Initiation of dialysis corrects uremia, which in turn improves uremic fetor and uremia-induced dysgeusia. Uremic fetor may improve with eating a low-protein diet.

Dysgeusia also improves with dialysis. Other confounding factors, however, may mask symptomatic improvement. The role of zinc deficiency in CKD patients remains controversial.[7–9] Poor oral hygiene may also contribute to dysgeusia.[10]

Anorexia

Anorexia (a lack or loss of appetite for food) occurs in late CKD stages and frequently continues into CKD stage 5 treated with dialysis. Most of the studies of anorexia, however, have been performed in dialysis patients. Malnutrition, cachexia, and reduced caloric and protein intake have been reported in patients with anorexia-receiving dialysis.[11–13] Lower quality of life indices, higher rates of hospitalization, and higher mortality risk have also been associated with anorexia.[13,14]

The exact pathogenesis of anorexia in uremic patients remains unknown and is likely to be multifactorial. Many mediators contribute to the control of appetite.[15,16] Orexigenic substances such as ghrelin, neuropeptide Y, and agouti-related peptide stimulate the appetite. Anorexigenic substances such as leptin, cholecystokinin, insulin, and melanocyte-stimulating hormone induce anorexia. Other factors such as serotonin, melanocortin, trypophan, corticotrophin-related hormone, TNF-alpha, and interleukin-1β play roles in modifying appetite and feeding behavior as well.[15–17] In patients with substantial decrements in glomerular filtration rate (GFR), high levels of proinflammatory cytokines, leptin, free tryptophan, serotonin (hyperserotoninergic-like syndrome) along with deficiency of neural nitric oxide, and disorders in various receptors such as melanocortin receptor-4 can be found within the cerebrospinal fluid, which individually may cause anorexia.[18]

Ghrelin plays a key role in anorexia.[19,20] Ghrelin, a gut peptide, stimulates the production of growth hormone from the pituitary gland.[21] The stomach synthesizes ghrelin that is then released into the general circulation.[20–22] CKD patients have high plasma ghrelin levels compared to healthy controls, due to its reduced renal excretion.[20,22] The biological effects of ghrelin are mediated through the growth hormone secretagogue receptor (GHS-R). Animal studies show uremic anorexia and GI motility dysfunction correlate with downregulation of ghrelin and GHS-R in the hypothalamus of rats with chronic renal failure.[23] The salutary effects of ghrelin on food intake and meal appreciation suggest that ghrelin could be an effective treatment for anorexic CKD patients. Three distinct forms of ghrelin exist: acyl ghrelin, des-acyl ghrelin, and n-octanoyl modified.[19] Conflicting results regarding circulating ghrelin levels

in CKD patients may result from confounding factors that affect its measurement. Some examples of confounding factors include age, gender, ethnicity, obesity, renal functional status, and ghrelin type.[19,20]

GI dysmotility, commonly found in patients with CKD, also contributes to anorexia.[24,25] Patients with CKD may present with delayed gastric emptying,[25–28] decreased small intestinal motility,[29] and irritable bowel syndrome.[30]

Anorexia and malnutrition have been associated with poor outcomes in individuals with CKD. In children and adolescents with CKD, weight loss occurs when eGFR decreases to $<35\ mL/min/1.73\ m^2$, and this weight loss was associated with higher risk for progression to end-stage renal disease (ESRD).[31] In adults, protein-energy wasting (PEW), a condition associated with a decline in body protein mass and energy reserves, has a prevalence of >20–25% in early CKD, which increases with CKD progression.[32] Potential causes of PEW include inadequate nutrient intake (i.e. anorexia, dietary restriction, socioeconomic constraints), urinary protein losses, hypercatabolism caused by comorbid illnesses or uremia, and metabolic acidosis.[32]

Removal of uremic toxins by dialysis improves anorexia.[16] For those patients already treated with dialysis who experience anorexia, daily dialysis may be needed for a period of time to improve anorexic symptoms.[16,33] The HEMO study, however, did not show a difference in dialysis-related anorexia in the high-dose thrice weekly compared to high-flux membrane treatment groups.[34]

Dietary adjustments such as the ingestion of branched-chain amino acid supplements improve appetite as well as protein and caloric intake.[33,35,36] Administration of branched-chain amino acids exerts significant antianorectic and anticachectic effects in uremic patients.[36]

A pharmacological approach may improve appetite or suppress symptoms. Megestrol acetate, a synthetic orally active derivative of the naturally occurring hormone progesterone, increases appetite *via* stimulation of neuropeptide Y in the hypothalamus. Megestrol acts by modulating calcium channels in the ventromedial hypothalamus, a well-known satiety center, and inhibition of proinflammatory cytokines such as IL-1, IL-6, and TNF-α.[37,38] Megestrol acetate improves protein and energy intake as well as appetite. However, adverse effects may limit the use of megestrol acetate in patients with severe decrements in GFR.[12,38] Common adverse effects include headaches, dizziness, confusion, diarrhea, hyperglycemia, thromboembolic phenomena, breakthrough uterine bleeding, peripheral edema, hypertension, adrenal suppression, and adrenal insufficiency.[12]

Hiccups

Hiccups consist of repetitive, involuntary, intermittent spasmodic contractions of the diaphragm. The inspiratory rush of air causes the epiglottis to close, causing the "hic" sound. Intractable hiccups occur with diaphragmatic irritation, hyponatremia, and uremia. Intractable hiccups may lead to malnutrition, weight loss, fatigue, dehydration, and insomnia.

Hiccups are generally self-limiting. Pharmacological interventions to stop intractable hiccups are shown in Table 33.1. Care should be taken when using high or

TABLE 33.1 Medications for Chronic Kidney Disease Patients with Upper GI Symptoms

Medication Class	Medication
ANTIEMETICS	
Dopamine antagonists (CNS)	Droperidol
	Haloperidol
	Chlorpromazine
	Promethazine
	Prochloperazine
Antihistamines (CNS H1 histamine receptor antagonists)	Diphenhydramine
	Dimenhydrinate
	Meclizine
	Promethazine
	Hydroxyzine
5-HT3 receptor antagonists (CNS and GI)	Granisetron
	Ondansetron
HICCUPS	
Antipsychotics	Chlorpromazine
	Haloperidol
Anticonvulsants	Phenytoin
	Valproic acid
	Carbamazepine
	Gabapentin
Muscle relaxants	Baclofen
	Cyclobenzaprine
Central nervous system stimulants	Methylphenidate
Dopamine antagonists	Metoclopramide
Tricyclic antidepressants	Amitriptyline
Proton pump inhibitors	
Others	Nifedipine

prolonged doses of those medications that are excreted by the kidneys (such as baclofen, gabapentin, metoclopramide) and cardioactive drugs such as quinidine are best avoided.

Stomatitis and Salivary Gland Inflammation

Oral bacterial urease converts urea to ammonia. High levels of salivary ammonia ulcerate the buccal mucosa causing uremic stomatitis, characterized by a red, thickened buccal mucosa with gray and gluey exudates.[5,6] Associated findings with uremic stomatitis include dry burning mouth, poor dental hygiene, glossitis, and parotitis. Uremia may also cause mucosal ulcerations, bleeding, or intramural hematoma.[4]

Stomatitis generally improves when CKD patients begin dialysis. Measures to keep the oral cavity infection-free should be recommended to patients.

Nausea and Vomiting

Nausea and vomiting commonly occur in CKD and dialysis patients regardless of CKD stage or dialysis status.[4,39] The exact mechanisms underlying the pathogenesis of nausea and vomiting remain elusive and appear likely to be multifactorial. Nausea and vomiting may be caused by encephalopathic or neurologic disorders associated with uremia. These nonspecific symptoms may result from responses to endogenous changes in bodily function or from exogenous stimuli.[39] Nevertheless, clinicians frequently base their decision to initiate dialysis on patient symptoms of nausea and vomiting, along with appropriate chemical indicators of uremia.

Uremia-associated nausea and vomiting usually improve with dialysis. However, the dialysis treatment itself may induce these symptoms. Acid–base disorders due to rapid infusion of acetate from acetate-based dialysate and compounded by delayed conversion to bicarbonate could cause nausea and vomiting.[40] Rapid changes and extreme fluctuation of blood pressure during dialysis, reaction to the dialyzer, or medications administered during the treatment may also cause nausea and vomiting.

Antiemetic agents may provide temporary symptomatic relief for uremia-related nausea and vomiting. Antiemetics by class of agents that may be used in CKD patients are listed in Table 33.1.

Limited data exist regarding the efficacy of antiemetics in CKD patients. Previously, the D_2-receptor antagonist haloperidol was the drug of choice to treat uremia-induced nausea. Because its metabolite may accumulate in renal failure, the recommended haloperidol dose should be 50% of normal. Metoclopramide may also be used to treat nausea, but there may be an increased risk of extrapyramidal reaction from drug accumulation, and the dosage will need to be substantially reduced as renal function declines. Cyclizine should be avoided as it may be associated with hypotension and tachyarrhythmia in CKD patients with cardiac disease.[41] Ondansetron, which selectively antagonizes serotonin 5-HT3 receptors, demonstrates more efficacy than metoclopramide, and the dose does not need to be adjusted with renal failure.[42]

Gastroesophageal Reflux Disease and Dyspepsia

Adult CKD patients compared to the general population do not demonstrate a higher incidence of gastroesophageal reflux disease.[43] The prevalence of *Helicobacter pylori* infection and peptic ulcer disease seem not to be different in CKD patients compared to the general population.[27] Positive *Helicobacter* serology was not related to the presence of dyspepsia or gastroparesis in uremic patients.[44] The evaluation of gastroesophageal reflux disease in CKD patients is similar to that of the general population.[45]

The approach to treating gastroesophageal reflux disease and dyspepsia includes nonpharmacologic approaches and pharmacotherapeutic maneuvers, similar to non-CKD patients.[45] Lifestyle modifications require patients to eat smaller, frequent meals and remain upright after meals for at least 3 hours before reclining. Foods such as alcohol, chocolate, citrus juice, and tomato-based products should be avoided. The addition of an H_2 antagonist or proton pump inhibitor (PPI) may also provide symptomatic relief. Adjustment of H_2 antagonist dose depends on the level of kidney function and degree of renal clearance. PPI effectively treat gastroesophageal reflux disease. However, side effects limit its long-term use.[46] Additional information on the association of PPI use and the risk of CKD will be discussed at the end of this chapter.

Aluminum-based and magnesium-based antacids can result in complications associated with excessive body levels of these cations. It may be prudent to avoid these medications altogether and use calcium-based antacids. The anion found in antacids will mask metabolic acidosis. Nephrologists frequently capitalize on antacid use to treat both gastroenterologic and renal disorders simultaneously. CKD patients cannot excrete a large bicarbonate load quickly. Therefore, administration of large amounts of bicarbonate equivalents could cause severe metabolic alkalosis in CKD patients. Thus, electrolyte and acid–base status need frequent monitoring in CKD patients using antacids.

Gastrointestinal Hemorrhage

Clinical findings of hematemesis, melena, hematochezia, a positive stool occult blood test, or unexplained anemia suggest the diagnosis of GI hemorrhage.

Individuals with mild to moderate CKD are at higher risk of GI hemorrhage. The risk of GI hemorrhage in an individual with CKD stage 3 was 1.5 times and CKD stages 4 and 5 were 7 times higher compared to CKD stage 1.[47] In addition, compared to urine albumin:creatinine ratio <10 mg/g, the risk of GI hemorrhage was twice as high in microalbuminuria and macroalbuminuria.[47]

Direct visualization by esophagogastroduodenoscopy provides an opportunity for diagnosis and management of lesions in the esophagus, stomach, or proximal duodenum. Occult and obscure GI hemorrhage may require repeat upper endoscopy or procedures allowing access to the small intestine.[48] Push enteroscopy allows further evaluation of approximately 10–50 cm of jejunal mucosa beyond the ligament of Treitz. Double balloon enteroscopy, a modified push enteroscopy, allows intervention capability including bleeding control with electrocoagulation, dilation, biopsy, and polypectomy.[48] Wireless video capsule endoscopy facilitates the identification of small bowel bleeding sources that elude detection by other endoscopic techniques.[49]

Occasionally, an imaging procedure may be required to identify a lesion not accessible by conventional endoscopy. Small bowel series and enteroclysis pose risks of barium and radiation exposure. Barium retention limits the ability to perform repetitive examinations in a timely fashion and may cause constipation or obstipation. Enteroclysis often fails to identify flat mucosal lesions such as angiodysplasias.

A technetium 99-m labeled red blood cell bleeding scan may be used to identify cryptic or brisk sources of blood loss. A bleeding scan may detect the source of hemorrhage if the bleeding rate is greater than 0.1–0.4 mL/min.

An angiographic study may follow a positive bleeding scan or be performed with a normal bleeding scan to localize the source of brisk hemorrhage.[50] Angiography may detect bleeding lesions or associated structural abnormalities that are not actively bleeding, such as angiodysplasias, tumors, and inflammatory lesions. Radiographic contrast–associated nephropathy limits angiography use in the setting of CKD. Life-threatening GI bleeding, however, may warrant the risks associated with contrast exposure in patients with CKD. In such situations, the risk from contrast-associated nephropathy must be carefully balanced against the benefits of the procedure.

The pathogenesis of GI hemorrhage in CKD patients remains uncertain. In advanced uremia, a progressive, diffuse, and erosive gastritis occurs with thinning of the mucosa, diffuse hyperemia, and bleeding.[6] Earlier accounts of uremic gastroenterocolitis described "mild edema and hemorrhage in the mucosa and submucosa to confluent superficial ulcerations with frankly necrotic areas."[51] Several factors contribute to GI hemorrhage in uremia.

The most common cause of upper GI bleeding (UGIB) in CKD patients is peptic ulcer disease, with its origin from gastric greater than duodenal sources.[52] Vascular ectasia occurs more frequently in CKD patients than in those with normal renal function. The prevalence of vascular ectasia seems to be related to the duration and severity of renal disease.[52] Uremic bleeding diathesis results from coagulation factor abnormalities, alteration of the fibrinolytic system, vascular abnormalities, and platelet dysfunction.[53–55]

In patients with obscure GI bleeding (OGIB), the incidence of small bowel vascular lesions was significantly higher in CKD patients than in age- and sex-matched non-CKD patients when capsule endoscopy was used for evaluation.[56] CKD stage 4 or greater was identified as an independent predictor of having vascular lesions in patients with OGIB.[57]

Clinicians debate the role of hypergastrinemia in causing upper GI pathology. An elevated gastrin level may be seen with CKD, but this is not consistent.[58] Anephric patients have elevated serum gastrin levels,[59] whereas 50% of patients with acute renal failure and 55% with CKD have elevated serum gastrin levels.[59,60] CKD patients also have high pro-gastrin-releasing peptide levels.[61] A low basal acid output, a high basal intragastric pH, and an increased peak acid output occur in response to gastric acid secretion studies in patients with both acute and chronic renal failure.[59] Elevated serum gastrin levels result from inadequate renal inactivation of gastrin.[62] However, hypergastrinemia was associated with hypochlorhydria rather than increased acid secretion in ESRD patients.[60]

Ulcerogenic medications such as salicylates, corticosteroids, nonsteroidal anti-inflammatory drugs, and iron may cause gastritis or duodenitis. *H. pylori* infection may also contribute to UGIB. The prevalence of *H. pylori* infection appears to be higher in CKD patients than in the general population.[63,64] However, no clear relationship has been established between *H. pylori* infection, dyspeptic symptoms, and GI lesions in CKD patients.[63]

Patients with CKD and UGIB have a 30% higher hospitalization rate compared to patients without renal disease.[65] The CKD patient population clearly has a

higher risk of morbidity and mortality associated with GI hemorrhage.

Fortunately, timely diagnosis of CKD and early initiation of dialysis with adequate clearance have decreased the incidence and prevalence of gastritis. Moreover, early medical management with initiation of PPI and H_2 receptor antagonists in symptomatic patients effectively corrects gastritis and duodenitis. PPIs become potent antisecretory agents by inhibiting the gastric H,K-APTase in parietal cells. By raising the gastric pH above 6, PPIs result in improvement of coagulation and platelet aggregation.[66,67]

Severe bleeding resulting in hemodynamic instability requires hemodynamic resuscitation, blood product transfusion, and correction of any metabolic abnormalities and coagulopathy.

Specific interventions to address platelet dysfunction include administration of deamino-8-D-arginine vasopressin (DDAVP), cryoprecipitate, estrogen, and dialysis.[68] DDAVP shortens bleeding time in uremic patients.[69] A dose of DDAVP 0.3 μg/kg intravenously becomes effective within 30 minutes and lasts for at least 4 hours.[70] DDAVP releases von Willebrand factor from endothelial cells. Once von Willebrand factor has been released, additional doses of DDAVP will not cause additional von Willebrand factor release. If DDAVP does not shorten a prolonged bleeding time with the initial dose, additional administration will not correct an abnormal bleeding time. Clinicians should monitor for the development of side effects of DDAVP, such as hyponatremia or hypertension.

An intravenous infusion of cryoprecipitate provides functional coagulation factors such as factor VIII, von Willebrand factor, and fibrinogen.[71] Volume overload in CKD patients may limit the use of cryoprecipitate.

Administration of estrogen corrects uremia-induced platelet dysfunction.[72] Estrogen becomes effective in 6 hours and the effect lasts for approximately 2–3 weeks.[72] Unexpected vaginal bleeding may occur in postmenopausal female patients. Male patients may develop unwanted female features with prolonged use of estrogen. Informing patients of possible side-effects associated with treatment with estrogen is essential.

Red blood cell transfusion to achieve a hematocrit level above 26% shortens bleeding time.[73] This increase in the number of circulating red blood cells possibly displaces platelets closer to the vascular endothelium, thereby improving clot formation. However, red blood cell transfusion places patients at risk for viral infections and exposure to antigens, which may negatively impact their candidacy for a kidney transplant.

Initiation of dialysis removes the uremic toxins associated with coagulopathy.[68,74] Dialysis, while frequently effective for the short term, does not completely correct platelet dysfunction. Patients with CKD who do not have a vascular access for dialysis will require a central venous catheter to initiate dialysis. Dialysis may be temporary if there are no other indications to continue dialysis once bleeding has been controlled.

Surgical intervention for GI hemorrhage rarely becomes necessary due to recent advances in endoscopic and radiographic procedures. Hemostasis under endoscopic intervention occurs with electrocauterization, epinephrine (adrenaline)/saline injection, hemoclip,[75] and argon plasma coagulation.[76–78] Angiographic embolization injects particles (i.e. gelatin sponge, polyvinyl alcohol, metallic coils, N-butyl cyanoacrylate) directly in the blood vessel to stop bleeding.[79]

The most frequent causes for lower GI bleeding in CKD patients are angioectasias, diverticulosis, hemorrhoids, and ischemic colitis. Angioectasias can be found throughout the GI tract. The management can be either localized endoscopic therapy and systemic hormonal treatment, or surgery for refractory cases.[80,81]

The outcome of GI bleeding in CKD and ESRD patients has improved with the introduction of advanced interventional endoscopy, *H. pylori* infection diagnosis and management, and widespread use of PPIs.

Diverticulosis

Diverticulosis occurs in patients with CKD without polycystic kidney disease at a rate similar to that of the general population.[82] Constipation due to dietary restriction of fluid, fruits, and vegetables as well as the use of phosphate binders predispose CKD patients to diverticular disease.

A higher prevalence of diverticular disease was previously reported to exist among patients with autosomal dominant polycystic kidney disease (ADPKD) with ESRD compared with other ESRD patients without ADPKD.[82] However, a prospective study compared ADPKD patients not on dialysis, with family members without ADPKD, and healthy controls and found no significant difference in diverticular disease among the three groups. Further, there were no differences among the groups in the percentage with only right-colon diverticula, the mean number of diverticula, or the size of the largest diverticula.[83]

Management of diverticulosis and diverticulitis in CKD patients is similar to that in the general population. Instituting preventive measures and decreasing risk factors may decrease diverticulosis and the number of episodes of diverticulitis. Patients may correct constipation by eating high-fiber foods or using the appropriate laxatives. An episode of diverticulitis requires treatment with antibiotic therapy, bowel rest, and a low-fiber diet.

Constipation

Causes of constipation in CKD patients are similar to those in the general population[84] (Table 33.2). CKD patients may also encounter an additional cause for constipation, such as use of oral phosphate binders.

Dietary factors play a key role in the pathogenesis of constipation. Fluid restriction to avoid hyponatremia and volume overload, as well as the elimination of many high-fiber, potassium-rich fruits and vegetable may contribute to constipation in CKD patients.

Side effects from medications may cause or worsen constipation. Prescribing medications that contain calcium or aluminum, such as antacid medications, worsen constipation. CKD patients frequently use calcium-based medications, such as calcium carbonate, to treat metabolic acidosis and hyperphosphatemia. Other medications frequently used in CKD patients, which can cause or worsen constipation, include diuretics to treat hypertension and volume overload, iron to treat iron deficiency anemia, opiates or analgesics for pain management, and antidepressants.

Metabolic disorders that induce constipation include diabetes mellitus, acidosis, neuropathy, and hypokalemia. Endocrine disorders managed by nephrologists that may cause constipation include hypercalcemia, hyperparathyroidism, milk–alkali syndrome, and pheochromocytoma. Other diagnoses to consider include gastroparesis, irritable bowel syndrome, eating disorders, depression, neurological conditions, and hypothyroidism.

The approach to managing chronic constipation is shown in Figure 33.2. The first step in treating constipation requires addressing the underlying cause. The second step requires modification of diet, which may not always be possible in CKD patients. Finally, laxatives may help loosen the stool and stimulate bowel movement[84] (Table 33.3).

CKD patients have disorders associated with renal handling of magnesium and phosphorus, often associated with the development of hypermagnesemia and hyperphosphatemia. Magnesium-based laxatives such as magnesium citrate, magnesium hydroxide, magnesium oxide, and magnesium sulfate should be used with caution or avoided in CKD patients. Similarly, phosphate-based laxatives, such as sodium phosphate, should be avoided in CKD patients.[85] The following categories of laxatives may be used in CKD patients without further compromising renal function.

TABLE 33.2 Chronic Kidney Disease Constipation: Common Causes

Category	Example
Intake	Insufficient fluid intake
	Inadequate fiber in the diet
	Excessive dairy products
	Disruption of regular diet or routine
Organic	Hypothyroidism
	Neurological conditions
	Irritable bowel syndrome
	Colon cancer
	Inactivity
Medications	Overuse of laxatives
	Antacid medications containing calcium or aluminum
	Phosphate binders containing calcium
	Calcium-based base equivalent to correct metabolic acidosis
	Narcotics
	Antidepressants
	Oral iron
Psychosomatic	Depression
	Eating disorder
	Stress
	Rectal pain

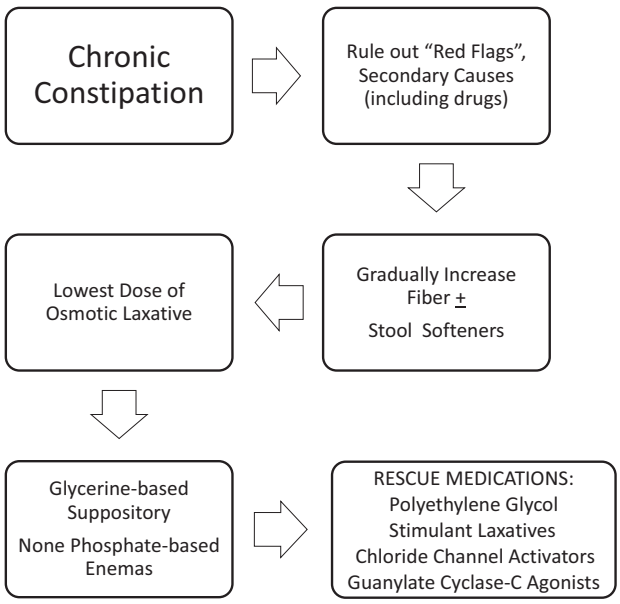

FIGURE 33.2 Algorithm recommended for the treatment of constipation.

TABLE 33.3 Chronic Kidney Disease Constipation: Appropriate Laxative Use

Type of Laxative	Generic Name
Bulk	
	Psyllium
	Calcium polycarbophil
	Bran
	Methylcellulose
	Guar gum
Osmotic Laxatives	
Poorly Absorbed Sugars	
Disaccharides	Lactulose
Sugar alcohol	Sorbitol
	Mannitol
Polyethylene glycol	Polyethylene glycol
Stimulant Laxatives	
Anthraquinones	Cascara sagrada
	Senna
Ricinoleic acid	Castor oil
Diphenylmethane derivatives	Bisacodyl
	Sodium picosulfate
Stool Softeners	Docusate sodium
Emollients	Mineral oil
Enemas, Suppositories	Mineral oil retention enema
	Tap water enema
	Soapsuds enema
	Glycerin suppository
	Bisacodyl suppository
Chloride Channel Activators	Lubiprostone
Guanylate cyclase-C agonists	Linaclotide
	Plecanatide

Adapted from Table 18.9. Lembo AJ, Ullman SP. Constipation. In: Feldman M, Friedman LS, Brandt LJ, editors. Feldman: Sleisenger and Fordtran's gastrointestinal and liver disease. *9th ed. Philadelphia, PA: Saunders; 2010:258–84; with permission from Elsevier.*

Bulk-forming laxatives generally contain fibers that add bulk and water to stool so that it can pass more easily through the digestive tract. Fiber can be found in foods such as apples, broccoli, prunes, bran, or medications such as psyllium, methylcellulose, and polycarbophil. The patient needs to drink adequate quantities of fluid, which may present an obstacle to using this class of laxative. Stool softeners, also known as emollients, such as docusate soften the stool for easier passage. Lubricants, such as mineral oil, allow for easier passage of stool.

The saline class of laxatives includes agents such as magnesium citrate, magnesium hydroxide, magnesium sulfate, and sodium phosphate. CKD patients should generally avoid this class of medication due to their kidneys' inability to efficiently excrete magnesium and phosphate. Stimulant laxatives enhance the movement of intestinal muscles and thus induce a bowel movement. Examples of stimulant laxatives include bisacodyl, senna, casanthranol, cascara, castor oil, and phenolphthalein. Osmotic laxatives increase the amount of fluid secreted within the intestines, resulting in softer stools. Examples of osmotic laxatives include lactulose, and polyethylene glycol. Enemas may be required in severe cases of constipation. Enemas containing just water, mineral oil, or soap may be used. Purgatives containing stimulants and osmotic agents may be used for colonoscopy bowel preparation. Phosphate-based purgatives have been associated with acute and chronic kidney injury and should be avoided.[86–88] Lubiprostone, a chloride channel activator, treats chronic idiopathic constipation and opioid-induced constipation. Linaclotide and plecanatide, guanylate cyclase-C agonists used in the treatment of chronic constipation or chronic irritable bowel syndrome, work by increasing the secretion of chloride and water in the intestines, resulting in softer stools and stimulating bowel movements.[89,90]

Diarrhea

Diarrhea describes stools that appear loose and watery. Diarrhea in CKD patients may occur because of an alteration in fecal bile acids and the presence of unusual keto-bile acids and low levels of deoxycholic acid.[91]

In general, diarrhea tends to be self-limiting. A patient with persistent diarrhea (greater than 4 weeks) requires further evaluation. The evaluation procedure for patients with CKD mimics that for patients with normal renal function. Patients with CKD have increased risks of incident and recurrent *Clostridium difficile*-associated diarrhea.[92]

Long-term ongoing diarrhea may result in derangements in volume, electrolyte, and acid–base status. A host of electrolytes such as potassium, magnesium, sodium, chloride, and bicarbonate, among others, can be lost with diarrhea. Excessive sodium depletion results in hypotension with or without orthostasis. Volume replacement with water will result in hyponatremia in CKD patients and will not correct hypotension. Stool bicarbonate loss may worsen metabolic acidosis due to renal disease.

Treatment consists of measures directed at the underlying disorder. Supportive care and symptomatic relief can be initiated while evaluating the etiology of diarrhea.

Electrolyte deficiencies usually require either oral or intravenous supplementation to restore normal total body levels. An ideal replacement solution for a patient with persistent diarrhea would contain sodium, potassium, magnesium, bicarbonate, and glucose. The replacement rate depends on the degree of volume and electrolyte depletion and on the extent of ongoing losses.

Antidiarrheal medications containing a heavy metal, such as bismuth, should be used with caution and avoided in late stages of CKD. Loperamide and diphenoxylate may be used, providing symptomatic relief.

General Complications After Surgery

Patients with CKD stages 3 and 4 have a higher incidence of postoperative infections than matched controls (60% vs. 40%) after colorectal surgery.[93] The exact mechanism underlying this finding remains unclear.

Gastroparesis

Gastroparesis consists of clinical symptoms and documentation of delayed gastric emptying.[94] Symptoms of gastroparesis include nausea, vomiting, early satiety, postprandial fullness, bloating, and upper abdominal pain. Complications of gastroparesis include esophagitis, Mallory–Weiss tear from chronic vomiting, malnutrition, volume depletion with AKI, electrolyte disturbances, and bezoar formation. Patients with diabetes mellitus and scleroderma often suffer from gastroparesis. The pathophysiology of gastroparesis in CKD remains undefined. Gastroparesis encompasses abnormalities of the autonomic nervous system, smooth muscle cells, and enteric neurons. The diagnosis of gastroparesis requires an upper endoscopy and gastric-emptying scintigraphy. Alternative diagnostic procedures include wireless capsule motility, antroduodenal manometry, and breath testing.[94]

Several studies have tried to delineate gastric-emptying time in both predialysis CKD and maintenance dialysis patients. There were conflicting results with regard to gastric-emptying duration in CKD patients.[95,96] Our understanding of how renal function affects gastric emptying needs further exploration.

Medical management of gastroparesis in CKD patients includes the use of dietary modification, prokinetic and antiemetic therapies.[97] A diet consisting of liquids and semisolids empties from the stomach more easily than solids. Fats and fibers tend to retard gastric emptying. Fat and fiber intake, therefore, should be minimized in CKD patients with gastroparesis. The recommended diet for patients with gastroparesis consists of multiple small low-fat, low-fiber meals daily. The patient should eat sufficient semisolids and drink liquids to obtain adequate calories, if solids cannot be tolerated. A patient may receive conflicting advice regarding fiber content if he/she also suffers from constipation. Instead of adding fiber to the diet, treatment of constipation with an osmotic laxative improves dyspeptic symptoms associated with gastroparesis as well as gastric-emptying delay. Additionally, CKD patients taking liquid diets have issues regarding volume and electrolyte disturbances. Approved treatment options for gastroparesis include metoclopramide and gastric electrical stimulation.[98,99]

There are several treatments for severe intractable gastroparesis, mostly in diabetic patients.[98] Such treatments may be applied to CKD patients, especially if they also have diabetes. The use of intrapyloric botulinum toxin injection *via* endoscopy shows promise.[98–100] The surgical approach to treat intractable gastroparesis involves resecting 70% of the stomach, including the antrum and pylorus, with closure of the duodenum and restoration of GI continuity with a 60 cm Roux-en-Y jejunal loop.[101] This procedure may correct intractable vomiting in patients with diabetic gastroparesis. Gastric peroral endoscopic myotomy (G-POEM), a minimally invasive surgical procedure, treats refractory gastroparesis by dissecting the muscular layer in the pylorus.[102] G-POEM results in improvement in the overall symptoms of gastroparesis, in gastric emptying, and in quality-of-life inventories.[103] The future use of ghrelin, ghrelin gene–derived peptides, and artificial analogues may hold promise for the treatment of gastroparesis as well as other GI disorders.[104]

Disorders of the Pancreas

Patients with CKD (and those receiving dialysis) may have elevated serum amylase, lipase, and trypsinogen levels in the absence of clinical pancreatitis. Multiple factors contribute to elevated enzyme levels, including decreased peripheral clearance, pancreatic overproduction, and increased release from the pancreas in addition to a decrease in renal clearance.[105–107]

Acute pancreatitis in CKD patients occurs frequently without known causes compared to non-CKD patients, suggesting a role of either renal failure or other factors.[108,109] IgG-4–related disease, a newly described form of autoimmune pancreatitis, may be associated with interstitial nephritis and membranous nephropathy.[110] CKD patients suffering from acute pancreatitis have high morbidity and mortality rates, regardless of

cause, compared to the general population.[109] The treatment of acute pancreatitis includes removing any offending agent, supportive care, and provision of symptomatic relief. Restriction of oral intake helps rest the pancreas. The main focus in treating acute pancreatitis involves appropriate volume resuscitation to maintain hemodynamic stability, keeping in mind that fluid may sequester in unconventional compartments. Analgesic administration aids in pain management. Patients may need nutritional support while on oral intake restriction. Once abdominal pain has resolved, oral feeding with foods low in fat and protein may be carefully started.

Disorders of the Gall Bladder

A cross-sectional study of hospitalized patients from Taiwan reported a higher incidence of gallstones in CKD patients compared to the general population after controlling for other risk factors. The etiology of this association remains unknown.[111]

GASTROINTESTINAL TRACT DISORDERS ASSOCIATED WITH RENAL INJURY AND CKD

Inflammatory Bowel Disease

In a case control study, 15.9% of patients with IBD (Crohn's disease and ulcerative colitis) had eGFR less than 60 mL/min/1.73 m^2.[112] Severe diarrhea and consequent fluid losses may cause decreased GFR. Rarely, the short bowel syndrome from multiple resections may be associated with hypochloremic metabolic alkalosis and decrements in GFR requiring aggressive volume repletion and blockade of gastric hypersecretion to correct renal functional, acid–base and volume disorders.[113] Crohn's disease may also be associated with enteric hyperoxaluria, as well as nephrocalcinosis and nephrolithiasis, with subsequent effects on renal function.[114]

Renal insufficiency from AA amyloidosis occurs as a rare complication of longstanding, uncontrolled IBD (especially Crohn's disease), but its incidence may be decreasing with better control of disease.[115]

Other rare causes of renal failure associated with IBD include glomerulonephritis and interstitial nephritis (including drug-induced interstitial nephritis especially with treatment using aminosalicylates).

Renal events associated with IBD have decreased due to a better understanding of the disease and its treatment. IBD pharmacotherapy currently includes aminosalicylates, antibiotics, corticosteroids, immunomodulators, and anti-TNF agents. Volume resuscitation to maintain hemodynamic stability during acute flares may limit the occurrence of AKI. A patient not responding to IBD medical management will require surveillance for renal complications.

Gastric Bypass and Renal Injury

Patients undergoing Roux-en-Y gastric bypass surgery develop kidney stones and renal injury. These patients usually exhibit hyperoxaluria or hypocitraturia.[116–118] Renal biopsies performed on patients who underwent Roux-en-Y gastric bypass with elevated serum creatinine concentration (S[Cr]) showed both acute and chronic changes.[119] Renal pathology revealed diffuse tubular degenerative changes, abundant tubular calcium oxalate deposits, and varying degrees of tubulointerstitial scarring.[119] Renal pathology also showed glomerulosclerosis, perhaps related to underlying conditions such as diabetes mellitus, obesity, and hypertension.[119] Postoperative decrease in GFR frequently resulted in rapid progression to a dialysis-dependent status.[119] Institution of pharmacotherapy aims to reduce hyperoxaluria and hypocitraturia. Potassium citrate or calcium citrate administration inhibits bone resorption by providing bioavailable calcium, reducing urinary saturation of uric acid, and increasing the inhibitory activity against calcium oxalate agglomeration by providing alkali, which increases urinary pH and citrate.[120]

Medications Causing Renal Injury

GI-associated medications may cause acute and chronic renal injury. CKD patients or those at high risk of developing kidney disease should use these medications with caution.

Case reports and case series describe renal injury (nephrocalcinosis and irreversible renal failure) after using oral sodium phosphate preparations.[86,88,121–123] Risk factors for kidney injury with oral sodium phosphate include hypertension, volume depletion, reduced GFR, or use of medications such as angiotensin converting enzyme inhibitors, angiotensin receptor blockers, or diuretics.[123] Kidney biopsies in patients with acute phosphate nephropathy show an interstitial pattern of calcium and phosphate deposition.[86] This class of medication should be avoided in patients with CKD or patients with these risk factors.

Medications used for treating IBD such as aminosalicylates (including mesalamine) have been associated with the development of interstitial nephritis.[124] Early identification and withdrawal of these drugs can lead to a partial or complete reversal of renal dysfunction.

PPI use has been associated with a higher risk of incident CKD.[46] The PPI class has also been associated with an increased risk of dementia,[125,126] *C. difficile* diarrhea and recurrence,[127,128] hypomagnesemia,[129] pneumonia,[130] vascular calcification,[131] neutropenia,[132] and bone fracture.[133] Many of these disorders have negative effects on kidney function.

Gut Microbiome

The gut microbiome plays important roles in both the maintenance of health and the pathogenesis of disease. Gut microbiome dysbiosis, resulting from alterations of composition and function of the gut microbiome and disruption of gut barrier function, exists in patients with CKD. Gut microbiome dysbiosis generates excessive amounts of uremic toxins. Most of them are derived from the unbalanced fermentation of nitrogen compounds in relation to nondigestible carbohydrates, such as p-cresyl sulfate and indoxyl sulfate in particular. The impaired intestinal barrier permits translocation of these toxins into the systemic circulation. These uremic toxins have been implicated in the progression of CKD, development of cardiovascular disease, and risk of death in CKD patients.[134,135] Evidence suggests that the gut microbiome is altered in patients with CKD.[136] Several factors contributing to gut microbiome dysbiosis in CKD include decreased consumption of dietary fiber, constipation, impaired protein assimilation, antibiotic use, and iron therapy.[134]

DISEASES AFFECTING THE KIDNEY AND THE GASTROINTESTINAL TRACT

Amyloidosis

Amyloidosis results from extracellular deposition of insoluble fibrillary protein in various organs. Amyloidosis may affect the entire GI tract, causing symptoms of macroglossia, vomiting, hemorrhage, and diarrhea. The spleen may become enlarged with risk of rupture. The diagnosis requires a tissue sample. When a kidney biopsy cannot be performed to diagnose CKD due to amyloidosis, tissue from the duodenum obtained during an upper endoscopy had a high sensitivity for diagnosing amyloidosis and highly correlated with the presence of renal amyloidosis.[137] In subjects with kidney biopsy proven AA amyloidosis, the frequency of GI amyloid deposition was duodenum 97%, antrum and rectal 76%, esophagus 59%, and gingival mucosa 32%.[137] GI involvement rarely occurs with AL amyloid, presenting in 8% of biopsies. Only 1% of patients had clinical manifestations.[138] The extent of GI involvement in patients with dialysis-related (β-2 microglobulin) amyloidosis remains unknown.

The treatment of AL amyloidosis has advanced rapidly with disease stabilization often occurring in patients treated early with antiplasma cell therapy.[139] Similarly, the use of targeted therapy against inflammatory cytokines in autoimmune disease has been associated with a decreased incidence of AA amyloidosis.[140] GI involvement may respond to symptomatic treatment (i.e. octreotide and antimotility agents for diarrhea).[141]

SUMMARY

GI symptoms and disease are common in CKD patients and may significantly impact quality of life and nutritional status. GI disorders may range from mild symptoms such as dysgeusia to life threatening ailments such as hemorrhage.

Many of the GI manifestations may have correctable underlying etiologies and should not be automatically ascribed to the uremic state. Close collaboration with the gastroenterologist is critical in elucidating and treating the cause of GI symptoms and hemorrhage. There are effective treatments currently available for symptomatic relief of common symptoms such as hiccups, constipation, nausea, and vomiting in CKD patients.

Ongoing research provides new insights into the relationship between the GI system and the kidney, with increasing awareness of their codependence in disease mechanism.

QUESTIONS AND ANSWERS

Question 1

A 61-year-old woman with CKD stage 4 presented with abdominal pain and bloody emesis. She has hypertension and type 2 diabetes mellitus. She did not have any overt uremic symptoms.

On examination, her blood pressure was 150/90 mmHg, pulse 88 beats per minute, and respiratory rate 20 breaths per minute. The patient presented with normal lung sounds on auscultation and percussion. On cardiac examination she had normal S1, S2 sounds without murmurs, or rub. The abdominal examination did not reveal any tenderness, masses, or organomegaly. She had 1+ pedal edema. She did not have asterixis.

Laboratory values revealed the following:

S[Na]139 mEq/L
S[K] 4.9 mEq/L
S[HCO3] 21 mEq/L
S[Cl] 105 mEq/L
BUN 98 mg/dL
S[Cr] 4.1 mg/dL
Glucose 188 mg/dL
S[Ca] 8.5 mg/dL
Hgb 8.3 g/dL
Hct 24%
Platelet count 200,000/μL

She underwent an upper endoscopic procedure.

Which of the following etiologies most likely contributed to upper GI bleeding in this patient?

A. Gastric cancer
B. Mallory Weiss tear
C. Peptic ulcer
D. Esophageal varices
E. Hiatal hernia

Answer: C

Peptic ulcer (C) most likely contributed to upper GI bleeding in this patient.

Peptic ulcer disease (gastric greater than duodenal) represents the most common cause of upper gastrointestinal bleeding (UGIB) in patients with CKD. Vascular ectasia occurs more frequently in patients with CKD than in those with normal renal function, and its prevalence seems to be related to the duration and severity of renal disease. Patients with CKD do not have an increased risk of gastric cancer. Mallory–Weiss tear may be seen with forceful vomiting. Esophageal varices accompany liver disease such as cirrhosis. Hiatal hernia does not appear to be more frequent in CKD patients. Increased intraabdominal pressure may unmask any abdominal hernia in a patient performing PD.

Question 2

A 62-year-old woman with CKD stage 4 has GI bleeding from duodenitis. She has a long history of left knee pain associated with a sport injury sustained as a young adult. She takes over-the-counter pain medications for symptomatic relief. Over the last few years she alternates between nonsteroidal anti-inflammatory medications and corticosteroids to treat her knee. On a routine medical examination five years ago, she had an elevated S[Cr] and bland urine. She underwent a kidney biopsy, which showed interstitial nephritis consistent with analgesic nephropathy. Last week, she complained of a constant dull mid epigastric discomfort, which worsened with eating food, and she saw tarry stools. A gastroenterologist diagnosed GI bleeding from duodenitis.

Which of the following does **not** contribute to upper GI hemorrhage in this patient?

A. Ibuprofen ingestion
B. Platelet dysfunction
C. Anemia
D. Corticosteroid use
E. Vitamin D supplementation

Answer: E

Vitamin D supplementation does not contribute to upper GI hemorrhage. Ulcerogenic medications such as salicylates, corticosteroids, nonsteroidal anti-inflammatory drugs, and iron may cause gastritis or duodenitis.[142] Thus, medications such as ibuprofen and corticosteroids can cause GI hemorrhage. CKD patients have platelet dysfunction as demonstrated by a prolonged bleeding time.[53–55] In addition, fewer red blood cells are trapped by the fibrin clot in the presence of anemia.

Question 3

A 63-year-old man has CKD stage 4 from hypertension. He requires four medications for adequate blood pressure control. A gastroenterologist diagnosed him with upper GI bleed and started him on a proton pump inhibitor last month. Persistent anemia and tarry stools led to his readmission to the hospital.

On physical examination, his blood pressure was 100/60 mm Hg with orthostatic changes, pulse 100 beats per min, respiratory rate 20 breaths per minute, and temperature 98.6°F. He had normal lung sounds to auscultation and percussion. He had normal S1 and S1 heart sounds without murmurs or rub. The abdominal exam did not reveal any tenderness, masses, or organomegaly. He had no pedal edema. Fecal occult blood test was positive.

Laboratory results:

PT: 13.0 seconds
INR: 1.0
PTT: 25 seconds
Bleeding time: greater than 15 minutes
Hgb: 7.0 g/dL
Hct: 21%
Platelet count: $300 \times 10^3/\mu L$
S[Cr]: 3.2 mg/dL
eGFR: 24 mL/min/1.73 m^2
BUN: 120 mg/dL

Which of the following should NOT be included in his treatment plan at this time?

A. Administer estrogen
B. Transfuse with packed red blood cells
C. Administer fresh frozen plasma
D. Administer DDAVP 0.3 μg/kg IV
E. Initiate hemodialysis

Answer: E

Initiation of hemodialysis (Answer E) does not belong in his treatment plan at this time. Although estrogen takes several days to become effective, it corrects prolonged bleeding time in uremic patients.[72] Estrogen may be used as a second tier agent to correct platelet dysfunction. This patient has severe anemia with hemodynamic compromise as evidenced by relatively low blood pressure and tachycardia. Volume resuscitation could be accomplished with crystalloid, colloid, or blood. Packed red blood cell transfusion would correct his volume deficiency as well as his anemia. In addition, an adequate number of red blood cells help plug the fibrin mesh in preparation to form a clot.[73] Fresh frozen plasma may be given if he has active bleeding and abnormal coagulation parameters.[71] Fresh frozen plasma also aids in correcting a prolonged bleeding time. Uremic platelets have a functional defect affecting the interaction of von Willebrand factor with glycoprotein IIb-IIIa. DDAVP releases von Willebrand factor from endothelial cells.[69,70] Once von Willebrand factor has been released, additional doses of DDAVP will not cause additional von Willebrand factor release. If DDAVP does not correct bleeding time with the initial dose, additional dosing will not correct an abnormal bleeding time.

His level of eGFR does not suggest the need for initiation of dialysis. An elevated BUN associated with upper GI bleeding is a result of nitrogen absorption from the gut. Intestinal bacteria with urease convert urea to nitrogen, which in turn is absorbed.

Question 4

A 64-year-old man has CKD stage 5 not on dialysis from polycystic kidney disease. He takes four antihypertensive medications to control his blood pressure. He presented to the emergency department with right-sided abdominal pain. The pain had no relationship to eating, bowel movements, or activity. He denied seeing black tarry stools or bright red blood in the stool.

On physical examination, his blood pressure was 140/90 mm Hg, pulse 70 beats per min, respiratory rate 12 breaths per minute, and temperature 100.6°F. He had normal lung findings on auscultation and percussion. He had normal heart sounds without murmurs or rub. The abdomen did not show any distention or protrusions. He expressed pain and rebound tenderness to abdominal palpation at the level of the umbilicus. The rectal examination did not reveal any hemorrhoids, masses, or tenderness. He had a negative Murphy's sign. His lower extremities did not have edema. Fecal occult blood test was positive.

On further questioning, he disclosed that he suffers from constipation. He tried to eat more vegetables but failed to maintain a daily intake of three servings. He takes docusate regularly and bisacodyl at least 4–5 times per month.

Laboratory results:

WBC: $11.6 \times 10^3/\mu L$
Hgb: 11.0 g/dL
Hct: 33%
Platelet count: $250 \times 10^3/\mu L$
S[Cr]: 6.2 mg/dL
eGFR: 10 mL/min/1.73 m^2
BUN: 70 mg/dL
Total Bilirubin: 0.2 mg/dL
AST: 15 IU/L
ALT: 15 IU/L

The patient awaits a CT scan of the abdomen.

What would be the most likely diagnosis among the differential diagnosis for right-sided abdominal pain in this patient?

A. Appendicitis
B. Cholecystitis
C. Diverticulitis
D. Abdominal wall hernia with bowel incarceration
E. Abdominal angina

Answer: C

Diverticulitis (Answer C) most likely caused his right sided abdominal pain.[82,83] Constipation due to dietary

restriction of fluid, fruits, and vegetables as well as the use of phosphate binders predispose dialysis patients to diverticular disease. The history and physical examination were not consistent with appendicitis, cholecystitis, or abdominal wall hernia. An imaging study, such as the abdominal CT scan, is a useful tool to differentiate these diagnoses. He did not have any episodes of low blood pressure or discomfort with meals to suggest abdominal angina.

Question 5

A 65-year-old woman with CKD stage 5 has a history of diabetes mellitus, hypertension, gout, coronary artery disease, congestive heart failure, and sleep apnea. She takes medications for her medical conditions with fair control and uses a continuous positive airway pressure device treatment of sleep apnea. She presented to the renal clinic for a follow-up visit and preparation for dialysis. She described nausea, morning heaving about once a week, loss of appetite, and a metallic taste.

On physical examination, she has a blood pressure of 150/90 mm Hg, pulse 63 beats per minute, respiratory rate 20 breaths per minute, and temperature 98.6°F. She has neck vein distention. She has bibasilar rales on lung examination. She has a grade 2/6 systolic ejection murmur but no rub on cardiac examination. The abdominal examination reveals normal bowel sounds on auscultation. The abdomen feels soft on palpation, and she has no guarding. She has 1+ pedal edema. She does not have asterixis.

Symptoms of nausea, vomiting, loss of appetite, and bad taste in the mouth may lead to all of the following **except**:

A. Poor quality of life
B. Weight loss
C. Low serum albumin (S[Alb]) level
D. Increased physical pain
E. Decreased urine output

Answer: D

Increased physical pain (Answer D) rarely accompanies GI uremic symptoms. Symptoms of nausea and vomiting may be unpleasant but rarely give rise to pain. Symptoms of nausea, vomiting, loss of appetite, and bad taste cause poor quality of life. Working individuals find it difficult to report to work and interact with coworkers. Patients may find it difficult to engage in activities outside of their home due to ongoing symptoms. Patients lose weight when they eat less. Poor protein intake results in a fall in S[Alb] level. The S[Alb] reflects nutritional status as well as inflammation in patients with CKD. Uremic patients frequently have cachexia and malnutrition from poor nutritional intake. Poor nutritional intake results from either dietary restriction or uremic symptoms. Nausea, vomiting, and poor intake may result in volume, acid/base, and electrolyte disorders.[4]

Question 6

A 66-year-old man with CKD stage 5 not on dialysis with a history of diabetes mellitus, hypertension, gout, coronary artery disease, congestive heart failure, and peripheral vascular disease presents with a complaint of constipation. He noticed occasional constipation for about three months. However, he now feels that if he does not take a laxative daily, he would not have a bowel movement.

He takes medications to control his diabetes mellitus, hypertension, gout, heart failure, and peripheral vascular disease. His medications include Lantus, Novolog, amlodipine, carvedilol, lisinopril, furosemide, calcium carbonate, vitamin D, metoclopramide, docusate, and bisacodyl.

On physical examination, he has a blood pressure of 150/90 mm Hg, pulse 72 beats per minute, respiratory rate 20 per minute, and temperature 98.6°F. He has neck vein distention and bibasilar rales. He has regular heart sounds without murmur or rub. The abdominal examination reveals normal bowel sounds. The abdomen feels soft on palpation, and he has no guarding. He has 2+ pedal edema. He does not have asterixis.

Laboratory results reveal the following: S[Na] 135 mEq/L, S[K] 5.4 mEq/L, S[Cl] 100 mEq/L, S[HCO3] 19 mEq/L, BUN 88 mg/dL, S[Cr] 7.1 mg/dL, S[Ca] 9.9 mg/dL, and glucose 133 mg/dL.

Possible mechanisms for constipation include all of the following **except**:

A. Ingestion of phosphate binder
B. Fluid restriction
C. Fruit restriction due to hyperkalemia
D. Gastroparesis
E. Decreased physical activity

Answer: E

Decreased physical activity does not cause constipation. Physical activity does not appear to play a role in bowel habits. Patients who remain bed-bound continue to have normal bowel movements. On the other hand, physically active people who eat a low fiber diet can suffer from constipation. Ingestion of phosphate binders, especially calcium-based medications, may cause constipation. Fluid restriction makes the stool hard and difficult to pass. Fruits have fiber and thus add bulk to stool. Most fruits contain high potassium content and

thus intake must be restricted in patients who present with hyperkalemia. Fruit ingestion plays an important role in preventing constipation. However, patients with gastroparesis eat a low-fiber diet to aid in gastric emptying. Gastroparesis may be associated with constipation. Treatment of constipation with an osmotic laxative improves dyspeptic symptoms and gastric-emptying delay. A high-fiber diet delays gastric emptying and therefore may worsen gastroparetic symptoms.[84]

Endocrine Complications of Chronic Kidney Disease

Laura LaFave[a], *Danielle Haselby*[b], *Allyson Hart*[b]

[a]Division of Endocrinology, Hennepin Healthcare, University of Minnesota Medical School, Minneapolis, MN, United States; [b]Division of Nephrology, Hennepin Healthcare, University of Minnesota Medical School, Minneapolis, MN, United States

Abstract

Endocrine disorders are common in chronic kidney disease (CKD), and the interaction between the endocrine and renal systems is complex. Hormones are both synthesized and excreted by the kidneys, and endocrinopathies also play a role in uremic dysfunction. We review the hypothalamic–pituitary–target organ axis and discuss how this axis is affected by CKD, with emphasis on target endocrine glands including the gonads, adrenal glands, liver, thyroid gland, and adipose tissue.

INTRODUCTION

The hypothalamic–pituitary–target organ axis, which governs the endocrine system, is exquisitely sensitive to changes in the body's homeostasis (Figure 34.1). The kidneys are complex organs that both synthesize and degrade hormones. Because of the interaction between these organ systems, endocrinopathies are common in chronic kidney disease (CKD) and play a role in the development of the uremic syndrome, such as protein calorie malnutrition, sexual dysfunction, and menstrual abnormalities. The mechanisms underlying endocrine disturbances in CKD are complex, including altered feedback mechanisms, changes in hormone production, and alterations in transport as well as metabolism and clearance (Table 34.1). The effects of endocrinopathies in CKD may manifest either due to changes in hormone concentrations themselves, or changes in the target organ response (Table 34.2). Some hormones, such as erythropoietin and 1,25 OH vitamin D, are produced by the kidneys, and inadequate levels of those hormones are seen in patients as kidney function declines. In addition, sexual dysfunction is a highly prevalent and multifactorial comorbidity in patients with CKD. We discuss both the clinical and laboratory endocrine abnormalities that may present in patients with CKD, with emphasis on target endocrine glands affected in CKD, including the gonads, adrenal glands, liver, thyroid gland, and adipose tissue.

MALE GONADAL AXIS IN CKD

The gonads are particularly prone to disturbances in the hypothalamic–pituitary (HP) axis in general, and there is no exception to this in the setting of CKD. In men, follicle stimulating hormone (FSH) and luteinizing hormone (LH), both gonadotropins produced by the pituitary gland, are elevated. FSH in men is responsible for spermatogenesis, stimulating testicular growth, and production of testosterone-binding globulin in the Sertoli cells. Although FSH is elevated in men with CKD,[1] they have decreased spermatogenesis and lessened fertility or infertility, possibly caused by primary testes dysfunction or resistance at the level of the testes to the effects of FSH. LH is also elevated in men with CKD, due to loss of pulsatile release of gonadotropin releasing hormone (GnRH) from the hypothalamus.

Hyperprolactinemia, common in men with CKD, likely contributes to loss of regulation of the gonadotropins. There is also decreased renal clearance of both LH and GnRH. In men, LH stimulates production of testosterone in the Leydig cells of the testes. However, despite elevations of gonadotropins, between 26% and 66% of men with CKD have low levels of testosterone (hypogonadism).[1] This state of hypergonadotrophic hypogonadism may reflect a resistance to gonadotrophic effects at

the level of the testes, possibly exacerbated by hyperprolactinemia. Because testosterone circulates bound to sex hormone binding globulin (SHBG), measurement of testosterone levels in men with CKD can be complicated by the altered protein metabolism that may be present due to the underlying kidney disease. Evaluation should include measurement of fasting morning samples on two occasions, with both total and free testosterone levels. Free levels can be calculated using the measured total testosterone level and SHBG.[2]

Hypogonadism in men with CKD presents clinically with low libido, erectile dysfunction, anemia, fatigue, depression, and decreased muscle mass.[3] In addition to symptoms, low testosterone levels have been linked to increased arterial stiffness and endothelial dysfunction that may increase the risk of cardiovascular (CV) events and disease.[4] Hypogonadism is also associated with decreased bone mineral density and osteoporosis, with increased risk of fractures in men with CKD.[5] Testosterone therapy in men with CKD may improve muscle mass and bone mineral density, but there is scant evidence showing that it ameliorates anemia or prevents fractures. Treatment with testosterone replacement using topical or intramuscular androgens is reasonable to consider in men with CKD with testosterone levels under 200 ng/dL, those who are symptomatic, or in those at high risk for fracture.[6] Adverse effects of testosterone therapy include benign prostatic hypertrophy, increased rate of prostate cancer, erythrocytosis, and venous thromboembolism. Perhaps most concerning in the CKD population is the possible increased risk of

CV disease, although studies continue to be conflicted and inconclusive. There are no randomized controlled trials of testosterone treatment in hypogonadal men with CKD.

FEMALE GONADAL AXIS IN CKD

Disorders of menstruation and fertility are very common but underrecognized in women with CKD. In a study of 100 women with CKD or end-stage renal disease (ESRD) who were referred to gynecology by nephrologists, 39% were referred for menstrual disturbances and 12% for menopause. However, 85% of those women were found to have menstrual disorders and over a third were in menopause, indicating that these endocrine disturbances were underestimated.[7] Nearly half of these women were aged less than 40 years, with 14% of the women under 40 found to have primary ovarian failure.

Most of the available literature evaluating sex hormones in women with kidney disease focuses on ESRD. Data on gynecologic issues and fertility across the spectrum of CKD are lacking. As CKD progresses, the normal cyclic release of GnRH is compromised. This in turn causes the loss of pulsatile secretion of the gonadotropins (LH and FSH) from the pituitary gland.

Hyperprolactinemia is also common in women with CKD. High levels of prolactin result from both reduced renal clearance, as well as upregulation of hormone production due to CKD-related inhibition of dopaminergic activity in the pituitary gland.[8] Increased prolactin levels interfere with normal cyclic GnRH secretion. The resulting loss of pulsatile LH and FSH release leads to the decline and ultimate absence of estradiol release. Women with CKD have high rates of irregular or absent menses, anovulation, and infertility. Hyperprolactinemia is clearly not the sole cause of ovarian dysfunction in CKD, however, as evidenced by the fact that treatment with bromocriptine (a dopamine agonist) lowers prolactin levels but does not restore gonadotropin response.[9]

One of the most significant effects of estrogen deficiency in women with CKD is bone disease. Women with amenorrhea have lower bone mineral density compared with menstruating female patients with CKD. Some small interventional studies show benefit of treatment with transdermal estrogen[10] or selective estrogen receptor modulators.[11] However, the safety and efficacy of long-term treatment with estrogen or SERMs in women with CKD has not yet been established.

Hypoestrogenemia is also a risk factor for hyperlipidemia and CV disease in women with CKD. In the general population, premenopausal age women enjoy relative protection from CV disease compared with age-matched men. Women less than 45 years old with ESRD treated with hemodialysis have similar rates of CV mortality compared to their male counterparts,[12] suggesting that hypoestrogenemia adversely affects CV risk in this population. Hyperprolactinemia is also associated with CV events and mortality in patients with CKD,[13] suggesting a possible therapeutic target for CV and renal protection.[14]

THYROID COMPLICATIONS OF CKD

Thyroid hormones are integral to the development of kidney size and function.[15] Thyroid hormones (mostly T4 and some T3) are produced in the thyroid gland. Thyrotropin Releasing Hormone (TRH) from the hypothalamus stimulates the production of thyrotropin, or TSH, in the pituitary. TSH in turn stimulates the production and release of mostly T4, as well as some T3, in the target gland. In the circulation T4 is converted into T3 by deiodinase enzymes. T3 is the more active form of thyroid hormone. TSH, T4, and T3 are feedback on the hypothalamus and pituitary in a complex and elegant loop. Patients with congenital hypothyroidism have an increased prevalence of kidney and urogenital malformations, indicating the important role these ubiquitous hormones play in renal development.[16] Thyroid hormones act on nuclear receptors in target cells and effect gene transcription, but they can also cause nongenomic effects by binding to different components of the cell membrane and plasma. In doing so they regulate protein synthesis and cell growth. Through these mechanisms, thyroid disease also alters renal physiology, with both direct renal and indirect CV effects on glomerular filtration rate (GFR) (Figure 34.2), as well as on renal tubular ion transport, resulting in alterations in sodium, water, and acid excretion.[17] Hypothyroidism is a well-recognized cause of hyponatremia due to a combination of decreased renal blood flow, impaired urinary dilution, and increased fractional excretion of sodium.[18,19] Hyperthyroidism is associated with polyuria secondary to increased water and solute excretion.[20]

Thyroid hormone levels themselves may also be altered in CKD. The most commonly observed thyroid function test change in CKD patients is low T3 levels. One study of 2284 CKD patients with normal TSH levels demonstrated an increasingly high prevalence of low T3 levels with declining GFR.[21] The conversion of T4 to T3 is lowered by malnutrition, inflammation, nonthyroidal illness, and some medications. Low T3 levels may be an indication of illness in patients with CKD.[22]

Because T4 is extensively bound to proteins, serum T4 levels in CKD patients may be low. Free T4 (unbound hormone) may be measured directly in serum, but typical analog assays of free T4 depend on protein

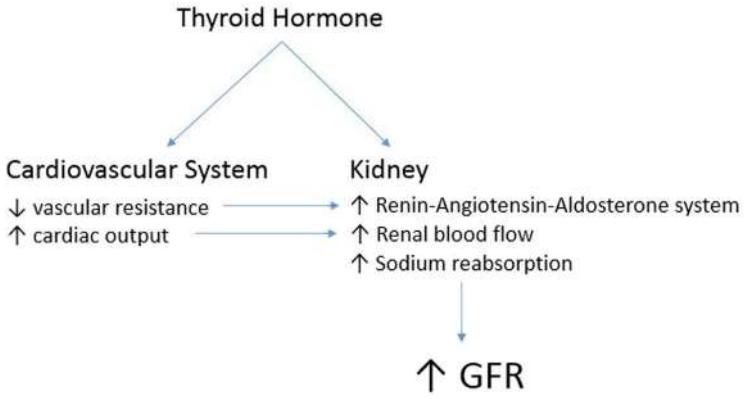

FIGURE 34.2 Effect of thyroid hormone on glomerular filtration rate (GFR).

binding, and also may not be reliable when circulating proteins or their levels are abnormal or in the presence of substances that inhibit protein binding (such as uremic toxins).[23] Measurement of Free T4 *via* equilibrium dialysis and radioimmunoassay can overcome this limitation by separating bound and free T4 and measuring the hormone directly.[24]

HYPOTHYROIDISM AS A COMPLICATION OF CHRONIC KIDNEY DISEASE

Although normal kidney development and function is dependent on a euthyroid state, it is well known that thyroid dysfunction, specifically subclinical and overt hypothyroidism, is more common in patients with CKD.[25,26] In over 14,000 participants in the Third National Health and Nutritional Examination Survey, patients with estimated glomerular filtration rate (eGFR) <30 mL/min/1.73 m^2 had twice the risk of hypothyroidism (defined as TSH greater than 4.5 mIU/L or treatment with levothyroxine) compared with patients with eGFRs >90 mL/min/1.73 m^2.[27]

There are several mechanisms by which CKD may lead to thyroid dysfunction. The metabolic acidosis commonly present in patients with CKD may result in thyroid hormone laboratory changes. Selenium is an important cofactor in the synthesis of thyroid hormone, and selenium deficiency is common in CKD patients. Iodine retention (from iodinated contrast[28] or high iodine diets[29]) because of impaired kidney function may also contribute to the development of hypothyroidism. Finally, heavy urinary protein losses in nephrotic syndrome may lead to total body thyroid hormone depletion, because most circulating thyroid hormone is protein-bound.[30]

Because both hypothyroidism and subclinical hypothyroidism are more common in patients with CKD, it is unclear whether treatment of patients with these conditions benefits kidney function. The benefit of treatment of subclinical hypothyroidism in general is widely debated in various clinical contexts. Historically, thyroid hormone deficiency was thought to be an adaptation to CKD, in that it allowed the body to conserve metabolism in catabolic renal patients.[31] However, more recent studies implicate an association between hypothyroidism and increased mortality in dialysis patients.[32] Some observational studies have shown that treatment with thyroid hormone replacement decreased CKD progression.[33] However, treatment with thyroid hormone does have a narrow therapeutic window. Overtreatment causing thyrotoxicosis could easily exacerbate protein catabolism, loss of bone mineral density, and increased risk of arrhythmia in an already vulnerable CKD patient population. Therefore, randomized trials evaluating the effect of thyroid hormone replacement in CKD patients are needed.

CORTISOL ABNORMALITIES IN CKD

The metabolism of adrenal hormones is also affected in CKD, although these abnormalities do not appear to be mediated through the HP axis. Kidneys metabolize cortisol and its metabolites, which are water soluble. The kidney is an important site of the conversion of active to inactive cortisol *via* 11-ß hydroxysteroid dehydrogenase type 2 (11-ßHSD2), which prevents unrestrained activation of the mineralocorticoid receptor by cortisol. In CKD, 11-ßHSD2 activity is reduced, and thus the half-life of cortisol is extended.[34] Free cortisol levels in plasma are disproportionately higher than total cortisol levels in patients with CKD, suggesting less binding of the hormone to albumin[35] and corticosteroid-binding globulin.

Higher levels of cortisol may be responsible for loss of bone density with resulting osteopenia or osteoporosis, redistribution of fat, and increased catabolism of protein

in CKD patients.[36] In addition, prehemodialysis patients with higher levels of cortisol were at higher risk of hospitalizations and malnutrition.[37] Because baseline levels of cortisol are higher in patients with CKD, it is reasonable to assume that evaluation of adrenal function may be affected in such patients. Cosyntropin stimulation testing with 1, 5, or 250 mcg of cosyntropin is normal in patients with CKD, as the diurnal variation in cortisol release is preserved.[38]

Testing for adrenal hyperfunction (hypercortisolism) is not reliable in patients with CKD. Therefore, the diagnosis of Cushing syndrome in patients with CKD is challenging. In patients without CKD, screening for hypercortisolism may be performed using urine, saliva, or serum. However, because urinary free cortisol (UFC) reflects glomerular filtration, 24-hour values are significantly lower in patients with CKD. Therefore, 24-hour urine collections for UFC levels are not reliable in CKD, as a falsely low UFC level can occur even at a GFR of 60 mL/min/1.73 m^2.[39] Although studies have shown preserved salivary cortisol levels in CKD patients,[40] midnight salivary cortisol tests to evaluate possible Cushing syndrome have not been validated in this population. Dexamethasone suppression with serum cortisol testing may be helpful in diagnosing hypercortisolism in patients with CKD, but it may require higher doses of dexamethasone to suppress the patients' cortisol level.[41]

Exogenous steroid metabolism is also altered in patients with CKD. Plasma protein binding of both dexamethasone and prednisolone is reduced. Dexamethasone clearance is increased, whereas prednisolone has decreased clearance. Although there are no adjustments provided in the drug labeling, attention should be paid to diminished dexamethasone or enhanced prednisolone clinical efficacy and adverse effects in CKD patients. The clearance of methylprednisolone is unchanged in patients with CKD.[42]

ADIPOSE TISSUE AND CKD

Adipose tissue is recognized as an endocrine organ, due to its production of a variety of biologically active substances, adipokines, which function as classically circulating hormones. Several adipokines have abnormal levels in patients with CKD, with varying clinical effects. Adiponectin is the most plentiful adipokine in the human circulation, acting as a cardioprotective protein, improving insulin sensitivity, and protecting the vascular system by suppressing the production of reactive oxygen species.[43] Despite the cardioprotective effects of adiponectin, however, elevated levels are a marker of increased mortality in patients with stage 3 and 4 CKD.[44] The mechanism underlying this association is unknown.

Leptin is also produced in adipocytes, and leptin levels are elevated in patients with CKD.[45] High levels of leptin are associated with vascular dysfunction and CV disease *via* reactive oxygen species and nitric oxide metabolites.[46] Furthermore, incomplete clearance of leptin by the kidneys leads to accumulation of proinflammatory cytokines, which may enhance renal damage.

Resistin is an adipokine that is increased in patients with CKD, principally due to reduced renal clearance. Resistin is found in the visceral adipose tissue—resident macrophages and is associated with inflammation, insulin resistance, and endothelial damage.[47] Serum levels of resistin are negatively associated with GFR.[48] Resistin promotes the expression of adhesion molecules, endothelin, and matrix metalloproteinases, leading to systemic vascular dysfunction.[49] High resistin levels were an independent risk factor for mortality in patients treated with hemodialysis.[50]

GROWTH HORMONE AXIS IN CKD

The growth hormone (GH) axis regulates the release of insulin-like growth factor (IGF), and is important in kidney development and disease.[51,52] Secretion of GH from the anterior pituitary is stimulated by GH-releasing hormone (GHRH) and inhibited by GH inhibiting hormone (GHIH, or somatostatin), which are then regulated *via* negative feedback from circulating GH. This axis affects renal plasma flow and sodium retention and volume expansion, through multiple mechanisms, likely through stimulation of the renin—angiotensin—aldosterone system. IGF-1 also plays a critical role in childhood growth and has anabolic effects in adults. GH deficient patients have been shown to have decreased total body water and extracellular volume, which corrects when they are treated with GH replacement. Similarly, patients with acromegaly and elevated GH levels have been found to have increased extracellular volume that normalizes after surgical removal of the GH-producing adenoma.[53]

Many derangements in the GH axis occur in CKD. Plasma GH levels may be normal or elevated in individuals with CKD. However, as in the case with gonadotropins, there is evidence of GH resistance at target organ sites. Children with CKD show growth retardation, and adults exhibit accelerated protein catabolism and protein malnutrition as a result of this resistance,[51] which is likely in part related to increased levels of circulating insulin-like growth factor binding proteins (IGFBPs) as well as impaired GH signal transduction through the JAK-STAT pathway.[54] In the setting of

CKD, production of IGFBPs in the liver is increased, and renal clearance of IGFBPs is diminished, leading to increased circulating levels. Given that insulin-like growth factor-1 (IGF-1) has a higher affinity for IGFBP than the IGF-1 receptor, high levels of IGFBP lead to decreased bioavailability of IGF-1.[55]

These effects are a particularly important clinical issue in children with CKD, where exogenous recombinant GH therapy should be considered for patients with eGFR <75 mL/min/1.73 m^2 and height in the third percentile, in whom other factors for poor growth including metabolic acidosis, hypothyroidism, and malnutrition have been excluded.[56]

CONCLUSION

Abnormalities in the HP axis, as well as altered target organ effects, are common as kidney function declines. Decreased clearance, changes in transport and metabolism, abnormal end-organ responses, and alterations in feedback mechanisms all play a role in the development of endocrinopathies, with both laboratory and clinical manifestations. Endocrine disorders also comprise many of the manifestations of the uremic syndrome, including protein calorie malnutrition, sexual dysfunction, and menstrual abnormalities. Clinicians caring for patients with CKD must be aware of these effects, as well as the increased prevalence of endocrine disorders in these patients. More research is needed to determine the optimal treatment of endocrine disorders in this population.

QUESTIONS AND ANSWERS

Question 1

Which of the following is a cause of infertility in men with CKD?

A. Low GnRH levels
B. Decreased FSH levels resulting in low testosterone
C. Elevated levels of gonadotropins (FSH and LH) resulting in high testosterone (hypergonadism)
D. Hyperprolactinemia resulting in loss of pulsatile release of GnRH and resistance to gonadotropins
E. Decreased pulsatile release of GnRH resulting in low gonadotropin and testosterone levels

Answer: D

CKD results in hyperprolactinemia, which inhibits the pulsatile release of GnRH as well as causing resistance to the gonadotropin hormones themselves. GnRH and gonadotropin levels are increased, not decreased, in CKD, therefore A, B, and E are not correct. Although FSH and LH are increased in CKD, testosterone levels are low (hypergonadotropic hypogonadism), likely due to resistance to the gonadotropins, therefore C is not correct.

Question 2

Which of the following is TRUE regarding women with CKD?

A. Hypoprolactinemia causes ovarian dysfunction women with CKD
B. Hypoestrogenemia may explain the increased risk of CV disease in women with CKD compared to women without CKD
C. Hypoestrogenemia has not been shown to increase the risk of bone disease in women with CKD
D. Bromocriptine, a dopamine agonist, has been shown to restore gonadotropin response in women with CKD
E. Hyperprolactinemia is common but is not associated with worse outcomes or infertility

Answer: B

In the general population, premenopausal women have a lower risk of CV disease compared to men. However, this difference is not seen in women with CKD, possibly due to hypoestrogenemia. Women with CKD tend to have hyperprolactinemia, rather than hypoprolactinemia, from both reduced renal clearance, as well as upregulation of hormone production due to CKD-related inhibition of dopaminergic activity in the pituitary gland, therefore A is not correct. Hypoestrogenemia is also a well-known risk factor for bone disease in women with CKD, therefore C is not correct. Bromocriptine (a dopamine agonist) lowers prolactin levels but does not restore gonadotropin response, suggesting that hyperprolactinemia is not the sole cause of ovarian dysfunction in women with CKD. Therefore, D is not correct. Finally, hyperprolactinemia is associated with both infertility and CV risk in women (E).

Question 3

Thyroid hormones have been found to have all of the following effects on the kidney EXCEPT:

A. Decreased renal blood flow
B. Upregulation of renin–angiotensin–aldosterone system
C. Increased sodium reabsorption
D. Increased water and solute clearance
E. Increased GFR

Answer: A

Thyroid hormones have both direct renal and indirect CV effects, resulting in increased GFR, sodium retention, water and solute clearance, and upregulation of the renin–angiotensin–aldosterone system, therefore B, C, D, and E are all true. Renal blood flow is increased, not decreased, by thyroid hormones through these mechanisms, therefore the correct answer is A.

Question 4

Which of the following is TRUE regarding thyroid function and patients with CKD?

A. Thyroid function tests can be interpreted the same way in patients with CKD as patients without CKD
B. Hypothyroidism is less prevalent in the CKD population than the general population
C. Thyroid replacement in patients with CKD and hypothyroidism have been shown to be efficacious in decreasing CKD progression in randomized clinical trials
D. CKD may increase risk of thyroid disease through iodine retention and urinary protein loss
E. Hypothyroidism is not associated with increased mortality in patients with CKD

Answer: D

Reduced iodine clearance as well as urinary protein loss of thyroid hormone may both contribute to the development of thyroid dysfunction due to CKD (Answer D). Thyroid function tests must be interpreted in caution in patients with CKD, as the typical analog assays of free T4 depend on protein binding and may not be reliable when circulating proteins levels are abnormal or in the presence of uremic toxins that inhibit protein binding, therefore A is not correct.

Hypothyroidism is more prevalent, not less prevalent, in CKD compared to the general population, and is associated with increased mortality, therefore B and E are not correct. Finally, although observational studies have shown that treatment with thyroid hormone replacement decreased CKD progression, randomized trials are lacking (therefore, answer C is not correct).

Question 5

All of the following statements are true regarding cortisol and CKD EXCEPT:

A. Cortisol levels are higher in patients with CKD due to decreased metabolism and increased half-life
B. Cortisol binding to albumin and corticosteroid binding globulin is altered in CKD, resulting in disproportionately higher free cortisol levels
C. Testing for Cushing syndrome in patients with CKD can be performed accurately using urine, saliva, or serum levels
D. Dexamethasone suppression tests may require higher doses of dexamethasone to suppress cortisol levels in patients with CKD
E. Clinical efficacy and adverse effects should be evaluated carefully in patients with CKD receiving exogenous steroids given the difference in clearance

Answer: C

Testing for Cushing syndrome in patients with CKD is challenging, as UFC may be falsely low due to decreased clearance and dexamethasone suppression testing may require higher doses, therefore C is the correct answer. Answers A, B, D, and E are all true statements.

Question 6

All of the following statements are true about hormone disorders in CKD EXCEPT:

A. Elevated adiponectin levels are associated with increased mortality
B. Circulating levels of growth hormone levels may be elevated in CKD, but there is impaired GH signal transduction *via* the JAK−STAT pathway
C. Children with GH deficiency and CKD should not be treated with GH
D. Resistin is elevated in CKD and is associated with insulin resistance, inflammation, and endothelial damage
E. Growth hormone has a role in renal function in adults as well as children with CKD

Answer: C

Growth hormone deficiency is particularly relevant in children with CKD, who should be considered for GH replacement therapy when other modifiable factors for short stature have been optimized, therefore C is the correct answer. Although treatment with GH is not indicated in adults with CKD, it does play a role in renal plasma flow and sodium retention, therefore answer E is a true statement. Answers A and D are also true statements.

[b]Departments of Medicine and Cell Biology, Washington University, St. Louis, MO, United States

Abstract

The disruption of a multiorgan systems biology produced by renal injury in early stages of kidney injury and disease was unrecognized until its elucidation during the investigation of the chronic kidney disease–mineral bone disorder (CKD-MBD). The disordered systems biology causes the CKD-MBD and contributes major components of increased cardiovascular risk for CKD patients. The outcome of the syndrome, in addition to previously recognized renal osteodystrophy (ROD), is increased cardiovascular mortality in CKD patients. The inception of the CKD-MBD was only recently realized to be with the early effects of kidney disease. Its pathophysiology involves circulating factors produced by renal repair and newly discovered hormones, such as fibroblast growth factor 23 (FGF-23) and cleaved klotho. Progressing from its inception, the disruption of the multiorgan system leads to the pathophysiology previously recognized as secondary hyperparathyroidism, hyperphosphatemia, calcitriol deficiency, and ROD that are now incorporated into the CKD-MBD syndrome, along with vascular disease (especially calcification) and cardiac disease (especially hypertrophy and heart failure). The new pathophysiology brings attention to extreme need for advances in treatment of the CKD-MBD, which is currently focused on the late components of the syndrome, and which have been shown in clinical trials not to affect the mortality associated with the syndrome.

INTRODUCTION

In 2006, the disorders of mineral and bone metabolism in CKD were enshrined in a new syndrome called the chronic kidney disease–mineral bone disorder (CKD-MBD). The CKD-MBD name was coined by the Kidney Disease: Improving Global Outcomes (KDIGO) foundation[1,2] for the syndrome associated with CKD in which disorders of mineral metabolism and renal osteodystrophy (ROD) are key contributors to excess mortality.[3–6] The pandemic of CKD and end-stage renal disease (ESRD) and the role of the CKD-MBD in the associated mortality make the syndrome a major health issue for Americans and all developed societies.[5,7–10] Recent advances define the CKD-MBD as a uniform complication of renal injury with wide variation in severity. The syndrome begins with renal injury early in CKD and contributes to the high mortality rates associated with CKD.[11] This chapter reviews recent pathophysiologic advances in the CKD-MBD and the classic pathophysiology of secondary hyperparathyroidism and ROD of CKD that have been incorporated into the syndrome. The result is the new understanding of a disordered systems biology involving the kidney, vasculature, heart, skeleton, and parathyroid glands, in CKD, contributing mortality risk beyond that due to kidney disease itself (Figure 35.1).[12]

PATHOBIOLOGY

Vascular

Abnormalities of the vasculature found in early CKD produce vascular stiffness and contribute to the development of left ventricular hypertrophy (LVH).[13,14] In addition, studies show that osteoblastic transition in arterial walls during early CKD progresses to vascular calcification,[15,16] a common phenomenon in the aging population that is accelerated in CKD to the highest level seen in clinical medicine. Vascular calcification further intensifies stiffness and development of LVH, all processes that contribute to cardiovascular risk and excess cardiac mortality. However, CKD directly

Chronic Renal Disease, Second Edition

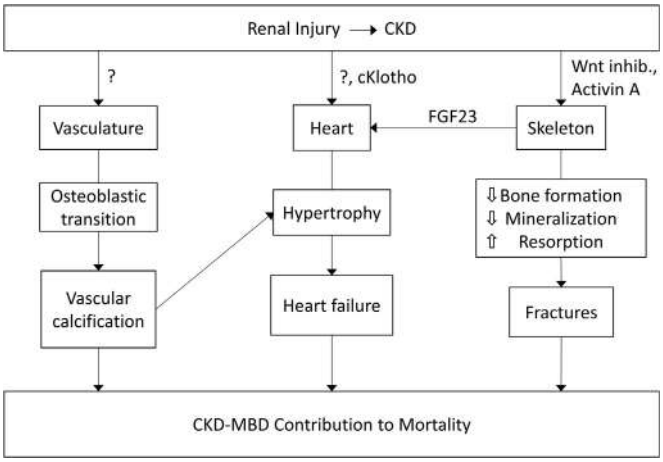

FIGURE 35.1 The disordered systems biology of the CKD-MBD. A multiorgan systems biology "wired" together in part by circulating communications is disordered in CKD. Renal injury increases circulating levels of factors affecting multiple organs peripheral to the kidneys. Key among these is the vasculature, affected very early in kidney disease by osteoblastic transition of cells in vessel walls. The heart's cardiomyocytes undergo hypertrophy due to a multitude of factors, including (1) unknown in nature and reductions in cKlotho; (2) due to vascular stiffness produced in part by vascular calcification; and (3) by high levels of FGF-23 acting through FGFR4.[89] The skeleton is immediately impacted during attempted renal repair by inhibitors of bone formation such as Dickkopf-1 and other Wnt inhibitors. The effects of peripheral organ damage lead to secondary pathologies of vascular calcification, cardiac hypertrophy, and renal osteodystrophy, culminating in the contributions of the CKD-MBD to the exaggerated mortality of CKD. *CKD-MBD*, chronic kidney disease—mineral bone disorder; *FGF-23*, fibroblast growth factor 23.

stimulates cardiac hypertrophy independent of arterial stiffness, further contributing to mortality.[17]

The pathogenesis of vascular calcification in CKD is complex.[18] Pathologically vascular calcification includes two types: neointimal and arterial medial. The pathogenesis of atherosclerotic neointimal calcification is multifactorial, but it involves activation of an osteoblastic differentiation program in cells of the neointima of atherosclerotic plaques and in cells of the arterial media.[19–22] Diffuse calcification of the arterial tunica media is referred to as Mönckeberg's sclerosis.[23] CKD is the most common cause of Mönckeberg's sclerosis, especially when it complicates diabetes mellitus. In translational models of atherosclerosis and diabetes (*ldlr−/−* with high fat feeding) mild renal insufficiency (equivalent to human stage 2 CKD) reduces the levels of aortic proteins involved in the contractile apparatus of smooth muscle.[15] This, coupled with evidence that vascular smooth muscle cells move into a dedifferentiated synthetic state from their normal contractile differentiated state,[24] represents significant evidence of large artery smooth muscle dedifferentiation in very early diabetic CKD.[25] Within the developmental program of mesenchymal stem cells and early progenitor cells, dedifferentiated vascular smooth muscle cells are susceptible to transition to the differentiation program of osteoblasts, which causes vascular calcification in CKD.[23,26] Osteoblastic transition of cells in the arterial walls produces CKD-stimulated calcification of atherosclerotic plaques and the vascular media.[16,19,23,27–29] The source of these cells may be mesenchymal progenitors from the adventitia moving into the media and expressing both smooth muscle and osteoblastic transcriptional programs,[30] although other lineage tracing studies support the role of vascular smooth muscle cells.[22,31]

Cardiac

Cardiac hypertrophy is highly prevalent in CKD patients. We found in a cohort of patients with CKD stage 3 from a single center clinic and a mean estimated glomerular filtration rate (eGFR) of 50 mL/min/1.73 m^2, an 80% incidence of LVH by CT scanning.[32] This is in concert with the results of larger population studies.[7,17] Cardiac hypertrophy is an early stage of cardiovascular disease leading to high rates of heart failure, sudden death, and even ischemic myocardial infarction.[7] The causes of cardiac hypertrophy in CKD are multifactorial, including vascular stiffness, fibroblast growth factor 23 (FGF-23),[33] and decreased αklotho—all components of the CKD-MBD (Figure 35.2). Vascular stiffness is a result of vascular calcification. The high levels of FGF-23 causing cardiomyocyte hypertrophy are also late in CKD compared with the early elevations in FGF-23.[34] We have found a new and novel cause of cardiac hypertrophy in our studies of activin receptor stimulation in CKD.[16,35] In three models of CKD in mice, cardiac hypertrophy develops during CKD, with reductions in GFR equivalent to human CKD stage 3. Inhibition of activin receptor type 2A prevents cardiac hypertrophy despite not affecting FGF-23 levels or fully restoring αklotho.[16,35] The mechanism of this effect will introduce a new therapeutic target for cardiovascular disease in CKD and the CKD-MBD.

Skeletal

Abnormalities of bone in the CKD-MBD begin with the renal response to injury due to activation of Wingless/Integration 1 (Wnt, a portmanteau of Wg and int) pathways in the kidney.[36,37] Canonical Wnt signaling transcriptionally stimulates production of multiple Wnt inhibitors which are secreted systemic factors.[38,39] As a result, kidney injury directly inhibits bone remodeling which is homeostatically Wnt dependent (Figure 35.2).[40–42] Skeletal inhibition of Beta catenin signaling and increased expression of osteocytic FGF-23

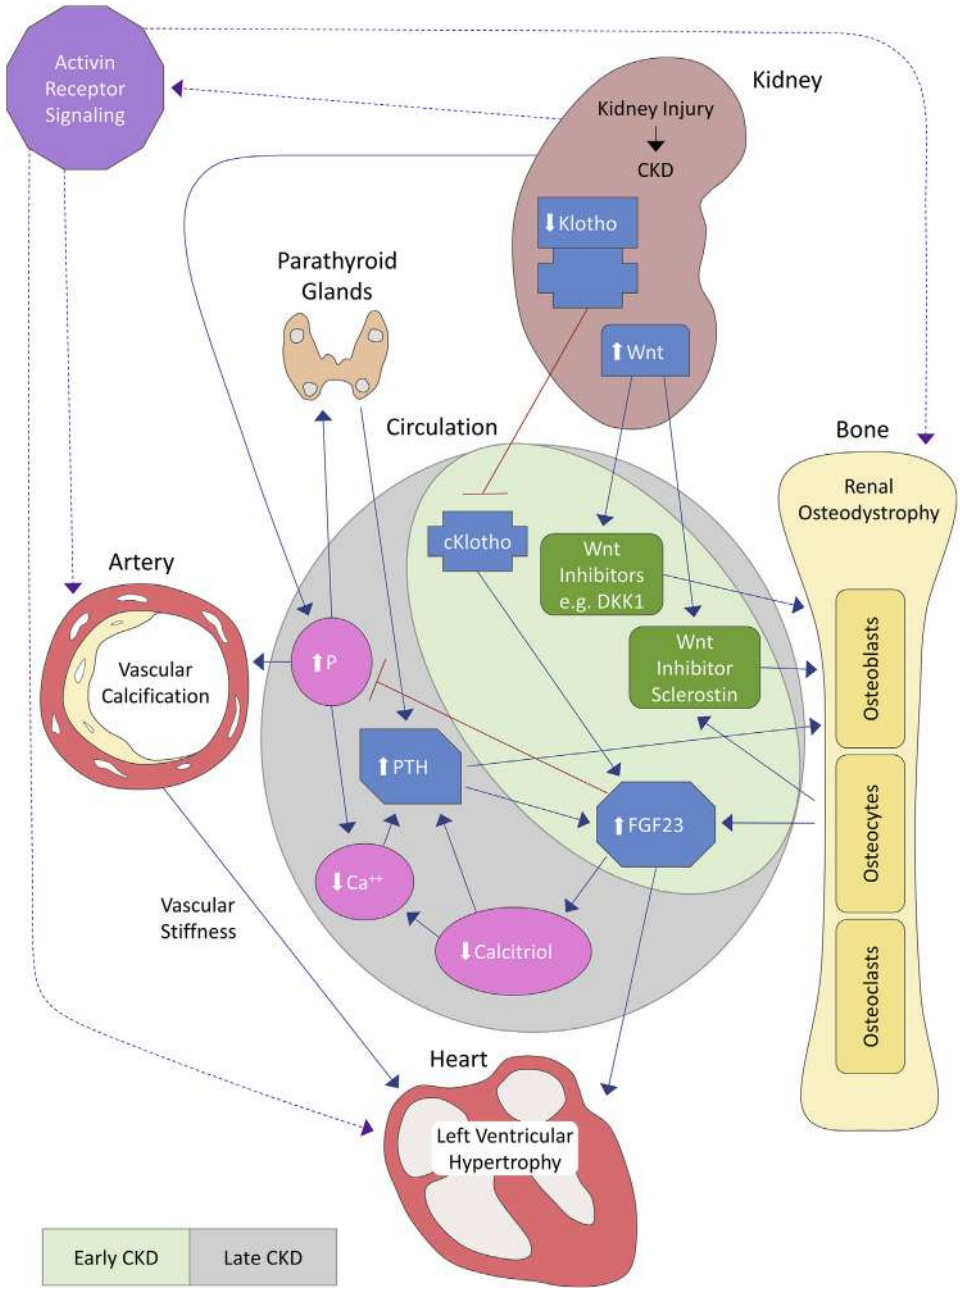

FIGURE 35.2 The disordered systems biology of the CKD-MBD. A multiorgan systems biology "wired" together in part by circulating communications is disordered in CKD. Kidney injury (*early CKD*) leading to CKD increases levels of some factors reaching the circulation, such as the Wnt inhibitor family, and decreases others, such a αklotho. Renal αklotho is a transmembrane protein, whose extracellular domain is cleaved by ADAMS 10 and 17,[80] producing circulating klotho (cklotho), whose hormonal functions include regulation of FGF-23 secretion by skeletal osteocytes.[79,80] The decrease in αklotho produced by renal injury immediately disorders regulation of FGF-23 secretion. The increased FGF-23 affects proximal tubular phosphate excretion and calcitriol production through activation of FGFR1C through the coreceptor function of αklotho.[185,186] The loss of klotho disorders phosphate excretion[100,187] leading to the development of hyperphosphatemia, calcitriol deficiency, hypocalcemia, and hyperparathyroidism as kidney disease progresses. Hyperphosphatemia stimulates vascular calcification already in progress from osteoblastic transition.[107,188] CKD activation of activin receptor signaling systemically contributes to vascular calcification, decreased bone formation, increased bone resorption, and cardiac hypertrophy, without affecting FGF-23 but increasing αklotho.[16,35,47] *CKD-MBD*, chronic kidney disease—mineral bone disorder; *FGF-23*, fibroblast growth factor 23.

are seen after a relatively mild reduction in the GFR, at stage 2 CKD.[43–45] These abnormalities affect cortical bone predominately in early CKD and progress to decreased cortical bone volume and porosity.[15] Abnormalities of remodeling, mineralization, and the material properties of bone develop in CKD, leading to major decreases in structural strength, fractures, and deformity associated with long-term disease (Figure 35.1).[46]

Recent studies demonstrate the progressive development of a remodeling imbalance during CKD due to stimulation of osteoclast number and function, and a relative decrease in osteoblast function in view of increased osteoblast number that fails to increase bone formation as expected.[16,47] This is fueled by hyperparathyroidism in collaboration with activin/activin receptor type II signaling (Figure 35.2).[16] The progression of the skeletal remodeling disorder in CKD to the familiar high-turnover state related to hyperparathyroidism begins from a low-turnover state produced by CKD-induced Wnt inhibition in early CKD.[39,44,45]

Plasma

In early CKD, before detectable changes in the S[P], S[Ca], or calcitriol levels, elevated FGF-23 and sclerostin levels largely from osteocytes (although the diseased kidney produces sclerostin[48]) and elevated parathyroid hormone (PTH) levels are observed[49–51] The early increase in FGF-23 in CKD[43,49] makes it a powerful biomarker, indicating that renal injury has affected osteocyte function and secretion.[43] If the hyperparathyroidism of early CKD is prevented, the prevalence of a low-turnover osteodystrophy (the adynamic bone disorder (ABD)) increases, further demonstrating the effects of kidney injury on the skeleton.[52] By the time ESRD develops, skeletal pathology is nearly universally present.[53]

PATHOGENESIS

Renal injuries produce circulating signals that affect the vasculature, the skeleton, and the myocardium. The skeleton is affected in at least two ways. One produces changes in remodeling and material properties. The second causes changes in the secretory properties of skeletal osteocytes (Figure 35.1). Renal injury and disease produce reactivation of developmental programs of nephrogenesis in an attempt at kidney repair. These programs are generally silent in the normal adult human kidney. The best studied example is the reactivation of the Wnt pathway[54,55] that controls tubular epithelial differentiation, proliferation, and polarity during nephrogenesis[56–60] and is a driving force in renal fibrosis in disease.[61–63] In the canonical Wnt signaling pathway, the transcriptional targets include a complex family of inhibitory proteins,[64] the Wnt inhibitors, including Dickkopf,[65] soluble frizzled-related proteins, and sclerostin.[48] Although Wnts are strictly autocrine/paracrine factors,[66] the Wnt inhibitors are secreted/circulating proteins.[67] The role of Wnt in renal development largely precedes the invasion of the microcirculation forming the glomerulus and the peritubular capillaries. Thus, the Wnt inhibitors were not designed as circulating humoral substances produced by the normal kidney. Their release into the circulation during kidney injury/repair represents a systemic pathologic insult inhibiting the physiologic roles of Wnt in the rest of the body. So far, this has been shown to have major consequences in the vasculature and the skeleton.[39,45,68]

The role of the Wnt inhibitor families in vascular function during early kidney disease was recently demonstrated by finding significantly increased renal expression of Wnt inhibitors in the injured kidney,[39,54] their increased presence in the circulation,[39] and the inhibition of one, Dickkopf 1 (Dkk1), by a monoclonal antibody.[39] Dkk1 neutralization was sufficient to decrease the CKD-stimulated dedifferentiation of the vasculature. Dedifferentiation was shown by decreased expression levels of proteins involved in smooth muscle contraction. Dkk1 neutralization increased smooth muscle contractile protein levels and inhibited osteoblastic transition. The levels of Runx2, the critical osteoblast transcription factor, and its transcriptional targets were decreased by Dkk1 neutralization, and the expression of klotho was increased. The result was that Dkk1 neutralization inhibited stimulation of vascular calcium levels in an atherosclerotic calcification model stimulated by early CKD.[15,39]

The skeleton is especially sensitive to circulating Wnt inhibition. Wnts have been shown to be the major stimuli of normal skeletal remodeling.[69] Genetic diseases are also produced by activating mutations in the Wnt coreceptor proteins, low-density lipoprotein receptor–related proteins 5 and 6 (LRP5/6),[42,70] and by inactivating mutations in Wnt inhibitor proteins, such as sclerostin, involved in the pathogenesis of sclerosteosis[71,72] and van Buchem's disease.[73] Wnts are also critical factors of the hematopoietic stem cell niche.[66,74,75] Their inhibition through circulating Wnt inhibitors is not tolerable, leading to adaptive production of another niche factor, PTH.[76,77] The adaptive increase in PTH prevents the expected inhibition of skeletal remodeling produced by circulating Wnt inhibitors.[45] Therefore, low-turnover osteodystrophy is not a generalized observation in early CKD, but it is observed when the increase in PTH is prevented.[52] In a preclinical model of atherosclerosis and type 2 diabetes, early CKD additively suppressed bone formation rates, especially in cortical bone. The effect was reversed by Dkk1 neutralization.[39]

Early CKD stimulates osteocyte production of FGF-23 and sclerostin.[43,49] Neutralization of Dkk1 did not affect increased FGF-23 levels, but decreasing urinary phosphate excretion without changing normal S[P] levels inhibited FGF-23 levels.[39] This is in agreement with

studies showing that the combination of dietary phosphate restriction and phosphate binders decreased FGF-23 levels in early CKD with normophosphatemia.[78] The concept that changes in urinary (tubular fluid) phosphate regulates osteocytic FGF-23 secretion is in agreement with the demonstrated hormonal function of cleaved klotho.[79] Thus, the physiologic paradigm is that regulation of disintergin metalloproteases ADAMS 10 and 17 by tubular fluid phosphate affects cleavage of membrane klotho producing the hormone, cleaved klotho, which regulates osteocyte secretion of FGF-23 (Figure 35.2).[79,80] The problem with the physiologic system is that CKD decreases tubular epithelial membrane klotho levels[81] eliminating the adaptive potential of increasing cleaved klotho levels in CKD and relegating regulation of FGF-23 secretion to increases in S[P] and other factors such as iron status and inflammation.[82,83] Stimulation of FGF-23 and sclerostin in early CKD produces an inhibition to skeletal remodeling that becomes a background as adaptive hyperparathyroidism maintains and even increases bone remodeling rates.[45,84] In addition to FGF-23, the increases in Dickkopf 1 and sclerostin, powerful inhibitors of Wnt signaling in early CKD, represent biomarker evidence of skeletal inhibition produced by renal injury. The loss of skeletal anabolism in CKD occurs in the presence of normal PTH, vitamin D, S[Ca], and S[P] levels. It is, however, not usually observed as the ABD because disturbed homeostasis in these factors stimulate PTH secretion. The sustained increase in PTH levels produced through adaptation to CKD increases remodeling rates and eventually produces an unwanted high-turnover disorder of skeletal remodeling, osteitis fibrosa.

Pathogenic Factors in the CKD-MBD

FGF-23

FGF-23 is the original phosphatonin (phosphate excretion regulating hormone) discovered in studies of autosomal-dominant hypophosphatemic rickets and oncogenic osteomalacia.[85,86] The principal hormonal functions identified for FGF-23 are regulation of proximal tubular [P] excretion, inhibition of CYP27B1, the 1α-hydroxylase synthesizing calcitriol in the proximal tubule, and stimulating the 25-hydroxyvitamin D3 24R-hydroxylase, 24-(OH) hydroxylase, CYP24A1. FGF-23 levels are stimulated by mild renal injury[49,87] and progressively rise during the course of CKD, due to increased secretion by osteocytes and decreased catabolism by the diseased kidney (Figure 35.2). FGF-23 contributes to maintenance of phosphate homeostasis during early CKD and causes vitamin D deficiency through increased catabolism. Hormonal FGF-23 is produced by osteocytes and osteoblasts, although it is expressed elsewhere in disease.[15] FGF-23 levels strongly associate with clinical outcomes of CKD,[88] especially with the intermediate surrogate, LVH.[33] Extremely high FGF-23 levels in CKD cause cardiac myocyte hypertrophy independent of klotho coreceptor function.[89] FGF-23 represents direct bone–kidney and bone–parathyroid and bone–heart connections in the systems biology involved in the CKD-MBD (Figure 35.2). The early stimulation of osteocyte FGF-23 secretion by renal injury is an example of kidney–bone communication, perhaps through regulation of AMP-activated kinase,[90] and preceding changes in S[P], calcitriol or PTH and proinflammatory cytokines, TNFα, or IL-1.

Klotho

FGF-23 signaling through FGF receptors requires the coreceptor function of alpha Klotho.[91] High Klotho expression has very limited tissue distribution, defining the tissue targets of FGF-23 as a hormone.[92,93] These targets are the proximal and distal renal tubules, the parathyroid glands, and the brain.[92,94] Secondly, Klotho is a single transmembrane pass protein with a large extracellular domain that possesses homology with glycosidases and functions as a glucuronidase, and a sialidase.[95,96] Thirdly, cleavage of the extracellular domain of klotho[80] and its shedding into the urine and blood suggested hormonal function of the protein,[97,98] which was shown to function in FGF-23 secretion by osteocytes.[79]

FGF-23 suppresses PTH secretion, and PTH gene expression through FGFR/Klotho signaling,[94] and PTH affects FGF-23 secretion. This physiologic system of osteocyte–parathyroid and parathyroid–osteocyte regulation does not operate appropriately in CKD.[99] The kidney–osteocyte, osteocyte–kidney signaling for phosphate homeostasis is not adaptive in CKD, due to the major decrease in klotho expression produced by renal injury,[100,101] limiting the role of cleaved klotho in osteocyte regulation, and leaving hyperphosphatemia as the main regulator of FGF-23 secretion in CKD. Furthermore, the loss of klotho expression in CKD limits FGF-23-stimulated signal transduction through FGF receptor/klotho complexes. One result is the loss of negative feedback to FGF-23 secretion and the continual production of FGF-23 and secretion by the osteocyte. In late CKD, the very high levels of FGF-23 permit anomalous FGF receptor activation independent of Klotho. This results in FGF-23-stimulated pathologic stimuli such as cardiac myocyte hypertrophy (Figure 35.2).[89]

Hyperphosphatemia

As renal injury decreases nephron number, phosphate excretion is maintained by reductions in the fraction of filtered phosphate reabsorbed by the remaining nephrons under the influence of FGF-23 and PTH.[102] The effects of FGF-23 stimulated by cleaved klotho before changes in

S[P] are limited by the loss of proximal tubular klotho.[100] The combination of FGF-23 and PTH effects to decrease proximal tubular phosphate reabsorption is sufficient to maintain phosphate homeostasis through stages 3–4 CKD when hyperphosphatemia ensues.[99] This is at the cost of higher PTH and FGF-23 levels. In stage 4 and 5 CKD, when renal injury is severe enough that the GFR reaches levels of less than 30% of normal, hyperphosphatemia develops due to decreased renal [P] excretion despite high PTH and FGF-23 levels.[99,103]

Failure of calcium and phosphorus deposition into the skeleton or excess resorption of the skeleton also contribute to abnormal S[P] and S[Ca] levels in CKD and ESRD.[104–106] The skeleton contributes to the pathogenesis of vascular calcification through contributing to hyperphosphatemia.[14,104] Signals deriving from the skeleton are direct causes of vascular mineralization. The best documented signal deriving from the skeleton is hyperphosphatemia.[107,108] Hyperphosphatemia stimulates osteoblastic transition in the vasculature[107,109] and directly contributes to mineralization through the calcium-phosphorus product (Figure 35.2).[108] Phosphorus is a signaling mechanism working through the Pit 1 and 2 sodium phosphate cotransport proteins as receptors for stimulation of MAP kinase signal transduction and stimulation of heterotopic mineralization of the vasculature in CKD.[108,110]

Hyperphosphatemia also decreases S[Ca] through physicochemical complexation (Figure 35.2) and suppresses 1α-hydroxylase activity, which results in further lowering of circulating calcitriol levels. Moreover, a direct stimulatory effect of phosphorus on parathyroid gland cells, independent of S[Ca] and calcitriol levels, produces increased secretion and nodular hyperplasia of parathyroid gland cells.[111,112] A direct stimulatory effect of inorganic phosphate, perhaps in the exchangeable inorganic phosphate pool, regulates osteocyte FGF-23 secretion.

Calcitriol Deficiency

The physiologic actions of FGF-23 from the osteocyte include inhibition of proximal tubular CYP27B1, 25-OH vitamin D 1α hydroxylase, and stimulation of CYP24A1, vitamin D 24-hydroxylase, decreasing calcitriol production, and producing vitamin D deficiency in early CKD. As CKD advances, the functioning nephron mass is decreased and this, combined with an increased phosphate load in the remaining nephrons and increased FGF-23 levels, results in calcitriol deficiency.[113] Calcitriol deficiency in turn decreases intestinal calcium absorption and leads to the development of hypocalcemia. Calcitriol deficiency in cases of advanced CKD in turn diminishes tissue levels of vitamin D receptors (VDRs), in particular, the VDR of parathyroid gland cells.[114] Because the chief cell VDR suppresses the expression of pre-pro-PTH mRNA, lower circulating calcitriol levels, together with a low number of VDRs in patients with ESRD result in stimulation of both synthesis and secretion of PTH[115] and resistance to the effects of calcitriol. The hypocalcemia in CKD stage 5 resulting from these pathophysiologic processes, unchecked by medical intervention is severe and resistant to therapy with calcium and calcitriol supplementation due to VDR deficiency.

Hypocalcemia

As CKD progresses, hypocalcemia develops due to decreased intestinal Ca absorption. Low blood levels of ionized calcium stimulate, whereas high S[Ca] suppresses PTH secretion. The action of calcium on parathyroid gland chief cells is mediated through a calcium sensor (CASR), a G-protein coupled plasma membrane receptor expressed in chief cells, kidney tubular epithelia, and widely throughout the body at lower levels.[116,117] The short-term stimulation of PTH secretion induced by low S[Ca] is due to exocytosis of PTH packaged in granules. Longer-term stimulation results from an increase in the number of cells that secrete PTH. More prolonged hypocalcemia induces changes in intracellular PTH degradation and mobilization of a secondary storage pool. Within days or weeks of the onset of hypocalcemia, pre-pro-PTH mRNA expression is stimulated. This effect is exerted through a negative calcium response element located in the upstream flanking region of the gene for PTH. Expression of the calcium receptor is suppressed by calcitriol deficiency and stimulated by calcitriol administration, suggesting an additional regulatory mechanism of the active vitamin D metabolite on PTH production. The decreased number of calcium-sensing receptors (CaSRs) with low circulating calcitriol may, at least in part, explain the relative insensitivity of parathyroid gland cells to calcium in patients undergoing dialysis.

Hyperparathyroidism

All of the mechanisms discussed above result in increased production of PTH and nodular hyperplasia of the parathyroid glands in CKD. The size of the parathyroid glands progressively increases during CKD and in dialyzed patients paralleling serum PTH levels. This increase in gland size is mainly due to diffuse cellular hyperplasia. Monoclonal chief cell growth also develops, resulting in the formation of nodules. Nodular hyperplastic glands have fewer VDR and CaSRs compared with diffusely hyperplastic glands, promoting parathyroid gland resistance to calcitriol and calcium. Sustained elevation in PTH levels, while adaptive to maintain osteoblast surfaces, produce an abnormal phenotype of osteoblast function and osteocyte stimulation, with relatively less type 1 collagen

and more RANKL ligand production than anabolic osteoblasts. A key component of the RANKL stimulation is osteocytic in origin. This leads to a high-turnover osteodystrophy, PTH receptor desensitization, and excess bone resorption.

Hypogonadism

Patients with ESRD have various states of gonadal dysfunction.[118–120] Estrogen and testosterone deficiency significantly contribute to the pathogenesis of ROD.[121,122]

Other Factors

Inflammatory mediators, acidosis,[123,124] aluminum, leptin, and retained catabolites are all potentially critical factors in the CKD-MBD that have not been well studied, or recently have become less important clinically. Some patients with CKD are treated with glucocorticoids, which affect bone metabolism. Patients maintained on chronic dialysis have retention of β2-microglobulin. Additionally, alterations in growth factors and other hormones involved in the regulation of bone remodeling may be disordered in CKD and ESRD, thus affecting bone remodeling and contributing to the development of ROD.

PATHOLOGY OF RENAL OSTEODYSTROPHY

With the advent of the CKD-MBD syndrome, the term ROD is restricted to the skeletal pathology of CKD and the modeling/remodeling disorders it causes. ROD is not a uniform disease. Depending on the relative contribution of the different pathogenic factors discussed above and their treatment, various pathologic patterns of bone remodeling are expressed in CKD and ESRD patients.[125]

Predominant Hyperparathyroidism Bone Disease, High-Turnover ROD, and Osteitis Fibrosa

Sustained excess PTH action results in increased bone turnover.[125–129] Osteoclasts, osteoblasts, and osteocytes are found in abundance. Disturbed osteoblastic activity results in a disorderly production of collagen, which results in formation of woven bone.[130] Accumulation of fibroblastic osteoprogenitors not in the osteoblastic differentiation program results in collagen deposition, and the development of fibrosis in the peritrabecular and marrow space.[28,125,131] The nonmineralized component of bone, osteoid, is increased, and the normal three-dimensional architecture of osteoid is frequently lost.[132] Osteoid seams no longer exhibit their usual birefringence under polarized light. Instead, a disorderly arrangement of woven osteoid and woven bone with a typical crisscross pattern under polarized light is seen. The mineral apposition rate and number of actively mineralizing sites are increased, as documented under fluorescent light after the administration of time-spaced fluorescent (tetracycline) markers.[133]

Low-Turnover Bone Disease, Adynamic Bone Disorder

Low-turnover uremic osteodystrophy is the other end of the spectrum of ROD.[134] The histologic hallmark of these disorders is a profound decrease in bone turnover, due to a low number of active remodeling sites, and suppression of bone formation and resorption.[135,136] Bone resorption is not as decreased as formation. The result is a low-turnover osteopenic condition. The majority of trabecular bone is covered by lining cells, with few osteoclasts and osteoblasts. Bone structure is predominantly lamellar. The extent of mineralizing surfaces is markedly reduced. Usually only a few thin, single tetracycline labels are observed. Two subgroups can be identified in this type of ROD, depending on the cause of events leading to a decline in osteoblast activity: first, the ABD and, secondly, low-turnover osteomalacia from aluminum intoxication, bisphosphonate administration, or other factors.[137–139]

We postulated that the ABD was caused by loss of skeletal anabolic activity,[125] which has subsequently shown to be true. First, we demonstrated that following renal injury, if S[Ca], S[P], PTH, and calcitriol were maintained normal, the ABD resulted,[52] and that it was corrected by a skeletal anabolic factor made in the normal kidney. Subsequently, we demonstrated that renal diseases increase inhibitors of Wnt in the systemic circulation,[39] and Sabbagh et al. showed that skeletal Wnt activity was suppressed in early CKD.[45] We showed that neutralization of a key Wnt inhibitor, Dkk1, was sufficient to correct the low-turnover osteodystrophy seen in a model of type 2 diabetes and early CKD.[39] In this model with further aging, resistance to PTH action is overcome by very high PTH levels and the osteodystrophy begins to convert into higher turnover rates. Thus, the complex pathophysiology of ROD has been further clarified.

Low-turnover osteomalacia is characterized by an accumulation of unmineralized matrix in which a diminution in mineralization precedes or is more pronounced than the inhibition of collagen deposition.[140–143] Unmineralized bone represents a sizable fraction of trabecular bone volume. The increased lamellar osteoid volume is due to the presence of wide osteoid seams that cover a large portion of the trabecular surface. The occasional

presence of woven bone buried within the trabeculae indicates past high bone turnover. When osteoclasts are present, they are usually seen within trabecular bone or at the small fraction of trabecular surface left without osteoid coating.

Mixed Uremic Osteodystrophy, High-Turnover ROD plus a Mineralization Defect

Mixed uremic osteodystrophy is caused primarily by hyperparathyroidism and defective mineralization with or without increased bone formation.[133,136,140] These features may coexist in varying degrees in different patients. Increased numbers of heterogeneous remodeling sites can be seen. The number of osteoclasts is usually increased. Because active foci with numerous cells, woven osteoid seams, and peritrabecular fibrosis coexist next to lamellar sites with a more reduced activity, greater production of lamellar or woven osteoid causes an accumulation of osteoid with normal or increased thickness of osteoid seams. While active mineralizing surfaces increase in woven bone with a higher mineralization rate and diffuse labeling, mineralization surfaces may be reduced in lamellar bone with a decreased mineral apposition rate.

ASSOCIATED FEATURES

Osteoporosis and Osteosclerosis

With progressive loss of renal function, cancellous bone volume may be increased along with a loss of cortical bone. This is in part due to deposition of woven immature collagen fibrils instead of lamellar fibrils. Thus, bone strength suffers despite the increase in mass detected by dual energy x-ray absorptiometry. Patients undergoing chronic dialysis might have a loss or gain in bone volume depending on bone balance. When the bone balance is positive, osteosclerosis may be observed when osteoblasts are active in depositing new bone, especially woven bone, thus superseding bone resorption. This is rare in the 21st century due to improved therapy of secondary hyperparathyroidism.[130]

In the case of negative bone balance, bone loss occurs in cortical and cancellous bone and is more rapid when bone turnover is high. In those cases, bone densitometry will detect osteopenia or osteoporosis.[144,145] The prevalence of osteoporosis in the population with CKD exceeds the prevalence in the general population.[146–148] Osteoporosis is observed in CKD before dialysis is required for ESRD.[149] When bone turnover is high, as in secondary hyperparathyroidism with osteitis fibrosa, bone resorption rates are in excess of bone formation, and osteopenia progressing to osteoporosis may result. When bone turnover is low, although both bone formation rates and bone resorption may be reduced, resorption exceeds bone formation, and loss of bone mass occurs. Thus, osteoporosis may be observed with either high-turnover[149–152] or low-turnover[153] forms of osteodystrophy. When bone resorption exceeds bone formation rates in CKD, positive phosphorus and calcium balance results in the development of hyperphosphatemia and hypercalcemia without an increase in skeletal mineral deposition, but with a stimulation of heterotopic mineralization, especially of the vasculature. The failure of the skeleton to absorb positive phosphate balance in CKD is an important stimulus to heterotopic mineralization and links the skeleton and osteoporosis in CKD to cardiovascular events and mortality.[107]

It is apparent that four forms of osteoporosis associate with the CKD-MBD: high-turnover ROD causing osteoporosis, low-turnover ROD causing osteoporosis, osteoporosis preexisting CKD, and osteoporosis due to gonadal hormone deficiency. In patients with osteoporosis and decreased eGFR, it is important to determine the presence of CKD, and the state of the CKD-MBD.

Bone Aluminum, Iron, Lanthanum, and Bisphosphonate Accumulation

Aluminum, iron, lanthanum,[154] and bisphosphonates accumulate in bone at the mineralization front, at the cement lines, or diffusely. The extent of stainable aluminum at the mineralization front correlates with histologic abnormalities in mineralization. Aluminum deposition is most severe in cases of low-turnover osteomalacia. Aluminum deposition, however, can be observed in all histologic forms of ROD. In patients in whom an increased aluminum burden develops, bone mineralization and bone turnover progressively decrease. These abnormalities are reversed with removal of the aluminum. Iron also accumulates at the mineralization front and can cause low-turnover forms of ROD and fractures[155,156] similar to aluminum, although much less is known regarding skeletal iron intoxication compared with aluminum intoxication.

Lanthanum has been added as a rare earth ion administered to CKD and ESRD patients as a phosphate binder. It is poorly absorbed, and its levels in bone are much lower than aluminum and not clinically relevant.[157] Therapy with lanthanum has not been shown to have long-term toxic effects, and studies suggest skeletal efficacy of lanthanum therapy.[158–160] Eight-year data suggest that the levels of skeletal accumulation remain below those associated with any biologic or toxic effects.[161] Lanthanum disappearance from bone deposits is slow, but not as slow as bisphosphonate disappearance.[157]

Bisphosphonates are drugs used in the treatment of osteoporosis and hypercalcemia.[162,163] There are increasing instances of bisphosphonate use in patients with CKD and ESRD especially for treatment of vascular calcification.[164] Many patients in the multiple bisphosphonate registration trials were retrospectively found to have reduced eGFR.[165,166] Generally, these were elderly women who most likely did not have kidney disease or the CKD-MBD because they did not have elevated PTH levels. Therefore, there is concern extrapolating data from these trials to patients with osteoporosis and CKD. The nature of the bone remodeling abnormalities in CKD, especially with woven bone formation and mineralization defects, conveys a high level of risk for skeletal deposition of a substance that once deposited may not be removed. Such a risk of long-term retention of an active drug inhibiting bone turnover is now being recognized with use of bisphosphonates in osteogenesis imperfecta, as is the rare side effect of the drugs, resulting in osteonecrosis of the jaw and atypical femoral fractures.[164,167] The FDA has added to its bisphosphonate warnings, due to the nephrotoxicity of potent bisphosphonates.[162]

Clinical Manifestations

Patients with early stage CKD are rarely symptomatic due to ROD and its skeletal pathology, but they are usually hypertensive. If the CKD-MBD contributes to hypertension, the pulse pressure may be high due to vascular stiffness and increased pulse wave velocity.[168] However, fracture risk for CKD patients is increased more than twofold above age-matched cohorts without CKD.[169,170] Stimulation of vascular calcification in the setting of disordered skeletal remodeling is a life-threatening complication of the CKD-MBD.[171,172] Vascular calcification produces vascular stiffness.[13] Vascular stiffness in CKD causes an increase in systolic blood pressure, a widening of the pulse pressure, and an increase in pulse wave velocity. All of these can lead to cardiac hypertrophy, heart failure, and cardiovascular mortality.[173]

Heterotopic Mineralization, Calciphylaxis, and Tumoral Calcinosis

Heterotopic tissue calcification may occur in the eyes and manifest as band keratopathy in the sclera or induce an inflammatory response, known as the red eye syndrome, in the conjunctiva. Calcium deposits are also found in the lungs, leading to restrictive lung disease. Deposits in the myocardium might cause arrhythmias, annular calcifications, valvular calcification, or myocardial dysfunction. Calcification of the kidney may contribute to the progression of CKD. Most soft tissue calcifications are attributed to the increased calcium phosphate product contributed to by ROD and excess bone resorption.

The syndrome of calciphylaxis is characterized by vascular calcification in the tunica media of peripheral arteries.[174,175] These calcifications induce painful violaceous skin lesions that progress to ischemic necrosis.[176] This syndrome is associated with serious complications and often death.

Tumoral calcinosis is a form of soft tissue calcification that involves the periarticular tissues. Calcium deposits may grow to enormous size and interfere with the function of adjacent joints and organs. Although this type of calcification is usually associated with high calcium phosphate products, its exact pathogenesis is poorly understood. The discoveries of three single gene mutations in FGF-23, Klotho, and GALNT3 causing inherited tumoral calcinosis shed light on the role of hyperphosphatemia in the pathogenesis of tumoral calcinosis.[177–179] The role of GALNT3 in hyperphosphatemia is associated with enzymatic degradation of FGF-23.

Bone Pain, Fractures, and Skeletal Deformities

Symptoms of ROD related to the skeleton appear in patients with advanced CKD.[180] Clinical manifestations are preceded, however, by an abnormal biochemical profile that should alert the physician and prompt steps to prevent more severe complications. When symptoms related to the skeleton occur, they are usually insidious, subtle, nonspecific, and slowly progressive.

Bone pain is usually vague, ill defined, and deep seated. Bone pain may be diffuse or localized in the lower part of the back, hips, knees, or legs. Weight bearing and changes in position commonly aggravate bone pain. Bone pain may progress slowly to the degree that patients are completely incapacitated. Bone pain in patients with ESRD usually does not cause physical signs. Local tenderness, however, may be apparent with pressure. Occasionally, pain can occur suddenly at one joint of the lower extremities and mimic acute arthritis or periarthritis not relieved by heat or massage. A sharp chest pain may indicate rib fracture. Spontaneous fractures or fractures after minimal trauma may also occur in vertebrae (crush fractures) and in tubular bones.

Bone pain and bone fractures can be observed in all patients with ESRD independent of the underlying histologic bone disease, especially when osteoporosis is present.[146] However, low-turnover osteomalacia and aluminum-related bone disease are associated with the most severe bone pain and the highest incidence of fractures and incapacity.

Skeletal deformities can be observed in children and adults. Most children with ESRD have growth

retardation, and bone deformities may develop from vitamin D deficiency (rickets) or secondary hyperparathyroidism.[123] In rickets, bowing of the long bones is seen, especially the tibiae and femora, with typical genu valgum that becomes more severe with adolescence. Long-standing secondary hyperparathyroidism in children may be responsible for slipped epiphyses secondary to impaired transformation of growth cartilage into regular metaphyseal spongiosa. This complication most commonly affects the hips, becomes obvious in preadolescence, and causes limping but is usually painless. When the radius and ulna are involved, ulnar deviation of the hands and local swelling may occur. In adults, skeletal deformities can be observed in cases of severe osteomalacia or osteoporosis and include lumbar scoliosis, thoracic kyphosis, and recurrent rib fractures.[181]

CONCLUSION

CKD produces a complex syndrome of disrupted systems biology that affects the vasculature, heart, skeleton, muscle, and mineral metabolism which contributes to mortality. The advances in our understanding of the CKD-MBD syndrome and its pathogenesis bring into focus the great need for new therapeutics. The 2017 update of clinical practice guidelines by KDIGO[6] demonstrates that our therapies are focused on the late components of the syndrome and have not improved its mortality in clinical trials (EVOLVE, OPERA, PRIMO) despite control of secondary hyperparathyroidism.[182–184] Thus, there is great need for discoveries related to therapeutic targets for the CKD-MBD cardiovascular components and development of therapeutic agents.

QUESTIONS AND ANSWERS

Question 1

A 46-year-old man with S[Cr] 2.9 mg/dL and eGFR 22 mL/min/1.73 m^2 is seen in clinic. The patient has small echogenic kidneys on renal ultrasound. One year earlier, S[Cr] was 2.13 mg/dL, S[Ca] was 9.1 mg/dL, and PTH was 105 pg/mL. His blood pressure is 150/94 mm Hg. Blood pressure medications include amlodipine 5 mg daily and lisinopril 20 mg daily. On these medications, the blood pressure was normal one year ago. The following blood tests are available:

S[Ca] 10.9 mg/dL
Ionized calcium 5.68 mg/dL (normal 4.64–5.16 mg/dL)
S[P] 3.8 mg/dL
PTH 8 pg/mL (normal 14–72 pg/mL)
25-Vitamin D 34 ng/mL (goal 30–80 ng/mL)
1,25-Vitamin D 20 pg/mL (normal 19–72 pg/mL)
S[Na] 138 mEq/L
S[K] 4.4 mEq/L
S[Cl] 94 mEq/L
S[HCO_3] 34 mEq/L

Which of the following statements regarding the hypercalcemia is most likely?

A. The hypercalcemia is due to severe secondary hyperparathyroidism from renal failure
B. The hypercalcemia is from primary hyperparathyroidism
C. The hypercalcemia is from exogenous calcium ingestion
D. The hypercalcemia is from an undiagnosed granulomatous disease
E. Vitamin D intoxication should be suspected

Answer: C

PTH is suppressed from hypercalcemia, which does not occur in either severe secondary hyperparathyroidism or primary hyperparathyroidism. Rather the high PTH drives the hypercalcemia in these conditions. Last year, the patient had a mildly elevated PTH and normal S[Ca] which would be compatible with secondary hyperparathyroidism from renal failure. Hypercalcemia with renal failure from a granulomatous disease such as sarcoidosis is sometimes seen, but the cause is an elevated 1,25-vitamin D value, which was not present in this case. The normal 25-vitamin D shows that the patient is not ingesting excessive amounts of vitamin D. The patient is also not taking a thiazide diuretic, which infrequently contributes to the development of hypercalcemia. The correct answer is that the hypercalcemia is from exogenous calcium ingestion, which is known as the milk alkali syndrome. The major clue is the elevated serum bicarbonate concentration. Renal failure in the absence of an exogenous source of bicarbonate is associated with metabolic acidosis because of a decreased capacity to excrete an acid load. Finally, the capacity to excrete an exogenous calcium load is decreased in renal failure because of decreased calcium filtration due to the deceased GFR.

Question 2

A 34-year-old male with stage 4 CKD, S[Cr] 3.5 mg/dL (eGFR 19 mL/min/1.73 m^2), and with urinary protein excretion less than 1 g/24 h is seen in your clinic. The blood pressure is controlled and the patient is asymptomatic. The following blood work is obtained:

S[Ca] 7.4 mg/dL
Ionized calcium 3.76 mg/dL (normal 4.64–5.16 mg/dL)
S[P] 6.6 mg/dL
PTH 629 pg/mL (normal 10–65 pg/mL)
1,25-Vitamin D 14 pg/mL (normal 19–72 pg/mL)
25-Vitamin D 16 ng/mL (goal >30 ng/mL)

Which of the following should be done first to treat the elevated PTH?

A. Begin treatment with a calcium-based phosphate binder and have the patient see a dietician to restrict dietary phosphate
B. Begin treatment with 1,25-vitamin D (calcitriol) to reduce the PTH and increase serum calcium (S[Ca])
C. Start cholecalciferol (vitamin D_3) at 2000 IU/day
D. Begin treatment with the calcimimetic cinacalcet to reduce the PTH value
E. Begin treatment with sevelamer

Answer: A

An approach to initiating treatment requires a firm understanding of the pathophysiology of hyperparathyroidism. The first step in treating an elevated PTH in a patient with CKD is to correct the abnormal serum phosphate (S[P]), (S[Ca]), and vitamin D values. Hypocalcemia stimulates PTH secretion contributing to the elevated PTH. Hyperphosphatemia exacerbates the hypocalcemia by increasing the calcemic resistance to PTH. Thus, the first step to treat hyperparathyroidism in this patient is to begin with a calcium-based phosphate binder which not only lowers the S[P] but also increases the S[Ca]. In addition, such an elevated S[P] in stage 4 CKD is somewhat unusual and suggests the patient is eating a high phosphate diet and would benefit from seeing a dietician. Starting treatment with 1,25-vitamin D (calcitriol) is not correct because it increases intestinal phosphate absorption, making the hyperphosphatemia worse. Starting treatment with cinacalcet

is also incorrect because marked hypocalcemia is already present and cinacalcet will lower S[Ca] further. In addition, in CKD patients not on dialysis, lowering PTH with cinacalcet decreases phosphate excretion which increases S[P]. Starting cholecalciferol to increase 25OHD to greater than 30 ng/mL is desirable, but not the best answer because it takes time for 25OHD values to increase, and the reduction in PTH is generally modest. As a general rule, 1000 IU of cholecalciferol will increase 25OHD values by approximately 10 ng/mL. Treatment with sevelamer would lower the S[P], which would improve the calcemic action of PTH, but in the presence of marked hypocalcemia, a calcium-based phosphate binder would serve the dual purpose of lowering S[P] and decreasing PTH levels by increasing S[Ca]. Once the hyperphosphatemia has been corrected, then 1,25-vitamin D (calcitriol) could be used to treat the hyperparathyroidism if hypocalcemia is still present.

Question 3

After the first generation PTH assay was developed in the late 1960s, elevated PTH values were shown to accompany the parathyroid gland hyperplasia known to be present in CKD. In the early 1970s, Slatopolsky and Bricker proposed the "trade-off" hypothesis, which stated that as a result of decreased renal function, phosphate retention would cause transient reductions in S[Ca] which would be corrected by increased PTH secretion, restoring the S[Ca] and S[P] to normal. The "trade-off" was maintenance of normal circulating calcium and phosphate concentration by a progressive increase in PTH levels and parathyroid gland hyperplasia. Subsequent studies with dietary phosphate loading and restriction established a central role for phosphate in PTH secretion and parathyroid gland hyperplasia. In azotemic animals, dietary phosphate loading increased PTH secretion and parathyroid gland hyperplasia, whereas dietary phosphate restriction had the opposite effect. Later studies showed that both the VDR and CaSR were present in the parathyroid gland.

Which of the following statements about parathyroid gland hyperplasia is not correct?

A. The progressive decrease in the VDR seen as parathyroid gland hyperplasia contributes to the development of parathyroid gland hyperplasia
B. Nodular hyperplasia precedes the development of diffuse parathyroid gland hyperplasia
C. A decrease in the CaSR is seen in parathyroid gland hyperplasia
D. High dietary phosphate given to azotemic rats increases PTH levels and PCNA positive cells, a marker of cell proliferation, in parathyroid gland
E. Clonal analysis of parathyroid nodules has shown that each nodule arises from a single clone of cells

Answer: B

As parathyroid gland hyperplasia develops, an increase in the number of secretory cells is followed by the development of diffuse hyperplasia. With continuing hyperplasia, the next stage is early nodularity, followed by multiple nodules in the parathyroid gland, which can evolve into a single nodule. During this evolution, the mass of the parathyroid gland continues to increase. By the time the weight of the parathyroid gland exceeds 500 mg (normal weight <40 mg), the vast majority of parathyroid glands have some form of nodularity. Individual parathyroid glands greater than 5000 mg can be seen, and asymmetry of the different parathyroid glands in a single patient is common. Diffuse parathyroid gland hyperplasia has a polyclonal origin, whereas nodular hyperplasia has a monoclonal origin. As progressive parathyroid gland hyperplasia develops, there is a decrease in both the VDR and CaSR which contributes to loss of sensitivity (suppressive effect) to vitamin D (calcitriol) and calcium. Because of the decrease in the CaSR, there were questions regarding whether azotemic patients with advanced secondary hyperparathyroidism (presumably nodular hyperplasia) would respond to the calcimimetic cinacalcet, which suppresses PTH secretion through its actions on the CaSR. For the above statements, B is incorrect because diffuse hyperplasia precedes nodular hyperplasia. A progressive decrease in the VDR and CaSR is seen as parathyroid gland hyperplasia progresses from diffuse to nodular hyperplasia. Finally, a high phosphate diet in azotemic rats has been shown to increase PTH levels and parathyroid cell proliferation.

Question 4

A 60-year-old man is referred to your office for evaluation of CKD. The past history is unremarkable except for stage 1 hypertension for 10 years, mild obesity, and benign prostatic hypertrophy. His eGFR has deteriorated over the past 12 months from 100 mL/min/1.73 m^2 to 45 mL/min/1.73 m^2. Several urinalyses obtained during the past year were bland except for trace protein by dipstick. A renal ultrasound obtained 3 months ago was unremarkable, with normal sized kidneys and no significant postvoid residual. He did not

use nonsteroidal antiinflammatory agents or herbal medications and reported no lower urinary tract symptoms.

The following:

S[Na] 140 mEq/L
S[K] 4.2 mEq/L
S[Cl] 107 mEq/L
S[HCO3] 25 mEq/L
S[Ca] 9.8 mg/dL
S[P] 7.0 mg/dL
BUN 35 mg/dL
S[Cr] 1.8 mg/dL
eGFR 45 mL/min/1.73 m^2

Which one of the following is true about his condition?

A. He should be started on a low phosphate diet
B. He needs to start on a calcium-containing phosphate binder
C. He needs to be started on a noncalcium-containing phosphate binder
D. The S[P] is elevated due to resistance to FGF-23
E. Free light chains should be measured

Answer: E

Hyperphosphatemia in CKD does not usually occur until the GFR is below 30 mL/min. In addition, S[Ca] is usually low normal or decreased when the S[P] is increased. In this case, the S[P] is high and S[Ca] is high normal. This profile can be seen in cases of pseudohyperphosphatemia, in which S[P] is actually normal, but appears elevated due to laboratory methodology. Dysproteinemias, such as multiple myeloma, are a common cause of pseudohyperphosphatemia. Excessive serum protein as seen in multiple myeloma may produce excessive turbidity and interfere with the colorimetric assay used to measure S[P]. Restricting dietary phosphate and using phosphate binders in the presence of pseudohyperphosphatemia can result in significant hypophosphatemia. Resistance to FGF-23 does occur with stage 3 CKD, but FGF-23 levels rise along with PTH levels in compensation, resulting in the maintenance of S[P] in the normal range.

Question 5

You are asked to consult on a 75-year-old man with worsening hyperphosphatemia. His past history is remarkable for hypertension, gastroesophageal reflux, elevated prostate-specific antigen (PSA), intermittent constipation, and schizophrenia. He has had stable CKD, with urinary protein excretion less than 1 g/24 h, following an episode of AKI 10 years ago, with a residual eGFR of 45 mL/min/1.73 m^2. His S[Ca] has fluctuated between 9.1–9.3 mg/dL and S[P] between 4.2 and 4.6 mg/dL. Because of an increasing PSA, he has undergone an extensive urologic evaluation during the past 6 months, including an MRI of the prostate, prostate biopsy, and transurethral prostatectomy. His only complaint is intermittent constipation. His estimated dietary phosphorus intake is approximately 700 mg per day. His medications include amlodipine, atorvastatin, doxazosin, omeprazole, and quetiapine.

The following laboratory data are obtained:

S[Ca] 8.2 mg/dL
S[P] 8.0 mg/dL
eGFR 35 mL/min/1.73 m^2

What would be the next appropriate steps in the management of the patient's hyperphosphatemia?

A. Reduce dietary phosphorus
B. Start calcium-containing phosphate binder
C. Start noncalcium-containing phosphate binder
D. Obtain further history regarding bowel habits and prostate procedures
E. Obtain CBC, CPK
F. D and E

Answer: F

The dietary phosphorus intake in this patient is relatively low and is unlikely to be the cause of the patients worsening hyperphosphatemia. He has had a decline in renal function which may be a factor contributing to the increased S[P], but his GFR is still at a level that is typically not associated with significant hyperphosphatemia. In this case, it would be important to look for additional endogenous or exogenous sources of phosphate. Hemolysis or rhabdomyolysis can result in an increased endogenous phosphate load. The patient is on a statin, which is a relatively common cause of rhabdomyolysis, which is associated with a rise in S[P] and decline in renal function. Some patients with schizophrenia can be obsessed with bowel cleansing and may use phosphate purges. In addition, the patient had recently undergone an extensive urological evaluation. Phosphate enemas are commonly used for bowel cleansing before urological procedures such as the prostate MRI, prostate biopsy, and transurethral resection. Although the small intestine is the primary intestinal site for phosphate absorption, the large bowel may also absorb phosphate, particularly if there is prolonged retention of the enema or bowel irritation. The use of phosphate purgatives may also explain the deterioration in renal function by inducing an interstitial nephritis from calcium-phosphate precipitation. Therefore, obtaining a careful history regarding the possible use of phosphate purgatories would be important in this case, particularly with the complaint of constipation. The use of phosphate binders would have little impact

in this case if the source of excessive phosphate load is endogenous or from the use of phosphate enemas.

Question 6

A 78-year-old man is admitted to the hospital with acute abdominal pain and vomiting. The patient has a history of congestive heart failure with an ejection fraction of 30% and is treated with furosemide 40 mg twice daily. On admission, the patient is somnolent and the systolic blood pressure is 90 mm Hg with a pulse of 46 bpm. He has a distended and tender abdomen. Pertinent laboratory results include white blood cell count 6900×10^9/L, hemoglobin 10.5 g/dL, S[Na] 140 mEq/L, S[K] 3.4 mEq/L, S[Cl] 104 mEq/L, S[Ca] 8.1 mg/dL, S[Alb] 4.2 g/dL, S[Cr] 2.1 mg/dL (baseline 1.5 mg/dL), and BUN 42 mg/dL. CT exam of the abdomen shows dilated loops of bowel and air fluid levels compatible with an ileus. The electrocardiogram shows prolonged PR and QT intervals and an increase in QRS duration. After your initial evaluation, you find the family in the waiting room. The family tells you that the patient was being prepared for colonoscopy to be performed that same day, but they did not know the medication he was taking. After obtaining that information, you measure the S[P] and S[Mg]. The S[P] is 2.2 mg/dL and the S[Mg] is 9.2 mg/dL. What are the two best answers?

A. Give intravenous furosemide
B. Give intravenous calcium
C. Give intravenous phosphate to correct the hypophosphatemia
D. Dialyze the patient
E. Wait for the magnesium load to be excreted

Answers: B and D

Magnesium citrate was given as the bowel preparation. 450 mL of magnesium citrate was prescribed to be taken at 7 pm and another 450 mL was prescribed to be taken in the morning 5 hours before the scheduled colonoscopy. The total elemental magnesium load is almost 9 g, while the recommended intake of elemental magnesium is approximately 350−400 mg daily. Thus, elderly patients with decreased renal function are clearly at risk for developing hypermagnesemia with toxic manifestations when give a magnesium load. The two best answers are B and D. Calcium is an antagonist of magnesium which acts as a calcium channel blocker. Calcium administration can reverse cardiac arrhythmias, hypotension, and other manifestations of hypermagnesemia. Hemodialysis with a magnesium free dialysate is an effective treatment because it rapidly lowers the magnesium concentration, reversing its toxicity. The Answer A, furosemide, is correct in patients with good cardiac and renal function and mild to moderate hypermagnesemia. Furosemide is often given with normal saline to enhance magnesium excretion at its primary excretory site in the thick ascending limb of Henle. However, the combination of furosemide and saline is not a good choice in this patient because of his congestive heart failure and decreased renal function. To measure the S[P] after learning the patient was given a bowel preparation was important because phosphate bowel preps are common and are associated with nephrotoxicity in older patients with decreased renal function. In addition, the observed hypocalcemia associated with phosphate toxicity would be consistent with the hypocalcemia seen in this patient. But the mild hypophosphatemia present in this patient immediately after taking the bowel prep essentially eliminates phosphate bowel preparation as the cause of this patient's illness. Even though mild hypophosphatemia is present, there is no indication to give phosphate, which could exacerbate the hypocalcemia. Finally, it is unlikely that the patient would spontaneously excrete his magnesium load before progressive complications occur.

Sleep Disorders in Chronic Kidney Disease

Lee K. Brown[a,b,c,d], *Mark L. Unruh*[a,e]

Abstract

Sleep is an essential function of life. Sleep clearly serves a crucial role in the promotion of health and performance. Poor sleep quality and sleep disorders have been a recurrent finding in patients with chronic kidney disease (CKD). Sleep disorders such as obstructive sleep apnea (OSA) can contribute to hypertension, diabetes (type 2 diabetes mellitus [T2DM]), cardiovascular disease (CVD), and worsen obesity, all of which are implicated in the etiology of CKD. CKD itself may lead to OSA. Mechanisms specific to OSA could hasten decline in renal function in and of themselves. OSA, in spite of its high prevalence, remains underdiagnosed and undertreated in CKD patients. Optimal sleep duration and quality play a significant role in improving control of T2DM. Insufficient sleep has been shown to increase the risk of obesity. Restless legs syndrome (RLS) and insomnia worsen health-related quality of life in CKD patients. RLS and depression are associated with increased mortality in CKD patients. There is emerging evidence linking insomnia and RLS to an increased risk of CVD, which is an important cause of mortality in CKD patients, and insomnia is increasingly recognized as having a causal link to dementia and white matter disease. Addressing sleep disorders could help to prevent not only the development but also the progression of CKD.

INTRODUCTION

Sleep is an essential function of life, consuming approximately one-third of our existence and clearly serving a crucial role n the promotion of health and performance. Sleep has been described behaviorally as "a reversible behavioral state of perceptual disengagement from, and unresponsiveness to, the environment."[1] Sleep appears to exert a restorative effect on the brain by allowing recovery of CNS neurons that undergo one or more reversible changes during wakeful activation. Recent work suggests that sleep facilitates the clearance of β amyloid by the glymphatic system.[2] Similar to diet and activity, sleep serves as an important regulator of somatic growth, maturation, and health. Moreover, sleep is an important enabler of protein synthesis and body repair. The negative effects of sleep deprivation include defects in cognition, vigilance, emotional stability, risk-taking, and possibly moral reasoning as well as an increase in appetite, and glucose intolerance.[3–6] Procedural, declarative, and emotional memory are impaired by lack of sleep, and functional MRI shows profound changes in regional cerebral activity related to attention and memory.[7] Widespread alterations of immune function and inflammatory regulators can also be seen.[5] Sleep and sleep quality may be impaired among those with chronic illnesses, particularly among individuals with chronic kidney disease (CKD).

In the past decade, CKD has been increasingly linked with poor sleep quality and a variety of sleep disorders. Sleep disorders such as obstructive sleep apnea (OSA) can contribute to hypertension, diabetes, cardiovascular disease, and obesity, all of which are implicated in the etiology of CKD (Figure 36.1). Although hypertension, diabetes, and obesity are risk factors for CKD, the causal relationship between sleep disorders and CKD is not yet well established. Although several risk factors for CKD are also commonly linked to sleep disorders such as OSA, OSA alone may also accelerate the progression of CKD. Thus, although it appears highly likely that a unidirectional or bidirectional relationship between CKD and OSA exists, the increased prevalence of both of these

disorders and their associated risk factors has made the direction of causality and underlying mechanisms difficult to ascertain. Certainly, this subject warrants further understanding because it is likely that clinicians must recognize and treat sleep disorders in CKD patients to slow the progression to renal replacement therapy. The aim of this chapter is to describe the important role sleep plays in patients with CKD. Three specific sleep disorders in CKD patients, insomnia, OSA, and restless legs syndrome (RLS), will be discussed (including their prevalence, pathogenesis, impact, and treatment).

INSOMNIA

Insomnia is defined as difficulty falling asleep, staying asleep, and/or the perception of inadequate sleep along with daytime consequences that cannot be attributed to another sleep disorder. The International Classification of Sleep Disorders [ICSD-3] diagnostic criteria for insomnia are shown in Table 36.1. In comparison with previous editions of the ICSD, insomnia is now classified as either Chronic Insomnia Disorder or Short-term Insomnia Disorder. The latter encompasses time-limited insomnia that is a result of a stressful event, whereas the former is further subdivided into insomnia disorders with distinct clinical and pathophysiologic correlates. Specific criteria for eight individual disorders associated with the symptom of insomnia are listed in the ICSD-3.

In the general population, insomnia symptoms occur in 30–40% of adults. Specific insomnia disorders occur in 5–10% of adults.[9] Studies in CKD patients have shown a wide range of estimates of chronic insomnia disorder, with a high prevalence of insomnia reported early in the course of CKD,[10] suggesting that this may be an important factor in the difficulty CKD patients have coping with their illness. Moreover, the prevalence of chronic insomnia disorder is higher with lower levels of kidney function.[11] Although chronic illnesses are a significant risk factor for insomnia, the presence of concurrent depressive symptoms is an even stronger risk factor. Moreover, the relationship between insomnia and depression is thought to be bidirectional. Longitudinal studies have shown insomnia to be a substantial risk factor for the subsequent development of depression, and this risk appears to extend over a large portion of a person's life.[12,13] Patients with CKD have an increased prevalence of both insomnia and depression, and therefore the presence of insomnia presumably would additively increase their risk of depression, nonresponse to treatment for depression, and any subsequent recurrence.

There remains some uncertainty regarding the prevalence of clinical insomnia in CKD patients, as most studies have relied on self-report rather than evaluation by a skilled practitioner. Several studies have reported a wide range of insomnia prevalence (14–85%) in CKD patients, based on patient reported questionnaires.[14–23] Cohen et al. reported that 69% of patients with CKD experienced pain; 55% had disordered sleep with scores on the Pittsburgh Sleep Quality Inventory (PSQI) >5.[17] Kurella et al. reported a prevalence of insomnia of 5–20% for all CKD patients, and in Caucasian and Asian subjects, lower kidney disease quality of life (KDQoL) scores were seen in advanced stages of CKD compared to early stages of CKD.[16] Interestingly, self-reported insomnia seemed to persist even after renal transplantation in two studies.[23,24] Another relevant question relates to whether insomnia symptoms differ with respect to dialysis modality. Knezevic et al. used the Insomnia Severity Index questionnaire to compare HD techniques consisting of online polysulfone bicarbonate hemodiafiltration (n = 43), high-flux polysulfone bicarbonate hemodialysis (HD) (n = 39), and low-flux polysulfone bicarbonate HD (n = 40).[25] Their data suggested a beneficial effect on insomnia symptoms by using high-flux membranes. Yet another controversy has been raised regarding whether sleep is disturbed by nocturnal treatment for end-stage renal disease (ESRD) by means of automated peritoneal dialysis (APD). Losso et al. examined this possibility using a battery of questionnaires administered to patients on HD, home-based continuous ambulatory peritoneal dialysis (CAPD), and APD.[26] Their data indicated that the

TABLE 36.1 International Classification of Sleep Disorders, Third Edition: Diagnostic and Coding Manual Diagnostic Criteria for Chronic Insomnia Disorder*

A	A complaint of difficulty initiating sleep, difficulty maintaining sleep, or waking up too early, sleep that is chronically nonrestorative or poor in quality, or (in children), resistance to an appropriate bedtime, or difficulty falling asleep without adult intervention.
B	At least one of the following forms of daytime consequences related to the nighttime sleep difficulty is reported by the patient:
	1. Fatigue or malaise
	2. Poor attention or concentration
	3. Social or vocational/educational dysfunction
	4. Abnormal mood or excessive irritability
	5. Inappropriate sleepiness
	6. Reduced motivation or energy
	7. Increased errors or accidents
	8. Impulsivity, hyperactivity, aggression, or other changes in behavior
	9. Concerns or worries about sleep duration, continuity, or quality
C	The insomnia symptom(s) occur in the setting of an adequate amount of time allotted for sleep and an environment conducive to sleep
D/E	Symptoms occur at least three times per week for at least 3 months
F	Symptoms are not better explained by another sleep disorder

* *Adapted from reference 8.*

prevalence of insomnia was similar between the HD (85 %), CAPD (81%), and APD (84%) groups ($p = 0.83$). Studies incorporating a thorough clinical history with a focus on the items listed in the ICSD-3 or a similar nosology are warranted to determine a more precise estimate of the rate of chronic insomnia disorder in CKD patients.

In addition to self-reported symptoms of insomnia, CKD patients have reduced sleep efficiency and poor sleep quality measured by actigraphy and polysomnographic (PSG) testing. Parker et al. reported PSG measures of sleep in 8 later-stage CKD patients and 16 patients on chronic HD.[27] In this study, both groups had reduced total sleep time and sleep efficiency in comparison with normative data. Analysis of quality of life (QOL) scores showed that CKD patients had lower psychological, spiritual, health, and functioning scores compared to HD patients, suggesting that the impact of having untreated CKD in and of itself is marked. The prospect of CKD progression and the eventual need for renal replacement therapy appeared to adversely affect sleep and QOL in the CKD patients. Roumelioti et al. also demonstrated delayed sleep onset and short and disrupted sleep in the CKD and ESRD population.[28] Agarwal and Light[29] and Barmer et al.[30] studied CKD patients using wrist actigraphy, demonstrating reduced sleep efficiency and poor sleep quality using this semi-quantitative technique. Disrupted sleep was associated with a decline in daytime activity, both in duration as well as in intensity, and poor QOL.

Importantly, the quality of sleep has been reported to decrease even in the early stages of CKD.[15] Sabbatini reported that progression of CKD was accompanied by progressive worsening of sleep quality. Over a 3-year time period, decline in both sleep quality as well as the expected worsening of kidney function were reported.[18] Ezzat et al. performed nocturnal PSGs in three groups of patients: those with CKD, those with ESRD treated with HD, and normal controls. In the ESRD group, PSGs were performed on the night of their HD, whereas the CKD subjects were age- and gender-matched, and metabolically comparable.[19] Both CKD and ESRD patients had reduced total sleep time and sleep efficiency in comparison with controls. The CKD group had normal sleep latency, whereas the HD group exhibited sleep latencies almost twice as long. HD patients exhibited significantly less REM sleep and an increase in brief arousals, which may have been a consequence of this group demonstrating more frequent apneas (despite attempts to limit the likelihood of sleep-disordered breathing in the subjects) and limb

movements. Additional analyses revealed inverse correlations between sleep disorders and levels of circulating hemoglobin and albumin, as well as creatinine clearance, and a positive correlation between disordered sleep and serum phosphate concentration (S[P]). In summary, CKD patients have an increased prevalence of insomnia and depression, decreased health-related quality of life (HRQOL), decreased daytime activity, and a progressive decline in sleep quality and kidney function.

Pathogenesis

Although it is unknown if there is a shared propensity for hyperarousal in CKD, it has been shown that CKD patients suffer marked socioeconomic and health-related stress as well as distress that could lead to the same result.[31] Converging evidence from physiological and psychological studies suggest that hyperarousal is common to individuals with insomnia.[32] Worry and rumination about life stresses result in hyperarousal, disrupted sleep, and foster insomnia. It is also likely that interplay exists between a genetic vulnerability to an imbalance between arousing and sleep-inducing brain activity, psychosocial/medical stressors, and perpetuating mechanisms, including improper sleep behaviors, learned sleep-preventing associations, and the tendency to worry and ruminate.[33] Insomnias were found to have a higher heart rate, decreased heart rate variability, and increased lower frequency spectral power—all characteristics of increased sympathetic activity that could then increase cardiovascular risk.[34] Patients with insomnia have increased cerebral glucose metabolism in pertinent CNS regions when studied by positron emission tomography scans,[35] characteristic of failure of arousal mechanisms to decrease in activity from wake to sleep states.

Impact

Insomnia in CKD patients has been shown to be independently associated with self-reported comorbidity, depression, RLS symptoms, and increased risk for OSA as assessed by the Berlin questionnaire. These observations are consistent with relationships observed in the general population. Insomnia has been associated with decrements in HRQOL, increased costs of care, poor work performance, and depression in the general population. Patients with severe insomnias have also been reported to have more medical problems, more physician office visits, more frequent hospitalizations, and more medication use compared to good sleepers, creating a significant economic burden.[36–38] Simon and Von Korff reported that mean total health care expenditures were 60% higher in insomniacs compared to controls.[39] Insomniacs report decreased alertness and fatigue[40] and show psychomotor performance deficits compared to normal sleepers during objective testing.[41] Meta-analysis of longitudinal epidemiological studies (spanning the years 1980–2010) demonstrate patients with insomnia have a twofold increased risk of developing depression compared to good sleepers.[42] Another longitudinal study by Laugsand et al.[43] reported a link between insomnia symptoms and subsequent risk of acute myocardial infarction over a 11-year time period in a sample of more than 50,000 individuals in Norway. Despite some study limitations, their results and other observational data[44–46] support the need for future studies to determine whether improving poor sleep quality might improve cardiovascular outcomes. Depression alone, which contributes to the incidence of insomnia, has already been associated with a substantially increased risk of death in CKD patients.[47]

Insomnia also appears to promote the occurrence and progression of CKD. In an ancillary study of the CRIC cohort, shorter and fragmented sleep using wrist actigraphy was associated with greater declines in kidney function and increased levels of proteinuria.[48] In arguably one of the most robust studies on this subject, patients in Japan exhibiting both short sleep and long sleep as well as poor sleep quality had an associated increased rate of progression to ESRD.[49] Huang et al., in a population-based retrospective study, demonstrated an increased incidence of CKD in individuals with non-apnea (e.g. insomnia) sleep disorders.[50] A similar study by Lin et al. reported similar results with respect to incident CKD in patients aged less than 65 years.[51] Yet another study, by Li et al., followed 11,040 Chinese adults and found that lower overall sleep quality was associated with higher odds of being at high to very high risk for CKD and proteinuria.[52] Lu et al. used a database incorporating 1,639,090 US Veterans and found that chronic insomnia was associated with a greater risk of both the initial development and the progression of CKD, but, interestingly, not of progression to ESRD.[53] The fact that these individuals tended not to progress to ESRD seems counterintuitive. Sasaki et al. found an association with the incidence of CKD in patients with insomnia, but only in those who were shift-workers, a hazard of shift work that has not heretofore been reported.[54]

Diagnosis and Treatment

Specific recommendations for the diagnosis and treatment of insomnia among patients with CKD are difficult to make because few studies of insomnia have focused

on this population. In general, a thorough clinical history is a foundation of chronic insomnia evaluation, and it should include a detailed interview with a focus on a description of the sleep disturbance experienced during the night, sleep habits, lifestyle patterns, sleep schedule, variability in sleep timing from day to day, daytime consequences of the sleep disturbance (including alterations in mood, subjective sleepiness, and fatigue), associated medical and psychiatric illness, intake of caffeine, alcohol, and medications that interfere with sleep. The specific cause for underlying insomnia, if identified, should be initially treated and then the patient should be reevaluated. Following the general principles of sleep hygiene will almost always be beneficial. These include exercising during the day (but not in the evening), reducing or eliminating caffeine intake, avoidance of alcohol and nicotine near bedtime, establishing a regular bedtime and *especially* a wake up time, avoiding eating close to bedtime, and use of the bedroom and bed for sleep and intimacy only.

Short-term (adjustment) insomnia lasts for a relatively brief time period, usually occurs in a temporal relationship with an identifiable stressor, and in most cases the patient will sleep better once the stressor resolves. Hypnotic agents are a treatment option in such cases, particularly if sleepiness from insomnia is causing impaired driving or represents a danger in operation of hazardous machinery in the workplace.[55] Guidelines promulgated by the American Academy of Sleep Medicine may be used as the basis of both nonpharmacologic and pharmacologic treatment for chronic insomnia, although the latter must be interpreted with due regard to those hypnotics that may be contraindicated or require more careful dosing in patients with CKD or ESRD.[56,57] In chronic insomnia disorder, cognitive behavioral therapy for insomnia (CBT-I) works equally well for both sleep onset as well as for maintenance insomnia. Cognitive behavioral therapy for insomnia includes stimulus control and sleep restriction therapies, training in relaxation techniques (including biofeedback and paradoxical intention) and cognitive reorientation of patient attitudes to reduce the anxiety experienced over an episode of poor sleep. CBT-I is grounded in the behavioral construct of insomnia pathogenesis, which holds that faulty attitudes toward sleep and unproductive strategies for dealing with disturbed sleep lead to perpetuation of the disorder.[55] According to two meta-analyses,[58,59] CBT-I treated patients fell asleep faster than 81% of controls and slept longer than 74% of their untreated controls. CBT-I has long-lasting efficacy that aids in the prevention of insomnia recurrences[60,61] and benefits patients with insomnia when it is comorbid with other disorders such as depression.[62] Although CBT-I has been of known benefit to insomnia patients, its implementation has been difficult, due to lack of provider time. Recently however, randomized controlled trials (RCTs) of CBT-I show effectiveness in more time-efficient settings, such as group therapy, and with lower-intensity interventions such as brief telephone consultation followed by internet-based fully automated therapeutic regimens.[63] The availability of internet-based or computer-based CBT-I has expanded greatly in the last few years, as has a variety of "self-help" treatment modalities, including written materials. Most have been validated experimentally. Ho et al. published a meta-analysis of these therapeutic modalities in 2015 and concluded that they demonstrated a reasonable degree of therapeutic efficacy overall.[64] Effect sizes, based on sleep diaries, indicated that sleep efficiency, sleep onset latency, and wake after sleep onset at immediate posttreatment were 0.80, 0.66, and 0.55, respectively, compared to waiting-list controls. Not included in this meta-analysis was a recent RCT of a specific CBT-I product that also demonstrated efficacy for insomnia treatment.[65]

The use of CBT-I has not been studied in patients with CKD or ESRD. However, numerous studies of CBT applied to patients with CKD and/or ESRD in general have suggested salutary effects with respect to depression and anxiety, which would therefore be expected to help ameliorate insomnia. These have included both internet-based CBT[66–68] and in-person CBT administered by trained personnel.[69,70] In addition, a RCT comparing CBT to sertraline for the treatment of depression in ESRD has been completed.[71,72] This investigation showed both treatments resulted in improvement of depressive symptoms, with scores modestly better with sertraline compared to CBT.[72]

When CBT-I fails or is not practical, the newer nonbenzodiazepine hypnotic agents (the so-called z-drugs: zolpidem, zaleplon, and zopiclone) have no significant adverse effects on sleep architecture, are less likely to result in tolerance, and are only infrequently associated with rebound insomnia on withdrawal, compared to benzodiazepines or most other hypnotics. The elimination of all three drugs and their metabolites involve almost exclusively nonrenal mechanisms. There was no accumulation of zolpidem in ESRD patients and no alteration in pharmacokinetics.[73,74] Eszopiclone in a dose of 3 mg has been shown to retain efficacy for over 6 months in one study.[75] Studies have shown improvement in HRQOL of patients with both depression and insomnia, when they were given eszopiclone 3 mg (for insomnia) along with fluoxetine for depression.[76] Clonazepam was more effective than zolpidem for disturbed sleep; however, zolpidem was better tolerated, in a sample of ESRD patients.[73] Another small study showed a trend toward improvement in the PSQI in ESRD patients treated with CBT-I and a small dose of hypnotic.[77]

Ramelteon is a melatonin receptor agonist with a Federal Drug Administration (FDA)-approved indication for the treatment of insomnia. Its elimination does not involve renal mechanisms. It theoretically may be of utility in CKD patients with insomnia. However, no information has appeared with respect to its use in this population. More recently, a new hypnotic, suvorexant, received FDA approval, but the utility in patients with CKD or ESRD is yet to be determined. Suvorexant acts *via* a novel mechanism as an orexin receptor antagonist, but it is not yet available on the market. Studies of suvorexant metabolism indicated that 66% of the drug is eliminated through the gastrointestinal tract, and 23% in urine, primarily as oxidative metabolites.[78] Despite the involvement of CYP3a enzymes in the oxidation of suvorexant, significant drug interactions *via* induction or inhibition of these enzymes were not felt to be of concern.[78] Several sedating antidepressant medications have been reformulated, or are prescribed off-label, as hypnotics including trazodone, doxepin, mirtazapine, and amitriptyline. Some of these agents have bioactive metabolites, long elimination half-lives, and/or are renally excreted. Little information is available concerning their utility in CKD patients with insomnia, and their use is discouraged.

Given the increased prevalence of insomnia in CKD patients and its impact, nephrologists should be vigilant in looking for symptoms of insomnia and depression in their patients, and at least should implement simple sleep hygiene measures for those with complaints of disturbed sleep. Clinicians should have a low clinical threshold for referral to sleep medicine physicians when more complicated issues arise. Given that cognitive behavioral therapy has efficacy in the treatment of major depression and insomnia in kidney failure patients,[72,79] it is a reasonable expectation that appropriate CKD patients may also benefit from CBT for insomnia.

SLEEP-DISORDERED BREATHING

OSA is highly prevalent and likely contributes to the substantial morbidity observed in the CKD population. OSA may also directly and indirectly contribute to the progression of CKD. OSA can contribute to systemic hypertension (HTN), type 2 diabetes mellitus (T2DM), and worsen obesity, all of which are associated with CKD. OSA has been described as "characterized by repetitive episodes of upper airway obstruction that occur during sleep, usually associated with a reduction in blood oxygen saturation."[80] An apnea is the cessation of airflow for more than 10 seconds despite continued inspiratory efforts. The definition of hypopnea as required by the Centers for Medicare and Medicaid Services is a 30% decrease in airflow or chest wall movement for at least 10 seconds, accompanied by oxyhemoglobin desaturation (by pulse oximetry) of 4% or greater.[81] An alternative definition of hypopnea, felt by most experts in the field to be more clinically relevant and recommended by the American Academy of Sleep Medicine, is a 30% decrease in airflow or chest wall movement from baseline for at least 10 seconds, accompanied by either a 3% or greater desaturation or EEG evidence of arousal. The presence of OSA is confirmed when the apnea–hypopnea index (AHI) is at least 5 per hour (total of apneas plus hypopneas divided by total sleep time). Various obstructive events must also be differentiated from central apneas, characterized by absent inspiratory effort as well as cessation of airflow, and mixed apneas where a central apnea concludes with one or more obstructed breaths.

Although somewhat less common, patients with CKD may also have central sleep apnea (CSA). CSA is a subtype of sleep-disordered breathing with a repetitive pattern of cessations (or reductions) and resumptions (or increases) of respiratory effort usually not accompanied by significant upper airway obstruction. The pattern of CSA may take the form of abrupt cessations of respiration or may assume the waxing and waning pattern of Hunter–Cheyne–Stokes breathing (HCSB). For all intents and purposes, the two phenotypes do not appear to differ with respect to pathogenesis, clinical significance, or treatment.

Establishing a diagnosis of OSA or CSA is best accomplished using in-center PSG, although home sleep apnea testing using portable equipment can be appropriate when adhering to published guidelines.[82] It is important to emphasize that these definitions rely on physiological recordings only and do not require the presence of symptoms of sleepiness, which may be less characteristic of OSA in the CKD population. Specifically, screening questionnaires for OSA that incorporate these and other variables have been shown to lack sensitivity in patients with CKD.[83] Intermittent hypoxia and increased sympathetic activity associated with OSA may be expected to lead to CKD, suggesting that OSA should be addressed by clinicians not just in ESRD but also in CKD patients. CSA is frequently even less symptomatic, particularly in patients who also suffer from heart failure. Such individuals are thought to suffer from sympathetic overactivity that prevents the perception of sleepiness.

Prevalence

The reported prevalence of OSA in CKD populations ranges between 27% and 71%.[27,28,84–96] Table 36.2 presents a summary of OSA studies in CKD patients. Risk factors for OSA in the general population, such as older

TABLE 36.2 Obstructive Sleep Apnea (OSA) Prevalence in Chronic Kidney Disease (CKD) Populations

Study	Participants	Findings
Canales[87]	508 elderly male >67 years.	Association of reduced renal function (as defined by higher cystatin-C concentration) with higher RDI did not persist after correction for BMI, sex, age (p for trend 0.34). When CKD was identified using Mayo clinic formula only, there was twofold greater OR of moderate to severe OSA. Association between CKD and OSA is not clear given the inconsistency of findings across different measures of renal function.
Canales[92]	2696 patients	S[Cr] measured an average of 3.4 year prior to PSG. Men >72 years of age, eGFR < 65 was not associated with increasing RDI. In men <72 years of age, eGFR < 65, association between RDI and eGFR was not statistically significant when corrected for BMI (p for trend 0.3)
Nicholl[90] Canada.	46CKD + OSA/73CKD alone. 46CKD + OSA/230OSA alone. CKD defined as eGFR < 60 mL/min/1.73 m^2	MVRA: only male gender was significantly associated with OSA in CKD patients. Daytime sleepiness was higher in CKD+OSA (39%/19%) compared to CKD only. Prevalence of sleep-related symptoms was lower in CKD+OSA compared to OSA alone suggesting MD should have low threshold to obtain PSG in CKD patients. Kidney function not assessed in 230 patients. Because respiratory effort assessment was not done, cannot distinguish if the apnea was obstructive or central.
Nicholl[91] Canada.	55 CKD 1−2/124 CKD 3−4/75 ESRD.	Increased prevalence of old age, BMI, CVA, and CHF in their patients, all of which increase risk of OSA. After MVA, only ESRD was associated with presence of SA. Because respiratory effort assessment was not done, cannot distinguish if the apnea was obstructive or central.
Fleischmann[86]	70(n GFR)/70 CKD 2/18 CKD 3	Prevalence of sleep apnea same between groups 80%/86%/94%. Type of apnea differed significantly. Number of central sleep apnea (CSA) in CKD 3 was 6 times >compared to CKD 2. Prevalence of OSA did not differ between groups. MRA: CKD 3, NYHA class ≥ 3 predicted CSA. Patients studied were referred because of suspected apnea.
Roumelioti[28]	89 CKD (GFR ≤ 40 mL/min/1.73 m^2)/75 HD/224.	Controls, CKD patient had higher median total sleep time and efficiency compared to HD patients. Presence of advanced CKD associated with 2.4 fold higher risk of severe OSA (AHI > 30) compared to control group whose kidney function was unknown.
Parker[27]	8 CKD (4−5)/16 HD.	CKD pt reported significantly poorer functional and psychological quality of life. All patients had reduced total sleep time and efficiency compare to normative data. HD pt had higher brief arousal index, trend toward higher RDI. Small sample size.
Sim[88]	1,102,089.	Prevalence of sleep apnea 2.54%. Diagnosis of SA was identified from database using ICD-9 codes. BMI data not provided so adjustment for obesity not possible. Average OR for SA by eGFR is 1.34. Their low prevalence compared to other smaller studies raise suspicion for underdiagnosis in their population.
Markou[85] Greece.	35 CKD Group A: CKD-4/Group B: CKD-5 not on HD.	Mild OSA in 54%, moderate OSA in 31%. No significant difference in AHI between group A and B. Group B had significantly low slow wave sleep. OSA unrelated to daytime sleepiness. Small sample. No control group. AHI did not correlate with kidney function except in nondiabetics.
Sakaguchi[89] Japan.	100 CKD (1−3), Median BMI 23	Mild OSA 32%, Moderate OSA 25%, Severe 8%. MLRA: 10 mL/min/1.73m^2 decrease in GFR associated with 42% increase in OR of OSA. Adjusted eGFR inversely correlated with AHI.
Iseki[93] Japan.	1624 OSA, 7454 control CKD defined as GFR < 60	CKD detected in 31% of OSA patients compared to 9% in control. In contrast to control group, prevalence of CKD decreased in OSA group as BMI increased, suggesting that physicians should have lower threshold in nonobese OSA patients for CKD. In Japan, where obesity is less prevalent, craniofacial bone structure difference may be a more important risk factor for OSA.
Chou[94] Taiwan.	40 patients c/o snoring.	Prospective study. No DM, HTN. Mild OSA 15%, Moderate 8%, severe 70%. Prevalence of CKD 18% in severe OSA patients. 37 patients had OSA of which 5 (14%) had CKD. All had severe OSA (5 out of 23, 18%). MVRA: AHI and desaturation index were independent predictors of UACR and eGFR respectively. Small sample.
Marrone Italy[96]	7700 in sleep centers across 26 sleep centers	OSA severity and lowest SpO2 were associated with moderate CKD

AHI, apnea hypopnea index; *BMI*, body mass index; *CSA*, central sleep apnea; *CHF*, congestive heart failure; *CKD*, chronic kidney disease; *CVA*, cerebrovascular disease; *DM*, diabetes mellitus; *eGFR*, estimated glomerular filtration rate; *ESRD*, end-stage renal disease; *HD*, hemodialysis; *HTN*, hypertension; *MLRA*, multiple linear regression analysis; *MRA*, multiple regression analysis; *MVA*, multivariate analysis; *MVRA*, multivariate regression analysis; *NYHA*, New York Heart Association; *OR*, odds ratio; *OSA*, obstructive sleep apnea; *PSG*, polysomnography; *RDI*, respiratory disturbance index; *S[Cr]*, Serum creatinine concentration; *SA*, sleep apnea; *UACR*, urine albumin:creatinine ratio; *Type II*, comprehensive portable PSG (unattended); *Type III*, modified portable sleep apnea testing (unattended; minimum of 4 channels including ventilation [at least 2 channels of respiratory movement or a combination of respiratory; movement and airflow]); heart rate or electrocardiography (ECG); and oxygen saturation; *Type IV*, continuous single- or dual-bioparameter recording (unattended).

age, diabetes, obesity, male gender, and smoking, are also prevalent in the CKD population.[97,98] The wide variation in prevalence estimates may be due to small sample sizes, selective recruitment, and imprecise definitions of sleep apnea and CKD. In addition, for patients with ESRD already on dialysis, Huang et al. found differences in the incidence of OSA that varied with the type of dialysis treatment.[99] The incidence rate of OSA was higher in the peritoneal dialysis (PD) cohort than the HD and control cohorts. Independent risk factors for OSA were, not surprisingly, also present, including age, gender, coronary artery disease, lipid disorders, chronic obstructive pulmonary disease, and hypertension. The severity of OSA was higher in PD patients than HD patients.

A relatively low prevalence of CSA in CKD patients has been reported.[28] However, most studies of sleep-disordered breathing prevalence in CKD have failed to distinguish between CSA events and OSA events, often due to the limited technology used to ascertain the presence of respiratory events during sleep. A recent systematic review by Nigram et al. estimated a point prevalence of about 10%, but acknowledged that the extant literature reports prevalence varying between an astounding 0 and 75%.[100]

Proteinuria

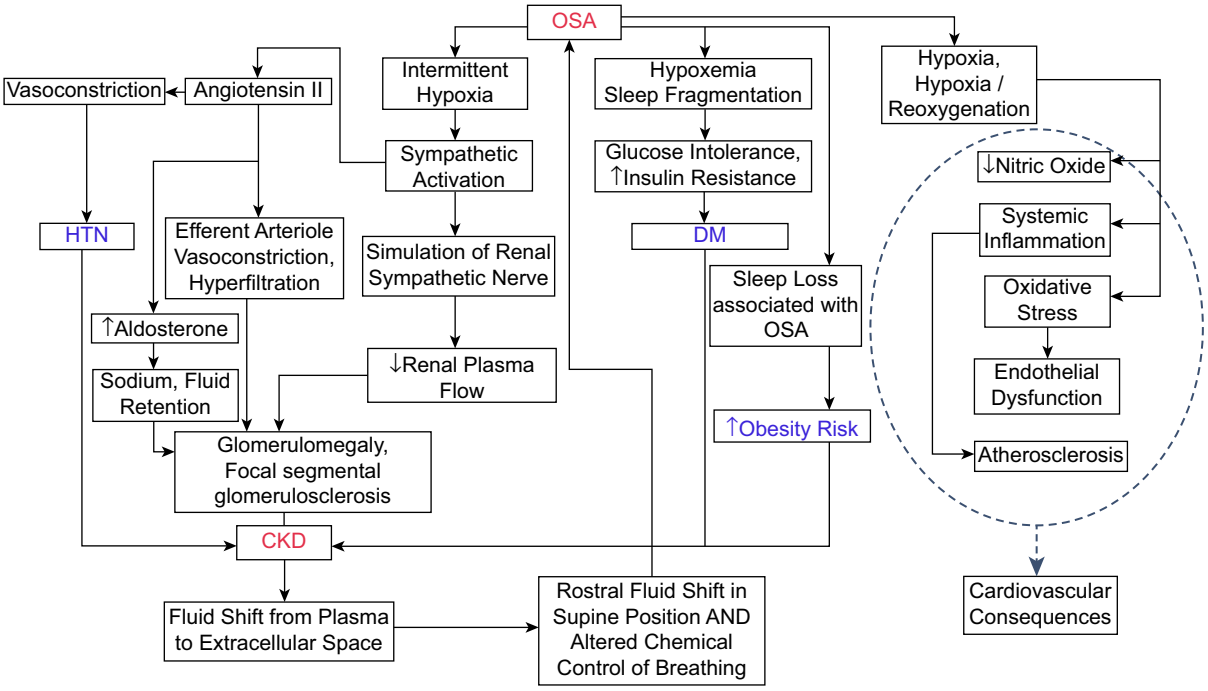
Although the severity of proteinuria is a key predictor of CKD outcomes, the relationship between proteinuria and OSA severity remains unclear. Frank proteinuria has been described in a very small study of OSA patients who, after treatment of OSA, showed improvement in proteinuria.[101] A study by Faulx of 496 adults showed that severe OSA is significantly associated with increased urine albumin excretion. This association remained significant after adjustment for confounding factors such as obesity, diabetes, hypertension, GFR, age, sex, and race.[102] Urinary albumin excretion in patients with OSA may result from an influence of OSA-related pathophysiologic changes on glomerular endothelial function. In a cross-sectional study from Greece published in 2008, nondiabetic adults with untreated HTN and OSA were compared with hypertensive patients without OSA. Patients with OSA were found to have a 57% increase in log 10 urinary albumin:creatinine levels (UACR) on average, which correlated with AHI and 24-hour pulse pressure, even after adjustment for confounders.[103] Presumably, the observed association of UACR with 24-hour pulse pressure relates to the mechanisms cited above.[104,105] In a prospective study by Chou et al., UACR showed a linear increase (3.6−16.5 mg/g) with the increase in sleep-disordered breathing severity (ranging from simple snorer to severe OSA).[94] On the other hand, Casserly et al.[106] published a cross-sectional study assessing the prevalence of nephrotic range proteinuria in OSA patients. Although proteinuria was not associated with OSA, microalbuminuria was not measured and the use of angiotensin converting enzyme inhibitors (ACEIs) by their patients may have impaired the ability to assess a potential association. In a study of 679 diabetic patients, more severe OSA was related to higher levels of albuminuria after adjusting for potential confounders.[107]

Pathogenesis

The pathogenesis of OSA in CKD patients (Figure 36.2) may be related to fluid overload leading to upper airway edema, reduced upper airway muscle tone due to putative or known CKD toxins, peripheral neuropathy due to underlying T2DM or CKD itself, aberrations in ventilatory control (perhaps due to enhanced peripheral and central chemoreceptor sensitivity or acidosis) contributing to an increase in respiratory control system "loop gain" and the development of unstable breathing during sleep, or some combination of these factors.[108] Patients with CKD usually have varying degrees of obstructive, mixed, and central sleep apneas.[27,28,84−86] Hypocapnia associated with chronic metabolic acidemia may lower the arterial pCO_2 to below the apneic threshold during sleep, predisposing to periodic breathing. Chronic acidemia in CKD patients may also alter the hydrogen ion set point for respiration.

It is generally accepted that OSA in most patients is the result of anatomic upper airway narrowing (such as from obesity) in combination with the state-dependent reduction in upper airway dilator muscle tone that occurs during sleep. In CKD, these mechanisms may be supplemented or even replaced by the aforementioned factors specific to CKD, such as ventilatory instability and volume overload. Although the lack of typical features may make OSA more difficult to recognize among CKD patients, it can also lead to disease-specific diagnostic and treatment approaches, such as early recognition and aggressive management of OSA in CKD patients. This approach may inhibit, or possibly prevent, the progression of CKD, by reducing the incidence or severity of HTN, type 2 diabetes, and obesity, known risk factors for worsening renal function.

CSA in CKD is exclusively hyperventilatory in nature. The pathogenesis of this variety of CSA/HCSB is a function of ventilatory control during sleep, the most important aspect of which is the presence of an apneic threshold for $PaCO_2$ that occurs only during nonrapid eye movement sleep. The most likely pathogenetic mechanism related to CKD involves fluid overload. Pulmonary capillary engorgement leads to increased



Abbreviations: OSA= obstructive sleep apnea; HTN = hypertension; DM = diabetes; CKD = chronic kidney disease

FIGURE 36.2 Pathophysiologic link between OSA, complications of OSA and CKD.

afferent tone from the juxta-capillary (J) receptors in the lungs, which promotes hyperventilation and drives the $PaCO_2$ to values adjacent to the apneic threshold and destabilizes ventilatory control. Heart failure and CKD are often seen together, and heart failure further promotes hyperventilation due to hypoxemia.

Effects of OSA on Renal Function

Although CKD may lead to OSA by a variety of mechanisms, and the above considerations clearly indicate a bidirectional relationship mediated by HTN, type 2 diabetes, and obesity, there are other mechanisms specific to obstructive respiratory events that arguably could hasten the decline in renal function in and of themselves. Intermittent airway occlusion during apnea or hypopnea leads to intermittent hypoxia, a known upregulator of inflammatory mediators and oxidative stress.[109,110] Strenuous inspiratory efforts against an occluded airway result in repetitive arousals associated with measurable degrees of sympathetic activation, leading to vasoconstriction. Increased sympathetic activity upregulates the production of angiotensin II, a potent vasoconstrictor, by stimulating the production of renin in the kidney. Angiotensin II also stimulates the adrenal cortex to secrete aldosterone, which decreases sodium excretion and causes water retention, key mechanisms for the control of blood volume and blood pressure. The vasoconstrictor response to angiotensin II is increased in patients with OSA and contributes to the secondary HTN[111] seen in 50% of OSA patients. Intermittent hypoxia decreases the bioavailability of nitric oxide, causing ischemia.[110] OSA has been linked to glomerular hyperfiltration and may be related to increased angiotensin II activity. Glomerulomegaly results from renal venous hypertension, and the characteristic histologic findings of glomerular hypertrophy and/or focal segmental glomerulosclerosis have been reported in OSA patients.[112–114]

In a small study, patients with OSA were found to have GFR within the normal range, but renal plasma flow was significantly lower than normal, pathognomonic of a high filtration fraction (FF). The FF before continuous positive airway pressure (CPAP) treatment was instituted was not significantly correlated with blood pressure, age, or body mass index; however, FF did correlate with increased hypoxemia. After treatment with CPAP, FF significantly decreased, suggesting that CPAP might ameliorate hyperfiltration and therefore prevent progressive decline in kidney function in CKD patients with OSA.[115] Biomarkers of inflammation, oxidative stress, and endothelial dysfunction are associated with worsening kidney function.[116,117] OSA, by acutely increasing sympathetic discharge to the kidney and other vascular beds during obstructive events, by raising BP during occlusive episodes and by a sustained increase in BP during wakefulness contributes to

progressive decline in kidney function.[118] Cycles of hypoxia and reoxygenation induce oxidative stress, which leads to endothelial cell injury and dysfunction.[109] Arterial stiffness is increased in patients with OSA.[119] Treatment of OSA with CPAP leads to significant decrease in measures of arterial stiffness. Higher arterial stiffness and lower arterial elasticity are linearly and independently associated with more rapid decline in renal function in persons with GFR $\geq$60 mL/min/1.73 m^2.[120] More recent data demonstrating that OSA bears a causal relationship to worsening renal function are now also available. Animal models of intermittent hypoxia have shed light on possible mechanisms that include oxidative injury in mice and rats,[121,122] and renal hypoperfusion in pigs.[123] One study in humans implicated activation of the renin–angiotensin system by recurrent hypoxemia.[124] Recent individual studies include a longitudinal, prospective study by Lin et al.[125] and a prospective study by Tahrani et al. in patients with diabetic nephropathy, demonstrated that estimated glomerular filtration rate (eGFR) declined more quickly over time in patients with OSA.[126] A systematic review and meta-analysis by Hwu et al. supported this finding.[127] These data suggest that treatment of OSA in CKD patients may attenuate the rate of decline of kidney function.

Impact

OSA may contribute to increased morbidity and mortality in CKD patients, in whom cardiovascular disease is an important risk factor for mortality. Population-based longitudinal studies, such as the Wisconsin Sleep Cohort[128] and the Busselton Health Study,[129] have shown significant increases in mortality in patients with untreated OSA. The former study found an almost fourfold greater risk of all-cause mortality and a fivefold increase in cardiovascular mortality for patients with severe OSA at a mean 13.8 years of follow-up.[128] The latter investigation demonstrated sixfold greater all-cause mortality for moderate to severe OSA after an average of 13.4 years of follow-up.[129] In the large multiethnic Sleep Heart Health Study, moderate to severe OSA was associated with an increased risk of death among men aged 40–70 years.[130] OSA has been independently linked to specific cardiovascular outcomes such as hypertension,[131] especially treatment-resistant hypertension, left ventricular hypertrophy, stroke,[132,133] myocardial ischemia,[134,135] arrhythmias,[136] fatal and nonfatal cardiovascular events,[137,138] and all-cause mortality.[128,129] Although studies searching for pathological lesions in the CNS in OSA patients have thus far been inconsistent, OSA is commonly associated with neurocognitive impairments. Specific deficits are found in intellectual ability, learning and memory, sustained and focused attention, executive function, information processing efficiency, and visual and psychomotor performance.[139–142] OSA has been strongly associated with depressed mood, metabolic disorders, and diminished HRQOL in the general population. OSA, particularly when associated with intermittent hypoxemia, is associated with erectile dysfunction.[143] OSA increases the risk for glucose intolerance, insulin resistance,[144,145] and overt clinical diabetes,[146] which itself is an important etiology of CKD.

Coexistent OSA is likely to be even more relevant in CKD patients because several important factors involved in the pathogenesis of CKD (such as HTN, T2DM, and obesity) are the same factors that result from, or are associated with, OSA in the general population. Sleep-related hypoxia and recurrent arousals due to OSA result in sympathetic activation leading to HTN, which then contributes to the development and progression of CKD.[147,148] Nocturnal hypoxia (Sao2 $<$ 90% for $>$12% of nocturnal monitoring time) is independently associated with increased (three times more likely) risk of accelerated loss of kidney function (GFR decline by $>$4 mL/min/1.73 m^2/year).[149] One study showed a very high prevalence of OSA in obese patients with drug-resistant hypertension (DRH).[150] Greater rostral fluid displacement centrally in patients with DRH has also been associated with more severe apnea compared to patients with HTN alone.[151] Spironolactone has been shown to reduce the severity of OSA in one small study of 12 obese patients with DRH, linking aldosterone-mediated fluid retention to the severity of OSA in these patients.[152] A large-cohort of VA CKD patients with incident OSA documented by administrative claims were demonstrated to have an increased risk of mortality, coronary artery disease, and CKD progression compared to patients without a diagnosis of OSA.[153] In this cohort there was only a slight attenuation in risk for adverse outcomes associated with treatment of OSA. To date, only limited hypothesis-generating studies have appeared concerning the potential bidirectional nature of causality between OSA and CKD.

Surprisingly few data are available concerning the impact of CSA/HCSB alone on patients with CKD. Only one relevant study, is that of Xu et al., who examined a cohort of patients with and without CKD for the presence of either OSA or CSA/HCSB.[154] Patients with an eGFR $<$ 60 mL/min/1.73 m^2 were far more likely to exhibit CSA/HCSB than other forms of sleep-disordered breathing, after adjusting for all potentially relevant confounders. Moreover, CSA constituted more than a fourfold increased risk for all-cause mortality after the data were adjusted for other related covariates. The authors concluded that CSA/HCSB was an independent risk factor for all-cause mortality in a nondialyzed population of patients with CKD.

Diagnosis and Treatment

The failure to recognize OSA and CSA/HCSB among CKD patients may be not only due to a lack of awareness by providers but also due to known variations in the clinical phenotype. Although the typical OSA patient may be readily recognized by providers when an obese individual complains of sleepiness and snoring, neither obesity nor somnolence is required for the diagnosis of OSA. The screening and diagnosis of OSA in patients with CKD remains challenging due to the lack of disease-specific screening tools and, if access to laboratory PSG is limited, the uncertain validity of home sleep testing in patients with complex comorbidities. The nephrologist should have a low clinical threshold for referral of CKD patients to either sleep medicine physicians for expert assessment and laboratory PSG. Certainly, CKD patients should be considered for PSG or referral when complaining of typical sleep-related breathing symptoms such as snoring, awakening with choking or gasping, or if they complain of daytime sleepiness despite allowing sufficient time for sleep. However, patients with less-specific findings such as difficult-to-control HTN, frequent awakenings, restless sleep, fatigue, depression, irritability, general impairment of daily function, impaired social interactions, and sexual dysfunction may also merit screening.[155] These same symptoms may also suggest the possibility of CSA/HCSB, although the diagnostic pathway remains the same as with OSA.

The gold standard for diagnosing OSA or CSA/HCSB is an overnight in-laboratory PSG. The American Academy of Sleep Medicine currently recommends that home sleep apnea testing only be used for diagnosis when the pretest probability for moderate to severe OSA is high and the patient does not have a significant comorbid medical condition. ESRD/CKD stage 2−5 would constitute a contraindication to home testing due to the possibility of CSAs, or if one or more sleep disorders in addition to OSA are suspected. Negative or technically inadequate home sleep testing in patients with a high pretest probability of moderate to severe OSA should prompt in-laboratory PSG.[82] In a descriptive study of 290 patients performing home sleep studies, those with CKD and ESRD were not significantly more likely than the general population to have an inadequate study.[156]

The converse of determining a suspicion for OSA in CKD has also been recently examined. Voulgaris et al. hypothesized that it might be possible to detect incipient CKD in patients with OSA, and examined Cystatin C (Cyst C) and neutrophil gelatinase-associated lipocalin (NGAL) as possible novel biomarkers for the earlier detection of latent kidney disease in individuals without relevant comorbidities.[157] After adjustment for age and BMI, serum NGAL levels were associated with AHI and minimum oxyhemoglobin saturation during sleep, whereas serum Cyst C levels were associated with percentage of time with oxyhemoglobin saturation <90%, average saturation, and minimum saturation during sleep. They concluded that these markers may allow for the early detection of latent CKD in OSA patients and that the strongest predictor of such a relationship appeared to be the degree of sleep-associated hypoxemia.

Although CPAP has demonstrated improved HRQOL and mood among those with moderate to severe OSA, the effect sizes of CPAP on cardiovascular outcomes have been more modest. A meta-analysis of nine trials demonstrated no significant impact of CPAP on any major cardiovascular event with substantial study heterogeneity.[158] Two meta-analyses that reviewed the RCT data on CPAP and blood pressure demonstrated that overall, CPAP therapy may lead to small (1−2 mm Hg), but statistically significant ($p = 0.001$), reduction in 24-hour mean blood pressure.[159] RCTs have repeatedly shown that CPAP therapy significantly improves or resolves subjective symptoms of daytime sleepiness in patients with severe OSA.[160] Most RCTs find inconsistent, if any, improvement in neurobehavioral performance parameters.[161,162] Data regarding the therapeutic effects of CPAP treatment on mood and HRQOL are also somewhat variable and inconsistent, but most trials found benefits of CPAP therapy compared with conservative treatment. In two meta-analyses, CPAP improved physical functioning, energy/vitality, and general well-being as measured by the Short-Form 36[163,164] among patients with sleep apnea. Subsequent clinical studies have demonstrated improvements in the disease-specific Functional Outcomes of Sleep Questionnaire and general HRQOL measures among those with moderate to severe OSA treated with CPAP.[165,166] More recently, the effect of OSA treatment on renal function has been studied in additional, well-performed clinical trials. A substudy of the international SAVE (Sleep Apnea Cardiovascular Endpoints) trial followed 200 of the 2,717 subjects with at least moderately severe OSA and established coronary or cerebrovascular disease who had OSA treated with CPAP.[167] CPAP treatment in these individuals did not alter renal function or the occurrence of renal adverse events. The authors also sought evidence of a dose−response relationship by analyzing changes in renal function vs. CPAP adherence; no such relationship was found. However, Li et al. were able to demonstrate a salutary effect of CPAP treatment of OSA in patients with respect to progression of CKD,[168] as were Koga et al.[169] A one-year randomized, controlled, nonblinded, parallel clinical trial is being conducted to compare conventional medical therapy or medical therapy plus CPAP in patients with OSA and CKD.[170]

We recommend that patients with OSA and CKD receive treatment when the AHI is 15 or higher, or when the AHI is 5–14 and the patient also exhibits excessive daytime sleepiness, impaired neurocognitive function, mood disorders, insomnia, or cardiovascular disease (HTN, ischemic heart disease, or stroke). Koga et al., in a study of 38 OSA patients, found that longer mean apnea duration and advanced age were associated with reduced eGFR, which improved following nightly CPAP use of more than 4 hours for 3 months.[169] Koyama et al., in a small study of congestive heart failure (CHF) patients who also had sleep-disordered breathing and CKD, showed improvement in renal function after using adaptive servo-ventilation (ASV, an advanced positive airway pressure modality), for 1 year.[171] Increases in LVEF positively correlated with improvement in renal function, and levels of CRP were negatively correlated with improvement in eGFR. It is presumed that ASV improved renal function by preventing inflammatory responses associated with sleep-disordered breathing (SDB).[169,171] The use of CPAP to treat OSA in patients with ESRD has a stronger evidence base than alternative approaches that involve oral appliances or upper airway surgery. Lifestyle approaches such as weight loss, and cessation of smoking and alcohol use are also recommended.

OSA, in spite of its high prevalence in the CKD population, remains underdiagnosed and undertreated. OSA likely increases the risk of cardiovascular insults and impairs HRQOL. Because studies have demonstrated markedly impaired HRQOL among patients with CKD and OSA, treatment of OSA should receive increased emphasis. Despite the benefits of treating OSA, there are a paucity of data regarding treatment of OSA in CKD patients. Data regarding adherence to CPAP use in OSA patients who have CKD are lacking. However, because CPAP use in symptomatic CKD patients may increase their daytime alertness, physical functioning, and social interaction, patients should have a significant incentive for using CPAP. Well-designed RCTs to determine the effect of treating OSA with CPAP on CKD progression are clearly needed.

The treatment of CSA/HCSB is more complex. Treatment modalities include oxygen, CPAP, bilevel PAP in spontaneous/timed mode (BPAP-S/T), ASV, phrenic nerve stimulation, acetazolamide or theophylline (which acts by reducing plant gain, a component of loop gain that, if excessive, destabilizes ventilatory control), and hypnotics to modulate respiratory arousal, and methods to increase $PaCO_2$ (exogenous administration of CO_2 or apparatus to increase respiratory dead space) to create more distance from the apneic threshold. Some of these methodologies are detailed in a recent publication.[155] The current state of knowledge suggests that one of the modalities of positive airway pressure or oxygen represent the most viable choices, along with optimizing the fluid status of the CKD patient, perhaps using diuretics. The goal would appear to be ameliorating any symptoms produced by CSA/HCSB because any effect on renal function by treating this form of sleep-disordered breathing is unknown.

RESTLESS LEGS SYNDROME (WILLIS–EKBOM DISEASE)

RLS, also known as Willis–Ekbom Disease (referring to the first description) is a neurological sleep disorder characterized by unpleasant sensations (usually in the lower extremities but sometimes involving the arms and trunk) in the evening that interfere with sleep onset, and which is diagnosed clinically. Although the symptoms present predominantly in the evening, they may occur at any time of day. Symptoms may be exacerbated by a resting position such as when HD patients are receiving dialysis. The symptoms are described by patients as unpleasant sensations in the extremities. The dysesthesia is often poorly characterized by the patient, but may be described as achy, itchy, painful, creepy—crawly sensations, most often in the lower extremities. Given the predilection of RLS symptoms for occurring in the evening, most patients with severe RLS note difficulty initiating sleep. Diagnostic criteria for RLS have been established by the International RLS Study Group (IRLSSG).[172] The revised IRLSSG diagnostic criteria for RLS are listed in Table 36.3.[173]

TABLE 36.3 Revised International Restless Leg Syndrome Study Group Diagnostic Criteria for Restless Legs Syndrome*

1	An urge to move the legs usually but not always accompanied by or felt to be caused by uncomfortable and unpleasant sensations in the legs.
2	The urge to move the legs and any accompanying unpleasant sensations begin or worsen during periods of rest or inactivity such as lying down or sitting.
3	The urge to move the legs and any accompanying unpleasant sensations are partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues.
4	The urge to move the legs and any accompanying unpleasant sensations during rest or inactivity only occur or are worse in the evening or night than during the day.
5	The occurrence of the above features is not solely accounted for as symptoms primary to another medical or a behavioral condition (e.g., myalgia, venous stasis, leg edema, arthritis, leg cramps, positional discomfort, habitual foot tapping).

* *Reprinted from reference 173.*

Prevalence

The prevalence of RLS among patients with CKD remains uncertain. Although many studies have suggested a prevalence of RLS as high as 5–15% in the general population,[174] observational studies in Europe and the US determined the prevalence of RLS prominent enough to occur at least twice a week and cause moderate or severe distress is between 1.5% and 3%.[174] RLS in ESRD patients has been reported in the US and internationally at a higher 12–25% prevalence.[175–177] Plantinga estimated the prevalence of RLS in CKD patients using data from the National Health and Nutrition Examination Survey. This ongoing study of multiple aspects of health in US adults incorporates in-home interviews followed by physical examinations and blood and urine collections at a mobile study center. Out of 930 patients, the prevalence of RLS in CKD patients was similar to that in non-CKD patients. The results for CKD patients, however, were considered unreliable because the relative standard error was ≥30%.[22] The diagnosis of RLS generally requires an evaluation by a physician with knowledge of RLS criteria and conditions with which it may be confused such as leg cramps. In another observational study of home PSG, 17.5% of participants with CKD stages 1–3 had RLS symptoms.[178] A study using claims data from the USRDS demonstrated that the ICD9 diagnosis of RLS was present less than 1% of the time, suggesting that RLS remains underdiagnosed in the US.[179] Riar et al. reported on the prevalence of RLS in children with CKD, finding a prevalence of 15% in 124 such individuals.[180] The number of days per week that subjects had symptoms was not given, and there was no significant association between RLS and CKD stage. Children with RLS rated their quality of sleep as poor, frequently used hypnotic medication, and had lower HRQOL by parent report.

Winkelmann et al. followed 11 patients with uremic RLS who underwent successful kidney transplantation. Symptoms of RLS resolved after transplantation, but reappeared in some of them after several years, and in most patients in whom the transplanted kidney was failing.[181] Molnar et al. reported on RLS in patients after renal transplantation, finding a 4.8% prevalence overall and an association with residual CKD. In groups formed on the basis of eGFR, the prevalence of RLS increased with decreases in renal function (2%, 5%, 7%, 24% in patients with eGFR ≥60 mL/min/1.73 m^2; eGFR 30–59 mL/min/1.73 m^2; eGFR 15–29 mL/min/1.73 m^2; and eGFR < 15 mL/min/1.73 m^2, respectively).[182] Similar findings of increasing RLS prevalence with declining kidney function were also reported by Aritake-Okada et al.[183] Quinn et al. reported iron deficiency and CKD stage 4 (eGFR 15–29 mL/min/1.73 m^2) were associated with a significantly higher odds ratio for RLS in a multivariate analysis.[184]

Pathogenesis

The pathophysiology of RLS among patients with CKD remains unknown. RLS is associated with downregulation of dopamine D_2 receptors in the putamen, and the degree of loss of receptors in RLS correlates with severity of the disorder.[185] Levels of tyrosine hydroxylase, the rate-limiting enzyme for dopamine synthesis, are increased in the substantia nigra in RLS, thought to be a compensatory mechanism to the reduction in dopamine receptors. Reduced putaminal D_2 receptors were seen in iron-deficient rats along with increased tyrosine hydroxylase levels in the brain.[185] These findings suggest a link between intracerebral iron deficiency and RLS. Genome-wide association studies have found predisposing polymorphisms in a variety of genes. Most common is BTBD9 on chromosome 6p with a protein product widely expressed in brain.[186] These observations relating BTBD9 to RLS have been extended to patients with ESRD in a small observational study.[187] Secondary causes of RLS include acquired iron deficiency,[184] CKD,[184] peripheral neuropathy, and a variety of medications. Among patients with CKD, the potential contributors to RLS include iron deficiency (which may be of minimal degree, not presenting as clinically apparent anemia), peripheral neuropathy, and the CKD-associated inflammatory state. All potentially contribute to the pathogenesis of RLS in CKD. In the presence of inflammation, iron deficiency may not be excluded even by high levels of ferritin. Fatigue, social isolation, helplessness, and pain are common symptoms of RLS,[188] and these problems may predispose to patient to depression.

Impact

General

Among the general population and those patients with CKD, RLS has been associated with an increased risk of cardiovascular disease, impaired HRQOL, cognitive dysfunction, daytime sleepiness, and psychiatric morbidity. A potential mechanism whereby RLS may produce CVD is autonomic arousal associated with periodic limb movements of sleep. Most often involving the legs, these repetitive contractions occur in about 80% of RLS patients and may be associated with arousals or awakenings. Just as in OSA, the increase in sympathetic outflow may promote HTN, increased coagulability, or a risk of plaque rupture.[189,190] Using Wisconsin Sleep Cohort data, Winkelman et al. reported that RLS

symptoms (even after adjustment for confounders) were associated with an approximately 2.5-fold risk of prevalent CVD.[191] Emerging evidence from prevalence studies of RLS indicates at least twice the risk of cardiovascular disease in these individuals.[192,193] RLS symptoms have a strong association with DSM-4 major depressive disorder and panic disorder in a community population.[193,194] Individuals with RLS are at least twice as likely to have scores indicating depression or anxiety disorders.[191] These findings have significant clinical implications, as medications commonly employed to treat these disorders may worsen underlying RLS.[194,195] Also, ongoing sleep disturbance is a risk factor both for the onset, as well as persistence of depressive disorders and suicide. QOL impairments are also significant in patients with moderate to severe RLS, comparable to or even more severe than those in patients with CHF or T2DM.[193] Patients with RLS scored lower across all eight subscales of the SF-36, with diminished physical and mental health scores.[174,196] An insomnia complaint is two to four times more likely in RLS patients compared to controls. This may mediate comorbidities commonly seen with RLS, including CVD, impaired perception of HRQOL, cognitive dysfunction, daytime sleepiness, and psychiatric morbidity.[189,197]

CKD

The presence of both RLS and CKD was significantly associated with depression and complaints of a sleep disturbance.[183] RLS symptoms are associated with depression in CKD patients.[198] A prospective study of kidney transplant patients tested the hypothesis that the presence of RLS predicts mortality in 804 transplant recipients. Using a multivariate Cox proportional hazard analysis, the presence of RLS was a significant risk factor for mortality with a hazard ratio of 2.[199] RLS has been associated with HRQOL, mood, and subjective sleep disturbance in CKD patients.

Diagnosis and Treatment

RLS is a clinical diagnosis based on the IRLSSG criteria. Laboratory PSG or other sleep studies are not necessary to establish the diagnosis. Iron should be supplemented orally in case of iron deficiency. Ferritin levels should be checked and iron supplementation should be commenced if the level is below 50 ng/mL. Additional diagnostic workup for blood loss or other causes of iron deficiency should not be neglected. Patients with malabsorption and intolerance to oral iron will require IV iron therapy. As ferritin is an acute phase reactant, the levels of ferritin may be high in the presence of inflammation, but including an iron level and iron saturation will help confirm iron deficiency.

Nonpharmacological measures to manage RLS symptoms include (i) elimination of alcohol, nicotine, (ii) caffeine reduction, (iii) moderate exercise, and (iv) discontinuation of offending medications, when possible. By definition, symptoms will respond to walking, massaging the affected limb, or other mechanical stimuli but will return when these maneuvers cease. A randomized trial of progressive exercise over 6 months reduced symptoms of RLS among HD patients. Examining the impact of exercise on RLS in the nondialysis population is an area of active investigation.[200] Given the circadian rhythmicity and exacerbation of RLS symptoms by rest, studies have suggested that time of day and mode of dialysis may be related to symptom severity. Patients undergoing HD earlier in the day and patients performing short daily home dialysis have reported decreased symptoms.

Pharmacological treatments include dopamine receptor agonists, such as ropinirole 0.25 mg or pramipexole 0.125 mg, taken 2 hours before the usual onset of symptoms. Medications are usually reserved for patients with RLS symptoms that occur at least twice a week. Dosages are increased after a few weeks if the patient is still symptomatic. Maximum approved dose for ropinirole is 4 mg and for pramipexole is 0.75 mg. Pramipexole is primarily excreted in its active form in the urine, which may limit its utility in CKD patients. Ropinirole is also excreted by the kidneys, but only after being extensively metabolized to mostly inactive derivatives. Serious side effects of these drugs include augmentation, impulse control disorders, and daytime sleepiness.[201] Augmentation consists of worsening of symptoms, early occurrence, or involvement of the arms or trunk that was not present prior to treatment. Augmentation is initially treated with additional doses of medication but may require discontinuation of the drug. Another dopamine agonist, rotigotine, is administered once a day as a patch and may be particularly useful in patients with augmentation due to its constant drug levels. Rotigotine is eliminated as inactive conjugates in the urine.

Patients with RLS symptoms occurring less than twice a week often respond to clonazepam 0.25 mg. For patients with RLS symptoms occurring at least twice a week, $\alpha 2\delta$ agents such as gabapentin and pregabalin are also options, particularly when RLS symptoms are characterized as painful or associated with possible neuropathy. Both gabapentin and pregabalin are eliminated by the kidney, and therefore the half-life increases with decrements in kidney function. Dose adjustment for gabapentin and pregabalin is required based on renal function. Gabapentin has been shown to reduce RLS symptoms in two studies among patients with RLS treated with HD. There are no studies evaluating the efficacy of pregabalin in CKD. Augmentation has not been reported with these drugs. Opioids may be considered

for treatment-resistant RLS. This class of drugs requires additional monitoring and has an increased risk of adverse events in the CKD population. Given the association between OSA and CKD detailed above, it is imperative to identify and treat OSA in such patients prior to consideration of opioid therapy.

CKD

There is a paucity of studies examining treatment of RLS among patients with CKD. A systematic review found nine RCTs for the treatment of RLS in HD patients and no studies in the CKD population.[202] Only one very small study reported in the German literature has reported on RLS treatment in CKD patients. In this report, CKD and HD patients treated with clonidine 0.075 mg showed improvement in RLS symptoms.[203] Treatment of anemia with erythropoietin and IV iron alone does not improve RLS symptoms in patients with renal failure.[204] Aerobic exercise training has been shown to improve RLS symptoms and QOL in HD patients.[205] A small study comparing gabapentin with levodopa showed that gabapentin was equally efficacious for RLS treatment in HD patients.[206] Ropinirole was found more effective than sustained release levodopa for RLS in HD patients.[207]

CONCLUSION

The diagnosis and treatment of sleep disorders in CKD may provide the opportunity to improve QOL and cardiovascular outcomes. Sleep disorders have been linked to the development of numerous chronic diseases. The treatment of sleep disorders in patients with chronic disease plays an important role in their management. Optimal sleep duration and sleep quality play a significant role in improving control of T2DM. OSA independently increases the risk for HTN and thus cardiovascular disease, a leading cause of death in CKD patients. Insufficient sleep increases the risk of obesity, and the effect is pronounced in children. Diabetes, hypertension, and obesity are all etiologies of CKD. Addressing sleep disorders could prevent both the development as well as the progression of CKD. Nephrologists should be vigilant in looking for symptoms of sleep disorders in CKD patients and address them as a part of the overall treatment regimen. Future prospective studies are critical to determine causal relationships. Does OSA contribute to the development of CKD and its progression? Does CKD contribute to the pathogenesis of OSA? Does CPAP treatment in OSA patients prevent onset of CKD and its progression? Studies of CPAP therapy in CKD patients may help to clarify the extent to which OSA contributes to the morbidity and mortality in this high-risk population.

QUESTIONS AND ANSWERS

Question 1

During an office visit, a 60-year-old woman with CKD complains about difficulty falling asleep until very late in the night and feeling tired during the day. She describes a crawly, achy feeling in her legs when she is trying to fall asleep, which gets better after walking or massaging her legs but returns when she stops. She has been trying to keep her mind occupied by reading and watching television but complains that the symptoms recur during the periods of inactivity. She occasionally experiences this in the evening while reading, but not earlier in the day. She lives alone and is not aware about whether she snores. Based on the history, which one of the following is the most appropriate next step in her evaluation?

A. Diagnostic sleep study
B. Actigraphy
C. Obtain serum ferritin level
D. Prescribe hypnotic agent
E. All of the above

Answer: C

This patient has symptoms of unpleasant sensations in her legs during periods of inactivity, particularly when she is trying to fall asleep. The dysesthesias are relieved by activity but recur during inactivity and are associated with sleep onset insomnia. The circadian variation in symptoms described by the patient is one of the key criteria for the diagnosis of RLS, and her description fulfills International Restless Legs Syndrome Study Group criteria for the diagnosis. Intra-cerebral iron deficiency is linked to RLS, and a serum ferritin level should be obtained to commence iron supplementation if lower than 50 pg/mL. The etiology of iron deficiency, if found, should be determined.

Question 2

A 60-year-old man has poorly controlled hypertension and CKD. The patient is being treated with amlodipine, lisinopril, and hydrochlorothiazide. He denies any symptoms of daytime sleepiness. However, his wife complains that she is unable to sleep because of his very loud snoring. She has been particularly worried over observing him gasping in his sleep when on his back. The patient has not been able to exercise as he is tired and gets out of breath easily. Physical examination reveals his height is 5 feet 8 inches, weight 240 pounds, blood pressure 180/95 mm Hg. Head Eyes Ears Nose and Throat: edematous soft palate, uvula is barely seen, teeth indention marks are seen along the tongue, neck circumference is 16.5 inches. Chest: clear. Cardiac: S4 gallop. Extremities: 1−2+ edema. An echocardiogram done the previous week showed left ventricular hypertrophy and mild pulmonary hypertension. S[Cr] is 1.5 mg/dL.

What is the most appropriate next step in the evaluation?

A. Cardiac catheterization
B. Renal angiography
C. Prescribe furosemide
D. Nocturnal polysomnogram
E. None of the above

Answer: D

Even though the patient does not endorse sleepiness, his clinical presentation is very suggestive of obstructive sleep apnea. Although he has risk factors for coronary artery disease, he more urgently requires evaluation for obstructive sleep apnea, because treatment for this would be expected to improve his blood pressure control, reduce the risk for cardiovascular sequelae, and may potentially prevent progression of CKD. Additional antihypertensive treatment may not be required once obstructive sleep apnea is controlled. Should treatment of obstructive sleep apnea not allow for satisfactory control of his blood pressure, evaluation for secondary causes of hypertension such as from renovascular disease can be considered; however, at this point it is not warranted.

Question 3

Obstructive sleep apnea increases the risk of which of the following?

A. Hypertension
B. Type 2 diabetes mellitus
C. Coronary ischemia
D. Worsening obesity
E. All of the above

Answer: E

Studies of obstructive sleep apnea in the general population have shown an increased risk of all these comorbidities. Furthermore, all these comorbidities are implicated in the progression of CKD. Strategies for minimizing these risk factors would improve the overall prognosis of CKD patients.

Question 4

A 70-year-old woman comes for routine follow-up of hypertension and CKD. The patient is concerned about her inability to sleep well for over a year or so,

perceiving her sleep to be not as restful as before. She denies daytime sleepiness but says she feels miserable during the day. She has not been able to enjoy the things she previously did, and she is not as active as before. She denies feeling depressed. Recently she began drinking 2 cups of coffee with her lunch to complete her afternoon chores. Her physical examination and laboratory blood tests, including her kidney function, appear unchanged from last visit. The most correct next step would be:

A. Prescribe zolpidem
B. Ignore her complaints, just order chemistries for the next visit
C. Ask her to cut down caffeine intake
D. Refer to a sleep specialist
E. None of the above

Answer: D

Even though the patient's hypertension and CKD appear to be optimally treated, her QOL is affected because of her insomnia complaint: sleep that she perceives as not restful along with impaired daytime function. Cutting down caffeine might help but her insomnia has preceded the increased caffeine intake and, given the impact of her sleep complaint including probable depression, she would certainly benefit from proper evaluation and not just a hypnotic agent. Evaluation for a sleep disorder may uncover SDB or periodic limb movement disorder that can be treated effectively. In the long term, she might benefit from cognitive behavioral therapy for insomnia as she may have thoughts and behaviors that could worsen her symptoms further that would be elicited during a sleep medicine consultation. If for a short time she requires hypnotics as well, the newer nonbenzodiazepine hypnotics such as zolpidem would be preferable given their efficacy and side effect profile, but this is best considered after the possibility of an intrinsic sleep disorder is eliminated.

Question 5

RLS has been shown to increase the risk of depression, insomnia complaints, and mortality among patients with CKD.

A. Yes
B. No

Answer: A

RLS is associated with increased mortality in patients with a renal transplant with CKD.[208] CKD patients with RLS have an increased risk of depression. Both CKD and RLS could additively increase their risk of insomnia.[183]

Question 6

In CKD patients, which of the following is correct?

A. Insomnia is independently associated with comorbidities, depression, RLS, and increased risk of obstructive sleep apnea
B. Depression is independently associated with increased mortality
C. RLS and CKD together increase the risk of depression and insomnia
D. All of the above
E. None of the above

Answer: D

Insomnia in CKD patients is independently associated with comorbidities including depression, RLS, and increased risk of obstructive sleep apnea.[11] RLS and insomnia both worsen heath-related QOL in CKD patients.[208] Emerging evidence links both insomnia and RLS to an increased risk of cardiovascular disease, which is the most important cause of mortality in CKD patients. Thus, it is critical to look for and address insomnia and RLS in CKD patients to improve overall prognosis.

Sexual Dysfunction in Chronic Kidney Disease

Kirsten Johansen

Division of Nephrology, Hennepin County Medical Center, Minneapolis, MN, United States

Abstract

Sexual dysfunction is common among men and women with chronic kidney disease (CKD) and is associated with depression and worse perception of quality of life. The pathophysiology is complex and may be related to hormonal disturbances related to CKD, comorbid conditions, medications, or psychosocial factors. We describe the prevalence, pathophysiology, diagnosis, and management separately for men and women. Because there are relatively few data directly addressing these issues among patients with nondialysis-dependent CKD, we have leaned heavily on the literature among patients with end-stage renal disease and on guidelines for treatment for the general population, emphasizing treatment differences related to CKD. Because sexual dysfunction is common, affects quality of life, and can be treated, it deserves more attention in the management of patients with CKD.

SEXUAL DYSFUNCTION AMONG MEN WITH CKD

Scope of the Problem

In men with CKD, sexual dysfunction often refers to erectile dysfunction (ED) alone but can also include decreased libido, difficulty with arousal, difficulty achieving orgasm, and ejaculatory abnormalities.[1] Sexual dysfunction is much more common in patients with chronic kidney disease (CKD) than in the general population, and the prevalence of ED increases with decreasing glomerular filtration rate (GFR).[2] Navaneethan et al. performed a meta-analysis and reported that 70% of men with CKD or end-stage renal disease (ESRD)[3] reported sexual dysfunction.[3] Because there were so few data on the prevalence and affects of sexual dysfunction in men with nondialysis-dependent CKD, it may be useful to examine the available data in patients with ESRD.[3] Seventy-five percent of patients treated with dialysis reported sexual dysfunction, but substantial heterogeneity in prevalence among studies was noted. Subsequently, a multinational cross-sectional study of 1611 men treated with hemodialysis demonstrated an 83% prevalence of ED.[4] Another study of men with stages 3–5 CKD not receiving renal replacement therapy (n = 81) reported an overall prevalence of ED of 76.5%, with a small gradient of prevalence with advancing stages of CKD that was not statistically significant (72.3% in stage 3 CKD, 81.5 in stage 4, and 85.7% in stage 5).[5] Sexual dysfunction often goes unaddressed by medical professionals. In one study of patients treated with hemodialysis, only 24.1% had talked to their doctor about their sexual activity. Only 55.4% were sexually active compared to 79% from the age-matched general population.[6]

Sexual dysfunction in patients with ESRD has been associated with impaired health-related quality of life (HRQOL), anxiety, and depression.[7–11] Patients with ED reported poorer social interactions, decreased emotional well-being, more role limitations due to emotional problems, and poorer social function than patients with ESRD who did not report ED.[11] Both the composite scores of the physical and mental components of quality of life of the SF-12 were lower among patients with ED, but after adjusting for age, diabetes, and comorbid conditions, ED remained associated only with lower mental composite score. Depression and anxiety are also associated with sexual dysfunction in hemodialysis patients.[1,7,9,12,13] The association is probably bidirectional, with depression causing or exacerbating ED, and ED leading to or worsening depression.[14,15] Overall, the strong association between sexual dysfunction and HRQOL raises the possibility that treatment of sexual dysfunction could improve HRQOL in the CKD population.[12] Given that poor HRQOL has been associated with adverse outcomes including death[16] and hospitalization,[17] alleviation of sexual dysfunction could have a major impact.

Chronic Renal Disease, Second Edition

Pathophysiology

Sexual dysfunction is a multifaceted problem that can be related to hormonal, vascular, neural, or psychosocial causes (Figure 37.1).[1] In CKD, available data indicate that libido and potency decline with progression of kidney disease, remain low during dialysis,[18] and improve after transplantation,[19] suggesting a direct role of uremia or uremic toxins, possibly acting to cause testicular damage and/or perturbations in hormone production and metabolism. In addition, medications, psychosocial issues, vascular disease, and neurologic disease are common causes of or contributors to sexual dysfunction.[20]

Testicular function is abnormal in the setting of uremia. Testicular damage and impaired spermatogenesis have been well documented in patients with nondialysis-dependent CKD and ESRD.[19–21] In addition, testosterone levels are low in men with CKD.[19,22–24] In a cohort study of 260 men treated with dialysis with a median age of 59 years, only 23% had normal testosterone levels.[22] Free testosterone levels are also low among men with nondialysis-dependent CKD,[19] although patients with nephrotic syndrome may have low sex hormone binding globulin (SHBG).[25]

Whether testicular dysfunction is the primary cause of low testosterone or whether there is a contribution of hypothalamic and/or pituitary dysfunction has been the subject of considerable study and debate. Gonadotropins are elevated in most studies of men with ESRD, but it has been difficult to ascertain whether the elevation of gonadotropins is high enough to suggest normal hypothalamic–pituitary function, or lower than expected, which would indicate a contribution of hypothalamic–pituitary dysfunction in addition to the testicular abnormalities.[19] Hyperprolactinemia is also common among patients with CKD, likely as a result of disturbed hypothalamic regulation of pituitary prolactin secretion, although use of some medications can exacerbate the problem. Both low testosterone and high prolactin have in turn been associated with sexual dysfunction among men, including decreased libido and ED.

Opioid-induced androgen deficiency has been described for decades,[26] but its importance may be increasing given the high frequency of chronic opioid use among patients with CKD. For example, a recent study reported that 64% of patients treated with dialysis received opioids over an 11-month period.[27] The incidence of hypogonadotropic hypogonadism among chronic opioid users ranges from 21% to 86%.[26] Its onset is rapid, occurring within hours to weeks of treatment initiation. It is dose-dependent. A recent meta-analysis found that testosterone was 165 ng/dL lower on average among those using opioids compared to those not

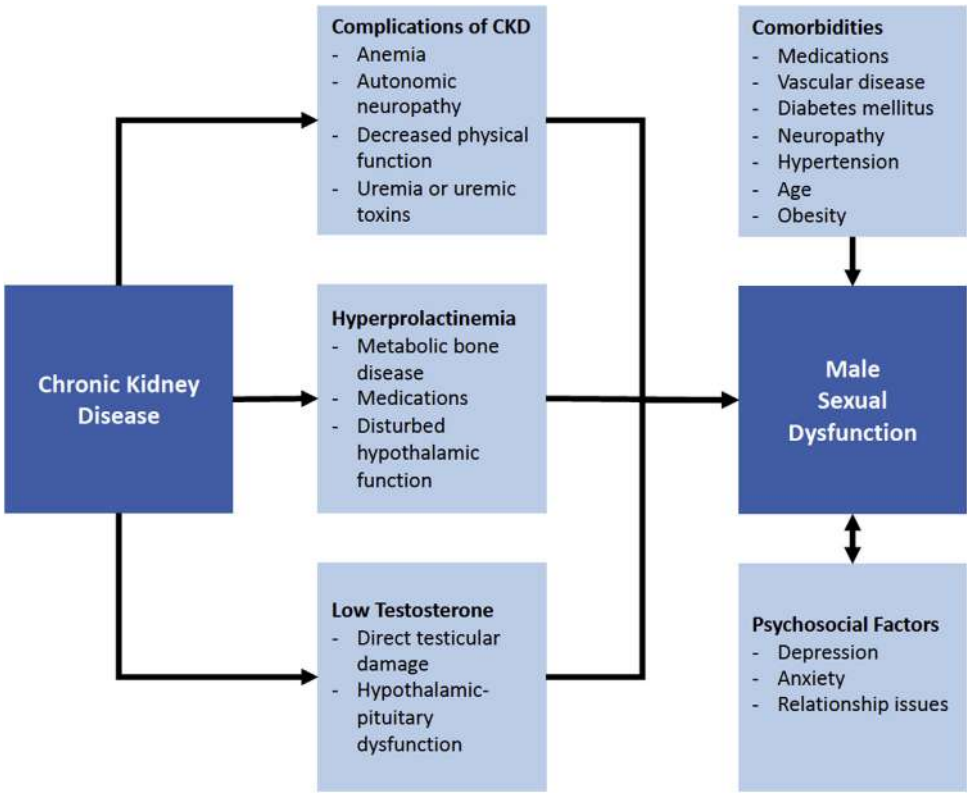

FIGURE 37.1 Factors contributing to male sexual dysfunction.

receiving opioids (95% CI 84−245 ng/dL lower) regardless of opioid type or indication for use.[28] Testosterone suppression is reversible on discontinuation of opioid treatment, within 24−72 hours in some cases, but it can persist for months or years after long-term use.[26]

Patients with CKD have several other risk factors for ED that may contribute to the high prevalence or worsen the severity of symptoms, but may be less likely to cause decreased libido, including older age, diabetes, hypertension, and neuropathy.[10] Erection involves responses to external stimuli through parasympathetic activity, release of nitric oxide, and smooth muscle relaxation resulting in blood flow into the penis.[29] Thus, any process that affects nervous system input, endothelial function, or systemic blood pressure has the potential to interfere with erectile function. Diabetes and hypertension, the most common causes of CKD, are both associated with vascular disease that can contribute to ED by limiting blood flow to the penis.[10,30] Furthermore, the treatment of hypertension can also cause or exacerbate ED, with centrally acting agents and beta blockers most commonly implicated.[20] One study among patients treated with dialysis found a higher prevalence of sexual dysfunction among patients not treated with angiotensin-converting enzyme inhibitor.[10] Anemia and autonomic neuropathy may also contribute to ED among patients with CKD. Finally, depression, anxiety, and difficulties with interpersonal relationships are potential causes of sexual dysfunction.[1]

Diagnosis

Diagnosis of male sexual dysfunction begins with a detailed medical and psychosocial history and physical examination (Table 37.1). The history should first define the problem, distinguishing ED and decreased libido from problems with ejaculation or orgasm, and establishing the time course and severity of symptoms.[31] It is also important to obtain a history of potential risk factors for ED, including the presence of vascular disease, diabetes mellitus, neuropathy or other neurological disorders, dyslipidemia, and hypertension, which are common among patients with CKD. Other clinical risk factors include obesity, smoking, endocrine disorders including gonadal dysfunction, as well as trauma, surgery or radiation to the pelvic organs.[31] Psychosocial factors such as depression, anxiety, alcohol or other substance abuse, and relationship issues involving a partner may also be important contributors to ED.[1] A thorough medication history should focus on antihypertensive medications, selective serotonin reuptake inhibitor (SSRI) antidepressants and venlafaxine, opioids, and antitestosterone agents. Antidepressants are the most common psychotropic drugs associated with ED, but antipsychotics such as risperidone and olanzapine have the highest likelihood of all psychotropic drugs of causing ED.[32] Physical examination should exclude anatomic abnormalities of the pelvis and genitalia and assess vascular and neurologic function. Specifically, resting and orthostatic vital signs should be obtained and lower extremity pulses examined.

The European Male Aging Study found that decreased frequency of morning erection, decreased frequency of sexual thoughts, and ED were related to free or total testosterone level, with a higher probability of symptoms among men with lower testosterone.[33] These authors proposed a syndrome of late-onset hypogonadism, requiring the presence of at least three sexual symptoms with a total testosterone level of less than

TABLE 37.1 History and Physical Examination for Male Sexual Dysfunction

Hypogonadal Symptoms	Medical & Surgical History Risk Factors	Psychosocial History Risk Factors	Potential ED-Causing Medication Review	Focused Physical Exam
- Decreased libido - Depressed mood - Fatigue - Muscle wasting	- Vascular disease - Diabetes mellitus - Hypertension - Dyslipidemia - Obesity - Endocrine disorders - Neuropathy - Other neurological disorders - Pelvic surgery or trauma - Pelvic radiation	- Smoking - Alcohol abuse - Other substance abuse - Depression - Anxiety - Relationship issues with partner	- Antihypertensives (beta-blockers, thiazides, calcium channel blockers) - SSRIs - Opioids - Antiandrogens (5-alpha-reductase inhibitors, spironolactone, ketoconazole, GnRH agonists)	- Resting and orthostatic vitals - Femoral pulses/ bruits and distal extremity pulses - Anatomic abnormalities of pelvis and genitalia (e.g. atrophic testicles, penile plaques in Peyronie's disease) - Neurologic exam (e.g. cremasteric reflex)

ED, erectile dysfunction; *SSRI*, selective serotonin reuptake inhibitor.

11 nmol/L (~320 ng/dL), which appears to be very similar to the disturbances reported by many men with CKD.

The American Urological Association,[31] the International Society for the Study of the Aging Male,[34] and the Endocrine Society[25] have released recently updated guidelines on ED and hypogonadism. ED guidelines recommend that clinicians measure testosterone level in patients presenting with ED with or without reduced sexual desire (libido).[31,34] The specific recommendation is that the initial diagnostic test for hypogonadism should be measurement of morning total testosterone level by a reliable assay, followed by confirmation of the diagnosis by repeating the measurement of total testosterone.[25] Because testosterone levels may decrease transiently in the setting of acute or subacute illness, evaluation should be avoided during such events. Determination of free testosterone level is recommended among patients whose total testosterone level is near the lower limit of the normal range, and among certain groups likely to have altered SHBG concentrations, including older patients who may have increased SHBG, as well as patients with obesity, diabetes mellitus, nephrotic syndrome, and those taking corticosteroids, in whom SHBG may be low.[25] Free testosterone can either be measured directly from equilibrium dialysis assays or calculated using total testosterone, SHBG, and albumin concentrations. Among patients with low testosterone, evaluation of LH, FSH, and prolactin may also be helpful. Overall, the much higher prevalence of sexual dysfunction and androgen deficiency among men with CKD suggests that a substantial proportion of men with symptoms are likely to have low testosterone. Formal vascular or neurological assessment and monitoring of nocturnal erections may be indicated in select patients in whom the organic nature of the problem is in doubt.[31,35]

Treatment

Lifestyle Modifications and Cardiovascular Risk Reduction

There is some evidence that lifestyle modification can improve ED. In obese men with ED, weight loss and increased physical activity were associated with an improvement in erectile function in about one-third of patients.[36] Lifestyle modifications such as Mediterranean diet, weight loss, and exercise improved ED in studies of men with hypertension, diabetes, or the metabolic syndrome.[37–39] Additionally, a meta-analysis looking at the aforementioned trials as well as two other trials of atorvastatin use found that statins and lifestyle modification were effective at improving ED in men.[40]

There has been considerable emphasis in recent years on the overlap between ED and cardiovascular (CV) diseases, and on the importance of lifestyle modification and CV risk management in men with ED. Not only does ED share common risk factors with cardiovascular disease (CVD), but ED is itself a marker of significantly higher risk of CVD.[41] These issues have been addressed in several multidisciplinary Princeton Consensus conferences dedicated to optimizing sexual function and preserving CV health, attended by urologists, cardiologists, and endocrinologists.[41] Recommendations from these conferences have been incorporated into ED practice guidelines.[31] Because incident ED has a similar or greater predictive value for CV events as traditional risk factors and may be the presenting symptom of CVD among men with silent coronary artery disease (particularly younger men), organic ED should alert the clinician to the possibility of increased CVD risk, even in the absence of symptoms or history. Consensus recommendations, which have been incorporated into recent guidelines,[31] are that CVD risk assessment should be performed and the results incorporated into the treatment plan for ED in affected patients (Figure 37.2).[41]

Assessment should include a history and physical examination to uncover other risk factors as well as a resting electrocardiogram, fasting lipids, and glucose. Lifestyle modifications and aggressive management of CV risk factors (e.g. hypertension, hyperlipidemia, hyperglycemia) is recommended. Additional noninvasive or invasive testing for CVD may be indicated at the discretion of the clinician or cardiologist. Given that sexual activity is comparable to mild to moderate intensity physical activity in the range of 3–5 metabolic equivalents (METs) or to climbing two flights of stairs or walking briskly,[42] CV risk stratification is recommended before treatment of ED and resumption of sexual activity (Figure 37.2).[31,41] The first steps are a careful history for CV events and symptoms and exercise tolerance. Individuals who have not had recent CV events and can perform routine moderate activities (3–5 METs) without symptoms are at low risk and can be treated for ED. Those who are unstable (e.g. NYHA class IV heart failure, uncontrolled hypertension, recent myocardial infarction without intervention) should be stabilized before resumption of sexual activity. Exercise stress testing is recommended for those at intermediate or indeterminate risk.

PDE5 Inhibitors

Phosphodiesterase-5 (PDE5) inhibitors (PDE5i) can be effective regardless of the underlying etiology or severity of ED (Figure 37.3). PDE5i act by inhibiting degradation of cyclic guanosine monophosphate (GMP) by PDE5, an enzyme present in the corpus cavernosum of the penis. During erection, cyclic GMP causes vascular smooth muscle relaxation leading to increased blood flow into the corpus cavernosum. In a meta-analysis of 27 trials enrolling 6659 men, sildenafil was more likely than

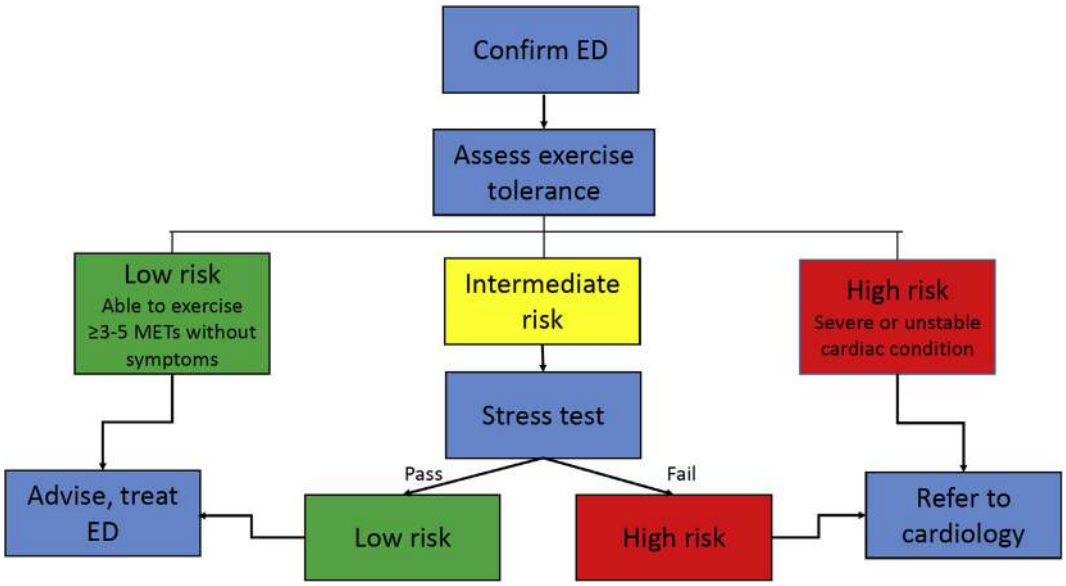

FIGURE 37.2 Cardiovascular risk stratification among men presenting with erectile dysfunction (ED).

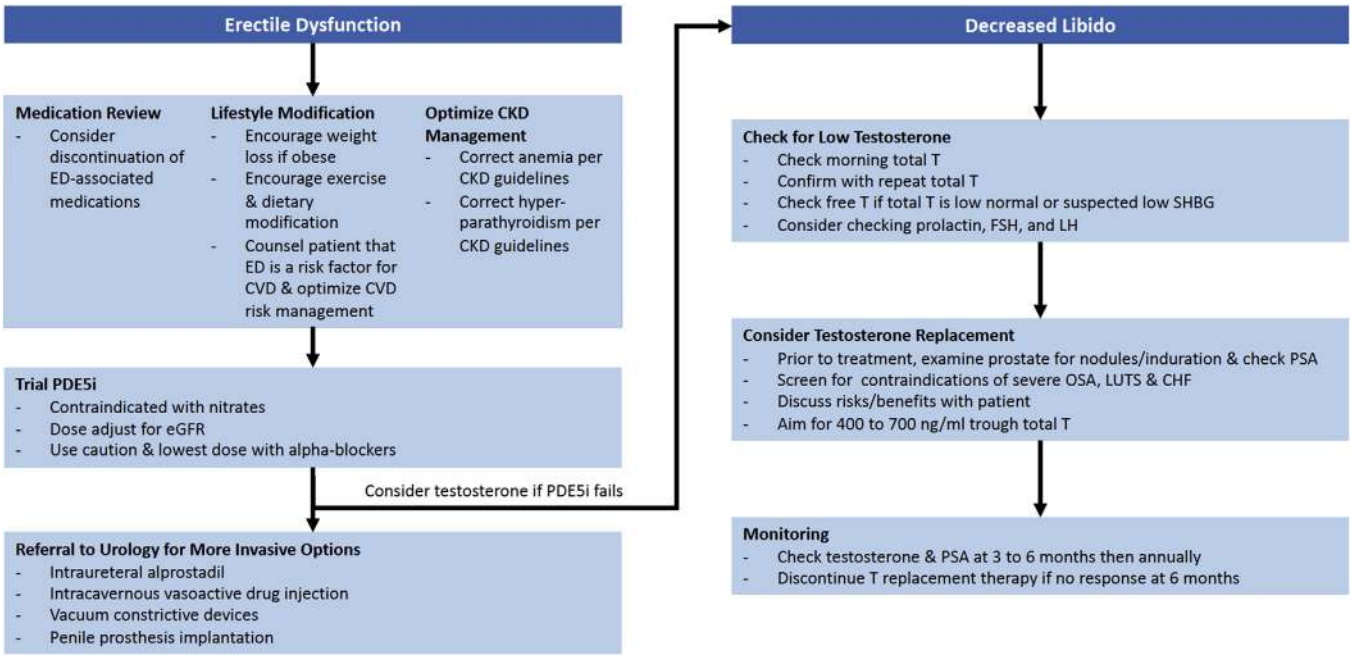

FIGURE 37.3 Evaluation and management of male sexual dysfunction. *CHF*, congestive heart failure; *CVD*, cardiovascular disease; *ED*, erectile dysfunction; *eGFR*, estimated glomerular filtration rate; *FSH*, follicle stimulating hormone; *LH*, luteinizing hormone; *LUTS*, lower urinary tract symptoms; *OSA*, obstructive sleep apnea; *PDE5i*, phosphodiesterase-5 inhibitor; *PSA*, prostate-specific antigen; *T*, testosterone.

placebo to lead to successful intercourse. Fifty-seven percent of intercourse attempts were successful among sildenafil-treated participants vs. 21% receiving placebo, and 83% of those assigned to sildenafil vs. 45% of men receiving placebo achieved at least one success.[43] Although there have been few direct comparisons of different PDE5i, the AUA notes that they appear to have similar efficacy in the general ED population.[31]

Inhibition of degradation of cyclic GMP can cause vasodilation and lead to hypotension, which may be of particular concern among patients with CKD. However, in a pharmacokinetic study of sildenafil among patients treated with hemodialysis, there was no increase in intradialytic hypotension when sildenafil was given immediately before a hemodialysis session.[44] Concomitant use of nitrates and PDE5i is contraindicated because

the combination can lead to severe hypotension. In addition, in patients taking alpha-blockers, commonly used for benign prostatic hypertrophy, using a PDE5i can also lead to symptomatic hypotension. It is recommended that patients treated with alpha-blockers should be on a stable dose before starting a PDE5i at the lowest dose. Alternatively, if the patient is already on a PDE5i, initiation of an alpha-blocker should be at the lowest possible dose. Other common side effects of PDE5i are headache, flushing, dizziness, nasal congestion, rhinitis, and dyspepsia. In the small studies of patients on dialysis or after kidney transplantion, headache was the most commonly reported side effect, and no reported severe adverse events related to PDE5i.[45–50]

The AUA strongly recommends that men who are prescribed a PDE5i be instructed carefully in their appropriate use. In particular, it should be explained that sexual stimulation is needed and that more than one trial with the medication may be needed to establish efficacy.[31] Guideline authors further noted that dose–response effects of PDE5i are relatively small and nonlinear, whereas stronger dose–response patterns have been observed for many adverse effects. Therefore, men should use the lowest dose that produces acceptable effects.

Although studies have examined the safety and efficacy of sildenafil among patients with ESRD,[45,51] there are no studies focusing specifically on patients with nondialysis-dependent CKD. A recent systematic review included six studies of PDE5i among patients treated with dialysis and after a kidney transplant.[45–50] These studies were all of modest size (13–60 participants) and short duration (1–2 months). Generally, there were marked improvements in sexual function, on the order of 75–85% among patients receiving PDE5i compared to 0–28% among patients receiving placebo. Of note, although there was consistent and substantial improvement in symptoms of ED and overall sexual function, libido and desire were not improved.

In the US, there are four PDE5i currently available: sildenafil, vardenafil, tadalafil, and avanafil. Although sildenafil is primarily eliminated by hepatic metabolism and excretion, its clearance is reduced in patients with CrCl <30 mL/min.[44,52] A lower starting dose of 25 mg daily as needed, approximately 1 hour before sexual activity and no more than once per day is recommended in these patients (https://www.accessdata.fda.gov/drugsatfda_docs/label/2014/20895s039s042lbl.pdf).

The pharmacokinetics of sildenafil among dialysis patients appears to be similar to that of healthy individuals without CKD, suggesting that the reduced clearance observed in the setting of advanced CKD is the result of inhibition of hepatic sildenafil metabolism by a uremic toxin that is removed by dialysis.[44] Vardenafil and avanafil do not require dose adjustment in CKD (https://www.accessdata.fda.gov/drugsatfda_docs/label/2007/021400s010lbl.pdf). Vardenafil has not been evaluated in patients treated with dialysis and therefore is not recommended in this population. Avanafil is not recommended for patients with CrCl <30 mL/min because of a lack of detailed pharmacokinetic data (https://www.accessdata.fda.gov/drugsatfda_docs/label/2007/021400s010lbl.pdf). Recommended dosing of tadalafil is 5 mg daily as needed among patients with CrCl 30–50 mL/min, with a maximum of 10 mg in 48 hours. For patients with CrCl <30 mL/min or ESRD treated with hemodialysis, the maximum dose is 5 mg every 72 hours (http://pi.lilly.com/us/cialis-pi.pdf).

A small retrospective study reported good efficacy among men on HD treated with low dose tadalafil for three months.[53] Among kidney transplant recipients, sildenafil and vardenafil do not appear to alter the pharmokinetics of tacrolimus, cyclosporine, or mycophenolate mofetil in a clinically significant manner.[46,50,54]

Testosterone

Testosterone replacement therapy is a reasonable option among men with low testosterone and sexual dysfunction, particularly if decreased libido is a prominent symptom, if PDE5i therapy has not been successful, or if other potential symptoms or sequelae of hypogonadism are present, such as muscle wasting or osteoporosis (Figure 37.3). A recent meta-analysis of four trials (1779 patients) of testosterone therapy for hypogonadism defined strictly on the basis of low testosterone plus at least one relevant sign or symptom, found that testosterone therapy was associated with small but significant increases in libido, erectile function, and sexual satisfaction compared to placebo.[55] Although some participants in these trials likely had CKD, there have been no CKD-specific studies. Lawrence et al. described their experience treating 27 dialysis patients with injected testosterone in a renal impotence clinic.[56] Sexual function was fully restored in only 3 patients (11%), but another 19 (70%) had partial responses. Five patients (18.5%) did not respond.[56]

A new Endocrine Society guideline published in 2018 recommends testosterone therapy in hypogonadal men to correct symptoms of testosterone deficiency, which can include decreased libido and ED.[25] The guideline stresses that diagnosis of hypogonadism be based on "unequivocally and consistently" low total and/or free testosterone concentrations, measured on two separate mornings when the patient is fasting, accompanied by symptoms and signs of testosterone deficiency. The authors recommend against testosterone therapy in patients with breast or prostate cancer, a palpable prostate nodule, prostate-specific antigen (PSA) greater than 4 ng/mL or PSA greater than 3 ng/mL in men at

high risk for prostate cancer. In hypogonadal men 55–69 years old who are being considered for testosterone therapy and have a life expectancy greater than 10 years, the guideline suggests discussing the potential benefits and risks of evaluating prostate cancer risk and prostate monitoring and engaging the patient in shared decision-making regarding prostate cancer monitoring. For patients who choose monitoring, clinicians should assess risk (by performing digital prostate examination and evaluation of PSA levels) before starting testosterone therapy and again after 3–12 months. Urological evaluation is recommended if PSA increases by >1.4 ng/mL above baseline, or to a concentration >4.0 mg/mL, or if a prostatic abnormality is detected on examination. These recommendations represent a distinct change from prior guidelines, which stated that PSA should be measured before considering testosterone therapy.[57] The shift appears to be a result of heightened awareness that it is not possible to distinguish prostate cancers that will remain indolent from those destined to be lethal. In addition, testosterone therapy increases the risk of detecting subclinical prostate cancer because of increased surveillance and testosterone-induced increase in PSA, leading to concern that many men are being subjected to harms of treatment of prostate cancer that might never become symptomatic.[25] In addition to known breast or prostate cancer, other potential contraindications to testosterone therapy include hematocrit greater than 50%, untreated severe obstructive sleep apnea, severe lower urinary tract symptoms, uncontrolled heart failure, myocardial infarction or stroke within the last 6 months, or thrombophilia.[25]

There are many types of testosterone preparations available, including injections, transdermal patches, gels, and solutions, nasal gel, buccal bioadhesive tablets and subcutaneous pellets. There are insufficient data to suggest important differences in efficacy among these. Thus, cost and patient preferences should dictate choice of therapy. There is no need for dose adjustment in CKD.[58] The primary goal of treatment is to alleviate symptoms. Available evidence from studies of healthy or hyopgonadal men suggests that the threshold testosterone level below which symptoms of sexual dysfunction occur varies among individuals but corresponds on average to the lower limit of the normal range for young men.[33,59–61] A recent study commissioned by the Endocrine Society in its guideline development process established harmonized testosterone reference ranges for total testosterone that can be applied across laboratories by cross-calibrating assays.[62] This process reduced intercohort variation in testosterone concentration substantially and resulted in a normal range of 264–916 ng/dL. The Endocrine Society guideline recommends using this range in defining testosterone deficiency and in targeting treatment.[25] They recommend monitoring testosterone level 3–6 months after initiation of treatment, and then annually thereafter, targeting testosterone levels in the mid-normal range. In men receiving injections of testosterone enanthate or cypionate, the recommendation is to aim for normal levels (400–700 ng/dL) one week after the injection. Unlike PDE5i, the effects of testosterone are not immediate. A recent review assessed the time course of testosterone effects on symptoms and found that the effects on libido and sexual satisfaction begin after approximately 3 weeks and peak at 6 weeks after initiation of testosterone therapy.[63] However, maximal effect on ED appears to take longer—usually by 3–6 months but sometimes up to 1 year.

The biggest safety concerns related to testosterone therapy are related to prostate cancer and CVD, but increase in hematocrit, acne, oiliness of skin, and breast tenderness are also common drug-related adverse events. Increased hematocrit is less likely to be a concern among patients with CKD although hematocrit should still be monitored with testosterone therapy.[25] There is little evidence that endogenous androgens are related to the development or progression of prostate cancer,[64] or that testosterone therapy increases the risk of prostate cancer or BPH.[55,64,65] However, testosterone can stimulate growth and aggravate symptoms in men with locally advanced and metastatic prostate cancer and increases the risk of prostate biopsy if patients choose to undergo surveillance for prostate cancer.[64–66]

Reliance on observational data and short-term studies has made it difficult to assess the CV effects of testosterone. There are no long-term data on testosterone therapy in CKD populations, and a relative paucity of long-term data in older men with late-onset hypogonadism from which clinicians could generalize to men with CKD. Observational studies show that men with CVD have lower testosterone levels.[67–69] Cross-sectional studies of risk factors for CVD have shown inverse correlations between testosterone levels and triglycerides, total cholesterol, low-density lipoprotein (LDL) cholesterol, and body mass index. Short-term testosterone administration has been linked to many positive effects on CV risk factors, including reduction in total and LDL cholesterol, improvement in insulin sensitivity, and decrease in visceral fat mass and markers of inflammation. Furthermore, short-term testosterone administration has been shown to have positive effects on vascular function, alleviating angina, and enhancing vasoreactivity in patients with CAD.[68] Low testosterone is associated with higher overall and CV mortality among men in the general population[69] and among ESRD patients.[23,24] Thus, with the exception of HDL cholesterol, which is generally unchanged or reduced after testosterone administration, observational data and outcome data based on surrogate markers suggest a

potential favorable risk profile of replacement testosterone therapy.

Indeed, early indications from prospective studies did not report an increase in CV risk with testosterone, including a meta-analysis of 51 studies of testosterone replacement therapy, which found that there was no significant effect on mortality, myocardial infarction, need for coronary revascularization, or arrhythmias.[7] However, there has been considerable controversy about how to interpret the conflicting results of more recent observational and randomized studies, some of which suggested that testosterone might increase risk of major adverse cardiovascular events (MACE), whereas others did not. Publication of a randomized controlled trial among older men with low testosterone and mobility limitations that was halted because of a higher rate of CV events among the participants receiving testosterone[70] and two large retrospective cohorts of patients treated in the Veterans Affairs system[71] and another large healthcare system[72] that found a higher risk of MACE among those treated with testosterone led the US Food and Drug Administration (FDA) to issue a black box warning (https://www.fda.gov/Drugs/DrugSafety/ucm436259.htm) about these risks. However, the methodology of these studies has come under considerable criticism.[73,74] Subsequent randomized trials have not found testosterone to be associated with higher risk.[75–77] Therefore, the review panel for the Endocrine Society guideline[25] and other experts[74] have concluded that the randomized trials of testosterone therapy have been neither large enough nor long enough to evaluate the effects on MACE, and that there is no clear evidence that testosterone increases the risk of MACE.

CKD-Related Factors

Anemia has been associated with reduced libido and ED, and treatment with erythropoetin has been associated with improvements in ED, sexual performance, and sexual desire in some ESRD patients.[1,78–81] Some investigators have suggested that favorable changes in hormone levels with correction of anemia could underlie this improvement.[79,82] These data were all among patients with ESRD and severe anemia at baseline who experienced very large increases in hematocrit in response to erythropoietin. It is unclear if there are any data to address whether smaller changes in hemoglobin within currently recommended target ranges have any relation to sexual function, but it is reasonable to treat anemia according to current guideline recommendations among men with CKD and sexual dysfunction.

Parathyroid hormone may contribute to sexual dysfunction in CKD by an unknown mechanism. A study of 20 dialysis patients with CKD and secondary hyperparathyroidism undergoing parathyroidectomy showed improvements in sexual function after surgery and concomitant reductions in prolactin levels.[83] Similar caveats apply to this study as to the studies of erythropoietin—that it does not address effects of more modern therapies for hyperparathyroidism.

Zinc deficiency is a known cause of hypogonadism. Zinc levels have been found to be low in some hemodialysis patients. Studies have examined oral zinc supplementation as well as zinc in the dialysate as a treatment for ED.[45] Among dialysis patients treated with oral zinc, testosterone was increased as was potency and frequency of intercourse. However, zinc in the dialysate did not improve testosterone, FSH, or LH levels. A study with oral zinc led to increased serum LH and testosterone without any effect on serum FSH and prolactin levels, but did not address changes in sexual function among patients treated with hemodialysis.[84]

Bromocriptine, a dopamine D2 agonist used in the treatment of hyperprolactinemia, was studied in the past in hemodialysis patients with sexual dysfunction. Although there was an improvement in sexual function, hypotension was a common and limiting side effect,[85] and this agent has been abandoned as a therapy for ED and hyperprolactinemia.

Conclusions

Sexual dysfunction is common among men with CKD and is associated with lower HRQOL. Causes of sexual dysfunction include vascular, hormonal, neurologic, and psychosocial factor. The presence of more than one factor is common, particularly among older patients with CKD. Guidelines for the treatment of male sexual dysfunction do not present a uniform treatment algorithm. Men should be counseled about lifestyle modifications and should have CKD-related complications of anemia and hyperparathyroidism treated in accordance with CKD-related guidelines. If additional treatment of sexual dysfunction is needed, PDE5i should be the first-line treatment for most patients. For patients with low serum testosterone levels who fail PDE5i, or in whom decreased libido is a particularly important symptom, testosterone therapy can be considered as long as the patient is aware of potential risks. In addition, low testosterone levels should be confirmed after PDE5i therapy because PDE5i use can increase testosterone levels.[64] Because PDE5i and testosterone operate by different mechanisms and have different side effect profiles, they can be combined to address ED and decreased libido.[64] Other options for patients who fail PDE5i and/or testosterone therapy include intraurethral alprostadil, intracavernous vasoactive drug injection, vacuum constrictive devices, and penile prosthesis

implantation.[86] Patients should be referred to a urology specialist for consideration and implementation of these strategies.

SEXUAL DYSFUNCTION AMONG WOMEN WITH CKD

Scope of the Problem

Female sexual dysfunction (FSD) is common among patients with CKD, yet it remains understudied and probably undertreated. FSD can be categorized as sexual desire disorders, sexual arousal disorder, orgasmic disorder, and sexual pain disorders.[87] Each of these is diagnosed based on the presence of the relevant symptoms causing marked distress or interpersonal difficulty.[88] Estimates of the prevalence of FSD, among women with and without CKD, vary depending on whether the presence of personal distress is considered in the definition.[89] A recent large survey of women in the US found that 44% reported at least one problem with sexual function, with low desire being the most common complaint. Sexually related personal distress was reported by 23%.[89]

Up to 30–80% of women with advanced CKD suffer from FSD.[90–92] It has been suggested that as renal function declines, the frequency of sexual dysfunction increases.[1,3,45,93] In a small study by Basok et al. that included patients with various stages of CKD and healthy controls, half of the participants in the control and postkidney transplantion groups met the criteria for FSD. The proportions of women with FSD were much higher in the other groups: 81% among women with nondialysis-dependent CKD, 66.7% among women on peritoneal dialysis, and 75% among women treated with hemodialysis.[94] A larger study among women treated with hemodialysis found a similarly high proportion (84%) experienced sexual dysfunction.[95] These studies suggest that symptoms become more common with more advanced CKD and return to approximately the level of sexual dysfunction experienced by women in the general population after transplantation. Mor et al. examined sexual function and satisfaction among older women on dialysis,[96] and an accompanying editorial[97] called into question whether sexual inactivity and lack of sexual desire should be classified as dysfunction in older women treated with dialysis. Among 125 women who completed repeated administrations of the Female Sexual Function Index, 89% of the scores were consistent with sexual dysfunction, consistent with prior reports. However, sexual inactivity was the most common reason for identifying sexual dysfunction (82%), which in turn was frequently due to lack of interest in sex (43%) or lack of a partner (39%) but rarely due to sexual difficulty (2%). Sixty-four percent of surveys indicated that participants were moderately to very satisfied with their sexual life, and few were interested in learning about treatment options. Thus, it is important to consider patients' age and degree of concern when evaluating sexual function.

Pathophysiology

The etiology of sexual dysfunction among women with CKD is complex (Figure 37.4). Sexual dysfunction in women with CKD has been attributed to both hormonal disturbances and psychosocial factors and may also be complicated or exacerbated by the use of multiple medications and the presence of comorbidities.[51] The majority of women with CKD are postmenopausal, which may be due in part to premature menopause, which occurs approximately 4.5 years earlier (at age 47 years) among women with CKD than among women with normal kidney function.[98,99] There are few studies evaluating ovarian failure in women with less-advanced CKD, but by the time women reach ESRD, the frequency of menstruation among women of childbearing age is approximately 8–10%, with anovulatory cycles occurring commonly.[98] The effects of hypogonadism can include FSD. The hormonal disturbances that lead to ovarian failure in women with CKD include abnormalities in the hypothalamic–pituitary–ovarian axis and elevated prolactin levels. Ovarian failure is characterized by low estradiol levels, which cause decreased blood flow to the vagina and the vulva. Decreased estrogen levels may also increase tissue fragility, dryness, irritation, and susceptibility to vaginal tissue trauma.[87] Ovarian failure among women with CKD can ultimately lead to decreased vaginal lubrication and atrophy, pain during intercourse, and FSD.[1,98,99] Elevated prolactin levels may also play a role in ovulatory dysfunction, and ultimately in symptoms of FSD in women with CKD.[1] Serum prolactin levels appear to rise with declining GFR.[100] Elevated prolactin levels are thought to contribute to symptoms of decreased libido.[1,101]

Psychosocial factors, including depression and poverty, may also be associated with FSD in women with CKD (Figure 37.4). In the general population, a deterioration in economic position is associated with an increase in risk for FSD, and higher education levels are inversely associated with the prevalence of FSD.[102] The association between depression and FSD is complex. Among patients with ESRD, depression is the most commonly encountered psychological problem and has been associated with sexual dysfunction and lower quality of life.[1,92,103,104] Similar to men, depression can interfere with libido and lead to decreased sexual activity.[1] On the other hand, FSD may lead to depression

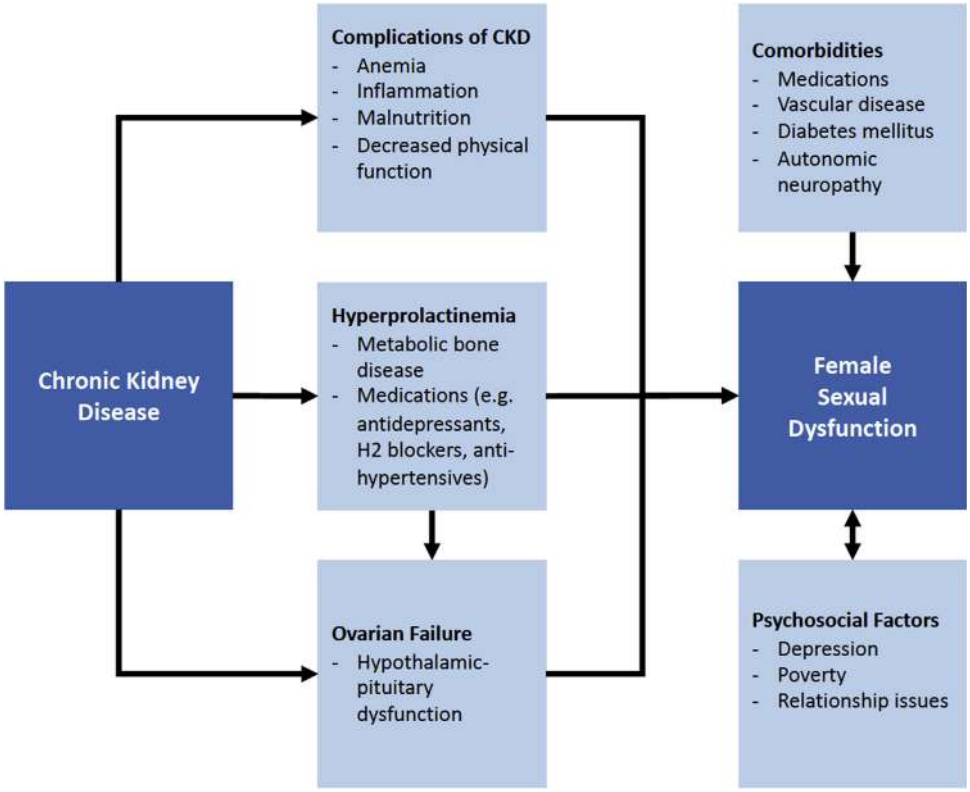

FIGURE 37.4 Factors contributing to female sexual dysfunction. *H2*, histamine 2.

or exacerbate preexisting depression, given the strong correlation between all categories of FSD and low feelings of happiness.[102] In addition, treatment of depression may contribute to the problem, as sexual dysfunction is a side effect of SSRIs in up to 30–70% of women.[105]

The presence of other comorbid illnesses including vascular disease, diabetes, and autonomic neuropathy also correlates with FSD in patients with CKD.[3,51] As vaginal sexual arousal is both a neuromuscular and vasocongestive event that relies on intact parasympathetic and inhibitory sympathetic input, women with CKD and autonomic neuropathy can be afflicted with sexual dysfunction.[106] Finally, commonly used medications in the CKD population, including antihypertensives, antidepressants, and histamine receptor blockers may also contribute to the frequent occurrence of sexual dysfunction.[51]

Diagnosis

The first step in diagnosing FSD begins with obtaining a detailed sexual history, which can be done with the aid of a questionnaire.[1,107,108] Although previously available assessments for FSD were one-dimensional, more recently, the normal female sexual response cycle is being recognized as a composite of a variety of domains, making a multidimensional instrument more appropriate.[108] Currently, FSD is defined using six separate domains, which include hypoactive sexual desire disorder, sexual aversion disorder, sexual arousal disorders, orgasmic disorders, sexual pain disorders, and noncoital sexual pain disorders.[108]

The next step in evaluating sexual function is to carefully review all medications, as patients with CKD are often prescribed multiple medications that may lead to sexual dysfunction (Figure 37.5). Consideration should also be given to obtaining hormone levels including FSH and LH among premenopausal women, and TSH and prolactin for all women. Although androgen levels continue to decrease in premenopausal women until they reach menopause, there is no proven clinical utility in monitoring androgen levels.[87] Further, parathyroid hormone and hemoglobin concentrations should be evaluated, as these are commonly abnormal and are associated with FSD. Finally, it is essential to screen for depression because of the high frequency of depression in the CKD and ESRD population, and the close associations between FSD and depression.[108,109]

Treatment

Given the high prevalence of FSD in the CKD population and its correlations with depression and perception

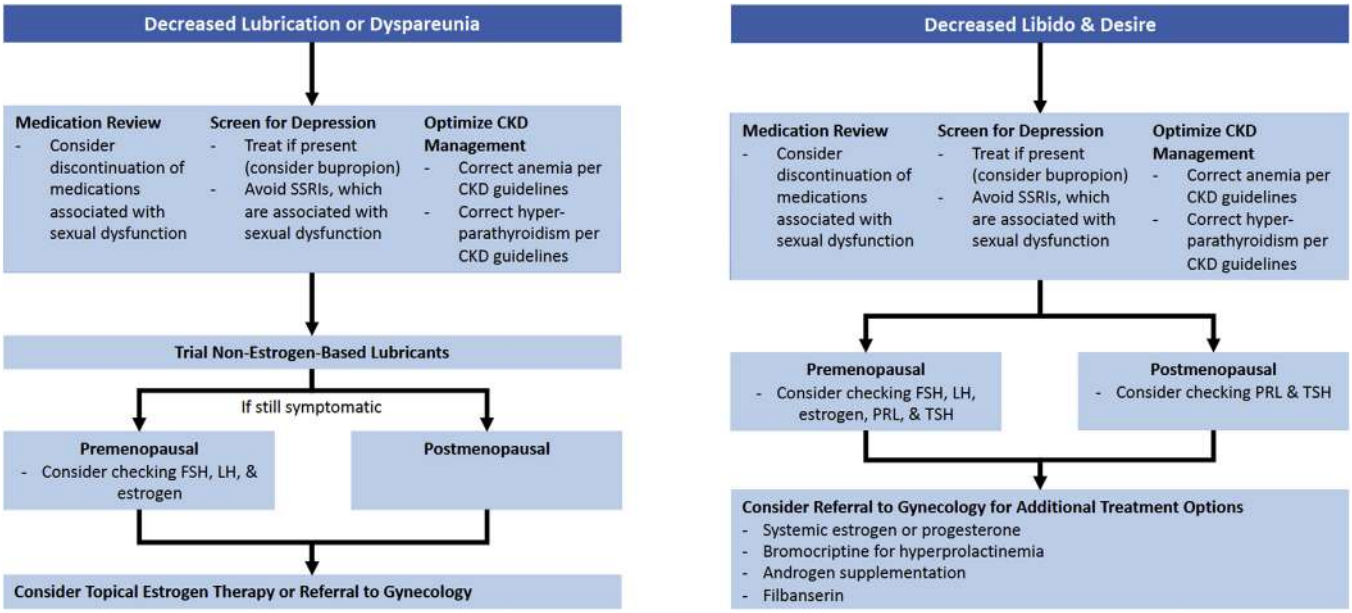

FIGURE 37.5 Evaluation and management of female sexual dysfunction. *FSH*, follicle stimulating hormone; *LH*, luteinizing hormone; *PRL*, prolactin; *SSRIs*, selective serotonin reuptake inhibitors; *TSH*, thyroid stimulating hormone.

of quality of life,[3] effective treatment of this problem is important as it may lead to improvements in these outcomes. Unfortunately, there are no randomized trials evaluating interventions for sexual dysfunction among women with CKD.[45] Treatment of FSD should take a systematic approach based on the findings of the evaluation and should follow guidelines established for women in the general population (Figure 37.5).[1,87] After initial evaluation, treatment can be initiated (Figure 37.5) or, depending on the comfort level and training of the physician, a referral can be made to a trained specialist, such as a gynecologist, marriage counselor, or sex therapist.[87]

Many patients with CKD are prescribed medications that may affect sexual function. After a thorough review of medications, unnecessary medications should be discontinued. Certain antihypertensive medications, histamine receptor blockers, and SSRI antidepressants are commonly used in the CKD population and are especially likely to be associated with FSD.[51,87] Consideration should be given to switching such medications to alternative drugs as a first-line approach for the treatment of FSD. Studies have shown that hypertensive women have worse sexual function than normotensive controls.[110,111] One study found approximately twice the prevalence of FSD among women with hypertension (42%) compared with women without hypertension (19%) in a group of relatively young participants.[110] Although this study did not report a difference based on type of therapy, a larger study by Doumas et al. reported that β-blocker administration was associated with a higher prevalence of FSD among 216 women with hypertension. However, no associations were found between FSD and the use of diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or calcium antagonists.[111] Smoking[110] and acute nicotine administration[112] have also been shown to be associated with sexual dysfunction among women.

If the evaluation reveals untreated depression, treatment of depression may ameliorate sexual dysfunction. However, because SSRIs may themselves cause decreased arousal, decreased sexual desire, and orgasmic dysfunction among women, they are not the treatment of choice. Alternatives, such as bupropion or nonpharmacologic treatments including cognitive behavioral therapy,[113] are preferred.[87] Among women with depression treated with SSRIs, decreasing the dosage of the SSRI may help to alleviate symptoms. However, if symptoms do not improve with this strategy or if depression worsens, the SSRI may need to be switched to an alternative medication class, and consultation with a mental health provider should be considered. Bupropion inhibits both dopamine and norepinephrine reuptake, has a very low incidence of drug-induced sexual dysfunction, and has even been shown to improve sexual function.[114] In a randomized, double-blind, placebo-controlled trial, 66 premenopausal women with hypoactive sexual desire disorder were studied. Women assigned to receive bupropion reported significant improvement, measured by an increase in the overall score on the Changes in Sexual Function Questionnaire, as well as on the arousal and orgasm subscales.[114] Although scores on the desire

subscale increased more in the bupropion group, this change did not reach statistical significance. Limited pharmacokinetic data suggest that elimination of bupropion or its active metabolites may be reduced in the setting of moderate to severe CKD, so it should be used with caution and the dose interval may need to be increased (i.e. dose frequency reduced).

The next step in the treatment of FSD is the alleviation of targeted symptoms including decreased vaginal lubrication and dyspareunia (Figure 37.5). The use of topical vaginal estrogen can aid lubrication and improve postmenopausal atrophy and lead to decreased dyspareunia. The American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin on FSD notes that treatment using tablets, gels, creams, and vaginal rings is equally effective.[87] Systemic absorption of topical estrogen is limited following intravaginal application, but the lowest effective dose should be used for the least amount of time to alleviate symptoms. The ACOG recommends beginning with daily treatment for a few weeks and then tapering down based on symptoms.[87] For women who cannot or choose not to use estrogen, nonestrogen water-based or silicone-based lubricants can also aid with lubrication and decrease dyspareunia.[87] Ospemifene, a nonhormonal selective estrogen receptor modulator, was approved by the FDA for once-daily administration for the treatment of moderate to severe dyspareunia due to menopause subsequent to the publication of the ACOG guidelines.[115] It carries a warning about risk of endometrial cancer, deep vein thrombosis, and stroke (https://www.accessdata.fda.gov/drugsatfda_docs/label/2013/203505s000lbl.pdf) and is contraindicated in women with breast cancer. Because it is hepatically metabolized (and therefore contraindicated in patients with severe hepatic failure), no dose adjustment is required in women with CKD. However, the CV risks noted in the FDA warning should lead to particular caution in the CKD population.

Among women with orgasmic disorders, vasoactive medications such as sildenafil are thought to increase pelvic blood flow to the clitoris and vagina in a manner similar to their effects among men.[87] However, the results of randomized clinical trials evaluating the efficacy of sildenafil for the treatment of sexual arousal disorder have been contradictory.[87,116–119] A recent review concluded that although data suggest a possible role of sildenafil for the treatment of FSD, the information should be interpreted cautiously because many of the studies were small and used nonvalidated assessment tools.[120] The safety and efficacy of sildenafil has not been established among women with CKD, and therefore it should be used cautiously in this population. The ACOG notes that more research is needed before a recommendation can be made.[87]

Although levels of circulating androgens among women correlate weakly if at all with sexual function,[121,122] many studies have evaluated the use of testosterone supplementation among women in the general population with hypoactive sexual desire disorder.[123–125] Several formulations have been tested, and there is evidence for a beneficial effect on sexual function with a dose–response effect, particularly for transdermal testosterone.[87,123,124] However, testosterone is not approved by the FDA for the treatment of hypoactive sexual desire disorder among women. The most studied formulation, transdermal testosterone in the form of a matrix patch, is not available in the US.[87] Furthermore, because of lack of long-term safety data, neither the Endocrine Society[124] nor the ACOG recommend long-term use (longer than 6 months) of testosterone.[87] If androgens are used in the short-term treatment of FSD, there is no role for monitoring androgen levels.[87] Rather, monitoring should focus on assessment for potential side effects, including acne and hirsutism, and adverse changes in lipid profiles. The use of androgen supplementation to treat sexual dysfunction has not been studied among women with CKD, and there are currently no recommendations advocating for or against such supplementation in the CKD population. Since the publication of the ACOG guidelines, flibanserin has been approved by the FDA for the treatment of premenopausal women with generalized hypoactive sexual desire disorder that causes marked distress (https://www.accessdata.fda.gov/drugsatfda_docs/label/2015/022526lbl.pdf) based on three randomized controlled trials reporting an increase in the number of satisfying sexual events, and in one study, an improvement in desire was reported. However, severe hypotension is a concern, particularly when flibanserin is combined with alcohol or moderate or strong cytochrome P450 3A4 inhibitors or in the setting of hepatic impairment. Therefore, flibanserin is available only through a restricted program in which prescribers must be certified by enrolling and completing training.

Treatment of hormonal abnormalities, including elevated prolactin levels and low estradiol and progesterone levels, may also improve sexual dysfunction in women with CKD. Hyperprolactinemia has been associated with decreased libido and is thought to contribute to ovulatory dysfunction, and ultimately to sexual dysfunction. Bromocriptine may reduce the prolactin level to a normal range, but gonadotropin concentrations are not always normalized and the drug is poorly tolerated.[1,98] Correction of secondary hyperparathyroidism may also lower prolactin levels, and use of 1,25-dihydroxy vitamin D_3 appears to reduce prolactin secretion in patients with CKD.[98,101]

There is also some evidence that recombinant human erythropoietin (rHuEPO) therapy may improve the function of the pituitary gonadal axis and reverse the hormonal alterations seen in women with CKD by lowering FSH, LH, and prolactin levels.[98] Given the associations of anemia with decreased sexual dysfunction, it is important to correct anemia to guideline-recommended target hemoglobin levels.[101] Consideration should be given to hormone replacement with estrogen with or without progesterone, but this decision should be made following a careful evaluation of the patient, and on a case-by-case basis.[1] Finally, referral for kidney transplantation is important because improvement in sexual function has been reported by 85–90% of female kidney transplant recipients.[98] Improvement in sexual function characterized by improved libido and increased frequency of intercourse has been linked to the normalization of the hormonal profiles following kidney transplantion.[98]

Conclusions

Sexual dysfunction is a common problem in women with CKD. As renal function declines its prevalence increases. Multiple factors including comorbid diseases, hormonal disturbances, psychosocial factors, mineral and bone disorders, medications, anemia, and autonomic neuropathy may contribute to the occurrence or severity of sexual dysfunction in women with CKD.[51] Sexual dysfunction adversely affects quality of life in many women due to its associations with decreased self-esteem, poor self-image, anxiety, and marital discord.[3] However, some women may be less bothered by sexual inactivity.[96] Providers should be sensitive to this issue, balancing the importance of treatment when symptoms cause distress and avoiding overtreatment if sexual satisfaction is not low.[97] Accurate diagnosis and appropriate treatment of this common problem are very important, and more studies are urgently needed to identify beneficial treatment options in this population.

QUESTIONS AND ANSWERS

Question 1

A 40-year-old woman with obesity, chronic kidney disease (CKD) stage 3, hypertension, and recently diagnosed depressive disorder returns for follow-up. She was started on citalopram for depression 3 months ago. Since then, her symptoms of anhedonia, depressed mood, fatigue, and decreased sleep have improved. She has no suicidal ideation. Despite these improvements, she notes new onset anorgasmia. On physical exam, her blood pressure is 120/70 mm Hg. Other vital signs are normal. BMI is 32 kg/m^2. Her physical exam is otherwise unremarkable. You discontinue her citalopram and start her on bupropion.

Which **one** of the following is **false** regarding depression and sexual dysfunction in CKD?

A. Reducing the dose of her citalopram may alleviate her sexual dysfunction
B. Bupropion increases measures of orgasm completion and sexual satisfaction in women
C. Selective serotonin reuptake inhibitors are the treatment of choice in the presence of depression and sexual dysfunction
D. Sexual dysfunction is associated with lower quality of life in both men and women with ESRD

Answer: C

Reducing SSRI dose can alleviate symptoms of sexual dysfunction, thus Choice **A** is true. Choice **B** is true, as bupropion increases measures of orgasm completion, sexual satisfaction, and sexual arousal in women. SSRIs may not be the treatment of choice in the presence of depression and sexual dysfunction because they can worsen sexual dysfunction. Therefore, Choice **C** is false. Bupropion would be a more reasonable choice given its aforementioned positive effects on sexual functioning. Choice **D** is true as lower quality of life in both men and women with ESRD is associated with sexual dysfunction.

Question 2

A 60-year-old man with hypertension, coronary artery disease, hyperlipidemia, anemia of chronic disease, and CKD stage 4 is evaluated for sudden onset ED. He notes that he still has nocturnal erections. He is on stable doses of carvedilol, furosemide, and benazepril for his hypertension for the past year. On physical exam, his blood pressure is 145/85 mm Hg. Other vital signs are normal. His BMI is 28 kg/m^2. Genital exam reveals no penile or testicular abnormalities. Femoral pulses are 2+ bilaterally without bruits and distal pulses are normal. Neurologic exam is unremarkable. Laboratory studies reveal a hemoglobin of 8.5 g/dL and a serum creatinine (S[Cr]) of 3.8 mg/dL.

Which **one** of the following is the **most likely** primary cause of his ED?

A. Medication side effect
B. Anemia
C. CKD
D. Psychogenic

Answer: D

The rapidity of the onset of his ED and presence of nocturnal erections are important historical clues in this question. The correct answer is Choice **D** as rapid onset ED with preserved nocturnal erections is indicative of psychogenic ED. If there is suspicion for psychogenic ED that is not evident from the history, nocturnal penile tumescence is a reasonable test to assess to rule out organic causes. Despite the likely primary psychogenic cause of ED in this patient, it is important to recognize that ED is usually multifactorial. All of the other answers are potentially contributory in this case. Medication side effect, Choice **A**, is a common cause of ED and should be reviewed carefully in patients with ED. Blood pressure medications, such as beta blockers, could be contributory in this case, but the stable doses and lack of hypotension make them a less likely primary cause. Anemia, Choice **B**, has been associated with reduced libido and ED and could be a contributing factor for this patient. Correcting anemia according to current guidelines for CKD may help with ED, although there are no specific data on whether small changes in hemoglobin improve sexual function in men. Worsening glomerular filtration rate is associated with an increased prevalence of ED. Thus, CKD, Choice **C**, could be contributing to his ED.

Question 3

A 30-year-old woman with CKD stage 4 due to IgA nephropathy returns to clinic for treatment of her CKD. She notes that she has not had a menstrual period for over 2 years and that her interest in sex has diminished lately. She is having intercourse less frequently, which is affecting her self-esteem and causing some discord with her partner. Her blood pressure is well controlled and other vital signs are normal. Her BMI is 22 kg/m^2. Her physical examination is unremarkable. Laboratory studies reveal a hemoglobin of 12.0 g/dL, a prolactin level of 700 mU/L (normal reference range <500 mU/L) and intact parathyroid hormone of 240 pg/mL.

Which **one** of the following is **false** regarding sexual dysfunction and amenorrhea in CKD?

A. Correcting hyperparathyroidism may lower her elevated prolactin

B. Kidney transplantation restores normal menstrual function in the majority of premenopausal women
C. Creatinine clearance (CrCl) has no correlation with prolactin level
D. Worsening anemia has been associated with decreased frequency of sexual intercourse

Answer: C

Correcting of hyperparathyroidism may lower elevated prolactin in women, thus Choice **A** is true. Treating hyperparathyroidism to CKD guideline-recommended targets may improve sexual dysfunction. Choice **B** is true since kidney transplantation has been shown to restore menstrual function in the majority of pre-menopausal women. Levels of sexual dysfunction return to approximately those of the general population after kidney transplantation in women. Choice **C** is false as there is a strong correlation between worsening CrCl and higher prolactin levels in women with CKD. Levels of prolactin are even higher in maintenance dialysis but improve after kidney transplantation. Choice **D** is true as worsening anemia has been associated with decreased frequency of sexual intercourse in women with CKD as well as worsened physical and sexual function.

Question 4

A 50-year-old man with type 2 diabetes mellitus, hypertension, hyperlipidemia, benign prostatic hypertrophy, and CKD stage 4 with an estimated glomerular filtration rate of 25 mL/min/1.73 m^2 complains of sexual difficulties. His sex drive and desire are intact, but he cannot achieve an erection. He is on a stable medication regimen that includes insulin glargine, lisinopril, furosemide, simvastatin, sevelamer, sodium bicarbonate, darbepoetin, aspirin, and doxazosin. His blood pressure is 115/65 mm Hg. Other vital signs are normal. His BMI is 32 kg/m^2. His physical examination, including vascular, neurologic, and genital exam, is unremarkable. You decide to treat him with a PDE5i.

Which **one** of the following is **correct** regarding the dosing of the PDE5i vardenafil in this patient?

A. Start vardenafil at 10 mg daily, twice the starting dose, since the patient is on doxazosin
B. Start vardenafil at 5 mg daily, the usual starting dose, as it does not need to be adjusted for reduced GFR
C. Start vardenafil at 2.5 mg daily, the smallest possible dose, because the patient is on doxazosin
D. Do not start vardenafil as it has not been studied in patients with CrCl <30 mL/min.

Answer: C

The dosing of PDE5i and the choice of which specific PDE5i to use are affected by CKD. Additionally, alpha-blockers, commonly used in males with benign prostatic hypertrophy, can interact with PDE5i. Choice **A** is incorrect as the dose of PDE5 inhibitors should be started at the lowest recommended dose when a patient is on a stable alpha-blocker dose due to potential symptomatic hypotension with this combination of medications. Vardenafil does not need to be adjusted for reduced CrCl, but Choice **B** is incorrect because the dose of vardenafil should be reduced to the lowest possible dose in the presence of doxazosin. Choice **C**, starting at the lowest possible dose, is correct. Choice **D** is incorrect, because vardenafil has been studied in patients with CrCl <30 mL/min. Avanafil, however, has not been studied in patients with a CrCl <30 mL/min and should be avoided in this population until more data become available. The starting doses of sildenafil and tadalafil should be reduced in patients with CrCl <30 mL/min, to 25 mg daily for sildenafil and to a maximum dose of 5 mg every 72 hours for tadalafil.

Question 5

A 65-year-old man with hypertension, hyperlipidemia, focal segmental glomerulosclerosis with chronic kidney disease stage 3 with an estimated glomerular filtration rate of 40 mL/min/1.73 m^2 is evaluated for decreased libido for the past year. He denies any difficulty with erectile function but reports increased fatigue and less physical activity. On physical exam, his blood pressure is 125/55 mm Hg. Other vital signs are normal. His BMI is 26 kg/m^2. Genital exam reveals no penile or testicular abnormalities. Digital rectal exam reveals a slightly enlarged prostate without induration or nodules. The remainder of his exam is unremarkable. Laboratory studies reveal a hemoglobin of 12.0 g/dL, a S[Cr] of 1.8 mg/dL, urine protein:creatinine ratio of 1.1 g/g, morning serum total testosterone of 50 ng/dL (reference range 264 ng/dL to 916 ng/dL), and PSA of 1.0 ng/mL (reference range <4.0 ng/mL). Serum testosterone is confirmed to be low on repeat measurement.

Which **one** of the following is **correct** regarding appropriate testosterone replacement after discussion with the patient, who desires testosterone replacement therapy?

A. Start intramuscular injections of testosterone ethanate every two weeks
B. Start testosterone subcutaneously implanted pellets
C. Start transdermal testosterone patches applied daily
D. Start testosterone topical gel applied daily
E. Start bioadhesive, buccal testosterone tablets applied to buccal mucosa twice per day
F. All of the above are reasonable regimens for testosterone replacement

Answer: F

Insufficient evidence is available to suggest significant differences in efficacy between different testosterone replacement preparations. Thus, Choice **F**, all of the above, is correct, and cost and patient preference should dictate the choice of therapy. The Endocrine Society Guidelines recommend the following regimens: Intramuscular injections, Choice **A**, of either testosterone ethanate or cypionate of 75−100 mg weekly or 150−200 mg every two weeks; Choice **B,** subcutaneously implanted pellets (dose and regimen vary based on formulation); One to two 5 mg transdermal testosterone patches, Choice **C,** applied daily to nonpressure areas of the skin; Choice **D,** 5−10 g of 1% testosterone gel applied to a covered area of skin daily; or 30 mg twice daily of bioadhesive, buccal testosterone tablets, Choice **E**.

Question 6

A 55-year-old man with obesity, hypertension, congestive heart failure, chronic atrial fibrillation, hyperlipidemia, and chronic kidney disease stage 3 with an estimated glomerular filtration rate of 40 mL/min/1.73 m^2 presents with complaints of ED, decreased libido, and fatigue. His heart failure has been well controlled. He is on stable doses of warfarin, atorvastatin, metoprolol, isosorbide dinitrate, hydralazine, and furosemide. On physical examination, his blood pressure is 120/65 mm Hg and heart rate is 60 beats per minute. His BMI is 35 kg/m^2. His lungs are clear, heart has an irregular rhythm without a gallop, jugular veins are nondistended, and he has no peripheral edema. Genital exam reveals no penile or testicular abnormalities. Digital rectal exam reveals a nonenlarged prostate without induration or nodules. Laboratory studies reveal a low total testosterone of 150 ng/dL (reference range of 300−800 ng/dL) and PSA of 0.5 ng/mL (reference range <4.0 ng/mL). Serum testosterone is confirmed to be low on repeat measurement.

Which **one** of the following is **false** regarding this patient with decreased libido and ED?

A. A PDE5i could be used in addition to testosterone to treat his erectile dysfunction.
B. Testosterone replacement therapy may enhance the anticoagulation effect of his warfarin.
C. Trials have been neither long enough nor large enough to provide clear data on the cardiovascular risks and benefits among patients with heart failure.
D. Low testosterone may be a marker of poor general health rather than a risk factor for CVD.

Answer: A

Although a PDE5 inhibitor can be effective for treating ED in a patient with low testosterone, Choice **A** is false in the case of this patient because he is currently on a nitrate, isosorbide dinitrate. The combination of PDE5i and nitrates is contraindicated because it can cause severe hypotension. Severe, uncontrolled heart failure is a contraindication to testosterone use. However, this patient has controlled heart failure. Choice **B** is true as testosterone can enhance the anticoagulation effect of his warfarin. Choice **C** is true and reflects experts' current conclusions regarding mixed and in many cases low-quality data about the potential cardiovascular risks of testosterone therapy among men at high risk of cardiovascular events. The risks and benefits of testosterone should be weighed carefully before deciding to treat patients with low testosterone. Choice **D** is true as low testosterone may be a marker of poor general health rather than a risk factor for CVD.

Water Homeostasis in Chronic Kidney Disease

Richard H. Sterns

University of Rochester School of Medicine and Dentistry and Rochester General Hospital, Rochester, NY, United States

Abstract

Normally the tonicity of the extracellular fluid is maintained within a narrow range, favorable to cellular well-being, by the osmoregulatory system. The kidney plays a central role in water homeostasis, guided by the antidiuretic hormone, arginine vasopressin, which is secreted by the posterior pituitary in response to changes in plasma tonicity. The kidney preserves water when it is scarce by concentrating the urine and eliminates excess water by urinary dilution. Chronic kidney disease impairs the ability to concentrate and dilute the urine maximally, restricting the responses to altered water intake and losses, making patients with kidney disease susceptible to hyponatremia and hypernatremia. Impaired concentrating ability also leads to increased vasopressin levels, which increase glomerular filtration rate. Vasopressin-induced hyperfiltration may be maladaptive, leading to kidney hypertrophy and accelerating the loss of renal function. Elevated vasopressin levels are particularly harmful in autosomal dominant polycystic kidney disease (ADPKD) because vasopressin promotes cyst formation. Vasopressin antagonists have been shown to retard progression of this condition. Many studies are currently underway testing the impact of increased water intake on the progression of ADPKD and other kidney diseases.

Water is the stuff of life and health requires precise control of water balance. Normally the salinity (also known as tonicity) of the extracellular fluid is maintained within a narrow range, favorable to cellular well-being, by the osmoregulatory system. The kidney plays a central role in water homeostasis, guided by the antidiuretic hormone (ADH), arginine vasopressin (AVP), which is secreted by the posterior pituitary in response to changes in plasma tonicity. The kidney preserves water when it is scarce by concentrating the urine and eliminates excess water by urinary dilution. The effect of kidney disease on water homeostasis has long been understood. Recently we have come to learn that water balance also has profound effects on the progression of kidney disease.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF WATER HOMEOSTASIS

The tonicity of body fluids is reflected by the serum sodium concentration, which is a function of the body's content of sodium and potassium (more precisely, the portion that is free in solution and not bound to proteoglycans in bone, cartilage, and connective tissue) divided by its content of water:

$$\text{Serum sodium concentration} \approx \text{Total body } (\text{Na} + \text{K})/\text{Total body water}$$

Changes in the serum sodium concentration are determined by the net balance of sodium and potassium (which alters the numerator of the equation) and the net balance of water (which alters the denominator).[1] The osmoregulatory system maintains the serum sodium concentration within a narrow normal range through changes in thirst, which controls water intake, and AVP, which controls water excretion.[2,3]

AVP, also known as ADH or vasopressin, is a nine amino acid peptide that is synthesized in hypothalamic neurons and stored in their axons that end in the posterior pituitary. Vasopressin release from the pituitary is stimulated by hypertonicity (usually associated with hypernatremia) and is inhibited by hypotonicity (associated with hyponatremia). In addition, hypotension and hypovolemia stimulate release of the hormone mediated by signals relayed to vasopressin secreting neurons through ascending neural pathways and by angiotensin II.

Deficiency of vasopressin causes neurogenic diabetes insipidus, a disorder characterized by the excretion of large amounts of dilute urine, and a susceptibility to hypernatremia if water losses are not replaced. The

Chronic Renal Disease, Second Edition

human disease is mimicked by the Brattleboro rat, a strain in which the gene coding for vasopressin synthesis is defective and the hormone cannot be synthesized. Excess vasopressin causes the syndrome of inappropriate antidiuresis (SIADH), a disorder characterized by water retention and a susceptibility to the development of hyponatremia if water intake is not restricted.

The concentration of vasopressin in the plasma normally falls below detectable levels when excess water intake causes the serum sodium concentration to fall below the threshold level for vasopressin secretion (approximately 135 mEq/L). At low serum sodium concentrations, the sensation of thirst is also suppressed. Above this threshold, as the serum sodium concentration rises because of renal or extrarenal water losses, there is a linear increase in vasopressin levels and thirst. The threshold for vasopressin secretion is set slightly lower than that for thirst so that water conservation by the kidney can make increasing water intake unnecessary unless there are large extrarenal water losses. Low levels of vasopressin result in the excretion of urine that is much more dilute than plasma, and high levels result in urine that is much more concentrated. When the urine osmolality is very low, a small change in plasma vasopressin level will cause large changes in urine flow rate, but when the urine becomes very concentrated, large changes in vasopressin result in much smaller changes in urine output.

Receptors for AVP in the kidney have been classified into two major subtypes—V1a and V2. V2 receptors (V2R) mediate the antidiuretic action of vasopressin.[3] Loss-of-function mutations in V2R cause nephrogenic diabetes insipidus, a disorder characterized by excretion of large volumes of urine because of the inability to respond to vasopressin. Gain of function mutations of V2R result in nephrogenic SIADH, a disorder characterized by water retention despite suppression of vasopressin secretion. Vasopressin is a vasoconstrictor (which is how it got its name), and its vascular effects are mediated by V1a receptors (V1aR), which are expressed on kidney arterioles.

Dilution of the urine is achieved by reabsorbing sodium without water in the ascending limb of the loop of Henle and distal convoluted tubule (which have low permeability to water) and in the collecting duct (which has low permeability to water when vasopressin levels are low). As vasopressin levels fall, aquaporin 2 water channels (AQP2) are removed from the luminal membrane of the collecting duct and relocated to intracellular submembrane vesicles that can be recycled back to the membrane in response to vasopressin when needed.[2] Without AQP2 in its luminal membrane, the collecting duct has a low permeability to water. A water impermeable collecting duct permits dilute luminal fluid formed in upstream diluting sites to be excreted in a dilute final urine.

The antidiuretic effect of vasopressin is mediated by peritubular V2R, through increases in vasopressin's second messenger, intracellular cyclic adenosine monophosphate (c-AMP). Antidiuresis results from three main effects of the hormone on principal cells of the collecting duct: (a) increase in water permeability along the entire collecting duct owing to the insertion of AQP2 water channels in the luminal membrane; (b) an increase in urea permeability in the terminal medullary collecting duct, owing to activation of the urea transporter UT-A1; and (c) stimulation of sodium reabsorption in the cortical and medullary collecting duct.[3] Vasopressin also activates V1aR in the kidney, which tends to limit its antidiuretic activity. Activation of V1aR stimulates formation of prostaglandins, which reduce V2-dependent c-AMP accumulation in principal cells, partially inhibiting all three V2 effects. Because urine is diluted along the nephron before it is concentrated in the medulla, vasopressin is not just required for concentration of the urine, but also for excreting a urine with an osmolality equal to plasma. This process occurs in the renal cortex, and it requires reabsorption of large amounts of water—more than is needed downstream to concentrate the urine.

When vasopressin makes the luminal membranes of the medullary collecting duct permeable to water, water flows out of the lumen, attracted by the hyperosmolar interstitial fluid surrounding the duct. Transport of sodium without water in the ascending limb is required to make the interstitial fluid of the renal medulla more concentrated than plasma. The thick ascending limb expresses V2R and vasopressin increases the number of Na-K 2Cl transporters at this site.[4] Formation of a concentration gradient in the medulla is augmented by accumulation of urea in the interstitium, when urea is transported out of the tubular lumen of the inner medullary collecting duct by its vasopressin-stimulated transporter. Accumulation of urea in the inner medulla is required for the excretion of a maximally concentrated urine (Figure 38.1).[5–7] By activating V1aR that are expressed on the medullary vasculature, vasopressin also reduces renal blood flow to the inner medulla without altering blood flow to the outer medulla, an effect that preserves the high concentrations of solute in the interstitium. Thus, vasopressin plays a role in the formation of the medullary concentration gradient, which provides the osmotic driving force for movement of water out of the collecting duct. Concurrently, by making the tubular membrane permeable to water, the hormone promotes excretion of a concentrated urine.

In addition to its important effects on the concentration of the urine, vasopressin alters the glomerular filtration rate (GFR).[6,8] Low levels of vasopressin result in a

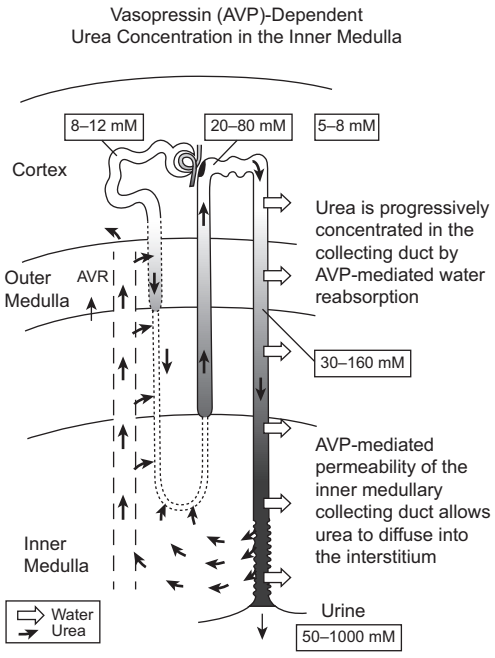

FIGURE 38.1 Vasopressin (AVP)-Dependent Urea Concentration in the Inner Medulla. The figure provides a simplified explanation of the complex mechanisms that result in a urea concentration gradient in the interstitium of the renal medulla (see more comprehensive discussion reviewed in reference 5). The figure depicts one nephron extending from the cortex to the inner medulla and a branch of the ascending vasa recta. In actuality, cortical nephrons differ in their anatomy and transport properties from juxtamedullary nephrons, which have loops of Henle that reach the inner medulla. The anatomy of the vasa recta, which is also complex, allows countercurrent exchange that prevents urea from being washed out of the medulla. Urea recycling and (possibly) pars recta urea secretion presents the inner collecting duct with large amounts of urea to maintain the urea concentration gradient. *Modified with permission from reference 7.*

low GFR and high levels of the hormone increase GFR. These changes, mediated primarily by V2R, are incompletely understood but may involve indirect effects of vasopressin-induced urea recycling on the sodium chloride concentrations achieved at the macula densa, which resets the tubulo-glomerular feedback mechanism controlling GFR (Figure 38.2).[9] Vasopressin-stimulated reabsorption of NaCl in the thick ascending limb of the loop of Henle may also contribute to the lower NaCl concentration at the macula densa. The macula densa expresses mRNA encoding the V1aR. Activation of V1aR in macula densa cells could potentially contribute to the changes in glomerular filtration that occur in response to vasopressin.[4]

Glomerular hyperfiltration due to vasopressin offsets the decreased fractional excretion of urea that occurs when concentrated urine is excreted.[7] Animals deprived of water or infused with the V2-agonist, desmopressin, so as to produce a sustained increase in urine osmolality, develop morphological and functional changes that are similar to those found with a high protein intake. Both conditions increase the plasma urea concentration, but azotemia is minimized by a concurrent increase in GFR. Brattleboro rats (which lack vasopressin, do not recycle urea, and do not accumulate urea in the inner medulla) do not exhibit an increased GFR when fed a high protein diet. Similarly, removing the renal papilla of normal rats, which interrupts urea recycling by ablation of the terminal part of the collecting ducts, where vasopressin initiates the process, results in a marked reduction in GFR despite presumably normal vasopressin levels. A low protein diet decreases the amount of urea that must be excreted. By eliminating urea recycling, low levels of vasopressin or papillectomy increase the fractional excretion of urea, making urea excretion more efficient. All these conditions allow the daily urea load to be excreted without a large increase in plasma urea levels, despite a low GFR. Conversely, a high protein diet increases the amount of urea that must be excreted. High levels of vasopressin decrease the fractional excretion of urea, making urea excretion less efficient. In these conditions a high GFR is required to avoid a large increase in plasma urea levels. When sustained, these adaptations may become maladaptive and accelerate progression of chronic kidney disease (CKD).[10]

URINARY CONCENTRATION IN CHRONIC KIDNEY DISEASE

The kidneys conserve water by excreting concentrated urine. A healthy young person can excrete urine four times more concentrated than plasma, with an osmolality of approximately 1200 mOsm/kg H_2O and a specific gravity of 1.030. Because the electrolyte (sodium plus potassium) concentration of the urine can exceed the plasma sodium concentration, excretion of hypertonic urine can prevent dehydration when extrarenal water losses are large or drinking water is scarce. Excretion of hypertonic urine makes increased water intake unnecessary when salt intake is increased.[11]

Kidney disease impairs the ability to concentrate the urine maximally. Platt noted in 1952, "One of the constant signs of renal failure is the inability of the kidney to produce a concentrated urine, and it is well known that the specific gravity of the urine becomes relatively fixed at 1.010, which is approximately that of blood plasma minus its proteins"—so called isosthenuria.[12] However, although urinary concentrating ability is impaired relatively early in the course of kidney disease, so that urine osmolality cannot be increased to 1200 mOsm/kg H_2O, in most causes of CKD, urine osmolality can still be raised above plasma osmolality until the GFR falls below 25 mL/min/1.73 m^2.[13] In a

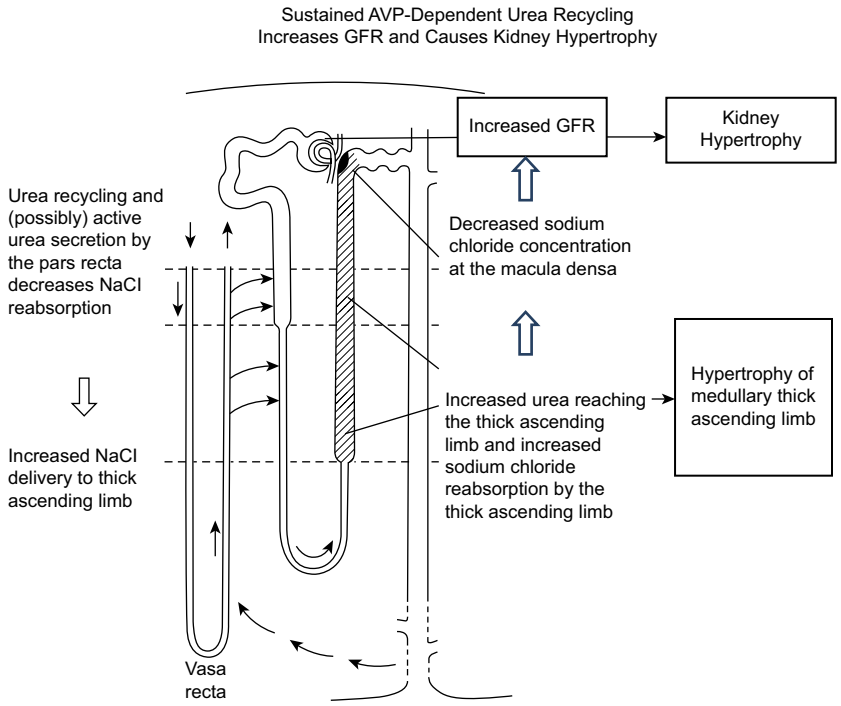

FIGURE 38.2 Theoretical mechanism for hyperfiltration and kidney hypertrophy caused by persistently high vasopressin levels. As in Figure 38.1, the figure depicts one nephron extending from the cortex to inner medulla. In actuality, cortical nephrons and justamedullary nephrons differ in their anatomy and transport processes (see more comprehensive model in reference 5). Urea recycling, enhanced active sodium reabsorption by the thick ascending limb of the loop of Henle, and, possibly, active secretion of urea by the pars recta (see evidence supporting this process in reference 5), result in a decreased sodium chloride concentration in the luminal fluid reaching the macula densa. This alters the set-point of tubulo-glomerular feedback that increases glomerular filtration rate (GFR). *Modified with permission from reference 6.*

study of 27 patients with stable chronic kidney disease (inulin clearances ranging from 6.9 to 38.9 mL/min), Kleeman et al. found urine osmolality after water deprivation and administration of pitressin (a pituitary abstract containing vasopressin) as low as 280 and as high as 392 mOsm/kg H_2O.[14] Similar findings were reported by Baldwin et al.[15]

Urine osmolality indicates how concentrated the urine is, but determination of solute-free water reabsorption (T^cH_2O) provides a better quantitative assessment of the kidney's ability to conserve water.[16] In the process of concentrating the urine, nephrons must reabsorb solute-free water from the initially isotonic glomerular filtrate. T^cH_2O is the difference between the volume of urine that would be required to excrete isosmolar urine (known as "osmolar clearance" or C_{osm}) and the actual urine volume. Osmolar clearance, which is expressed as a volume per unit time, equals the rate of solute excretion divided by the plasma osmolality (P_{osm}). The rate of solute excretion equals Urine osmolality (U_{osm}) multiplied by the urine flow rate (V):

$$C_{osm} = U_{osm} \times V/P_{osm}$$

Because T^cH_2O equals the difference between urine flow rate and osmolar clearance:

$$T^cH_2O = V(1 - U_{osm}/P_{osm})$$

Urine osmolality is altered by the rate of solute excretion ($U_{osm} \times V$). Even in the presence of high concentrations of ADH, when the normal kidney is presented with more solute to excrete, urine osmolality falls as the solute load rises, approaching (but still remaining higher than) plasma osmolality.[17] Although urine osmolality falls as osmolar clearance increases, solute-free water reabsorption increases, reflecting the increasing urine flow rate of an osmotic diuresis.

A limited ability to concentrate the urine in kidney disease could be caused by decreased renal mass (and a decreased number of normally functioning nephrons) or it could be caused by pathological dysfunction of remnant nephrons. According to the intact nephron hypothesis, if dietary intake (and urinary solute excretion) remains constant as disease progresses, each nephron must excrete a larger fraction of the filtered solute load, so that remnant nephrons are subjected to an osmotic diuresis.[18]

Supporting the intact nephron hypothesis, Baldwin et al. studied 25 patients with a variety of kidney diseases and found that water reabsorption (T^cH_2O) corrected for inulin clearance (C_{in}), a measure of GFR, was unimpaired, and, in some cases T^cH_2O/C_{in} was even higher than that in normal controls.[15] Studies in experimental animals with reduced renal function confirmed these observations.

Bricker studied dogs with a unilaterally diseased kidney (induced with pyelonephritis or local infusion of aminoglycoside), allowing comparison between the affected and unaffected kidney in a nonuremic environment.[18] During an osmotic diuresis induced by infusing mannitol, T^cH_2O corrected for glomerular filtration rate (T^cH_2O/GFR) was the same in the experimental and control kidneys, supporting the hypothesis that surviving nephrons reabsorb water normally in kidney disease.

Other investigators found evidence of dysfunctional water reabsorption in patients with kidney disease that are unexplained by an osmotic diuresis. In the study by Kleeman et al., urine osmolality was lower in patients than in controls with normal kidney function across a broad range of solute excretion. Impaired concentrating ability was attributed to additional pathological processes beyond that of a simple osmotic diuresis.[14] Similar conclusions were reached by Dorhout-Mees who measured T^cH_2O in 19 patients with kidney disease undergoing an osmotic diuresis induced with mannitol.[19]

Tannen and colleagues found that 11 of 13 patients with advanced kidney disease (creatinine clearance <15 mL/min) had a urine osmolality lower than plasma osmolality (by a mean of 17 mOsm/kg H_2O) despite administration of maximal doses of vasopressin (Figure 38.3).[20] This finding differs from the response of a normal kidney to an osmotic diuresis in the presence of vasopressin, where the urine osmolality, although reduced, remains higher than plasma osmolality. In response to vasopressin, water channels (aquaporins [AQPs]) are inserted in the luminal membrane of the renal collecting duct, allowing water to equilibrate with the interstitium of the renal medulla, which always has a higher osmolality than plasma. Thus, the finding of vasopressin-resistant fixed hyposthenuria suggests an intrinsic disorder in the function of the renal collecting duct.

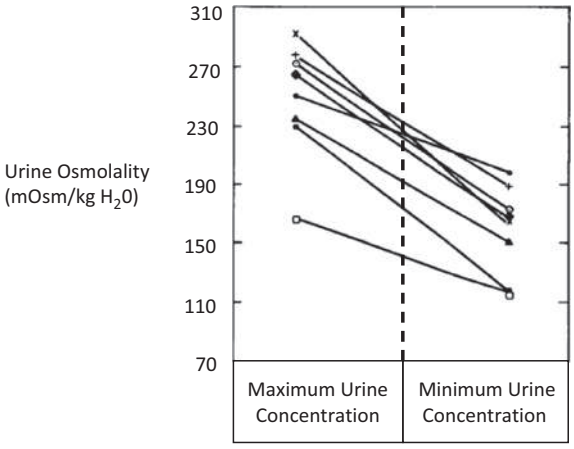

FIGURE 38.3 Maximum and minimum urine osmolality in 13 patients with advanced chronic kidney disease (CKD) (serum creatinine (S[Cr]) >7 mg/dL). Maximum urine osmolality was determined by fluid deprivation followed by administration of exogenous vasopressin. Minimum urine osmolality was determined by a standard water load of 20 mL/kg of body weight. *Modified from Figure 3 in reference 20.*

Loss of the Medullary Concentration Gradient in Chronic Kidney Disease

Concentration of the urine requires generation of a hyperosmolar interstitium in the renal medulla. The medullary concentration gradient is created by active transport of sodium from the lumen to the interstitium by the water-impermeable thick ascending limb of the loop of Henle, and by accumulation of urea in the interstitium owing to vasopressin-responsive urea transporters in the papillary collecting duct (Figure 38.1).[7] Gilbert et al. found that the medullary concentration gradient was lost in rodents with experimental pyelonephritis, but not in uninephrectomized control animals.[21] Micropuncture studies showed that reabsorption of sodium by the thick ascending limb was unimpaired in animals with pyelonephritis, but urea accumulation in the medulla was greatly diminished. Similarly, in rodent models, removal of the renal papilla, where urea transporters are located, markedly impairs renal concentrating ability, whereas it was unimpaired in animals with a comparable decrement in GFR induced with 65% nephrectomy, leaving the papilla intact.[22] Human counterparts of the papillectomy experiments can be found among patients with sickle cell disease, polycystic kidney disease (PKD), and medullary cystic disease.[23–25] Patients with these disorders have disproportionately severe pathology in the inner renal medulla and exhibit severely impaired concentrating ability despite only mildly reduced GFR.

Impaired Collecting Duct Water Permeability in Chronic Kidney Disease

The finding of fixed hyposthenuria in patients with advanced renal failure, unresponsive to vasopressin, suggests abnormal water permeability of the renal collecting duct, where, in response to vasopressin, the luminal fluid

normally achieves osmotic equilibrium with the surrounding medullary interstitium. Vasopressin resistance has been studied in animal models of kidney disease, some of which (e.g. the 5/6 nephrectomy model) may not accurately mimic human kidney disease.

Vasopressin-independent defects in water permeability have been found in isolated perfused cortical collecting ducts obtained from uremic rabbits.[26] The defect is associated with decreased generation of c-AMP in response to vasopressin and with a decreased response to an analogue of c-AMP (indicative of a postreceptor signaling defect). Cultured inner medullary collecting tubular cells obtained from 5/6 nephrectomized rats also fail to generate c-AMP in response to vasopressin. They exhibit a marked decrease in the number of vasopressin receptors, decreased levels of mRNA for synthesis of the receptor, and reduced expression of AQPs 1, 2, and 3.[27,28] All three AQP play a role in the renal concentrating mechanism—AQP 1 in the descending limb of Henle's loop, AQP 2, in the luminal membrane of principal cells of the collecting duct, and AQP 3 in the basolateral membrane of the principal cells.[29] Decreased expression of AQP 2, but not AQP 1 and 3, would be the expected effect of a reduced number of vasopressin receptors.

Impaired Capacity to Concentrate Urea in Chronic Kidney Disease

In CKD, the capacity to concentrate urea in the medullary interstitium and in the urine is much more impaired than the capacity to concentrate other solutes. Hu et al. found a 30-fold decrease in the U/P urea concentration ratio after 5/6 nephrectomy, whereas the U/P osmolality ratio declined only fourfold. The selective impairment in urinary urea-concentration is explained by a large and early fall in collecting duct urea transporters.[30] Because of the almost complete disappearance of UT-A1 message and protein in this model, vasopressin cannot increase urea permeability of the terminal collecting duct, and urea can no longer be delivered to the papillary interstitium. The mRNA for urea transporters in the vasa recta and thin limbs of the loop also fell progressively after 5/6 nephrectomy, falling in established renal failure to 10% or less of that in control rats. These findings strongly suggest that the overall defect in urinary concentrating ability observed in CKD is caused by an almost complete loss of the capacity to accumulate and recycle urea in the medullary interstitium. The accumulation of sodium chloride, which depends on countercurrent multiplication of the single effect generated in thick ascending limbs, is probably much less affected, so that the urine can remain moderately hypertonic to plasma.

URINARY DILUTION IN CHRONIC KIDNEY DISEASE

In contrast to the extensive number of studies exploring the mechanism for impaired urinary concentration in kidney disease, urinary dilution has been given relatively little attention. Defects in urine dilution appear later in the course of kidney disease than diminished concentrating ability.

Urine osmolality indicates how dilute the urine is, but determination of free water clearance (C_{H2O}) provides a better estimate of the kidney's ability to generate solute-free water.[31] C_{H2O} is the difference between osmolar clearance (C_{osm}) and urine flow rate:

$$C_{H2O} = V - C_{osm} = V(1 - U_{osm}/P_{osm})$$

When the kidney is presented with increased solute loads during a water diuresis, with low levels of vasopressin, urine osmolality rises, approaching but remaining below plasma osmolality.[31] Although the urine becomes less dilute as osmolar clearance increases, free water clearance increases, reflecting the increasing urine flow rate caused by a combined osmotic and water diuresis.

In Kleeman's study, only 1 of the 27 patients responded normally by excreting urine with a urine osmolality <100 mOsm/kg H_2O. In eight patients, the minimum urine osmolality was ≥ 200 mOsm/kg H_2O.[14] However, C_{H2O}/GFR was actually higher in the patients with CKD. Similarly, eight of the subjects studied by Tannen et al. who were unable to elaborate a urine more concentrated than plasma in response to vasopressin reduced urine osmolality by 50–112 mOsm/kg H_2O in response to a water load (Figure 38.3).[20] However, none of these patients were able to attain a urine osmolality <100 mOsm/kg H_2O, which is the normal response to a water load.

Studies in dogs mimic findings in patients with CKD. In a model with unilateral renal dysfunction, the abnormal kidney had a lower C_{H2O} than the contralateral control following a 40–70 mL/kg intragastric water load administered after volume expansion with isotonic saline to increase solute excretion.[18] However, C_{H2O}/GFR was actually higher in the abnormal kidney, suggesting that remaining nephrons were diluting the urine normally, and that the overall limitation in water excretion was related to the decrease in GFR, which reflects a reduced population of functioning nephrons.

IMPAIRED WATER HOMEOSTASIS IN CKD PATIENTS

People without kidney disease and a normally functioning osmoregulatory system can increase urine osmolality to as high as 1200 mOsm/kg H_2O and decrease it

to as low as 50 mOsm/kg H_2O. On a typical Western diet providing 900 milliosmoles of solute daily, a maximally concentrated urine reduces daily urine volume to 0.75 L. A maximally dilute urine allows excretion of 18 L of urine, providing a robust defense against both dehydration and the development of hyponatremia.[31] Progressive loss of renal function narrows these options for patients (Figure 38.4).

A patient with CKD whose urine cannot be concentrated above 300 mOsm/kg H_2O must excrete at least 3 L of urine to excrete the 900 milliosmoles generated by a typical Western diet. Because bladder capacity is about 500 mL, the defect in urinary concentration results in nocturia. The defect also makes patients with CKD susceptible to the development of dehydration and hypernatremia if water is scarce, thirst is impaired, or patients are too ill to seek water for themselves.

If the urine cannot be diluted below 200 mOsm/kg H_2O, urine volume on a diet generating 900 milliosmoles of solute is limited to 4.5 L/day. On a protein restricted, low-salt diet generating only 400 milliosmoles of solute, maximum urine volume is reduced to 2 L/day (Figure 38.4). Thus, the inability to maximally dilute the urine makes patients with advanced CKD on a low-salt, low-protein diet, susceptible to the development of hyponatremia if they drink more water than is eliminated by extrarenal losses, or it they are infused with large volumes of hypotonic fluid.

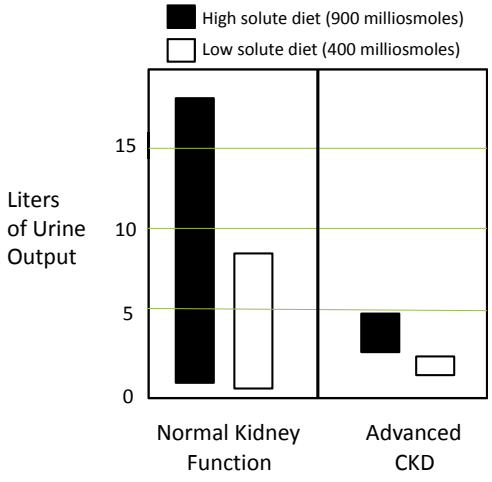

FIGURE 38.4 Restricted variation in urine volume in advanced chronic kidney disease (CKD). The figure illustrates the range of urine volumes when the urine is maximally concentrated and when it is maximally dilute. The panel of the left depicts urine volumes in a patient without kidney disease who is able to concentrate the urine to 1200 mOsm/kg H_2O. The panel on the right depicts urine volumes in a patient with kidney disease who is only able to concentrate the urine to 300 mOsm/kg H_2O and is unable to dilute the urine to a concentration below 200 mOsm/kg H_2O.

HYPONATREMIA AND HYPERNATREMIA IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Impaired ability to concentrate and dilute the urine would be expected to result in a higher than normal incidence of abnormal circulating sodium concentrations among ambulatory and hospitalized patients with CKD.

A study of 655,493 US Veterans with nondialysis-dependent CKD found that, at baseline, 13.5% were hyponatremic (serum sodium concentration <135 mEq/L) and 2% were hypernatremic (serum sodium concentration >145 mEq/L).[32] During a 5.5-year median follow-up, 26% of the patients had at least one episode of hyponatremia, and 7% had at least one episode of hypernatremia. The relatively high prevalence of hyponatremia may reflect the inclusion of hospitalized patients, the older age (mean 74 years) of the subjects, and comorbidities. Hyponatremia was twice as common in patients with early stages of CKD compared to CKD stages 3–5 (Figure 38.5). This finding suggests that hyponatremia in these patients was caused by nonosmotic release of vasopressin rather than an impaired ability to dilute the urine due to parenchymal kidney disease. Unlike hyponatremia, the prevalence of hypernatremia increased with the severity of renal impairment. These findings are consistent with the known defects in water homeostasis in CKD. The ability to concentrate the urine is lost sooner than the ability to dilute the urine during the course of progressive kidney disease. Therefore, the defense against hypernatremia is lost before the defense against hyponatremia. Consistent with this observation, a prospective study of 2182 ambulatory patients with CKD seen in outpatient

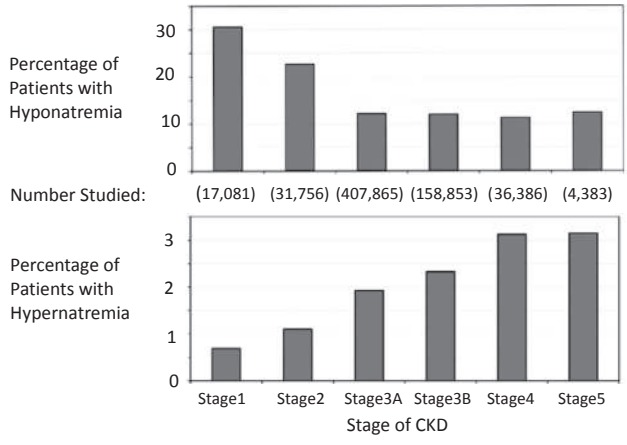

FIGURE 38.5 Incidence of hyponatremia and hypernatremia in a study of 655,493 US Veterans with nondialysis-dependent CKD. *Modified with permission from reference 32.*

clinics in the US followed for a mean of 1.8 years found hypernatremia to be more common than hyponatremia.[33]

In the general population, both hyponatremia and hypernatremia, even when mild, are associated with excess mortality.[34] Hyponatremia is associated with a poorer prognosis of several conditions, including heart failure, myocardial infarction, pulmonary infections, stroke, malignancy, and hepatic cirrhosis, but it is not known whether this means that hyponatremia results in mortality or that patients with more lethal conditions are more likely to develop hyponatremia. This observation is also true for patients with CKD.

A recent meta-analysis investigated the association of hyponatremia (serum sodium concentration <135−136) and hypernatremia (serum sodium concentration ≥145 to 144) with all-cause mortality risk in patients with CKD treated and untreated with dialysis.[34] From the seven included observational studies, the authors found that hyponatremia at the start of the studies (baseline hyponatremia or hypernatremia) and time-averaged sodium levels during the course of observation (time-dependent hyponatremia or hypernatremia) were independently associated with increased risk of all-cause mortality in patients with CKD. The risk of all-cause mortality increased by 41% for CKD patients with time-dependent hyponatremia and by 65% for patients with time-dependent hypernatremia. The mortality risk for CKD patients who had baseline hyponatremia increased by 34%. The association of baseline hypernatremia with all-cause mortality was not statistically significant. These findings suggest that in patients with CKD, the association between serum sodium concentration and all-cause mortality was U-shaped. In this study, the stage of kidney disease, among patients not requiring dialysis, did not affect mortality risk. However, the association between all-cause mortality and baseline hyponatremia was greater among patients undergoing dialysis than patients with CKD who did not require dialysis (hazard ratio 1.27 vs. 1.41). Among patients undergoing maintenance hemodialysis, a 4-mmol/L increase in baseline sodium level was associated with 19−28% lower risk of all-cause mortality in maintenance hemodialysis patients, but an elevated serum sodium level also conferred a higher risk of all-cause mortality (i.e. the association was U-shaped). The mechanism for the increased mortality associated with hyponatremia and hypernatremia is unknown. Currently there are no data demonstrating that correcting an abnormal serum sodium concentration reduces mortality.

Hyponatremia, even when mild and seemingly asymptomatic, has been shown to be associated with an increased risk of falls and fractures, abnormal gait, osteoporosis, and poorer performance on cognitive tests.[35] There is some evidence, albeit derived from extremely small studies, that correction of hyponatremia improves gait. A single case report convincingly showed that removal of a tumor causing chronic SIADH improved osteoporosis.[36,37]

Although evidence is lacking that correction of mild, chronic hyponatremia improves morbidity and mortality, many clinicians choose to treat the condition in patients without CKD. Some may also choose to treat mildly hyponatremic patients with CKD, but therapeutic options are more limited.

EVALUATION AND TREATMENT OF HYPONATREMIA IN CKD

Treatment of hyponatremia in patients who have impaired kidney function is similar to that in patients without kidney disease. Offending pharmacologic agents should be stopped, underlying endocrine disorders should be treated, and conditions that might be responsible for hyponatremia, such as liver disease and heart failure should be diagnosed and treated. However, some diagnostic approaches and therapeutic interventions must be modified.

Urinary sodium concentration is traditionally used as a marker to distinguish between the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and hypovolemic hyponatremia. Patients with CKD are unable to promptly reduce urine sodium losses when they become hypovolemic. Thus, patients with CKD who are hypovolemic may be misdiagnosed as having SIADH if the diagnosis is based on urine sodium concentrations. It is for this reason that normal kidney function is one of the criteria for making the diagnosis of SIADH. Normal saline solution is considered the treatment of choice for hypovolemic hyponatremia conditions. However, patients with CKD also have limitations in their ability to excrete sodium when volume overloaded. Also, unlike hypovolemic, hyponatremic patients without kidney disease, patients with advanced CKD may not respond by excreting maximally dilute urine when given isotonic saline. Thus, isotonic saline may be less effective in correcting hyponatremia in such patients, and its administration may be complicated by undesirable volume overload.

Water restriction, limiting isotonic saline to the amount needed to correct hypotension or prerenal azotemia, may be the best approach for treating hyponatremia in patients with advanced CKD. The effectiveness of water restriction can be predicted from the urine to plasma electrolyte (sodium + potassium) concentration ratio, as this ratio determines the fraction of urine volume that is electrolyte-free water.[31] As previously mentioned, C_{H2O} is the difference between urine

volume (V) and the urine to plasma osmolality ratio multiplied by V. This measurement helps quantify the kidney's processing of the glomerular filtrate. However, the serum sodium concentration is determined by the body's content of soluble sodium and potassium divided by total body water.[1] Changes in the body's content of urea, which contribute substantially to urine osmolality, do not change the serum sodium concentration. Therefore, to quantify losses that will change the serum sodium concentration, electrolyte-free water clearance (determined by urine concentrations of sodium and potassium) rather than C_{H2O}, (determined by urine osmolality), is the relevant measurement.[31]

$$\text{Electrolyte} - \text{free water clearance} = V[1 - \text{Urine}([Na + K]/\text{Plasma}[Na])].$$

If the electrolyte concentration of the urine is higher than the plasma sodium concentration, water restriction will predictably be ineffective.[31] However, this is unlikely to occur in patients with advanced kidney disease who excrete isosmolar or hypo-osmolar urine (fixed isosthenuria or hyposthenuria). Because urea comprises approximately one-third to one-half of excreted urinary solutes, urine electrolyte concentrations account for about half to two-thirds of the urine osmolality. With a urine osmolality equal to plasma osmolality, urine electrolyte concentration will be substantially lower than the serum sodium concentration, and urinary electrolyte-free water losses will contribute to correction of hyponatremia. Thus, fluid restriction can be expected to be a relatively effective therapy in hyponatremic patients with advanced CKD until patients become oliguric.

Consider a CKD patient with a serum sodium concentration of 120 mEq/L and a plasma and urine osmolality of 260 mOsm/kg H_2O. If dietary sodium and potassium provided 140 mEq of electrolytes (280 milliosmoles) for excretion, and dietary protein provided 240 milliosmoles of urea and ammonium salts, an isosmolar urine containing 520 milliosmoles of solute would be excreted in 2 L of urine. Each liter of urine would contain about 70 mEq of electrolyte (contributing 140 mOsm/kg H_2O to the total urine osmolality of 260 mOsm/kg), the urine to plasma electrolyte ratio would be 0.6, and electrolyte-free water clearance would be 0.4 times urine output ($0.4 \times 2\ L = 0.8\ L$ daily). Allowing for insensible losses, a 0.8 L fluid restriction would be expected to gradually increase the serum sodium concentration. Urinary electrolyte-free water losses diminish and water restriction becomes increasingly ineffective with lower dietary protein intakes and/or decreasing urine volumes associated with extremely low GFR.

Several pharmacologic agents have been used in the treatment of euvolemic hyponatremia. Demeclocycline has been used to treat SIADH because it acts on the collecting tubule cells to diminish their responsiveness to ADH. However, demeclocyline should be avoided in patients with kidney disease because it is nephrotoxic, particularly in patients with impaired liver function.[38]

Vasopressin V2R antagonists (a class of drugs known as "vaptans") have been shown to reliably increase serum sodium concentrations in a variety of clinical settings, but many trials have excluded enrollment of patients with moderate to severely decreased kidney function.[39] Preliminary pharmacodynamic studies with a single oral dose of 60 mg of tolvaptan demonstrated increased free water clearance in normonatremic patients with a creatinine clearance of 15–30 mL/min.[40] The response appears to be delayed, but it results in an increase in serum sodium concentrations similar to that in patients without kidney disease. Vasopressin V2R antagonists are likely to be less successful in patients with creatinine clearance <15 mL/min, but some response (increased urine flow and decreased urinary osmolality) was observed in patients with CKD stages 4 and 5, and congestive heart failure.[41] Although proven to be effective in maintaining a normal or near normal serum sodium concentration with long-term use, tolvaptan is extremely expensive and concerns about hepatotoxicity at high doses have led to mandates for monitoring liver function tests.

Although not formally studied, in CKD, high-dose loop diuretics can be used alone or in addition to water restriction to enhance water excretion. It is important to carefully monitor volume status and serum electrolyte levels on a regular basis to ensure that the patient does not become severely volume depleted, hypokalemic, or hypomagnesemic.

Oral urea promotes urinary electrolyte-free water losses, and urea has been used successfully to treat both acute and chronic hyponatremia. In a small unblinded, nonrandomized study in ambulatory patients with chronic hyponatremia, urea was found to be as effective as vasopressin antagonists in normalizing the serum sodium concentration and was comparably well tolerated.[42]

The use of urea to treat hyponatremia in patients with CKD has not been well studied. Administration of urea inevitably increases the BUN, and there is some concern that such an increase may have adverse effects.[10] At concentrations found in patients with CKD, urea forms cyanate, which causes protein carbamylation, a process that alters several enzymes and hormones, impairs leukocyte function, and aggravates oxidative stress. Increased urea levels can also interact with intestinal microbial flora with urease activity, potentially disrupting intestinal barrier dysfunction. Bankir has presented evidence that, like uric acid and ammonia, urea is probably actively secreted in the pars recta of the proximal

tubules by an energy-dependent process that increases active metabolic demand on the proximal tubular epithelium to raise the urea concentration in the lumen above that of the surrounding interstitial fluid.[5] GFR is markedly elevated in clinical situations of increased urea excretion associated with increased vasopressin secretion (an association that enhances intrarenal urea recycling and reduces the fractional excretion of urea). Administration of a large hypertonic urea load to rats, increasing urea excretion in a limited amount of urinary water results in a large increase in GFR, similar to the effect of a large protein load. The intrarenal mechanism that induces such vasopressin and urea-dependent hyperfiltration is not yet fully understood. The resulting high intraglomerular pressure and plasma flow could theoretically result in renal injury.[10]

Osmotic Demyelination in Kidney Disease

Osmotic demyelination syndrome can complicate overly rapid correction of hyponatremia (>8 mEq/L/day) in patients who have adapted for >48 hours to a serum sodium concentration <120 mEq/L.[43] The disorder presents in a delayed fashion one to several days after a large increase in serum sodium concentration. A variety of clinical findings emerge, including swallowing dysfunction and quadriparesis (symptoms of central pontine myelinolysis) and behavioral disturbances, movement disorders, and seizures (symptoms of extrapontine myelinolysis). Magnetic resonance images are often normal at the onset of neurological symptoms. After approximately two weeks, if symptoms persist, magnetic resonance images will show demyelinating lesions in the central pons and/or symmetrical extrapontine lesions in regions such as the basal ganglia, thalamus, and subcortex, where gray and white matter are closely admixed.

Many patients treated with maintenance hemodialysis who drink excessive amounts of water routinely experience large swings in serum sodium concentration with each dialysis. Despite this, there have not been any convincing published reports of osmotic demyelination after routinely scheduled hemodialysis. This may be because maintenance dialysis treatments are frequent enough that the brain has not yet fully adapted to the low serum sodium concentrations that develop between treatments. In addition, high levels of brain urea may protect against osmotic demyelination. Rapid correction of chronic hyponatremia results in cell injury because of cellular dehydration. During dialysis, urea is removed from the plasma more rapidly than it is removed from the brain, resulting in an osmotic gradient favoring water flow into brain cells.[44] After 5/6 nephrectomy in rats, expression of the urea transporter in brain, UT-B1, is reduced by half, whereas expression of brain AQP, AQP-4, is doubled.[45] These findings suggest that, during dialysis, the dehydration of brain cells caused by a rapid increase in serum sodium concentration is partially offset by brain cell swelling caused by rapid removal of urea.

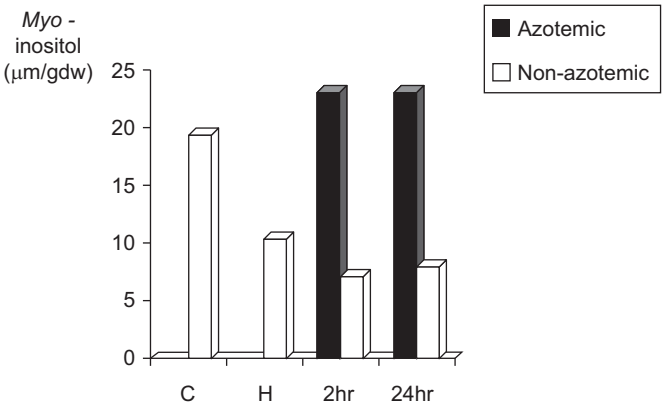

FIGURE 38.6 Enhanced brain uptake of myoinositol in uremia. The figure depicts the brain content of myoinositol in control rats without hyponatremia (C), after induction of hyponatremia (H), and 2 hours and 24 hours following rapid correction of hyponatremia. The brain content of myoinositol and other organic osmolytes is reduced comparably by hyponatremia in both uremic and nonuremic animals. After rapid correction of hyponatremia, uremic animals normalize the brain content of myoinositol and other organic osmolytes much more rapidly and uremic animals develop less severe osmotic demyelination than nonuremic animals. *From Figure 1 in reference 46 with permission.*

Depletion of organic osmolytes in response to hyponatremia is thought to make astrocytes vulnerable to injury when hyponatremia is corrected more rapidly than these solutes can be recovered.[1] In animal models, recovery of brain organic osmolytes, particularly myoinositol, occurs much sooner after rapidly correcting severe hyponatremia in uremic animals than in nonuremic controls (Figure 38.6). The uremic animals had a dramatic reduction in the incidence and severity of demyelinating brain lesions.[46]

However, uremia does not provide full protection from dialysis-related osmotic demyelination syndrome.[47,48] There have been a few case reports of osmotic demyelination syndrome with typical symptoms and imaging findings after correction of severe hyponatremia in peritoneal and hemodialysis patients.[49,50] The risk is likely to be much higher in severely hyponatremic patients with acute kidney injury, patients initially starting on dialysis therapy, and patients with end-stage renal disease (ESRD) who have not been dialyzed for some time.

When a patient who needs to be started on dialysis has severe hyponatremia, the dialysis regimen should be adjusted.[51] One option is to provide conventional dialysis, using a dialysate sodium concentration of 130 mEq/L and limiting blood flow to 50 mL/min, limiting dialysis time to two hours. Other options

include continuous venovenous hemodialysis, with a dialysate sodium concentration adjusted to 6 to 8 mEq/L above the serum sodium concentration or continuous hemofiltration with a similarly adjusted sodium concentration of the replacement fluid.[52] These latter options are preferred when the serum sodium concentration is <115 mEq/L, because in standard hemodialysis, dialysate sodium concentration cannot be decreased to <130 mEq/L. When these options are unavailable, or replacement fluid sodium concentration cannot be adjusted, an alternative approach is to prevent a rapid increase in serum sodium concentration by infusing 5% dextrose in water during the dialytic procedure.

Peritoneal dialysis can be used to increase the serum sodium concentration in hyponatremic patients with ESRD. Nolph et al. showed that during a hypertonic exchange with dextrose-based solutions, serum sodium concentrations increase with removal of an ultrafiltrate hyponatremic to extracellular fluid.[53] Therefore, treatment of hyponatremia with peritoneal dialysis is performed most effectively with repeated rapid exchanges of hypertonic dextrose solutions to promote electrolyte-free water removal.

EVALUATION AND TREATMENT OF HYPERNATREMIA IN PATIENTS WITH CKD

Patients with advanced CKD may develop hypernatremia when water losses caused by their inability to concentrate the urine are not replaced. In patients with normal kidney function, the failure to concentrate the urine in response to hypernatremia suggests a diagnosis of either neurogenic or nephrogenic diabetes insipidus.[1] In patients with advanced CKD, failure to concentrate the urine is the expected effect of the kidney disease and not a consequence of vasopressin deficiency. Treatment entails restoring water losses in the form of parenteral or enteric water intake. Administration of vasopressin is not helpful.

EFFECT OF WATER AND VASOPRESSIN ON PROGRESSION OF CKD

The kidney's role in maintaining water homeostasis has been understood for centuries. More recently, evidence has emerged that water balance and modulation of vasopressin levels or vasopressin action can affect renal function.[10]

Because vasopressin is unstable in the test tube and technically difficult to measure, vasopressin assays are unreliable unless done in research laboratories. Copeptin consists of the C-terminal portion of pro-AVP, the precursor of AVP. It is released with vasopressin in equimolar amounts. Copeptin has a longer half-life and is more stable and easier to measure than vasopressin. Plasma copeptin levels correlate with AVP levels and have been used as a surrogate measure for vasopressin secretion.[25] A study of renal transplant donors showed that copeptin levels do not change after nephrectomy (which results in a fall in GFR), suggesting that decreased clearance of copeptin does not account for changes in copeptin levels associated with kidney disease.[54]

The first evidence that vasopressin affects the progression of kidney disease was provided by experiments by Bouby et al. in 5/6 nephrectomized rats.[55] Vasopressin levels and urine osmolality were reduced by feeding the animals a water-rich gel. Animals provided with this regimen exhibited a significant reduction in proteinuria, kidney hypertrophy, glomerular lesions, interstitial injury, and mortality compared to animals with 5/6 nephrectomy that were fed dry food. Similarly, 5/6 nephrectomized Brattleboro rats, which are congenitally deficient in vasopressin, developed less kidney hypertrophy, hyperfiltration, and progression of CKD than 5/6 nephrectomized animals with normal vasopressin secretion. Administration of the synthetic vasopressin, desmopressin (a selective V2R agonist), to Brattleboro rats increased the rate of progression of CKD. Okada et al. showed selective blockade of vasopressin's V1a or V2Rs reduced protein excretion.[56] Histologic evidence of renal injury in rats with adriamycin-induced nephrotic syndrome and treatment of 5/6 nephrectomized rats with a selective V1a antagonist reduced proteinuria and progression of focal glomerulosclerosis.[57,58] Treatment of rats with puromycin aminonucleoside-induced nephropathy with the selective V2R antagonist, tolvaptan diminished proteinuria, decreased S[Cr], and reduced histologic evidence of podycyte injury.[59] Prolonged infusion of a V2R antagonist prevented albuminuria in rats with streptozotocin-induced diabetes mellitus.[60] Similarly, vasopressin-deficient Brattleboro rats with streptozotocin-induced diabetes mellitus do not develop an increase in GFR, and they have less albuminuria and less-intense kidney hypertrophy than diabetic Long Evans rats with intact vasopressin secretion.[61]

In animal models, maintaining a high urine osmolality causes glomerular hyperfiltration and kidney hypertrophy. The effect is analogous to the effect of high protein intake[10]. Animal models have shown that a high protein diet increases glomerular filtration. When increased intraglomerular pressure is sustained, it damages remaining glomeruli. GFR is markedly increased in rats when urine osmolality is raised by a one-week

infusion of the selective V2R agonist, desmopressin. Conversely, GFR falls when vasopressin secretion is inhibited by increasing water intake. Chronic infusion of vasopressin to Brattleboro rats (which lack the hormone) or chronic moderate dehydration in normal rats (which results in endogenous vasopressin secretion) results in kidney hypertrophy, with features that resemble those found in animals chronically fed a high protein diet.

The relationship between GFR and urine osmolality is "J-shaped," such that the rise in GFR with increasing osmolality is only observed when urine osmolality exceeds plasma osmolality. When urine osmolality is more dilute than plasma, vasopressin-dependent hyperfiltration disappears, or can even be reversed. If GFR were to decrease when there was a need to excrete excess water, it would be disadvantageous, because excretion of maximally dilute urine requires adequate delivery of fluid and solutes to the renal diluting sites.

Theoretically, water losses caused by the concentrating defect in CKD could lead to a compensatory increase of vasopressin, which then promotes progression of kidney disease because of hyperfiltration. Glomerular hyperfiltration induces a vicious cycle that leads to progressive renal damage.[10]

There is evidence that vasopressin may alter the progression of kidney disease in humans. A study of 979 patients with diabetes not taking renin–angiotensin–aldosterone inhibitors found that a higher baseline level of copeptin (a surrogate for vasopressin) is significantly associated with higher baseline urinary albumin:creatinine ratio and lower baseline estimated glomerular filtration rate (eGFR) values. Among 756 patients who were followed for an average of 6.5 years, higher copeptin levels were significantly associated with a more rapid decline in eGFR.[62] The association between copeptin and declining renal function was stronger than that for BMI or hemoglobin A1c levels. In three large prospective community-based European cohorts, high levels of plasma copeptin at baseline were associated with an increased incidence of microalbuminuria and stage 3 CKD, and more rapid decrease in eGFR over time during follow-up.[63] The risk associated with high plasma copeptin was similar to the risk associated with high blood pressure and arterial hypertension and was higher than the risk associated with high total cholesterol.

A 7-year prospective study of a community-based cohort of 2144 patients with preserved GFR found that kidney function declined significantly more slowly (odds ratio 0.46–0.66) in adults with the highest urine volumes (>3 L) than in those with the lowest urine volumes (<1 L), supporting a potential role of higher fluid intake in reducing the risk of kidney disease.[64] Similarly, a study of 273 patients with CKD stages 1–4 found that, adjusted for baseline creatinine clearance and use of diuretics, the risk of starting dialysis was approximately doubled for each doubling of urine osmolality, rising from a 15% risk when baseline urine osmolality was 315 mOsm/kg H_2O to a 34% risk when baseline osmolality was 775 mOsm/kg H_2O.[65]

In contrast to these findings, a *post hoc* analysis of the Modification of Diet in Kidney disease study found that higher urine volume patients with established CKD was associated with a faster decline in renal function.[66] However, the statistical association between rising S[Cr] and urine volume did not persist after controlling for use of diuretics and antihypertensive medications.[67]

A short-term pilot study showed that increased water intake can decrease plasma copeptin concentration in patients with stage 3 CKD.[68] Recently, in a randomized intervention study of patients with stage 3 CKD, coaching to increase water intake did not significantly slow the decline in kidney function after 1 year as compared to patients who were maintained on their baseline water intake.[69] However, in the high water intake group, 24-hour urine volumes were only modestly increased and plasma copeptin slightly lower during follow-up. The study may have been underpowered to detect a clinically important difference.

Autosomal Dominant Polycystic Kidney Disease

Vasopressin plays a pivotal role in the pathogenesis of adult dominant polycystic kidney disease (ADPKD). Vasopressin stimulates the formation of c-AMP, which is a potent stimulator of cyst growth in distal nephron segments that express V2Rs. By cross breeding vasopressin-deficient Brattleboro rats and rats with hereditary PKD, Wang et al. produced rats with PKD that produced no vasopressin. Compared to PKD rats with intact vasopressin secretion, the vasopressin-deficient PKD rats had lower renal c-AMP and almost complete inhibition of cystogenesis. Administration of desmopressin (a selective V2 receptor agonist) to the vasopressin-deficient animals increased renal c-AMP and restored the full cystic phenotype.[70] In an *in vitro* study, Reif et al. found the addition of the V2R antagonist, tolvaptan, to cultured human ADPKD cells inhibited vasopressin-stimulated cell proliferation and fluid secretion.[71]

Several lines of evidence in humans support the important role of vasopressin in the progression of PKD shown in animal models. The ability to concentrate the urine diminishes in ADPKD before GFR begins to decline.[25] It has been suggested that this is caused by cystic distortion of the medullary countercurrent mechanism that interferes with urea recycling. The urine to plasma urea concentration ratio (U/P urea) can be used to identify concentrating defects in patients with

ADPKD as it correlates strongly with maximum urine osmolality after water deprivation. There is a negative association between U/P urea and copeptin levels in patients with ADPKD whose GFR is normal, and total kidney volume is strongly associated with U/P urea and plasma osmolality. These findings suggest that as disease progresses in ADPKD, the cystic kidney develops a concentrating defect, leading to water loss and an increase in plasma osmolality. Responding to increased plasma osmolality, vasopressin levels rise to preserve water balance. Vasopressin then promotes cyst formation, further impairing the ability to concentrate the urine, creating a vicious cycle that results in progressive decline in kidney function. Higher copeptin levels are independently associated with more rapid disease progression in patients with early ADPKD.[72] This supports a causal role of vasopressin in progressive disease, but it could also mean that progressive disease, by impairing urinary concentration, results in higher levels of vasopressin (and copeptin).

Evidence for a causal role for vasopressin in disease progression in patients with ADPKD was provided by the Tolvaptan Efficacy and Safety in Management of Autosomal Dominant Polycystic Kidney Disease and Its Outcomes (TEMPO) 3:4 trial, which found that in patients with early-stage ADPKD (mean eGFR 82 mL/min/1.73 m^2), administration of tolvaptan, an AVP-V2R antagonist, significantly slows the increase in total kidney volume by one-half and the decline in kidney function by about one-third after three years of follow-up.[73] An open label extension of the study showed that the beneficial effects of tolvaptan were maintained for an additional 2 years. The Replicating Evidence of Preserved Renal Function: An Investigation of Tolvaptan Safety and Efficacy Trial confirmed the efficacy and safety of tolvaptan in patients with CKD stages 2 to 4.[74] Tolvaptan (at an initial dose of 90 or 60 mg in the morning and 30 mg in the evening) resulted in a significantly slower decline in eGFR compared with placebo over the course of one year (-2.3 mL/min/1.73 m^2 vs. -3.6 mL/min/1.73 m^2, $p < 0.001$). It has been estimated that tolvaptan treatment started in a patient with ADPKD and an eGFR of 41 would extend the time to reach CKD stage 5 from 6.2 to 9.0 years. Tolvaptan has been approved for the treatment of ADPKD in several countries including the US. In addition to side effects from polyuria and thirst and the need for monthly monitoring of liver function tests, use of the drug may be limited by its high cost.

It has been hypothesized that ingestion of enough water to cause a water diuresis would lower vasopressin levels, and, like administration of a vasopressin antagonist, protect against progressive disease. It is difficult for patients to maintain a high enough fluid intake to suppress vasopressin secretion when eating a diet high in protein and salt. In a small randomized trial of patients with stage 1 and 2 CKD, Amro et al. showed that a low osmolar diet (1500 mg sodium and 0.8 g protein/kg body weight) led to a significant decrease in the water intake required to achieve the target urine osmolality of 280 mOsm/kg (from 2.5-5.02 L vs. 1.5–3.7 L).[75] Plasma copeptin levels fell in the 17 patients with a dietary intervention but not in 17 controls maintained on their customary diet. The reduction in mean urine osmolality achieved in this trial was equivalent to that reported in the TEMPO 3:4 trial (426 to 258 compared to 472 to 264 mOsm/kg H_2O).[73] A multicenter, prospective, randomized controlled trial is currently underway, which will study the effect of increased fluid intake and decreased dietary solute intake (designed to decrease urine osmolality to $\leq$270mOsmol/kg) on the progression of kidney volume, eGFR, and copeptin levels over a planned three years of follow-up.[76] Unfortunately, because of cost considerations, the study will not include a tolvaptan-treated comparison arm.

QUESTIONS AND ANSWERS

Question 1

A 25-year-old woman with Bartter's syndrome (a congenital disorder caused by dysfunction of sodium, potassium, and chloride transport in the ascending limb of the loop of Henle) develops progressive renal failure due to nephrocalcinosis and focal segmental glomerular sclerosis. She comes to you complaining of polyuria. She has been taking sodium and potassium supplements for her entire life. The need for potassium replacement has declined as her renal failure progressed. Blood pressure is 160/90 mm Hg, lungs are clear and cardiac examination is normal except for mild pretibial edema. Liver function tests are normal. Blood glucose is normal. eGFR is 15 mL/min/1.73 m^2, urine output is 8 L/day, plasma osmolality is 280 mOsm/kg H_2O, BUN is 60 mg/dL, and serum sodium concentration is 128 mEq/L.

A 24 hour urine reveals:

Osmolality 164 mOsm/kg H_2O
Sodium 41 mEq/L
Potassium 23 mEq/L
Chloride 45 mEq/L
Creatinine 13.9 mg/dL

Which of the following are TRUE regarding C_{H2O} and C_{osm} in this patient.

A. C_{H2O} and C_{osm} are equal
B. C_{H2O} is less than C_{osm}
C. C_{H2O} is more than C_{osm}
D. C_{H2O} is more than 50% of the patient's GFR
E. C_{osm} is more than 50% of the patient's GFR

Answer: B
The urine output (V) equals the sum of
$C_{H2O} + C_{osm.} = 8$ L/day
$C_{osm} = (U_{osm} \times V)/Posm = (164 \times 8)/280$
$= 4.7$ L/day
$C_{H2O} = V - C_{osm} = 8{-}4.7 = 3.3$ L/day
The GFR is 15 mL/min = 21.6 L/day; therefore, neither C_{H2O} nor C_{osm} is larger than GFR.

In this patient, the large urine output is due to an osmolar clearance (4.7 L/day) that is 1.7 L/day higher than the 3 L/day osmolar clearance found in patients on a typical Western diet. The high osmolar clearance (an osmotic diuresis) is due to sodium and potassium wasting caused by Bartter's syndrome, which is treated with sodium and potassium supplements. A pressure natriuresis, caused by the patient's high blood pressure and volume overload, may be contributing to the osmotic diuresis. Although free water clearance (C_{H2O}) is not as large as osmolar clearance (C_{osm}), it is markedly higher than the slightly negative free water clearance found in patients who are eating and drinking normally. It is indicative of a concurrent water diuresis.

Question 2

Which of the following statements are TRUE regarding the cause of the above patient's polyuria.

A. She has diabetes insipidus and administration of desmopressin will determine whether the cause is central or nephrogenic
B. She has diabetes insipidus and measurement of copeptin will determine whether the cause is central or nephrogenic
C. She has nephrogenic diabetes insipidus
D. The sole reason for her polyuria is an osmotic diuresis caused by sodium and potassium supplements
E. None of the above

Answer: E
The very high free water clearance (C_{H2O}), reflecting a dilute urine, with an osmolality lower than plasma osmolality, indicates that the patient's large urine output is, in part, due to a water diuresis. Therefore, although the patient also has an osmotic diuresis, Answer D is incorrect. A water diuresis can be caused by central diabetes insipidus, nephrogenic diabetes insipidus, or primary polydipsia. The low-serum sodium concentration indicates that primary polydipsia must be a major part of the explanation for her water diuresis. It is possible that she has central or nephrogenic diabetes insipidus as well, but these diagnoses cannot be entertained until the urine osmolality is reassessed after the plasma osmolality has normalized.

Question 3

Which of the following causes the above patient's urine osmolality to be lower than her plasma osmolality?

A. Impaired sodium, potassium, and chloride reabsorption in the ascending limb of the loop of Henle
B. Decreased urea reabsorption in the papillary collecting duct
C. Low levels of vasopressin
D. All of the above
E. None of the above

Answer: C

The patient's serum sodium concentration is low, which suppresses vasopressin secretion by the hypothalamus. This results in a low urine osmolality in both normal subjects and in patients with CKD. The ability to dilute the urine is preserved in patients with CKD until the GFR falls below 15 mL/min, and some patients with a GFR <15 mL/min will respond to a water load with a fall in urine osmolality. Answers A and B explain why this patient is unable to concentrate her urine. Concentration of the urine depends on sodium, potassium, and chloride transport in the ascending limb and urea reabsorption in the papillary collecting duct. Impaired function of the ascending limb actually reduces the ability to dilute the urine and cannot be the reason that the patient's urine is dilute. Decreased urea reabsorption in the collecting duct does not enhance the ability to dilute the urine.

Question 4

Which of the following causes the above patient's serum sodium concentration to be lower than normal?

A. The high BUN
B. Inability to concentrate the urine due to the defect in the ascending limb
C. Decreased urea absorption in the papillary collecting duct
D. SIADH
E. None of the above

Answer: E

The serum sodium concentration is lower than normal because, despite the retained ability to excrete urine more dilute than plasma, the patient is unable to dilute the urine maximally. Her urine electrolyte (Na + K) concentration is 64 mEq/L, half her serum sodium concentration. Therefore, her 8 L of daily urine output is half electrolyte-free water. She must be drinking more than 4 L of electrolyte-free water daily to have become hyponatremic.

Although the high BUN increases plasma osmolality, it does not affect the serum sodium concentration. This is because urea, unlike glucose or mannitol, is an ineffective osmole that does not dilute the serum sodium concentration by osmotically attracting water from the intracellular space.

Inability to concentrate the urine and decreased urea reabsorption in the papillary collecting duct, part of the processes involved in the generation of the medullary concentration gradient, do not affect the ability to dilute the urine.

The diagnosis of SIADH cannot be made in patients with advanced CKD.

Question 5

Which of the following would be appropriate counseling for this patient regarding her water intake:

A. A high water intake will delay progression of your kidney disease
B. Your polyuria will resolve if you decrease your water intake to 2 L/day.
C. Your serum sodium concentration will normalize if you decrease your water intake
D. All of the above
E. None of the above

Answer: C

As noted in the answer to question 4, the urine electrolyte concentration is half the serum sodium concentration, indicating that water restriction will be effective in raising the serum sodium concentration.

Although there is evidence in experimental animals that a high water intake delays progression of kidney disease, this has not yet been proven in humans.

Although polyuria will likely improve by decreasing water intake, it may not completely resolve for two reasons: (a) part of the diuresis is due to increased osmolar clearance, and (b) the patient may have fixed hyposthenuria due to her kidney disease. Hyposthenuria (even when the serum sodium concentration is normal or high) is a feature of some variants of Bartter's syndrome.

Question 6

A 30-year-old man with a family history of ADPKD is found to have S[Cr] of 1.4 mg/dL and multiple cysts in both kidneys. Which one of the following would be appropriate counseling for this patient regarding his water intake:

A. High water intake will definitely delay progression of your kidney disease
B. If you decide to treat your disease with a high water intake, a high-protein, high-salt diet will make it easier for you to suppress vasopressin secretion and achieve a target urine osmolality of 280 mOsm/kg H_2O.
C. Tolvaptan therapy has been shown to decrease progression of kidney disease in some patients like you
D. All of the above
E. None of the above

Answer C

Vasopressin promotes the growth of renal cysts in ADPKD. By suppressing vasopressin secretion, a high water intake would be expected to be effective in delaying progression of ADPKD; however, it has not been proven to do so. Tolvaptan, a vasopressin receptor antagonist, which blocks the effect of vasopressin on renal cyst growth, has been shown to delay progression of ADPKD in therapeutic trials.

A low-protein, low-salt diet makes it easier to lower the serum sodium concentration enough to suppress vasopressin secretion by drinking water. Higher protein intakes increase urine electrolyte-free water excretion, making it harder to drink enough water to achieve this goal.

CHAPTER

39

Sodium Metabolism in Chronic Kidney Disease

Surabhi Thakar, Mark S. Paller

University of Minnesota, Minneapolis, MN, United States

Abstract

Sodium balance is reasonably well maintained in chronic kidney disease (CKD) patients until renal function is extensively diminished. Patients do not usually develop either edema or sodium depletion during the early stages of CKD. The adaptive response to decreasing glomerular filtration rate (GFR) in the face of a constant (or high) sodium intake is an increase in the fractional excretion of sodium (FE_{Na}). This, in turn, requires a reduction in sodium reabsorption per nephron. In most circumstances, this is protective and prevents or limits sodium retention and extracellular fluid volume expansion. However, if dietary sodium intake is suddenly or greatly reduced, the chronically diseased kidney cannot immediately adjust. Distal nephron tubular function is not permanently impaired because the kidney can adequately adjust to decreases in sodium intake if the changes occur slowly. Hypertension is very common in CKD patients. Control of extracellular fluid volume through diet, and dialysis prescription in the case of end-stage renal disease, is the most effective means of controlling blood pressure. The KDOQI Clinical Practice Guidelines recommends that dietary sodium intake be limited to no more than 2.4 g/day.

SODIUM HOMEOSTASIS AND SODIUM METABOLISM

The body maintains homeostasis by protecting sodium balance more vigorously than it does water balance or acid–base balance. It should be no surprise then that sodium balance is reasonably well maintained in chronic kidney disease (CKD) until renal function is extensively diminished. In normal individuals, sodium balance is maintained by coordination of the afferent sensors and the efferent actions of the kidneys. In individuals with CKD, the same pathways are relevant.

The regulated (i.e. perceived) portion of total body sodium is the intravascular fluid volume. The afferent sensors for intravascular volume include baroreceptors in the arterial circulation, in the aortic arch and carotid sinuses, cardiac receptors in the atria, and receptors in the renal arteries. Sympathetic nerves to the kidney, as well as circulating norepinephrine, are the main communication mode between the arterial baroreceptors and the kidneys.[1] The renal baroreceptors also mediate renin release, and the subsequently generated angiotensin II becomes an additional circulating signal to the kidneys. Angiotensin II-stimulated aldosterone further influences renal sodium handling in the collecting duct. The cardiac baroreceptors release natriuretic peptides that alter distal nephron sodium handling.[2]

The intrarenal mechanisms whereby sodium handling and ultimately urinary sodium excretion can be altered include glomerular filtration, peritubular physical forces, renal sympathetic nerve activity, aldosterone, natriuretic peptides, prostaglandins, and other vasoactive substances, including vasopressin, endothelin, and nitric oxide.[2–8]

Since the 1960s, it has been recognized that glomerular filtration rate (GFR) and aldosterone are not the most important controlling factors for renal sodium excretion. Scientists sought the so-called third factor. Although the third factor was discovered to be an atrial natriuretic factor, in actuality there are several hormones, autacoids, and intrinsic vasoactive controllers of sodium excretion (see above).[9]

ALTERATIONS AND ADAPTATIONS IN CKD

Body Fluid Spaces

Total body water is increased in most patients with CKD.[10] Because total body water is expressed in units of body weight, this could reflect an absolute increase in water, a decrease in body fat, or a combination. Because water is distributed in lean body tissue, a decrease in fat tissue would be expressed as an increase in water per unit of body weight. Because CKD is often

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00039-5

associated with malnutrition and an expected loss in fat tissue, the extent of a true increase in total body water, if any, in patients is not precisely known.

Measurements of extracellular fluid volume, also expressed per unit of body weight, have also been reported as being increased when measured as exchangeable bromide or sulfate in CKD. Exchangeable sodium has also been employed as a measurement of extracellular fluid volume. However, unlike bromide, sulfate, or chloride, sodium does enter cells. In CKD, exchangeable sodium is usually elevated. On the other hand, the magnitude of total body potassium and intracellular potassium is either normal or low, suggesting a substitution of sodium for intracellular potassium. Circulating inhibitors of Na/K ATPase, including endogenous ouabain, accumulate in patients with CKD and may be the responsible for this electrolyte shift.[11] Therefore, in CKD, the exchangeable sodium measurement may not be an accurate predictor of extracellular fluid volume. Measurements of blood volume using chromium-labeled red cells or radio-iodinated albumin have usually been normal in CKD. In summary, although there are abnormalities of intracellular sodium levels and of total body sodium in CKD, extracellular fluid volume measured by older methods is usually normal, at least until profound decreases in renal function occur.

Bioelectrical impedance analysis (BIA) may detect early changes in the extracellular volume when other clinical indicators, such as edema, are not evident, especially in early stages of CKD. Bellizzi et al. performed anthropometry and BIA in an outpatient CKD population and found, compared with healthy subjects, patients with CKD had higher total body water, even in early phases of renal disease.[12] A recent prospective observational study using Chronic Renal Insufficiency Cohort, which included patients with mean estimated GFR of 20–70 mL/min/1.73 m^2, found BIA-derived measures of tissue hydration were significantly associated with death and incident heart failure.[13] More data are required, however, to validate these measures in patients with CKD.

CONTROL SYSTEMS

Several physiologic phenomena are involved in the normal control of sodium metabolism by the kidneys (Table 39.1). When renal function is reduced, there must be quantitative changes in these factors to maintain sodium balance.

Increased Fractional Excretion of Sodium

As patients develop CKD with a slowly progressive course, they do not usually develop either edema or sodium depletion. If sodium intake remains constant and the number of functioning nephrons decreases, then sodium excretion per nephron must increase.

TABLE 39.1 Factors Affecting Renal Sodium Excretion

1. Glomerular filtration rate
2. Aldosterone
3. Peritubular physical factors
4. Renal sympathetic nerve activity
5. Natriuretic peptides
6. Prostaglandins
7. Others (AVP, endothelin, nitric oxide)

Slatopolsky and colleagues studied subjects with CKD with GFR between 3 and 25 mL/min on a 1400 and a 2800 mg/day sodium diet.[14] The subjects were able to maintain external sodium balance without a change in GFR. Calculations suggested that small, imperceptible increases in GFR could not have accounted for the doubling of sodium excretion when switching from the lower to the higher sodium diet. Therefore, a decrease in tubular reabsorption, or increase in excretion, must have occurred. A similar response to saline infusion was observed.

Role of Mineralocorticoids

Aldosterone levels are often elevated in CKD. However, aldosterone *per se* is not responsible for adaptation to changes in sodium intake. In the studies by Slatopolsky and colleagues, half of the subjects were maintained on a high fixed dose of exogenous mineralocorticoid, and the ability to maintain sodium balance when increasing dietary sodium was preserved.[4] In CKD, increased aldosterone secretion is probably much more important for maintaining potassium homeostasis than sodium balance.[15]

Natriuretic Peptides

Three types of natriuretic peptides are involved in sodium homeostasis—atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide. The release of these peptides is caused by atrial and ventricular wall stretch, and they act to facilitate sodium excretion in the collecting tubule. Thus, to maintain sodium homeostasis in the face of decreasing renal function, increased secretion of natriuretic peptides occurs.

The most useful biomarkers to assess the status of the natriuretic peptide system in heart failure are BNP and NT-proBNP. Ventricular myocytes synthesize pre-proBNP, a 134 amino acid peptide, which is then cleaved to proBNP and a 26 amino acid fragment.

ProBNP, the secreted peptide, is cleaved by corin to yield BNP and an N-terminal, 76 amino acid fragment NT-proBNP. NT-proBNP has a longer circulating half-life than does BNP. It is often the biomarker of choice. However, NT-proBNP is cleared by the kidneys alone, and so accumulates as GFR declines. In most settings, NT-proBNP is a better reflection of GFR than of left ventricular function.[16] In studies of patients with end-stage renal disease (ESRD), essentially all patients have elevated ANP, BNP, and NT-proBNP.[17] These levels fall after hemodialysis, depending on the dialysis membrane used, but the decrease in levels does not correlate well with changes in volume status during dialysis. Still, Sommerer et al. found that NT-proBNP levels were 3247 pg/mL in hemodialysis patients with euvolemia, but 11,988 pg/mL in those with volume overload.[18] BNP should probably not be used as a screening tool for left ventricular dysfunction in CKD but can be used to serially follow a patient when GFR remains relatively constant.

"Magnification Phenomenon"

To explain how the kidneys maintain sodium, or other solute, homeostasis in the face of a decreasing number of functioning nephrons as would occur in CKD, Bricker and his colleagues developed the "magnification phenomenon" theory. "This transformation in nephron function in uremia constitutes the central and pivotal feature of the magnification phenomenon, which is defined as follows: *the addition or loss from extracellular fluid of any given amount of a substance that is actively regulated by the kidneys will evoke an excretory response per nephron that varies inversely with the number of surviving nephrons.*"[19] Epstein et al., who employed thermoneutral water immersion to the neck to acutely redistribute blood volume to the central circulation, provided one of the best demonstrations of the magnification phenomenon.[20] This maneuver is comparable in effect to a sudden volume expansion by infusion of 2 L of normal saline. At baseline, CKD subjects with GFR between 3 and 65 mL/min had FE_{Na} of 2.8% compared with FE_{Na} of 0.5% in control subjects. During 4 hours of water immersion, FE_{Na} increased to 6.9% in the CKD subjects, whereas FE_{Na} increased only to 1.4% in control subjects. Therefore, natriuresis in response to acute volume expansion was magnified. However, despite this adaptation, natriuresis was incomplete within this time frame. CKD subjects excreted only 28 mEq Na in 4 hours, whereas normal subjects excreted 51 mEq Na in 4 hours.

Adaptation to Changes in Sodium Intake

CKD has long been considered to be a "salt wasting" condition. Unlike normal individuals, those with CKD were observed to be unable to reduce urinary sodium concentration to near zero when sodium intake was severely restricted. In 1966, Coleman et al. carefully studied 14 subjects with GFR between 3 and 20 mL/min during sodium restriction and water diuresis.[21] They were interested in determining whether sodium wasting was the consequence of an "inadequate capacity of the distal nephron to reabsorb sodium" or "an inability to lower the concentration of sodium in distal tubular fluid below a relatively high fixed minimal value." Urine sodium concentration (U_{Na}) during sodium restriction was relatively high, 9–27 mEq/L. The lowest daily urinary sodium excretion ($U_{Na}V$) in any subject with CKD was 12 mEq/day. 11 of 14 subjects with CKD were in net negative Na balance during the two to three weeks of study. In contrast, normal subjects reduced U_{Na} to between 2 and 8 mEq/L. Water diuresis increased urine flow without changing urinary sodium concentration, so that sodium excretion rose in direct proportion to urine flow. Salt wasting in CKD was attributed to the failure of the patients with CKD to reduce U_{Na} below a relatively high fixed value.

Danovitch, Bourgoignie, and Bricker challenged the concept that CKD is an intrinsically salt-wasting condition and, instead, posited that an increase in sodium excretion per nephron is an adaptive response to falling GFR in the face of constant sodium intake.[22] They studied five people with CKD during a stepwise, rather than abrupt, reduction in sodium intake. These subjects had GFR between 5 and 16 mL/min and had dietary Na intake slowly reduced over a period of 1½ or more months. They all achieved a final U_{Na} of <10 mEq/L and $U_{Na}V$ <10 mEq/day as long as initial sodium losses were replaced.

These seemingly contradictory sets of observation can be synthesized as follows. The adaptive response to decreasing GFR in the face of a constant (or high) sodium diet is an increase in the FE_{Na}. This, in turn, requires a reduction in sodium reabsorption per nephron. The precise cellular and nephronal mechanisms for this decrease in sodium reabsorption in CKD have not been completely characterized but are likely to be qualitatively similar to those operative in normal kidneys. The renal response has the appearance of impaired distal nephron tubular function. In most circumstances, this is protective and prevents or limits sodium retention and extracellular fluid volume expansion. However, if dietary sodium is suddenly or greatly reduced, the kidney cannot immediately adjust. Then, there will be a large net negative sodium balance, or salt wasting. Distal nephron tubular function is not permanently impaired because the kidney can adequately adjust to decreases in sodium intake if the changes occur slowly enough.

CLINICAL IMPLICATIONS

Rate of Altering Sodium Intake or Excretion

Neither sodium retention nor sodium wasting is a major clinical problem in CKD under steady-state conditions until GFR is severely diminished (i.e. CKD stage 5). Abrupt increases in sodium intake cause volume expansion and edema, but not when similar increases in sodium intake are gradually introduced. Correspondingly, volume depletion does not occur when sodium intake is gradually reduced or when diuretics are gradually introduced. However, sudden decreases in sodium intake or increases in sodium loss cannot be completely defended in advanced CKD. This may explain the apparent frequency of episodes of acute reductions in renal function (prerenal azotemia) in CKD with gastrointestinal fluid losses caused by vomiting or diarrhea.

Sodium and HTN in CKD

Hypertension is very common in CKD, occurring in 60−100% of patients.[23] In ESRD patients, control of extracellular fluid volume (volume status) through diet and dialysis prescription is the most effective means of controlling blood pressure (BP). Hypertension in those with lesser degrees of CKD is also believed to be a consequence of sodium retention.

Vasavada and Agarwal performed balance studies in subjects with stage 2 or 3 CKD to examine the relationship between sodium balance and BP.[24] On a constant sodium diet, they found an inverse relationship between GFR and extracellular volume (measured as extracellular water [ECW]/lean body weight [LBW] by electrical impedance). A single administration of furosemide or torsemide caused natriuresis, an 8% decrease in ECW, and increased plasma renin activity. During three weeks of diuretic therapy, ECW partially returned to baseline, BNP decreased by 45%, and BP was significantly lower. The mean decrease in systolic BP was 9 mm Hg. Although these studies did not follow subjects beyond 3 weeks, some reasonable extrapolations can be made. In CKD, as GFR worsens there is expansion of the extracellular fluid space which is associated with an increase in BP. Diuretic therapy can partially reverse the sodium retention and decrease BP.

Blood pressure response to dietary sodium intake varies among individuals. The concept of salt sensitivity is that a meaningful change in BP results from a change in dietary salt intake. Salt sensitivity has recently been suggested to be a function of nonosmotic storage of sodium in the skin interstitium and of endothelial dysfunction caused by deterioration of the endothelial glycocalyx layer.[25,26] Luft et al. have extensively reviewed the regulatory mechanisms regarding sodium handling in the skin interstitium, such as the role of negatively charged glycosaminoglycans in sodium hemostasis, which is independent of renal function. Immune cells such as macrophages function as local osmoregulators and hence regulate the interstitial electrolyte composition mainly by lymphatic clearance.[27,28]

Lymphatic capillaries act as buffers by clearing the excess interstitial sodium.[29] In a recent study done in 99 patients with mild to moderate CKD, skin sodium content was measured using ^{23}Na magnetic resonance imaging. Skin sodium content strongly correlated with systolic pressure and LVH and was a better predictor of LVH than BP or total body hydration (measured by bioimpedance spectroscopy).[30] In another study, patients with refractory hypertension had increased skin sodium content.[31] Whether dietary sodium restriction or diuretic use can lead to a decrease in the skin sodium content has not yet been evaluated.

The glycocalyx is a protective layer on the endothelial (luminal) surface of blood vessels, which prevents adhesion of circulating red blood cells. The glycocalyx is a negatively charged biopolymer composed of heparan sulfate residues, which has a capacity to buffer sodium. The glycocalyx also selectively controls endothelial sodium permeability. A proposed mechanism for salt sensitivity is that a disrupted glycocalyx has a low buffering capacity and increased permeability that can lead to sodium accumulation in the interstitial space. Kumpers et al. found that CKD was associated with reduced endothelial glycocalyx integrity, which likely puts this population at increased risk of salt sensitivity.[32]

Sodium intake is also an important modulating factor for BP in patients being treated with antihypertensive medications. Heeg et al. examined the effect of the angiotensin-converting enzyme inhibitor lisinopril in nondiabetic, proteinuric kidney disease.[33] When subjects increase, sodium intake from 50 to 200 mmol/day, BP increased 3%. Importantly, high sodium intake also abolished the lisinopril-induced decrease in proteinuria.

PROGRESSION OF CKD

The links between hypertension and progression of CKD and between sodium and hypertension are well recognized. Higher BP is correlated with greater risk for progression of CKD.[34,35] As CKD worsens, a greater proportion of patients develop hypertension.[36] Therefore, sodium restriction would seem prudent in CKD. Some authors also suggest that sodium might have direct microcirculatory effects (i.e. glomerular) that would be harmful in CKD.[37,38]

A double-blind, placebo-controlled, randomized cross-over trial was conducted assessing the effect of high and low sodium diets on ambulatory BP and

extracellular volume.[39] Salt restriction of 60–80 mmol compared with 180–200 mmol resulted in a mean reduction in the BP of 10/4 mm Hg in three weeks. Extracellular fluid volume and body weight were reduced as well. Patients with CKD were more sensitive to this intervention. A larger study with longer follow-up needs to be conducted to confirm these findings. However, this study emphasizes the role of sodium restriction in patients with CKD as a modifiable risk factor.

Proteinuria is a generally accepted intermediate endpoint in studies of the risk for progression of CKD. In the above study, those randomized to a low salt diet also had a significant reduction in proteinuria and albuminuria.[38] The effects of lisinopril to reduce proteinuria can be abrogated by high sodium intake. The antiproteinuric effects of the calcium channel antagonist diltiazem can also be abrogated by a high sodium intake, apparently independent of any effect on BP.[40] In an important study of nondiabetic, proteinuric renal disease, Vogt et al. observed that losartan lowered proteinuria by about 30% and that a low sodium diet (1200 mg) decreased proteinuria by 22%.[41] Combining diet with angiotensin blockade lowered proteinuria by 55% such that sodium restriction and angiotensin blockade were additive. Hydrochlorothiazide (25 mg daily) could be substituted for the low sodium diet with equivalent benefits.

CLINICAL GUIDELINES

In CKD, sodium balance is best maintained by following the guidelines outlined in Table 39.2. The NKF KDOQI (National Kidney Foundation Kidney Disease Outcomes Quality Initiative) Clinical Practice Guidelines on Hypertension and Antihypertensive Agents in Chronic Kidney Disease recommends that dietary sodium intake be limited to no more than 2.4 g/day (100 mmol/day).[42] This recommendation is based on strong evidence that shows that the altered sodium handling in CKD has a major role in hypertension in CKD. The specific recommendation of <100 mmol/day is based on the results of the DASH-Sodium Trials.[43]

The KDIGO (Kidney Disease: Improving Global Outcomes) Clinical Practice Guideline for the Management of Blood Pressure in Chronic Kidney Disease recommends lowering sodium intake to <2 g/day (90 mmol/day), a level not very different from the KDOQI recommendation.[44] These guideline authors cite the observations that lowering sodium intake reduces blood pressure in the general population, and that CKD patients have sodium retention that is associated with an elevation in BP. Both guidelines warn that some patients with tubulointerstitial disease may have true salt wasting and need to be carefully observed for signs of volume depletion when dietary sodium is restricted.

There is a growing emphasis on reversing the metabolic acidosis that usually accompanies CKD to prevent bone and muscle disease. The 2003 KDOQI Guidelines state that in CKD patients "serum levels of total CO_2 should be maintained at ≥22 mEq/L (22 mmol/L). If necessary, supplemental alkali salts should be given to achieve this goal."[45] The KDIGO Guidelines make a nearly identical recommendation.[34] Sodium bicarbonate administration causes extracellular fluid expansion. Although almost all Na administered as sodium chloride is retained within the extracellular space, approximately three-fourth of Na administered as sodium bicarbonate remains in the extracellular space.[46,47] Practically speaking, there is little difference between NaCl and $NaCO_3$.[48] Therefore, if one prescribes three 650 mg sodium bicarbonate tablets daily to treat low serum bicarbonate, this represents a sodium load of about 500 mg.

TABLE 39.2 Clinical Guidelines for Maintenance of Sodium Balance in CKD

1. Limit dietary sodium intake to 2.0–2.4 g/day
2. Use diuretics to manage edema or hypertension
3. Do not make sudden or large changes in sodium intake or excretion. Rather, make stepwise changes to allow for renal adaptation

Use of Diuretics

In addition to dietary sodium restriction, diuretics have an important role in the treatment of hypertension and edema in CKD patients. The KDOQI Clinical Practice Guidelines on Hypertension and Antihypertensive Agents in Chronic Kidney Disease states "Diuretics are useful in the management of most patients with CKD. They reduce ECF volume; lower blood pressure; potentiate the effects of ACE inhibitors, ARBs, and other antihypertensive agents; and reduce the risk of CVD in CKD."[25] Thiazide diuretics, given once daily, are recommended for those with GFR >30 mL/min. Loop diuretics, given once or twice daily, are recommended for those with GFR <30 mL/min. Loop diuretics can be combined with thiazides for those with ECF volume expansion and edema.

Effects of Other Drugs

Use of vasodilators for hypertension may result in the development of edema, even at higher levels of GFR. This effect can certainly be observed in patients with advanced CKD. Similarly, inhibition of cyclooxygenase by NSAIDS frequently causes sodium retention and edema in normal subjects. This effect can also occur in CKD patients. The effect in CKD may be magnified if NSAIDS result in a marked decrease in GFR.[49]

CONCLUSION

Sodium balance is reasonably well maintained in CKD until renal function is seriously diminished. Patients do not usually develop either edema or sodium depletion. The adaptive response to decreasing GFR in the face of a constant (or high) sodium diet is an increase in the fractional excretion of sodium (FE_{Na}). This, in turn, requires a reduction in sodium reabsorption per nephron. In most circumstances, this is protective and prevents or limits sodium retention and extracellular fluid volume expansion. However, if dietary sodium is suddenly or greatly reduced, the kidney cannot immediately adjust. Distal nephron tubular function is not permanently impaired because the kidneys can adequately adjust to decreases in sodium intake if the changes occur slowly. Hypertension is very common in CKD. Control of extracellular fluid volume through diet, and dialysis prescription in the case of ESRD, is the most effective means of controlling blood pressure. The KDOQI Clinical Practice Guidelines recommends that dietary sodium intake be limited to no more than 2.4 g/day in patients with CKD.

QUESTIONS AND ANSWERS

Question 1

A 73-year-old man has new complaints of ankle swelling. He has stable CKD stage 3, thought to be a consequence of long-standing hypertension, and a past history of myocardial infarction at age 69. He has otherwise been quite healthy and active and still works full time as a financial advisor. On physical examination, his BP is 143/89 mm Hg, heart rate 72 bpm, and O_2 saturation 98%. Because of a thick neck, it is difficult to estimate central venous pressure. His lungs have rare basilar rales and no wheezes, his heart rate rhythm is normal without murmurs, and his abdomen is obese without a palpable liver. His pulses are intact, and he has trace ankle edema.

Laboratory:

Electrolytes normal
Glucose 95 mg/dL
S[Cr] 1.7 mg/dL
Estimated GFR 44 mL/min/1.73 m^2
Urinalysis—no blood or protein

Which **one** of the following is true regarding his condition?

A. He should be treated for deep venous thrombosis
B. His edema is caused by impaired sodium excretion due to CKD
C. He should be given a prescription for furosemide 40 mg daily and told to return only if his edema worsens
D. He should be evaluated for liver disease or heart failure
E. Small amounts of peripheral edema are normal for men in this age group

Answer: D

A is incorrect because bilateral edema is rare in deep venous thrombosis and there is nothing in the history or examination to suggest that diagnosis. **B** is incorrect because sodium balance is usually preserved until greater losses of GFR. **C** is incorrect because one should not treat this patient without further consideration of the possible causes of sodium retention, which could be serious.

D is correct. Because mild to moderate CKD should not cause sodium retention, other possibilities must be considered. These include heart failure, especially in a patient with known coronary heart disease. Cirrhosis is also a possibility that needs to be further explored. **E** is not true and a specific etiology is usually responsible.

Question 2

A 59-year-old woman with a number of chronic illnesses complains of recent onset of exertional dyspnea. She has a history of type 2 diabetes mellitus, CKD stage 4, hypertension, mitral regurgitation, obesity, and asthma. Her dyspnea has not responded to her asthma inhaler. She has chronic leg swelling which has not worsened. Her diabetes has been under good control. She is an imprecise historian. Physical examination reveals BP 132/83 mm Hg, heart rate 77 bpm, respiratory rate 12 per minute, O_2 saturation 95%. She is obese and her neck veins are difficult to evaluate. Her lungs have a few rales in the mid-left without wheezes. Her heart sounds are distant with a grade 4/6 systolic murmur. An S3 is noted. She has 1−2+ lower extremity edema.

Laboratory:

Na 143 mEq/L
K 4.8 mEq/L
Cl 109 mEq/L
HCO_3 20 mEq/L
Glucose 139 mg/dL
S[Cr] 2.7 mg/dL (unchanged from baseline)
Estimated GFR 20 mL/min/1.73 m^2
NT-proBNP 2472 pg/mL (normal 0−125 pg/mL)

Which **one** of the following is true regarding her condition?

A. She has decompensated heart failure because her NT-proBNP is elevated, reflecting ventricular distension
B. She probably has asthma because her S[Cr] has not increased
C. The NT-proBNP is not useful in this setting
D. She has diabetic ketoacidosis because she has an elevated anion gap
E. Obesity can be ruled out because it does not cause dyspnea

Answer: C

A is incorrect. NT-proBNP is certainly elevated in decompensated heart failure and in a person with normal kidney function this value would be strong evidence for congestive heart failure. However, NT-proBNP is excreted by the kidneys. In patients with advanced CKD, NT-proBNP is a better indicator of GFR than of left ventricular function, and in such patients it should not be used to diagnose heart failure. **B** is incorrect because she has no wheezes and there is no constant relationship between asthma and renal function. **D** is incorrect because her blood glucose is not markedly elevated and she has only a small anion gap which is consistent with CKD alone. **E** is incorrect because obesity, often associated with deconditioning, is a frequent cause of dyspnea.

Question 3

A 46-year-old man with idiopathic membranous nephropathy and CKD stage 4 has more difficulty in controlling blood pressure. He has recently been taking lisinopril 40 mg daily, metoprolol 100 mg twice daily, and furosemide 40 mg daily. He has proteinuria less than 500 mg/24 h and BP greater than 150/95 mm Hg on several occasions. He does not wish to take additional medications. His physician counseled him to restrict his sodium intake, which was estimated to exceed 4 g daily because of a diet based on fast foods and canned goods.

The patient vowed to get his diet and blood pressure under control, started cooking all his own meals, and eliminated prepared foods, high sodium foods, and added salt from his diet. A dietician later estimated that his daily sodium intake was now less than 1500 mg. When he saw his physician three weeks later for reevaluation, his BP was 123/78 mm Hg but S[Cr] had increased from 3.0 mg/dL (estimated GFR 24 mL/min/1.73 m^2) to 4.5 mg/dL (estimated GFR 16 mL/min/1.73 m^2). He claims to feel well, but misses salty foods. Urinalysis shows trace protein, no cells or casts. Electrolytes were normal.

Which **one** of the following is true regarding the decrease in his kidney function?

A. He probably has acute interstitial nephritis from one of his medications
B. He probably has prerenal azotemia because of intravascular volume depletion
C. He would have developed the same problem even if he had gradually decreased his dietary sodium over a period of several weeks
D. He needs to start hemodialysis
E. He should be given one liter of normal saline immediately

Answer: B

A is incorrect because he is taking no new medications and his urinalysis is unchanged. **B** is correct. He decreased his sodium intake very rapidly and by a large amount. His kidneys could not adapt rapidly enough so he developed large urinary sodium losses and intravascular volume depletion leading to prerenal azotemia. **C** is incorrect because a gradual reduction in sodium intake would have allowed his kidneys to adapt without incurring large net sodium losses. **D** is incorrect because dialysis is not indicated at this level of renal function in the absence of symptoms and because the change in renal function should be reversible if his sodium intake is slowly liberalized. **E** is incorrect because there is no urgency to reverse the volume depletion and because sudden overcorrection could lead to edema or heart failure.

CHAPTER

Potassium Metabolism in Chronic Kidney Disease

Biff F. Palmer[a], *Deborah J. Clegg*[b]

[a]Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX, United States;
[b]University of California at Los Angeles, Medical Center, Los Angeles, CA, United States

Abstract

Adaptive increases in renal and gastrointestinal excretion of K^+ help to prevent hyperkalemia in patients with chronic kidney disease (CKD) as long as the glomerular filtration rate (GFR) remains >15–20 mL/min. In these patients K^+ balance is maintained by increased K^+ secretion per functioning nephron, which is mediated in part by elevated plasma K^+ concentration, aldosterone, increased flow rate, and enhanced Na^+–K^+-ATPase activity. Fecal losses of potassium also increase in CKD patients. These adaptive mechanisms are effective in preventing hyperkalemia, provided that urine output is in excess of 600 mL/day. However, limits of adaptation render the CKD patient susceptible to hyperkalemia with even minor perturbations in these factors. Such is the case in patients with diabetes, where decreased mineralocorticoid activity is often an early finding caused by hyporeninemic hypoaldosteronism, or in patients primarily with renal tubular injury, as in tubulointerstitial renal disease. In these settings, hyperkalemia often develops with only mild or moderate reductions in GFR. Once the GFR falls to <15 mL/min, an inflection point is reached whereby small incremental losses in renal function require progressively steeper rises in steady state S[K] to maintain total body K^+ balance. Certain medications can impair potassium handling and excretion in CKD patients. At this level of renal function the impact of factors known to adversely affect K^+ homeostasis is significantly magnified. In clinical practice hyperkalemia is usually the result of a combination of factors superimposed on renal dysfunction.

INTRODUCTION

This chapter deals with potassium (K^+) metabolism in patients with chronic kidney disease (CKD). After a description of the scope of the problem and brief discussion of normal renal K^+ homeostasis, the chapter outlines adaptations in renal K^+ handling, which characterize CKD. The approach to and treatment of K^+ disorders in CKD patients up to the point at which renal replacement therapy is required will be the focus of the chapter.

SCOPE OF THE PROBLEM

Hyperkalemia is typically defined as a serum potassium concentration (S[K]) of >5.0 or >5.5 mEq/L, with the upper limit of normal varying across guidelines and publications.[1–4] It is relatively uncommon to find hyperkalemia in individuals with normal renal function. In patients with CKD, however, the incidence ranges from 5% to 50%.[5] In patients with CKD loss of nephron mass is counterbalanced by an adaptive increase in the secretory rate of K^+ in remaining nephrons, such that K^+ homeostasis is generally well maintained until the glomerular filtration rate (GFR) falls below 15–20 mL/min.[6] More severe renal dysfunction invariably leads to K^+ retention and hyperkalemia unless dietary intake of K^+ is reduced. In a random sample of 300 CKD patients (serum creatinine concentration [S[Cr]] ranging from 1.5 to 6.0 mg/dL), excluding diabetics and those taking drugs that interfere with angiotensin II synthesis or effect, the incidence of hyperkalemia has been noted to be 55% (K^+ ≥5.5 mEq/L).[7]

The relationship between hyperkalemia and renal function has been documented in a large, retrospective Veterans Affairs (VA) study, where the incidence of hyperkalemia (≥5.5 mEq/L) was 8.9% in a control cohort (defined by an estimated glomerular filtration rate [eGFR] ≥60 mL/min/1.73 m^2) and increased to 20.7%, 42.1%, and 56.7% in patients with stage 3, 4, and 5 CKD, respectively.[8] Furthermore, the odds of hyperkalemia in patients with stage 3, 4, and 5 CKD were 2.24, 5.91, and 11.0, respectively. Comparable

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00040-1

results to the VA study were obtained from the Humedica database in an analysis of 1.7 million persons with S[K] measurements on 2 separate occasions from 2008 to 2012.[9,10] The prevalence of hyperkalemia, defined by the highest reported S[K] value ≥5.1 mEq/L during the study period, was 8.5% for subjects without CKD. By comparison the incidence of hyperkalemia progressively increased with advancing stages of CKD being 22.8%, 32.7%, 46.9%, 56.5%, and 68.7% in patients with CKD stage 3a, 3b, 4, 5, and end-stage renal disease (ESRD) respectively. The number of risk factors present in individuals significantly contributes to the variability in incidence rates, with the risk factors being increased age, diabetes mellitus, hypertension and/or heart failure, and the use of medications such as renin–angiotensin–aldosterone system (RAAS) inhibitors[11] (Table 40.1).

Although adaptive mechanisms in the CKD patient may attenuate cardiac toxicity from increased S[K], hyperkalemic events are still associated with an increased risk of death in this population.[8] The electrocardiogram in a hyperkalemic subject can progress from normal to ventricular tachycardia and asystole in a precipitous manner.[12] In the VA study, a hyperkalemic event increased the risk of death within 1 day across all groups, even those without CKD, because hyperkalemia can lead to cardiac arrhythmias and increased mortality.[8] There are data suggesting a U-shaped relationship between plasma K^+ and mortality, with mortality increasing at low and high plasma K^+, especially in those with cardiorenal manifestations including hypertension, CKD, and ESRD.[13] The frequency of hyperkalemia in the CKD patient makes a strong argument for early referral and management of these patients in a clinic environment focused on the management of this common electrolyte disorder.[14]

Although loss of kidney function is the single most important cause of hyperkalemia, in clinical practice this electrolyte disorder is usually the result of a combination of factors limiting renal K^+ excretion superimposed on renal dysfunction (Table 40.1). Such is the case in diabetic patients, where decreased mineralocorticoid activity is often an early finding due to hyporeninemic hypoaldosteronism or in advanced stages of heart failure with accompanying reductions in distal delivery of Na^+ combined with concurrent use of drugs that interfere with the RAAS. In these settings hyperkalemia is common and can develop with only mild or moderate reductions in the GFR. One study attempted to identify all of the factors known to interfere in K^+ homeostasis simultaneously present during a single clinic visit in a population of CKD patients.[5] These patients were receiving regular follow-up in a clinic specifically designed and structured to optimize the care of advanced CKD. Despite the focus of the clinic the mean S[K] was increased over 5.1 mEq/L in 54.2% of patients. Although the average eGFR of the entire study population was 14.4 mL/min/1.73 m^2, those with hyperkalemia had a significantly lower eGFR compared to those without (14.8 vs. 13.5 mL/min/1.73 m^2). In addition to worse renal function, hyperkalemic patients had significantly lower serum bicarbonate concentrations (22.5 vs. 24.1 mEq/L).

TABLE 40.1 Causes of Hyperkalemia

- Pseudohyperkalemia
- Cellular redistribution
  - Mineral Acidosis
  - Cell shrinkage (hypertonicity)
  - Deficiency of insulin
  - β-Blockers
  - Hyperkalemic periodic paralysis
  - Cell injury
- Excess Intake (very rare)
- Decreased Renal Excretion
  - Decreased distal delivery of Na^+ (oliguric renal failure)
  - Mineralocorticoid deficiency
  - Defect of cortical collecting tubule

NORMAL POTASSIUM HOMEOSTASIS

Potassium plays a key role in maintaining cell function. All cells possess a Na^+–K^+-ATPase, which pumps Na^+ out of the cell and K^+ into the cell. This leads to a K^+ gradient across the cell membrane ($K^+_{in} > K^+_{out}$), which is partially responsible for maintaining the potential difference across the membrane. This potential difference is important to the function of all cells, but it is especially important in excitable tissues such as nerve and muscle. For these reasons, the body has developed numerous mechanisms for defense of S[K]. Total body K^+ is approximately 50 mEq/kg, which in a 70 kg person would be 3500 mEq. The majority (98%) of this K^+ is within cells, with only 2% in the extracellular fluid. The normal concentration of K^+ in the extracellular fluid is 3.5–5.3 mEq/L. Large deviations from these values are not compatible with life. The typical American diet includes 50–100 mEq/day of K^+. Approximately 90% of the daily K^+ intake is excreted in the urine, while 10% is excreted in the GI tract. The kidney and gastrointestinal tract respond directionally when K^+ intake increases or decreases.

NORMAL RENAL POTASSIUM HANDLING

Potassium is freely filtered by the glomerulus. The bulk of filtered K^+ is reabsorbed in the proximal tubule and loop of Henle, such that only 10% of the filtered load

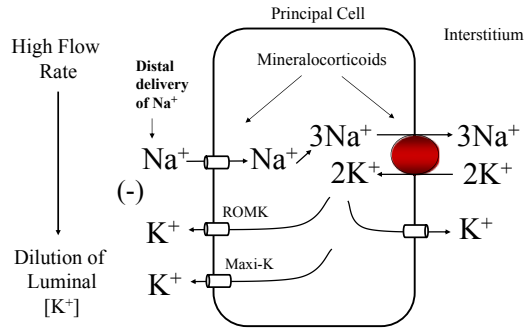

FIGURE 40.1 Model for renal regulation of K^+ secretion by the principal cell in the collecting tubule.

reaches the distal nephron. In the proximal tubule K^+ absorption is passive and is in rough proportion to Na^+ and water absorption. In the thick ascending limb of Henle, K^+ reabsorption occurs *via* transport on the apical membrane Na^+–K^+–$2Cl^-$ cotransporter. Secretion of K^+ occurs in the distal nephron primarily in the initial collecting duct and the cortical collecting duct. Under most physiologic and pathologic conditions, K^+ delivery to the distal nephron remains low and is fairly constant. By contrast, the rate of K^+ secretion by the distal nephron varies significantly and is highly regulated according to physiologic needs. K^+ secretion in the distal nephron is generally responsible for most of urinary K^+ excretion.

The specialized cell that is responsible for K^+ secretion in the initial collecting duct and the cortical collecting duct is the principal cell (Figure 40.1). The cellular determinants of K^+ secretion include the cell K^+ concentration, luminal K^+ concentration, transepithelial potential difference (voltage) across the luminal membrane, and the permeability of the luminal membrane for K^+. Two of the most important factors that influence these determinants are mineralocorticoid activity and the distal delivery of Na^+ and water.[15,16]

Aldosterone interacts with the intracellular mineralocorticoid receptor in the principal cell to stimulate K^+ secretion by affecting several of these cellular determinants. First, aldosterone stimulates Na^+ reabsorption across the luminal membrane by increasing the open probability of the epithelial sodium channel on the apical membrane, which increases the electronegativity of the lumen, thereby increasing the electrical gradient favoring K^+ secretion. Second, aldosterone increases intracellular K^+ concentrations by stimulating the activity of Na^+–K^+-ATPase in the basolateral membrane. Third, aldosterone directly increases the permeability of the luminal membrane to K^+. Thus, aldosterone increases the rate of K^+ secretion by increasing cell K^+ concentration, increasing luminal membrane K^+ permeability, and making the luminal potential more negative.

An increase in the distal delivery of Na^+ stimulates K^+ secretion by causing the luminal potential to become more negative. When K^+ is secreted in the collecting duct, the luminal K^+ concentration increases, which decreases the diffusion gradient and slows further K^+ secretion. At high luminal flow rates the same amount of K^+ secretion will be diluted by the larger volume, such that the increase in luminal K^+ concentration will be less, thus facilitating ongoing K^+ secretion.

Two populations of K^+ channels have been identified in the cells of the cortical collecting duct (Figure 40.1). The renal outer medullary K^+ channel is considered to be the major K^+ secretory pathway. This channel is characterized by having low conductance and a high probability of being open under physiologic conditions. The maxi-K^+ channel, or BK channel, is characterized by a large single channel conductance, which is relatively quiescent in the basal state. This channel becomes activated under conditions of increased flow. In addition to increased delivery of Na^+ and dilution of luminal K^+ concentration, recruitment of maxi-K^+ channels plays an important role in mediating flow-dependent increased K^+ secretion.

There are new data and evidence to suggest that the distal nephron can actually act as a "*K^+ sensor*," whereby small changes in extracellular K^+ concentration can lead to direct changes in the K^+ secretory mechanism through alterations in activity of the with no lysine family of kinases and their regulatory proteins SPAK and OxSR1.[17,18]

POTASSIUM HOMEOSTASIS IN ACUTE KIDNEY INJURY

There are a number of features characteristic of acute kidney injury (AKI), which makes hyperkalemia particularly common. When the cause is acute tubular necrosis or tubulointerstitial renal disease, there is often widespread injury to the late distal tubule and collecting duct, leading to direct injury of cells responsible for K^+ secretion. AKI is often associated with severe reduction in the GFR (<10 mL/min), which itself becomes rate limiting for K^+ secretion. The rapidity of renal functional loss precludes adequate time for normal renal and extrarenal adaptive mechanisms to adequately develop. In patients with more severe injury manifested clinically by oligoanuria, there is a marked reduction in distal delivery of salt and water, which contributes to decreased distal K^+ secretion. In nonoliguric AKI, hyperkalemia tends to be less common because distal delivery of salt and water is plentiful. Patients with AKI are more likely to have severe acidosis, increased catabolism, and tissue breakdown, all leading to release of intracellular K^+ into the extracellular compartment. This release of K^+ in the setting of impaired renal K^+

secretion makes life-threatening hyperkalemia a common occurrence in AKI patients.

POTASSIUM HOMEOSTASIS IN CKD

Potassium homeostasis is more complicated in CKD than in AKI. In addition to the decreased GFR and secondary decrease in distal delivery, there is nephron dropout and a smaller number of collecting ducts to secrete K^+. However, this is counterbalanced by an adaptive process in which the remaining nephrons develop an increased ability to excrete K^+. As a result hyperkalemia (S[K] >5.5 mEq/L) is uncommon in patients with CKD until the GFR falls below 15–20 mL/min.

Studies both in experimental animals and humans have provided insight into the nature and localization of the adaptive increase in renal K^+ secretion. In conscious dogs with a unilateral remnant kidney, K^+ secretion per nephron increases fourfold by 18 hours and approaches 85% of the control animals seven days after removal of the contralateral intact kidney[19] (Figure 40.2). The ability to maintain urinary K^+ secretion in the face of a marked reduction in functioning nephron mass requires the amount of K^+ excreted per unit GFR (fractional excretion of K^+) to markedly increase.

In a study of normokalemic patients with stage 4 CKD, the fractional excretion of K^+ was 126% compared with 26% in normal controls.[20] The fractional excretion of Na^+ in the two groups was 2.3% and 15%, respectively. Following the intravenous administration of amiloride, the fractional excretion of K^+ decreased by 87% in the patients with CKD compared with 19.5% in control patients. These findings support the idea that patients with CKD are able to maintain a normal S[K] through an adaptive increase in renal K^+ secretion that is largely amiloride sensitive.

Despite this adaptation, the ability to further augment K^+ secretion in response to an exogenous load is extremely limited, such that hyperkalemia can result from even modest increases in K^+ intake. When dogs with remnant kidneys are challenged with an acute intravenous infusion of K^+, the increment in renal K^+ secretion is approximately 50% less than in controls, and marked hyperkalemia develops.[21] In both the remnant and control groups renal K^+ excretion is directly related to the S[K], but the relationship is markedly attenuated in the remnant group. In the first 5 hours following the K^+ infusion, control animals excreted 65% of the K^+ load compared to only 35% in the remnant group. Nearly 24 hours is required to reestablish K^+ balance in dogs with reduced renal mass. During this time, plasma K^+ and aldosterone levels are significantly greater than in controls. Studies in patients

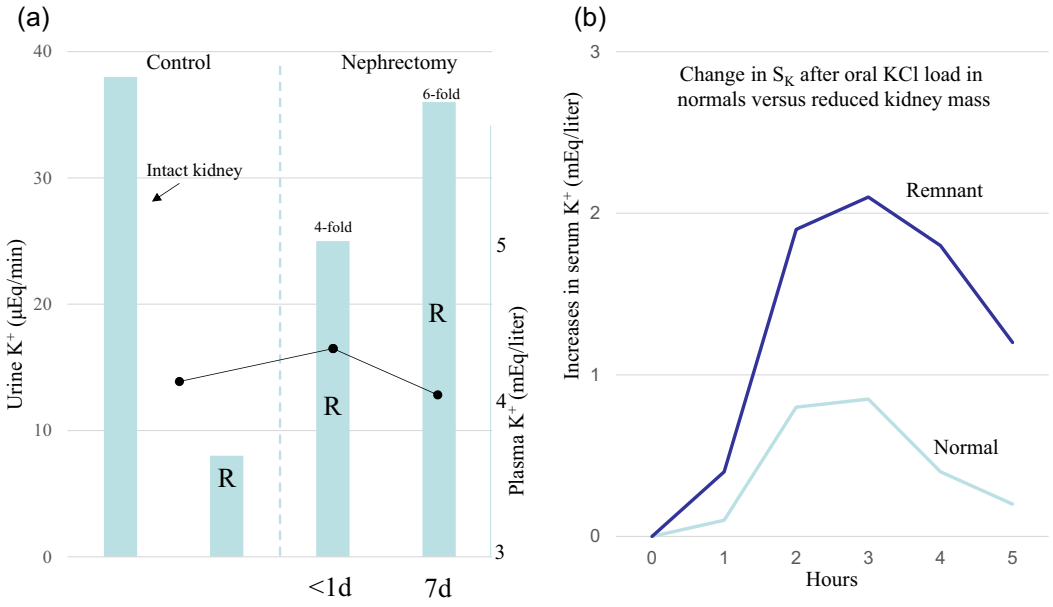

FIGURE 40.2 Studies in experimental animals show minimal change in the plasma potassium concentration following a reduction in renal mass due to an adaptive increase in potassium secretion by remaining nephrons (a). For this reason, hyperkalemia tends to be uncommon until the glomerular filtration rate (GFR) falls below 15 mL/min. The development of hyperkalemia with less severe reductions in GFR can be traced to one or all of the following: decreased distal Na^+ delivery, disturbances in the renin–angiotensin–aldosterone system, and/or abnormalities in the distal nephron. (b). Despite the adaptation, the ability to further augment K^+ secretion in response to an exogenous load is extremely limited, such that the increase in plasma K^+ concentration and time to normalization are both increased in the remnant kidney. *Adapted from references 21 and 23.*

with CKD also show a similar impairment in the ability to acutely excrete a K^+ load. Such patients develop more severe and prolonged hyperkalemia following a K^+ challenge.[22,23]

The nature of the adaptive process that facilitates K^+ excretion in patients with CKD is thought to be similar to the adaptive process that occurs in response to high dietary K^+ intake in normal subjects.[24] Chronic K^+ loading in animals augments the secretory capacity of the distal nephron so that renal K^+ excretion is significantly increased for any given plasma K^+ level. Increased K^+ secretion under these conditions occurs in association with structural changes characterized by cellular hypertrophy, increased mitochondrial density, and proliferation of the basolateral membrane in cells in the distal nephron and principal cells of the collecting duct. Increased S[K] and mineralocorticoids independently initiate the amplification process that is accompanied by an increase in Na^+–K^+-ATPase activity.

Studies in animal models show the cortical collecting duct is an important site of K^+ adaptation in surviving nephrons of animals with reduced renal mass. K^+ secretion is increased in perfused cortical collecting tubules taken from remnant kidneys of uremic rabbits fed a normal diet.[25] However, if dietary K^+ intake is reduced in proportion to the reduction in renal mass, this adaptation is prevented and K^+ secretory rates remain within the normal range. Reduction in renal mass leads to amplification of the basolateral membrane area and an increase in Na^+–K^+-ATPase activity similar to that described when dietary K^+ intake is increased in animals with intact kidneys.[26–28] Loss of renal mass also leads to an increase in Na^+ delivery and apical Na^+ transport in this segment.[29] Increased apical Na^+ entry provides a further stimulatory effect on Na^+–K^+-ATPase activity. Changes in S[K] and mineralocorticoids independently mediate these adaptive structural and functional changes.

Aldosterone plays an important role in the ability to augment K^+ secretion in the setting of CKD. Tubular hypertrophy, increased basolateral folding, and increased Na^+–K^+-ATPase activity in the collecting duct in remnant kidneys are similar to that in experimental models of chronic mineralocorticoid administration.[30] There is a wide variability in aldosterone levels in patients with CKD, with studies showing either increased, normal, or decreased values. Part of this variability is due to the failure to consider the prevailing plasma K^+ concentration and variations in Na^+ intake. In addition, many patients with CKD have low plasma renin activity. In this setting, impaired aldosterone secretion and hypoaldosteronism are the result of low circulating renin levels. When normalized for the plasma renin activity, levels of aldosterone are typically in the normal range when the GFR is $>50–60$ mL/min.[31] However, with more severe reduction in renal function there is a progressive increase in plasma aldosterone levels.

EXTRARENAL K^+ HOMEOSTASIS IN CKD

Under normal circumstances increases in plasma K^+ concentration following K^+ ingestion are minimized by physiologic mechanisms that shift K^+ into cells, before its excretion by the kidney. This maintenance of internal K^+ balance is primarily regulated by catecholamines, insulin, and to a lesser extent aldosterone. In pathologic states changes in blood pH and plasma tonicity also influence K^+ distribution within the body.

As renal function declines the cellular uptake of K^+ becomes an important defense against the development of hyperkalemia. Studies in humans and experimental models of reduced renal mass have produced conflicting results regarding whether disturbances in extrarenal K^+ disposal are a characteristic feature of CKD.[32] To the extent internal K^+ homeostasis is impaired, the defect cannot be attributed to increased cellular or total body K^+ content because these are either normal or often reduced.[33,34] Decreased intracellular K^+ content has been attributed to decreased activity of the Na^+–K^+-ATPase, which is a characteristic finding in uremia.[35,36] Studies in red blood cells taken from uremic patients show diminished activity of the pump, which can be reversed when cells are incubated in normal plasma. Pump activity has also been shown to improve following dialysis.[35,37–39] On the other hand, red blood cells taken from normal individuals and incubated in uremic plasma acquire the defect.

Studies in skeletal muscle from uremic patients show decreased K^+ concentration, increased Na^+ concentration, and decreased resting membrane potential.[40] After 7 weeks of hemodialysis, these physiologic parameters can be restored to normal, suggesting the presence of a circulating inhibitor of the Na^+-K^+-ATPase in some uremic patients.[41] In other patients, there may be a decrease in the number of pump sites rather than decreased activity. Decreased pump activity or decreased number of pumps may account for the impaired extrarenal K^+ disposal reported in some uremic patients.

Plasma norepinephrine and epinephrine concentrations as well as sympathetic nerve activity (at least to the leg muscles) are increased in patients with advanced CKD compared to normal controls.[42,43] In addition the metabolic clearance rate of insulin falls with loss of renal function.[44] The increase in circulating insulin and catecholamine levels may serve to attenuate uremia-induced alterations in cell function, which normally are responsible for sequestering K^+ in the intracellular compartment.[45]

By the time patients reach ESRD extrarenal K^+ homeostasis becomes more overtly impaired.[46] Fernandez et al. compared the disposition of an oral K^+ load (0.25 mEq/kg/body weight) in a group of dialysis patients and in normal controls.[47] The normal controls excreted 67% of the K^+ load within 3 hours and translocated 51% of the retained K^+ intracellularly. In contrast, the dialysis patients did not excrete any of the K^+ and only 21% of the retained K^+ was translocated intracellularly. The increment in plasma K^+ was significantly different between the two groups. The plasma K^+ concentration increased by 1.06 mEq/L in the dialysis patients, whereas only a 0.39-mEq/L increase was noted in the control group. The impairment in K^+ disposal persists even when the K^+ load is accompanied by oral glucose, although glucose-induced stimulation of insulin attenuates the maximal rise in S[K] levels.

GASTROINTESTINAL EXCRETION OF K^+ IN CKD

In patients with renal failure, a significant proportion of daily K^+ excretion occurs *via* the gastrointestinal tract. Gastrointestinal losses are important in maintaining K^+ balance in chronic dialysis patients because hemodialysis removes approximately 80−100 mEq/treatment (300 mEq/week) yet dietary K^+ intake is usually 400−500 mEq/week. In a balance study performed in patients treated with peritoneal dialysis, 25% of the daily K^+ intake was lost in the feces.[48,49] The amount of K^+ excreted in the stools correlates directly with the wet stool weight. Therefore, constipation should be avoided because it will decrease the gastrointestinal elimination of K^+ and increase the tendency toward hyperkalemia.

The mechanism of increased gastrointestinal K^+ loss is not known. The process appears to be due to active secretion, as it is unrelated to plasma K^+ or total body K^+.[50,51] Hemodialysis patients continue to have enhanced rectal K^+ secretion even after dialysis with their plasma K^+ being less than that of controls. Potassium transport in the large intestine was recently studied in ESRD patients using a rectal dialysis technique.[52] Rectal K^+ secretion was found to be threefold greater in ESRD patients compared to control patients with normal renal function. When barium (a K^+ channel inhibitor) was placed in the lumen, colonic K^+ secretion was reduced by 45% in the ESRD patients, whereas no effect was seen in the control group. Immunostaining using an antibody directed to the α-subunit of the high conductance K^+ channel protein revealed greater expression of the channel in surface colonocytes and crypt cells in the ESRD patients, whereas only a low level of expression was observed in the control group. These data are consistent with increased expression of K^+ channels as the mechanism for the adaptive increase in colonic K^+ secretion in ESRD patients.

Elevated levels of plasma aldosterone may play a role in stimulating the gastrointestinal excretion and cellular uptake of potassium in ESRD patients. Exogenous administration of mineralocorticoids decreases S[K] in anuric dialysis patients, presumably by increasing colonic potassium excretion.[53] In a prospective study, fludrocortisone administered at 0.1 mg/day was compared with no treatment in 21 hyperkalemic hemodialysis patients.[54] At the end of 10 months, the S[K] in the two groups was not statistically different. However, there was a decrease in S[K] compared with pretreatment values in patients who received the drug.

A recent study examined the effects of glycyrrhetinic acid food supplementation on the S[K] in a group of maintenance hemodialysis patients.[55] This substance inhibits the enzyme 11β-hydroxysteroid dehydrogenase II, which is found not only in the principal cells of the renal collecting duct but also epithelial cells in the colon. This enzyme converts cortisol to cortisone, thereby ensuring the mineralocorticoid receptor remains free to only interact with aldosterone, because cortisone has no affinity for the receptor. In 9 of 10 patients given the supplement there was a persistent decrease in measured predialysis S[K]. In addition, treatment with the supplement significantly decreased the frequency of severe hyperkalemia. These beneficial effects occurred without weight gain or increases in systemic blood pressure suggesting glycyrrhetinic acid supplementation may be of benefit in enhancing colonic K^+ secretion and minimizing the risk of hyperkalemia in dialysis patients.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers (ARBs) have both been reported to cause hyperkalemia in patients treated with hemodialysis and peritoneal dialysis.[56,57] The development of hyperkalemia with these drugs may be due to decreased colonic K^+ excretion resulting from lower circulating levels of aldosterone or decreased activity of angiotensin II. Enhanced colonic K^+ excretion in renal failure has been attributed to upregulation of angiotensin II receptors in the colon, suggesting that angiotensin II has a direct effect in stimulating colonic K^+ excretion.[58] Blocking the mineralocorticoid receptor with spironolactone given at a dose of 25 mg/day does not raise S[K] in hemodialysis patients.[59]

APPROACH TO THE HYPERKALEMIC PATIENT WITH CKD

Pseudohyperkalemia is an *in vitro* phenomenon due to the mechanical release of K^+ from cells during phlebotomy or specimen processing. This diagnosis is

made when the S[K] exceeds the plasma K^+ concentration by >0.5 mmol/L. Common causes of pseudohyperkalemia include fist clenching during phlebotomy, application of tourniquets, and use of small-bore needles. Pathologic causes of pseudohyperkalemia are mostly seen in the setting of hematologic disorders such as thrombocytosis and pronounced leukocytosis. The incidence of pseudohyperkalemia increases during the winter, when samples are likely to be exposed to lower ambient temperatures during transport. Higher ambient temperatures decrease the frequency of this complication. A spurious increase in plasma K^+ concentration should be considered when accompanied by a very low plasma Ca^{++} concentration. *In vitro* contamination with potassium ethylenediaminetetraacetic acid (K-EDTA), a liquid used as an anticoagulant in certain sampling tubes, can cause this problem through Ca^{++} chelation and simultaneous release of K^+.

After excluding pseudohyperkalemia, one must consider increased dietary intake of K^+ as the underlying cause of hyperkalemia. Dietary sources particularly enriched with K^+ include melons, citrus juice, and salt substitutes. Other hidden sources of K^+ reported to cause life threatening hyperkalemia include raw coconut juice (K^+ concentration of 44.3 mmol/L) and Noni juice (56 mEq/L). Although clay ingestion can cause hypokalemia due to binding in the gastrointestinal tract, river bed clay is K^+ enriched (100 mEq K^+ in 100 g clay) and can cause life-threatening hyperkalemia in CKD patients. Ingestion of burnt match heads (cautopyreiophagia) can also be a hidden source of K^+. This activity was found to add an additional 80 mmol of K^+ to one dialysis patient's daily intake and produced a plasma K^+ concentration of 8 mmol/L.

In the absence of pseudohyperkalemia or increased dietary K^+ intake, development of hyperkalemia in a previously stable CKD patient can be traced to one or more of three abnormalities: a primary decrease in distal delivery of salt and water, a primary decrease in mineralocorticoid levels, or an abnormal cortical collecting duct.[60]

Decreased Distal Delivery of Sodium

Mild to moderate reductions in renal perfusion do not typically cause distal delivery of Na^+ to fall to a level that impairs K^+ secretion sufficiently to result in clinically significant hyperkalemia. In untreated congestive heart failure S[K] is typically normal or high normal despite the reduction in distal Na^+ delivery as long as the impairment in cardiac function and renal perfusion is not severe. When such patients are treated with ACE inhibitors or ARBs, the fall in circulating aldosterone concentration will typically be counterbalanced by increased distal Na^+ delivery, so S[K] remains stable. The increase in distal Na^+ is due to the afterload-reducing effects of these drugs, causing an improvement in cardiac output and renal perfusion.

When renal perfusion becomes more severely reduced, as in intractable congestive heart failure, proximal reabsorption can become so intense that very little Na^+ escapes into the distal nephron. Lack of Na^+ availability can begin to impair renal K^+ secretion, particularly in the setting of CKD, where baseline aldosterone levels are often reduced and the capacity for increased production is limited.

Elderly patients are prone to intravascular volume depletion due to poor intake and impaired renal Na^+ conservation. The resultant decrease in distal Na^+ delivery put these patients at risk for hyperkalemia, because age is also associated with impaired release of renin and aldosterone in response to volume depletion.[61] This risk increases further with concurrent use of renin–angiotensin–aldosterone blockers.

Primary Decrease in Mineralocorticoid Activity

Decreased mineralocorticoid activity can result from disturbances that originate at any point along the RAAS. Such disturbances can be the result of a disease state or be due to effects of various drugs (Figure 40.3).

Hyporeninemic hypoaldosteronism is a common feature in CKD patients with a GFR of 20–60 mL/min, particularly in the setting of diabetes mellitus or interstitial renal disease. Hypoaldosteronism is primarily the result of reduced plasma renin and angiotensin II activity. In some patients plasma renin activity is normal, but the secretory response of aldosterone is blunted in response to angiotensin II infusion, suggesting an intra-adrenal defect.[62] In diabetic animals the impaired response of the zona glomerulosa cells to angiotensin II is caused by a postreceptor defect, specific to angiotensin II, because the aldosterone secretory response to ACTH is not diminished.[63]

In patients with normal renal function, hypoaldosteronism alone may not be sufficient to cause marked hyperkalemia, because any rise in S[K] will have a direct effect to enhance distal tubular K^+ secretion. This direct effect is diminished in the setting of CKD, suggesting hypoaldosteronism and decrease in renal function have synergistic effects in impairing renal tubular K^+ secretion.

Several factors have been proposed to cause both the renal and adrenal functional changes. These include a defect in prostaglandin production and/or the presence of volume expansion. Prostaglandins normally stimulate renin secretion by the juxtaglomerular cells in the kidney and facilitate the stimulatory effect of angiotensin II on aldosterone release in the adrenal gland.[64] Volume expansion promotes the release of atrial

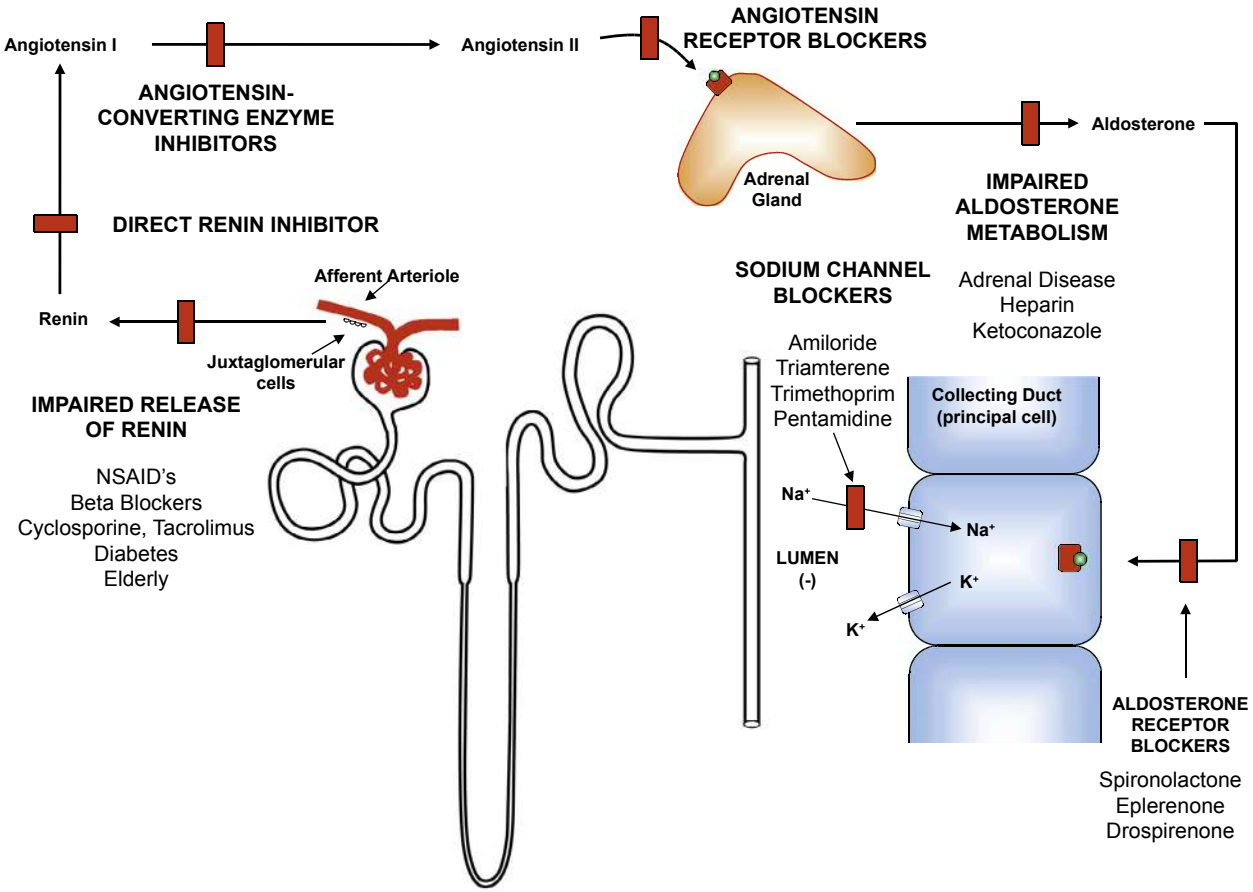

FIGURE 40.3 The renin–angiotensin–aldosterone system and regulation of renal K^+ excretion. Aldosterone binds to a cytosolic receptor in the principal cell and stimulates Na^+ reabsorption across the luminal membrane through a well-defined Na^+ channel. As Na^+ is reabsorbed the electronegativity of the lumen increases, thereby providing a more favorable driving force for K^+ secretion through an apically located K^+ channel. The permeability of the anion that accompanies Na^+ also influences K^+ secretion, with less permeable anions having a greater stimulatory effect on K^+ secretion. Disease states or drugs that interfere at any point along this system can impair renal K^+ secretion and increase the risk of hyperkalemia. In many patients this risk is magnified due to disturbances at multiple sites along this system.

natriuretic peptide, which in turn suppresses both renin secretion and aldosterone release.[65]

The ACE inhibitors and ARBs impair urinary potassium excretion by interfering with the stimulatory effect of angiotensin II on aldosterone secretion in the adrenal gland. The development of hyperkalemia is usually seen when mineralocorticoid levels are already decreased prior to the administration of the drugs, either as a result of a disease state or due to effects of other drugs (Table 40.2).

Hyperkalemia has been reported to develop in 44–73% of transplant patients treated with the immunosuppressive drugs cyclosporine or tacrolimus.[66] These drugs suppress renin release and directly interfere with renal K^+ secretion in the collecting duct.[67] Beta adrenergic blockade can predispose to the development of hyperkalemia through two potential mechanisms.[68] These drugs block the stimulatory effect of the sympathetic nervous system on renin release. In addition, these drugs can interfere with the cellular uptake of K^+ through decreased activity of Na^+–K^+-ATPase.[69]

DISTAL TUBULAR DEFECT

Certain interstitial renal diseases can affect the distal nephron specifically and lead to the development of hyperkalemia in the presence of only mild decreases in GFR and normal aldosterone levels. Amiloride and triamterene inhibit Na^+ transport, which makes the luminal potential more positive and secondarily inhibits K^+ secretion. A similar effect occurs with trimethoprim and accounts for the development of hyperkalemia following the administration of the antibiotic trimethoprim–sulfamethoxazole.[70] Spironolactone and eplerenone compete with aldosterone and thus block the mineralocorticoid effect.

TABLE 40.2 Risk Factors for Hyperkalemia

- Chronic kidney disease: risk is inversely related to GFR and increases substantially below an eGFR of 30 mL/min/1.73 m^2
- Diabetes mellitus*
- Decompensated congestive heart failure
- Medications
  - Inhibition of renin release from juxtaglomerular cells
    - Nonsteroidal anti-inflammatory drugs
    - Beta blockers
    - Calcineurin inhibitors: Cyclosporine, Tacrolimus
  - Inhibition of aldosterone release from the adrenal gland
    - Heparin
    - Ketoconazole
  - Mineralocorticoid receptor blockade
    - Spironolactone
    - Eplerenone
  - Blockade of epithelial sodium channel blocker in renal collecting duct
    - Amiloride
    - Triamterene
    - Trimethoprim
- K^+ supplements, salt substitutes, certain herbs, and K^+-enriched foods in setting of impaired renal excretion

**A spectrum of abnormalities in the renin–angiotensin–aldosterone system has been described in patients with diabetes mellitus, including hyporeninemic hypoaldosteronism as well as normal renin release but a diminished capacity to release aldosterone. Hypoaldosteronism combined with dysfunction of collecting ducts due to diabetic nephropathy and treatment with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers put CKD patients at particularly high risk for hyperkalemia.* GFR, *glomerular filtration rate.*

TREATMENT OF HYPERKALEMIA IN THE CKD PATIENT

The initial approach is to review the patient's medication profile and whenever possible discontinue drugs that can impair renal K^+ excretion. Patients should be specifically questioned regarding the use of over-the-counter nonsteroidal anti-inflammatory drugs, as well as herbal remedies, because herbs may be a hidden source of dietary potassium. Patients should be placed on a low K^+ diet, with specific counseling against the use of K^+-containing salt substitutes. Diuretics are particularly effective in minimizing hyperkalemia. Diuretics enhance renal K^+ excretion by increasing the delivery of Na^+ to the collecting duct. In patients with a GFR greater than 30 mL/min, thiazide diuretics can be used. With more severe renal insufficiency loop diuretics are required.

In patients with CKD and metabolic acidosis, administration of sodium bicarbonate is an effective strategy to minimize increases in S[K]. Sodium bicarbonate increases renal K^+ excretion as a result of increased distal Na^+ delivery and will shift K^+ into cells as the acidosis is corrected. Ensuring that the patient is first on effective diuretic therapy will lessen the likelihood of developing volume overload as a complication of sodium bicarbonate administration.

The development of hyperkalemia after the administration of renin–angiotensin blockers is of particular concern because patients at highest risk for this complication are often the same ones who derive the greatest cardiovascular benefit. It is now commonplace to treat hypertension and decrease cardiovascular events in high-risk patients by using ACEIs and ARBs. After publication of the Randomized Aldactone Evaluation Study trial, which demonstrated a mortality benefit when an ACEI was added to an ARB, rates of hospitalization for hyperkalemia increased significantly, from 2.4/1000 patients in 1994 to 11.0/1000 patients in 2001.[71] Additionally, mortality related to hyperkalemia increased from 0.3 deaths/1000 patients to 2.0 deaths/1000 patients. This surge in hyperkalemia and its associated complications is in contrast to the relatively low rate of hyperkalemia of 2% noted in the trial, likely due to enrollment of patients at low risk for this complication. Additionally, study subjects had their laboratory values closely monitored, as well as were restricted from taking other drugs known to cause hyperkalemia. Given the positive findings obtained from the trial, physicians increased the number of prescriptions written for spironolactone. Unfortunately, similar precautions with respect to patient selection and monitoring were not employed in more general clinical settings.

Hyperkalemia resulting from RAAS blockers can pose a therapeutic dilemma because current guidelines for patients with CKD, heart failure, and hypertension recommend treatment with RAAS inhibitors, yet the risk of hyperkalemia often leads to modifications in dosing or even discontinuation of these effective medications.[1,3,72,73] For example, the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative guidelines actually advocates use of ACEIs and ARBs at moderate to high doses because of their efficacy.[4] Despite these recommendations, most patients with CKD stage 3–4, heart failure, or diabetes mellitus are not receiving maximum/effective doses of RAAS inhibitors, due to the potential risk of hyperkalemia. In fact, data from a large retrospective analysis of a claims database in the US found that 62% of patients with at least one of these conditions received a lower than recommended dose of the RAAS inhibitor. Only 22% were receiving the recommended dose, and 15% had actually discontinued the medication.[9] The study found that those subjects receiving the labeled doses had their medication either down titrated or discontinued in 38% of cases, when the S[K] was 5.1–5.4 mEq/L. In 47% of cases the medications were modified when the S[K] was ≥5.5 mEq/L. Notably, adverse cardiorenal outcomes increased with RAAS inhibitor dose reduction or discontinuation, particularly in the cohorts with CKD and heart failure.[9] A similar adverse effect on outcomes

was observed in a cohort of 295 mostly elderly hospitalized heart failure patients with CKD.[74] One or more perceived contraindications to ACEI therapy was present in 52 of the patients. The cumulative 4-year survival in this subgroup of patients who did not receive therapy with ACEIs was only 3%. By contrast, when such patients were discharged on ACEIs, the cumulative survival increased sixfold from 3% to 19%. These findings are particularly important because more than 50% of patients with congestive heart failure have some level of CKD, which is among the strongest predictors of death in patients with underlying heart disease. In summary, optimizing the therapeutic dosage of RAAS inhibitors is critical to achieve the greatest cardiovascular benefit, but difficult to achieve due to the potential risk of hyperkalemia.

There are strategies the clinician should use to optimize RAAS blockers in patients at risk (Table 40.3). The initial approach is to better define the risk of hyperkalemia by accurately assessing the level of renal function. In general, this risk will increase as renal function declines. An eGFR of 30 mL/min/1.73 m^2 should be considered a threshold at which the likelihood of developing hyperkalemia substantially increases.[75] The clinician should review the patient's medication profile, and whenever possible discontinue drugs that can impair renal K^+ excretion. Use of over-the-counter nonsteroidal anti-inflammatory drugs is a common cause of hyperkalemia in this setting. Patients should be educated on sources of K^+ in the diet and should be strongly encouraged to avoid the use of K^+-containing salt substitutes, as well as herbal remedies, because herbs may be a hidden source of dietary K^+. Correction of metabolic acidosis in patients with CKD is an effective strategy to minimize the potential for developing hyperkalemia.[60] Ensuring the patient is first on effective diuretic therapy will lessen the likelihood of developing volume overload, although $NaHCO_3$ administration causes less sodium retention compared to NaCl in CKD patients.[76]

The level of renal function should not be the *sole* determinant regarding whether RAAS inhibitors should be initiated or continued. Withholding these drugs simply based on the level of renal function will unnecessarily deprive many patients of the cardiovascular benefit they would have otherwise received, particularly because numerous steps can be taken to minimize the risk of hyperkalemia. The successful implementation of these steps was demonstrated in a randomized, double blind study of 224 patients with S[Cr] of 3.1–5.0 mg/dL.[77] Administration of 20 mg/day of benazepril reduced the composite endpoint of doubling of the S[Cr], ESRD, or death compared to placebo. During the 3-year study, hyperkalemia (defined as a S[K] >6.0 mmol/L) developed in six patients treated with benazepril and five receiving placebo, resulting in only three withdrawn from the study. Hyperkalemia in the remaining eight patients was successfully treated with dietary modifications, diuretic therapy, and optimization of acid–base balance.

Close monitoring is required but not always implemented when prescribing drugs that interfere with the RAAS. In a retrospective cohort study conducted in 10 health maintenance organizations, the frequency of S[K] and S[Cr] monitoring was assessed in patients labeled as being treated with ACEIs or ARBs for at least 1 year.[78] More than two-thirds of the 52,906 patients were identified received laboratory monitoring. The likelihood of monitoring increased with advancing age, more frequent outpatient visits, recent hospitalizations, concomitant use of drugs such as potassium salts, diuretics, and digoxin, and comorbidities such as diabetes, congestive heart failure, and CKD. Of concern, nearly one-third of patients prescribed these drugs had no laboratory monitoring over a 1-year period.

Even the discovery of hyperkalemia during laboratory testing does not guarantee appropriate follow-up. In a retrospective observational cohort study of a large primary care practice, 109 instances of hyperkalemia (defined as S[K] >5.8 mEq/L) were identified in 86 patients.[79] Although more than half of the patients were recalled to the clinic for retesting, 25% of the cases had no repeat testing until they were seen on routine follow-up visits or when they came to the clinic for unrelated issues.

TABLE 40.3 Approach to Patients at Risk for Developing Hyperkalemia When Using Drugs That Interfere with the Renin-Angiotensin-Aldosterone System

- Accurately assess level of renal function to better define risk
- Discontinue drugs that interfere with renal K^+ secretion, inquire about herbal preparations, and discontinue nonsteroidal anti-inflammatory drugs, including the selective cyclooxygenase 2 inhibitors
- Low K^+ diet, inquire about K^+-containing salt substitutes
- Thiazide or loop diuretics (loop diuretics necessary when eGFR <30 mL/min/1.73 m^2)
- Sodium bicarbonate to correct metabolic acidosis in CKD patients
- Initiate therapy with low dose ACEI or angiotensin receptor blocker
  - Measure K^+ one week after initiation of therapy or after increasing dose of drug
  - For increases in S[K] up to 5.5 mEq/L, decrease dose of drug. If taking some combination of ACEI, angiotensin receptor blocker, and aldosterone receptor blocker discontinue one and recheck S[K]
  - The dose of spironolactone should not exceed 25 mg daily when used with an ACEI or angiotensin receptor blocker. This combination of drugs should be avoided with GFR <30 mL/min
  - For S[K] ≥5.6 mEq/L despite above steps, consider K^+ binding drug such as patiromer or ZS-9 before discontinuing RAAS blocker

ACEI, angiotensin-converting enzyme inhibitor; *GFR*, glomerular filtration rate; *RAAS*, renin–angiotensin aldosterone system.

The lack of appropriate follow-up is of particular concern because the electrocardiogram in a hyperkalemic patient can precipitously progress from normal to ventricular tachycardia and asystole. Most physicians are familiar with the findings of peaked T waves and the sine wave pattern that typify hyperkalemia. Profound bradycardia is a less well-appreciated manifestation of hyperkalemia. Particular attention should be given to patients with underlying disturbances of cardiac conduction because even mild degrees of hyperkalemia may precipitate heart block.

Once the decision has been made to initiate an ACEI or an ARB in a high-risk patient, one should begin with low doses and recheck S[K] within one week of starting the drug (Table 40.3). If S[K] is normal, then the dose of the drug can be titrated upwards, rechecking S[K] within one week following an increase in dosage. If S[K] rises to 5.5 mEq/L, in some cases, lowering the dose will reduce S[K] and allow the patient to remain on the RAAS blocker at a lower dose. In patients receiving some combination of an ACEI, ARB, and an aldosterone receptor blocker, discontinuation of one drug or the other may also be effective in lowering S[K]. In patients at risk for hyperkalemia, ARBs and direct renin inhibitors should be used with the same caution as ACEIs. When S[K] is greater than or equal to 5.6 mEq/L, despite following the above precautions, one can consider the use of a K^+ binding drug before making the decision to avoid the use of RAAS blockers.

POTASSIUM BINDING THERAPY

Pharmacological management of hyperkalemia has relied for over 50 years on chronic use of sodium-polystyrene sulfonate (Kayexalate), which binds K^+ in the gastrointestinal tract. This binder, however, is poorly tolerated and has been linked to gastrointestinal toxicity. Moreover, long-term administration is linked to serious side effects, such as rare cases of intestinal necrosis, resulting in a black-box warning by the Food and Drug Administration.[80] In addition, the ability of this drug to lower S[K] over and above the effect of increased stool volume brought about by the coadministration of sorbitol is minimal.[81] The efficacy of sodium-polystyrene sulfonate for the chronic treatment of hyperkalemia has not been well studied, and the drug is not formally approved for this indication. The drug was found to be superior to placebo in a 7-day study of mild hyperkalemia in outpatients with CKD.[82] Volume overload is a concern because use of sodium-polystyrene sulfonate exchanges sodium for potassium. There are new oral compounds, patiromer, and sodium zirconium cyclosilicate (ZS-9), which are K^+-binding drugs shown to be effective in preventing the development of hyperkalemia. Patiromer, and more recently, ZS-9, have been approved for clinical use. Both are indicated for the treatment of hyperkalemia. The use of these agents for emergent treatment of hyperkalemia has not been well studied.

Patiromer is a nonabsorbed free-flowing powder of small, spherical beads (~100 μm in diameter) that bind K^+ in the gastrointestinal lumen, thereby reducing luminal concentrations of free K^+ and increasing fecal excretion. Due to the use of calcium as the exchange ion, there were initial concerns that patiromer might increase calcium levels. A phase 1 study of healthy adult volunteers, however, indicated that only a small fraction of the calcium is available for absorption, whereas the remaining calcium is excreted through the gastrointestinal tract still bound to patiromer.[83] Calcium may form complexes with anions such as phosphate in the gastrointestinal lumen, accounting for the ability of the drug to modestly lower S[P] levels.[84] Patiromer effectively decreases S[K] in high-risk patients on RAAS blockers, including those with heart failure, CKD, and diabetic nephropathy.[85,86] In a study of over 300 patients with diabetic nephropathy with either mild to moderate hyperkalemia, patiromer lowered S[K] in a dose-dependent manner, with the greatest reduction in those with higher starting values. The drug remained effective in controlling plasma K^+ concentration over a 44-week maintenance phase despite ongoing administration of RAAS inhibitors. The drug was well tolerated, with the main adverse events being constipation (infrequent and self-limiting) and hypomagnesemia, which required magnesium replacement in a small number of subjects.

ZS-9 is a nonabsorbed microporous compound that binds K^+ throughout the gastrointestinal tract. The pore size renders it highly selective for K^+, compared to calcium or magnesium ions. The drug is effective in lowering plasma K^+ concentration in a dose-dependent manner, with the greater reductions in those with the highest levels.[87,88] The randomized, controlled, phase 3 Hyperkalemia Randomized Intervention Multidose ZS-9 Maintenance (HARMONIZE) trial, evaluated the safety and efficacy of ZS-9 in outpatients with hyperkalemia (S[K] $\geq$5.1 mEq/L). A total of 258 patients received ZS-9 at 10 g TID during an initial 48-h, open-label phase. The 237 patients achieving normokalemia (S[K] 3.5–5.0 mEq/L) were randomized to maintenance with ZS-9 at doses of 5, 10, or 15 g QD or placebo for 28 days. During the initial open-label phase, mean S[K] levels fell from 5.6 mEq/L at baseline to 4.5 mEq/L at 48 hours. During maintenance, S[K] remained significantly lower in all ZS-9 groups compared with the placebo group ($p < 0.001$). The early onset of action with ZS-9 is notable and has been observed consistently across clinical studies. Adverse event rates, including

events in the gastrointestinal tract, were generally comparable between ZS-9 and placebo. The compound does release sodium. This can be a concern when used in patients in heart failure, where edema and volume overload can become a clinical issue. Edema occurred more frequently with the 10-g and 15-g doses than with placebo, with most cases of edema reported in heart failure patients.[89] In comparison, evidence of increased edema was not seen in another phase 3 study in which ZS-9 was administered at doses ranging from 1.25 to 10 g TID during the first 48 hours and then QD during maintenance for 12 days.[88]

The ability of these drugs to allow ongoing use of RAAS blockers in patients with a history of hyperkalemia suggests these agents could prove useful in allowing patients at risk for hyperkalemia to liberalize their diets to be enriched in fruits and vegetables. It is important to note, however, that none of the trials so far have specifically tested dietary liberalization in patients with CKD. This would be an important area to explore, because dietary liberalization would improve the quality of life in patients at risk who are subjected to significant restrictions on foods that may ultimately benefit them.[90]

SUMMARY

Adaptive increases in renal and gastrointestinal excretion of K^+ help prevent hyperkalemia in patients with CKD as long as the GFR remains >15–20 mL/min. Once the GFR falls below these values, the impact of factors known to adversely affect K^+ homeostasis is significantly magnified. Impaired renal K^+ excretion can be the result of conditions that severely limit distal Na^+ delivery, decreased mineralocorticoid levels or activity, or a distal tubular defect. In clinical practice hyperkalemia is usually the result of a combination of factors, including administration of medications that interfere with normal K^+ handling, superimposed on renal dysfunction.

QUESTIONS AND ANSWERS

Question 1

A 23-year-old man is evaluated because of increasing dyspnea. He has HIV infection. During his most recent clinic visit 2 months ago he was found to have a CD4 count of 210 cells/μL and a HIV RNA level of 14,000 copies/mL. Highly active retroviral therapy was started at that time. He now presents with shortness of breath and a chest radiograph showing bilateral infiltrates. His BP on admission to the hospital is 120/76 mm Hg. Labs on admission show (mmol/L): Na 131, K 4.8, Cl 95, HCO_3 22, BUN 20 mg/dL, S[Cr] 1.3 mg/dL. Further evaluation leads to a diagnosis of pneumocystis carinii pneumonia. Due to a history of allergy to sulfa-containing drugs he is treated with pentamidine and continued on his antiretroviral therapy. Laboratory examination 1 week later shows (mmol/L): Na 132, K 6.2, Cl 100, HCO_3 18, BUN 21 mg/dL, S[Cr] 1.4 mg/dL. The urinalysis is normal.

Which ONE of the following is the most likely cause of the increased S[K] in this patient?

A. Rhabdomyolysis due to antiretroviral therapy—induced muscle toxicity
B. Cell shift due to development of antiretroviral therapy—induced lactic acidosis
C. Blockade of distal renal tubule potassium excretion due to pentamidine
D. Development of proximal RTA as a result antiretroviral therapy
E. Addison's disease due to adrenal HIV infection

Answer: C

Pentamidine in the tubular lumen of the collecting duct competes for Na movement on the epithelial Na channel. The decrease in Na reabsorption decreases luminal electronegativity, thus decreasing the driving force for potassium secretion. Although rhabdomyolysis (Choice A) can be a cause of hyperkalemia, there is no other evidence of this disorder. In particular the S[Cr] is unchanged and there is no mention of dipstick positive blood in the absence of red blood cells to indicate the excretion of myoglobin in the urine. Lactic acidosis (Choice B) can be associated with hyperkalemia due to leakage of K out of cells as a result of cell death or ischemia. The absence of an increased anion gap excludes this disorder. Highly active antiretroviral therapy (Choice D) can be associated with the development of proximal renal tubular acidosis. However, proximal RTA gives rise to hypokalemia. Adrenal insufficiency (Choice E) can occur in HIV-infected patients due to a variety of causes, often infectious in origin, such as cytomegalovirus-induced adrenalitis. The short time course in this case is inconsistent with this diagnosis. In addition, hyperkalemia due to adrenal insufficiency would be accompanied by other findings such as a normal gap metabolic acidosis, hyponatremia, and evidence of renal salt wasting.[75,91,92]

Question 2

A 67-year-old man with stage 3 CKD secondary to diabetic nephropathy underwent coronary artery bypass graft due to three-vessel coronary artery disease. The anesthetic regimen consisted of high-dose sufentanil and midazolum. Succinylcholine was used for muscular relaxation. Standard depolarization cardioplegia was used. Surgery was performed using nonpulsatile cardiopulmonary bypass under moderate hypothermia. Intravenous epsilon-aminocaproic acid (EACA) was given to decrease perioperative bleeding. Two units of packed red blood cells and 1200 mL of D5NS were given intraoperatively. During the final 30 minutes of the procedure peaked T waves were noted on the monitor. The S[K] was found to be 6.7 mmol/L.

Which ONE of the following is not in the differential diagnosis of the hyperkalemia that developed in this patient?

A. A potassium load from the cardioplegia solution used to stop the beating of the heart
B. Cell depolarization induced by succinylcholine leading to a K shift out of intracellular compartment
C. K shift out of intracellular compartment due to administration of EACA
D. K shift out of intracellular compartment due to hypothermia
E. Hemolysis due to a transfusion reaction

Answer: D

Hypothermia is associated with hypokalemia due to a shift of potassium into the intracellular fluid compartment. All of the other choices are potential causes of hyperkalemia in the case presented. Cardioplegia solutions (Choice A) are used to arrest the heart in bypass operations and are potassium enriched. Succinylcholine (Choice B) is a muscle relaxant used in the induction of anesthesia. In susceptible individuals the drug causes hyperkalemia due to widespread cell membrane depolarization. EACA (Choice C) is an antifibrinolytic agent used to stop bleeding. This agent is structurally similar to the cationic amino acids lysine and arginine. The cellular uptake of EACA in a manner similar to the effect of cationic amino acids leads to the efflux of K from the intracellular fluid space. A hemolytic reaction in association with blood transfusion (Choice E) during the operative procedure would be in the differential diagnosis of hyperkalemia.[93–96]

Question 3

A 38-year-old woman with ESRD due to diabetes is taken to the operating room for incision and drainage of a perirectal abscess. Meds: metoprolol 50 mg twice daily. VS: T 37.8 C, P 94, RR 18, BP 140/84 mm Hg. Labs: (mmol/L) Na 138, K 5.1, RR 103, HCO3 21, S[Cr] 9.4 mg/dL, BUN 65 mg/dL. She was last dialyzed one day prior to admission. In the operating room the BP drops to 90/60 mm Hg. A neosynephrine drip (phenylephrine) made up in a D5W-containing solution is started and continued throughout the procedure with stabilization of BP. In the recovery room profound weakness is noted preventing extubation of the patient. Repeat electrolyte measurements show a S[K] of 6.6 mmol/L.

Which ONE of the following is the most likely explanation for the development of hyperkalemia during the operative procedure?

A. Beta adrenergic stimulation leading to K efflux from the intracellular compartment
B. Alpha adrenergic stimulation leading to K efflux from the intracellular compartment
C. Metoprolol-induced suppression of renin leading to hypoaldosteronsim
D. Insulin resistance leading to impaired insulin mediated K uptake into the intracellular compartment
E. Rhabdomyolysis as a complication of malignant hyperthermia

Answer: B

Phenylephrine is an alpha adrenergic receptor agonist used to support blood pressure. Alpha adrenergic stimulation leads to K^+ efflux from the intracellular to extracellular fluid space. It is likely that the risk for hyperkalemia was further increased due to K^+ release from injured tissue during the abscess drainage procedure in a patient with limited renal function. Beta adrenergic stimulation (Choice A) causes hypokalemia by shifting K^+ into the intracellular fluid space. Beta receptor blockade (Choice C) can suppress renin and potentially cause hypoaldosteronism, but impairment of renal K^+ secretion through this mechanism would not be an issue in a dialysis patient. Insulin resistance (Choice D) is often present as a complication of uremia, but would not explain the acute development of hyperkalemia in this patient. Malignant hyperthermia (Choice E) can cause hyperkalemia as a result of rhabdomyolysis, but the absence of fever makes this diagnosis unlikely.[97,98]

Question 4

A 38-year-old woman with a strong family history of cardiovascular diseases and hypertension is recently diagnosed with essential hypertension. Her blood pressure on three separate measurements averaged 154/94 mm Hg. Current medications include a daily multivitamin and birth control pills. The physical examination and laboratory examination are normal. Because the patient was using birth control pills, her primary care physician was comfortable prescribing lisinopril 10 mg daily. One month later the patient returns for follow-up. Blood pressure is 142/88 mm Hg. Laboratory examination shows (mmol/L) Na 140, K 5.5, Cl 100, HCO_3 22, S[Cr] 0.8 mg/dL, BUN 10 mg/dL. The physician refers the patient to a nephrologist for evaluation of hyperkalemia.

Which ONE of the following is the MOST likely risk factor for the development of hyperkalemia after prescribing an ACEI in this patient?

A. High-grade bilateral renal artery stenosis
B. Underlying pseudohypoaldosteronism type II
C. Acquired adrenal insufficiency
D. Mineralocorticoid-blocking activity in birth control pill
E. Daily ingestion of bananas.

Answer: D

The oral contraceptive, Yasmin-28, contains the non–testosterone-derived progestin drospirenone, which possesses mineralocorticoid-blocking effects similar to what is seen with spironolactone. The product labeling recommends K^+ monitoring in the first month after prescribing the drug for those patients who are receiving K^+ supplements, renin–angiotensin blockers, or nonsteroidal anti-inflammatory drugs (NSAIDs). Despite this recommendation, there are many instances where monitoring does not occur or patients are prescribed the contraceptive in the setting of other drugs that either provide a K^+ load or interfere with renal K^+ secretion. There is nothing in the clinical history to suggest the disease states provided in Choices A, B, and C. The K^+ load contained in bananas would be unlikely to cause hyperkalemia in the setting of normal renal function, making Choice E incorrect.[99–101]

Question 5

A 65-yr-old man is referred for evaluation of an increased S[Cr] and hyperkalemia. The patient complains of intermittent abdominal pain over the last month. Medications: lisinopril/hydrochlorothiazide 10/25 mg daily for hypertension treatment for the last 7 years. His past medical history is only significant for a motor vehicle accident 8 months ago in which he suffered a retroperitoneal bleed. Laboratory studies at the time of discharge were normal. Physical examination BP 158/94 mm Hg, P 92 bpm. The remainder of the

examination is only significant for mild periumbilical tenderness. Laboratory examination: WBC 9.0, Hematocrit 32%; Na 138, K 5.9, Cl 108, HCO_3 19 (mmol/L); S[Cr] 2.3 mg/dL, BUN 38 mg/dL. UA: SG 1.010 trace protein, 0−1 RBC, 0−1 WBC. An abdominal sonogram shows normal sized kidneys with slight enlargement of the urinary pelvis on both sides. There is no hydroureter.

Which ONE of the following is the MOST likely cause of the development of hyperkalemia and renal failure in this patient?

A. Pseudohypoaldosteronism type 1
B. Use of over-the-counter NSAID
C. Urinary obstruction
D. Angiotensin-converting enzyme inhibitor therapy
E. Use of the herb Chan Su

Answer: C

This patient presents with renal failure of unclear etiology in the setting of unremarkable urine sediment. Even though the renal sonogram shows no evidence of hydronephrosis, urinary obstruction needs to still be excluded in this setting. The history of a retroperitoneal bleed makes this patient at risk for retroperitoneal fibrosis, which can lead to obstructive uropathy in the absence of hydroureter. Unexplained hyperkalemia in association with a normal gap hyperchloremic metabolic acidosis (type IV renal tubular acidosis) is a common feature of obstructive uropathy. Pseudohypoaldosteronism type I (Choice A) is characterized by salt wasting and hyperkalemia, typically presenting in childhood. It is not a consideration in this case. Use of NSAIDs (Choice B) can be a cause of hyperkalemia, and they can cause AKI, but usually when given to patients with a contracted extracellular fluid volume. The patient was taking an ACEI on a chronic basis and therefore is unlikely to have suddenly developed hyperkalemia, making Choice D incorrect. Chan Su (Choice E) is a herb containing a digoxin-like substance that when ingested in large amounts can be a cause of hyperkalemia. The features of the clinical case make this diagnosis unlikely.[102,103]

Question 6

A 55-year-old man with long-standing diabetes mellitus is referred for evaluation and treatment of diabetic nephropathy. His only medication is celecoxib 200 mg/day for treatment of mild degenerative joint disease. Physical examination is significant for a blood pressure of 146/92 mm Hg and trace pedal edema. Labs show (mmol/L) Na 142, K 5.7, Cl 108, HCO_3 18, S[Cr] 2.0 mg/dL, 4.6 g urinary protein/24 hours. His primary care physician has been reluctant to start either an ACEI or an ARB because of the increased S[K].

Which ONE of the following would be the BEST approach to this patient?

A. Make a note in the chart that this patient should never be treated with ACEI or ARB due to refractory hyperkalemia
B. Discontinue the COX-2 inhibitor and initiate therapy with hydrochlorothiazide
C. Discontinue COX-2 inhibitor
D. Discontinue the COX-2 inhibitor, initiate therapy with a loop diuretic, and add $NaHCO_3$ tablets
E. Start therapy with an angiotensin receptor blocker at schedule routine follow-up

Answer: D

The patient has diabetic nephropathy and would benefit from use of a renin−angiotensin system blocker to slow the progression of renal disease and to provide cardiovascular protection. Choice A is incorrect because several steps can be taken in such a patient to both correct and minimize the development of hyperkalemia, allowing the successful use of these drugs. Choice B is incorrect from the standpoint of using a thiazide diuretic. Thiazides are largely ineffective at an eGFR of <30 mL/min/1.73 m^2. Discontinuation of the COX-2 inhibitor would be of benefit but would not likely lower blood pressure to goal or fully correct the hyperkalemia. Angiotensin-receptor blockers should be used with the same caution as ACEIs in patients at risk for the development of hyperkalemia. Therefore Choice E is incorrect. Discontinuation of the COX-2 inhibitor along with use of a loop diuretic and administration of bicarbonate is the best answer. The loop diuretic will help lower S[K] through its effects on increasing distal Na delivery and flow rates. Loop diuretics will also be of benefit in treating the hypertension. $NaHCO_3$ is also of benefit in minimizing the risk of hyperkalemia by correcting metabolic acidosis. The salt load will not be problematic while being used in the setting of effective diuretic therapy.[75,77]

Calcium, Phosphate, and Magnesium Metabolism in Chronic Kidney Disease

Silvia Ferrè[a,b], *Javier A. Neyra*[a,d], *Orson W. Moe*[a,b,c]

[a]Charles and Jane Pak Center for Mineral Metabolism and Clinical Research, University of Texas Southwestern Medical Center, Dallas, TX, United States; [b]Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX, United States; [c]Department of Physiology, University of Texas Southwestern Medical Center, Dallas, TX, United States; [d]Department of Internal Medicine, Division of Nephrology, Bone and Mineral Metabolism, University of Kentucky, Lexington, KY, United States

Abstract

Disturbances in calcium (Ca^{2+}), phosphate (Pi), and magnesium (Mg^{2+}) homeostasis contribute to Chronic Kidney Disease Mineral and Bone Disorders (CKD-MBD), which encompasses abnormalities in mineral metabolism and bone, extraskeletal calcification, and cardiovascular disease. Although the role of excess Pi is unequivocal in CKD-MBD, the role of Ca^{2+} and Mg^{2+} is less clear. Understanding how Ca^{2+}, Pi, and Mg^{2+} disturbances affect the onset and progression of CKD-MBD is essential to achieving the ultimate goal of developing individualized effective treatments that target different facets of CKD-MBD pathophysiology in each patient. Pi load to the organism can be reduced by dietary modifications, binders, and/or modifiers of intestinal epithelial transport. Ca^{2+} and/or Mg^{2+} supplements (or avoidance) should be prescribed only to those who will benefit based on Ca^{2+} and Mg^{2+} status. Multiple therapies targeting more than one pathophysiologic factor involved in Ca^{2+}, Pi, and Mg^{2+} balance will be required to treat CKD-MBD.

INTRODUCTION

Public Heath Scope

Chronic kidney disease (CKD) is a systemic condition with global public health impact affecting more than 10% of the general population.[1] CKD is characterized by progressive deterioration of renal function with progression to dialysis-dependence, end-stage renal disease (ESRD), or unfortunately very commonly to death. The "CKD phenotype" can be also viewed as a state of accelerating aging.[2] Cardiovascular disease (CVD) is the leading cause of death in patients with CKD, accounting for over 50% of deaths.[3] Unfortunately, there are few specific and effective therapies to retard CKD progression and prevent or ameliorate extrarenal complications, in particular CVD.

Mineral and bone disorders are common in patients with CKD and substantially contribute to the large burden of CVD observed in these patients.[4,5] CKD-Mineral and Bone Disorders (CKD-MBD) is a collective term encompassing a wide range of biochemical and pathological features (Figures 41.1 and 41.2).[6] Phosphate (Pi) assumes a central role in CKD-MBD with less well defined roles for calcium (Ca^{2+}) and magnesium (Mg^{2+}).

New "Players" in CKD Relevant to Mineral Balance

Three new molecules deserve introduction. α-Klotho is highly expressed in the kidney with a membrane-bound form serving as a coreceptor for fibroblast growth factor 23 (FGF-23). α-Klotho is cleaved and released from the kidney into the circulation.[7] CKD is a state of α-Klotho deficiency.[8] Soluble α-Klotho influences multiple cellular and endocrine pathways, protecting against kidney fibrosis and oxidative stress.[9,10] α-Klotho–deficient mice share similar features of CKD-MBD and exhibit more susceptibility and rapid progression of CKD, vascular calcification (VC), bone loss, neurodegeneration, and pathologic cardiac remodeling.[11] Better understanding of the molecular mechanisms of how α-Klotho deficiency dysregulates the CKD-MBD axis is direly needed.

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00041-3

Initially identified from rare genetic and acquired hypophosphatemic disorders, FGF-23 has emerged as a biomarker of morbidity and mortality in CKD patients.[12,13] As α-Klotho levels decline, FGF-23 resistance ensues.[14] The increased morbidity associated with FGF-23 is proposed but not yet proven to be due to its off-target effects, including left ventricular hypertrophy (LVH), inflammation, immune dysfunction, bone loss, and inhibition of erythropoiesis leading to anemia.[15,16]

A divalent cation that has received less attention is Mg^{2+}. Recent studies support that low serum Mg^{2+} concentration S[Mg] is a predictor of all-cause death—in particular CV death—in patients with different strata of CKD.[17] These findings opened new potential avenues of intervention in CKD patients at risk of CVD. Thus far, there are only small short studies suggesting beneficial effects of Mg^{2+} supplementation on surrogate markers of CVD in CKD patients.[18,19]

Although standard therapies targeting the reduction of CVD in CKD patients have mostly focused on traditional risks such as smoking cessation, blood pressure, cholesterol, and glycemic control, CVD remains a major burden in the debilitated CKD population.[6] We are in dire need of novel pathophysiology-based therapeutic strategies against the CKD-MBD–CVD disease complex.

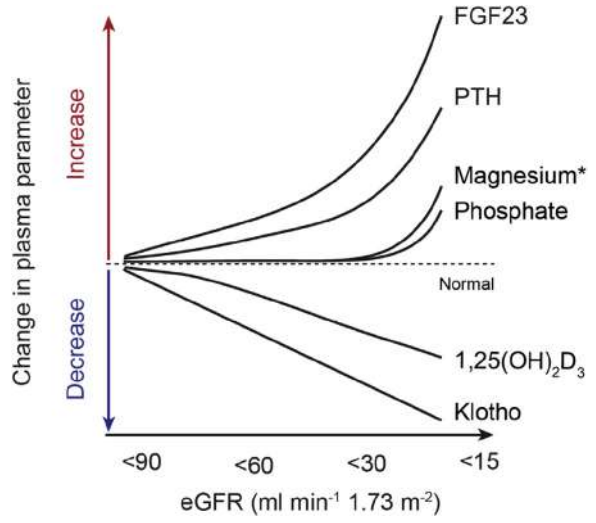

FIGURE 41.1 Proposed model of changes in plasma mineral parameters with different stages of CKD. FGF-23: Fibroblast growth factor 23; PTH: parathyroid hormone; $1,25(OH)_2D_3$: 1,25-dihydroxy-vitamin D_3; eGFR: estimated glomerular filtration rate. *Unlike hyperphosphatemia, hypermagnesemia is seen only in a fraction of patients near ESRD.

PATHOPHYSIOLOGY

Calcium (Ca^{2+}) Homeostasis

Maintenance of body Ca^{2+} homeostasis is important for many physiological functions including intracellular signaling, neuronal excitability, muscle contraction, and bone formation. The body houses 99% of the Ca^{2+} in bone, with 1% in the intracellular and extracellular space. Plasma Ca^{2+} levels (P[Ca]) are maintained within

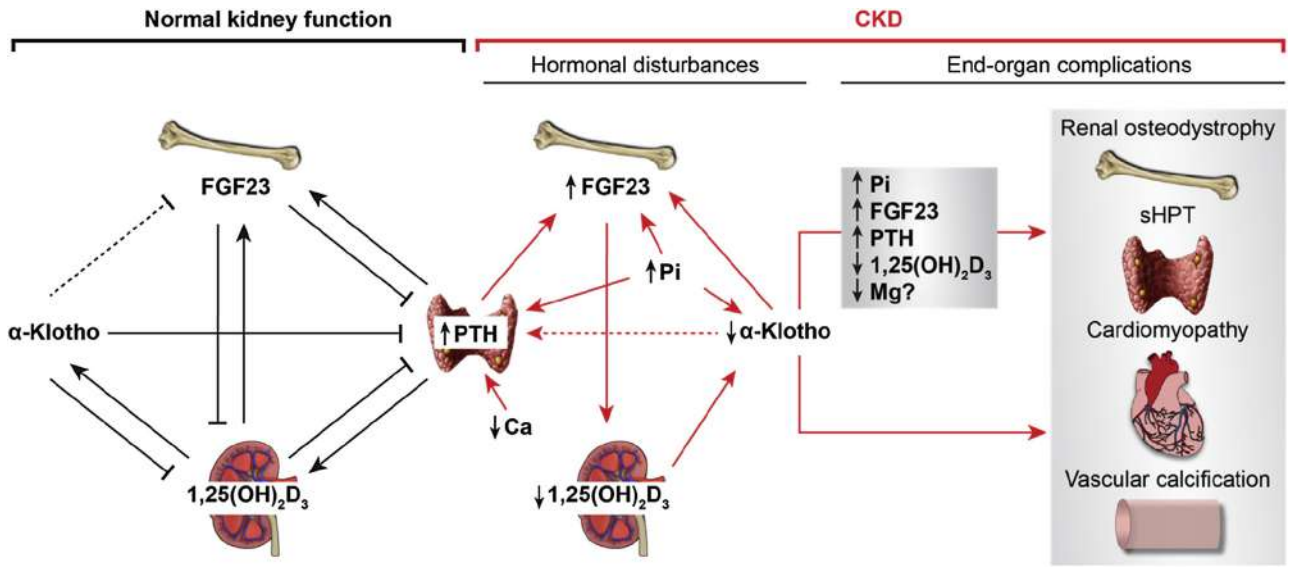

FIGURE 41.2 Regulatory network of mineral metabolism with normal kidney function and in chronic kidney disease (CKD). α-Klotho deficiency is the earliest abnormality in CKD and is likely the initiator of CKD-related mineral dysregulation that can lead to end-organ complications. The α-Klotho/Mg crosstalk is not currently defined. The conglomerate of abnormalities is believed to be pathogenic for multiple end organs complications. FGF-23: Fibroblast growth factor 23; PTH: parathyroid hormone; $1,25(OH)_2D_3$: 1,25-dihydroxy-vitamin D_3; Pi: phosphate; Ca: calcium; Mg: magnesium; sHPT: secondary hyperparathyroidism.

a narrow range, between 9–10 mg/dL (2.2–2.6 mM) *via* concerted actions of intestinal Ca^{2+} absorption, exchange of Ca^{2+} to and from bone, and renal Ca^{2+} excretion.

In the kidney, 50–60% of the total plasma Ca^{2+} is filtered, either in its ionized form or complexed with other ions.[20] After filtration, >95% of Ca^{2+} is reabsorbed along the tubules. Filtered Ca^{2+} is reabsorbed through paracellular pathways in the proximal tubule (PT) and the thick ascending limb (TAL) of Henle), where it is functionally coupled to Na^+ reabsorption.[20] Along the distal convolutions of the nephron, Ca^{2+} reabsorption is accomplished by transcellular transport. Approximately 10% of the filtered Ca^{2+} is reabsorbed in the late distal convoluted tubule (DCT2) and the connecting tubule *via* the epithelial Ca^{2+} channel, transient receptor potential vanilloid 5 (TRPV5).[21] Ca^{2+} is extruded in the renal interstitium to reenter the bloodstream by the Na^+/Ca^{2+}-exchanger and the plasma membrane Ca^{2+}-ATPase.[20] A few percent of the filtered Ca is excreted by the kidney into the urine.[20]

Intestinal Ca^{2+} absorption is the sum of two components.[22] The first is saturable, transcellular, active transport, which is largely regulated by the active form of vitamin D (1,25-dihydroxyvitamin D [$1,25(OH)_2D_3$]). Transcellular Ca^{2+} absorption is highest in the proximal small intestine, mediated by the transient receptor potential vanilloid subtype 6 (TRPV6).[23] The second is unsaturable, paracellular, passive diffusion that is linearly related to dietary Ca^{2+} load. The relative contribution of the paracellular and transcellular pathway to the total amount of calcium that is absorbed from the intestine depends on dietary supply and bodily needs.[22] Finally, bone is a large exchangeable reservoir for Ca^{2+}, mostly as hydroxyapatite. The maintenance of mineral stores in bone depends on the balance between bone mineralization and resorption. Various TRP channels, including TRPV4, TRPV5, and TRPV6 are involved in calcium homeostasis in bone.[24] Expression studies have also reported calcium-sensing receptor (CaSR) transcripts in both osteoblasts and osteoclasts.[25]

Hormones classically involved in Ca^{2+} homeostasis are $1,25(OH)_2D_3$, parathyroid hormone (PTH), and calcitonin (CT).[26] In hypocalcemia, reduced binding of Ca^{2+} to the CaSR in the parathyroid glands induces rapid PTH release from the secretory granules, delays PTH degradation, and over the long term can result in parathyroid hyperplasia.[26] Increased levels of circulating PTH restore normal plasma Ca^{2+} level through Ca^{2+} resorption from bone, increase in Ca^{2+} reabsorption in the kidney *via* TRPV5,[27] and activation of $1,25(OH)_2D_3$ synthesis in the parathyroid glands,[20,26] which activates VDR-mediated enhanced intestinal Ca^{2+} absorption.[20,28] This regulatory system promotes a tri-organ network to restore Ca^{2+} levels.[20] As negative feedback, $1,25(OH)_2D_3$ represses the transcription of PTH and may have an indirect effect on PTH release by increasing the expression of CaSR. Hypercalcemia acts through CaSR to inhibit PTH release and stimulates the secretion of CT by the thyroid C cells, which counteracts hypercalcemia by decreasing osteoclast-mediated bone resorption.[29]

Phosphate (Pi) Homeostasis

Inorganic phosphate (Pi) is the third most abundant anion in the human body, accounting for about 1% of total body mass. Approximately 85% of total Pi is stored in bone in the form of apatite, contributing to bone structure. About 15% is distributed in soft tissues, and only 1% is contained in the rapidly exchangeable plasma pool. Pi balance depends on dietary intake and intestinal absorption, distribution among organs, and renal excretion.

Renal Pi excretion depends on the balance between filtration and reabsorption. Tubular Pi reabsorption occurs mainly in the PT, where at least three different Na^+-driven Pi transporters mediate the initial step of Pi reabsorption across the apical brush border membrane: NaPi-IIa (Npt2a, SLC34A1), NaPi-IIc (Npt2c, SLC34A3), and PiT2 (SLC20A2).[30] The basolateral exit pathway for Pi remains unknown. The three Pi transporters expressed in the PT exhibit different transport modes, sensitivity to pH, and dynamics of regulation by dietary Pi intake and phosphaturic hormones. Intestinal Pi absorption has dual pathways, consisting of a transcellular, transporter-dependent pathway, and a paracellular route. The transcellular route involves the Na^+-driven Pi transporter NaPi-IIb (Npt2b, SLC34A2), mostly expressed in the jejunum in humans.[31] The expression of NaPi-IIb is regulated by dietary Pi intake and $1,25(OH)_2D_3$.[32]

The main hormones regulating serum Pi are PTH, $1,25(OH)_2D_3$, and FGF-23 with its co-receptor α-Klotho. FGF-23 is a bone-generated humoral phosphaturic hormone.[33] Secretion of FGF-23 by bone is induced by Pi, $1,25(OH)_2D_3$, and PTH.[14] α-Klotho serves as a co-receptor for FGF-23.[14] *α-Klotho* gene expression is inducible by $1,25(OH)_2D_3$, in the distal convoluted tubule (DCT), and to a lesser extent in the PT and parathyroid glands.[34] Kidney and parathyroid α-Klotho expression mark these organs as FGF-23 targets, regulating both Pi and Ca^{2+}. In the kidney, both FGF-23 and α-Klotho suppress Pi reabsorption and $1,25(OH)_2D_3$ synthesis. In the parathyroid, FGF-23 suppresses PTH secretion, which may also contribute to the ability of FGF-23 to reduce $1,25(OH)_2D_3$ synthesis.[35] Thus, FGF-23 is both a phosphaturic hormone and the counter-regulatory hormone to $1,25(OH)_2D_3$,[35] which jointly promote negative Pi balance. *α-Klotho*-deficient mice show high levels of circulating FGF-23, likely caused by resistance, and

phenotypically similar to *Fgf-23*$^{-/-}$ mice with severe growth retardation, accelerated aging, vascular and ectopic calcifications, bone mineralization defects, increased serum Pi, and increased $1,25(OH)_2D_3$ levels.[34,36] Deletion of *Fgf-23* from *α-Klotho*$^{-/-}$ mice does not worsen the phenotype, confirming that FGF-23 requires α-Klotho.[37] The extracellular domain of membrane α-Klotho is shed by secretases and released into the circulation, cerebrospinal fluid, and urine as soluble α-Klotho.[35] Soluble α-Klotho exerts multiple biological actions on distant organs, including increase in renal Ca^{2+} reabsorption through modulation of the TRPV5 channel.[38] Thus, α-Klotho's action on the kidney is to promote Pi excretion and prevent renal Ca^{2+} loss.

Magnesium (Mg^{2+}) Homeostasis

There are approximately 24 g of Mg^{2+} in the body, of which 53% is stored in bone, 46% is in tissues, and the remaining 1% is in the extracellular space. Plasma Mg^{2+} levels are maintained around 1.6–2.6 mg/dL (0.7–1.1 mmol/L). Approximately 60–70% of the total plasma Mg^{2+} is filtered through the glomeruli, with 10–20% reabsorbed by the PT. The majority (65–70%) is taken up in the cortical TAL *via* the paracellular route, facilitated by the tight junction proteins, claudin-16, and claudin-19.[39] Of the filtered Mg^{2+}, 10–15% reaches the early DCT (DCT1), where Mg^{2+} is actively transported, which is critically influenced by cellular energy metabolism. The DCT1 determines the final urinary Mg^{2+} excretion by reabsorbing Mg^{2+} *via* the epithelial Mg channel, transient receptor potential melastatin 6 (TRPM6).[40] Families with monogenetic forms of hypomagnesemia have allowed the identification of a complex network of genes involved in active renal Mg^{2+} handling.[41] Up to now the gene/protein encoding for the basolateral Mg^{2+} extrusion in the kidney remains unknown. No significant Mg^{2+} reabsorption occurs in the more distal nephron segments. Overall, less than 5% of the filtered Mg^{2+} normally appears in the urine.

Between 25% and 75% of the Mg^{2+} from dietary sources is absorbed in the intestine, depending on the bioavailability and the needs of the body. When Mg^{2+} intake is normal, the transcellular pathway, involving TRPM6, is responsible for approximately 30% of total absorption, a fraction that increases when dietary intake is low.[22] Paracellular transport is responsible for approximately 70% of Mg^{2+} absorption when luminal concentrations are normal to high.[22] However, Mg^{2+}-specific intestinal paracellular channels are not yet elucidated.

Our understanding of the molecular mechanisms underlying Mg^{2+} handling in bone is limited. Dietary depletion leads to reduced bone Mg^{2+} content without affecting plasma Mg^{2+} levels, indicating that bone acts as a storage compartment from which Mg^{2+} is released in the situation of low Mg^{2+} supply. TRPM6 and TRPM7 are expressed in various osteoblast cell lines.[42] The physiological relevance of this observation for Mg transport in bone is not yet clear.

A comprehensive model describing systemic Mg^{2+} regulation is still missing. Thus far, epidermal growth factor, insulin, and estrogens have been suggested as magnesiotropic hormones by increasing renal reabsorption *via* TRPM6.[40] Mg^{2+} can bind and influence the activity of the CaSR, albeit with a much lower affinity than Ca^{2+}, and therefore may influence parathyroid PTH release.[43] However, hypomagnesemia is associated with a paradoxical block of PTH secretion and hypoparathyroidism, possibly secondary to impaired signaling downstream from the CaSR, secondary to intracellular Mg^{2+} deficiency.[43] Segmental Mg^{2+} transport experiments conducted in mice along the gastrointestinal tract showed that $1,25(OH)_2D_3$ does not affect Mg^{2+} absorption.[22]

Ca^{2+}, Pi, and Mg^{2+} Disturbances in CKD

With progression of CKD, the normal homeostatic mechanisms in Ca^{2+}, Pi, and Mg^{2+} balance are altered. Currently, CKD is often considered a state of accelerated aging associated with α-Klotho deficiency and Pi retention.[44,45] It is hypothesized that α-Klotho deficiency is the earliest biomarker of CKD and the initiator of CKD-related mineral dysregulation.[44,45] As α-Klotho levels declines progressively in CKD, FGF-23 expression increases. High serum phosphate concentration (S[P]) and PTH levels and low $1,25(OH)_2D_3$ levels accompany these changes (Figure 41.1). The first measurable decline in urinary α-Klotho levels occurs as early as stage 1 CKD[46] and is directly correlated with estimated glomerular filtration rate (eGFR),[47] suggesting that urinary soluble α-Klotho may be a good biomarker for early CKD detection. The reduction of serum α-Klotho starts at stage 2 CKD,[48] preceding the elevation of serum FGF-23, PTH, and S[P]. Serum α-Klotho levels progressively lower with more advanced CKD stages.[45,49] One study estimated the fall in serum α-Klotho to be 3.2 pg/mL for each 1 mL/min/1.73 m^2 decrease in eGFR.[50] *α-Klotho* mRNA in the kidney is decreased and positively correlates with eGFR.[51,52] CKD in rodents showed serum α-Klotho decrease that was comparable in magnitude to that of decreased α-Klotho protein in kidney and urine.[46] In CKD, low α-Klotho confers FGF-23 resistance contributing to a compensatory increase in blood FGF-23 levels to maintain Pi homeostasis (Figures 41.1 and 41.2). Preclinical studies show that both FGF-23 and α-Klotho levels are both predictive and pathogenic for kidney disease progression, extrarenal complications such as uremic cardiomyopathy, and mortality.[50,53–55] As CKD progresses, the increase in FGF-23 suppresses

$1,25(OH)_2D_3$ production, leading to $1,25(OH)_2D_3$ deficiency (Figures 41.1 and 41.2). Low $1,25(OH)_2D_3$ and high plasma Pi increase PTH, which contributes to the high FGF-23 levels in advanced CKD (Figures 41.1 and 41.2). By stage 4 CKD and ESRD, most patients exhibit frank hyperphosphatemia and secondary hyperparathyroidism (sHPT), marked elevations of FGF-23, and $1,25(OH)_2D$ deficiency (Figure 41.1).

Hypocalcemia is a late event in CKD that is sometimes seen in stage 5 CKD and ESRD. One major cause is reduced $1,25(OH)_2D_3$ that diminishes intestinal Ca^{2+}absorption (Figure 41.2). In addition, there is reduced mobilization of Ca^{2+} from bone due to decreased sensitivity to PTH in conjunction with $1,25(OH)_2D_3$ deficiency. Hyperphosphatemia and the secondary increase in FGF-23 levels inhibit 25-hydroxyvitamin D 1-hydroxylase in the kidney. This is combined with the loss of renal tissue and the consequent reduction in the enzyme availability and $1,25(OH)_2D_3$ production (Figure 41.2). There is a dramatic decrease in urine Ca^{2+} excretion in CKD, which represents the appropriate homeostatic response to maintain balance in the setting of decreased intestinal Ca^{2+} absorption.[20] However, many patients receive Ca^{2+} in the form of Ca^{2+}-containing Pi binders or $1,25(OH)_2D_3$, which can result in positive Ca^{2+} balance and net retention of Ca^{2+}.[56,57] Both negative and positive Ca^{2+} balance constitute potential health threats in CKD. Negative balance may increase risk for osteoporosis and fractures, which compounds the various CKD-specific bone complications. Positive calcium balance may increase risk for extraskeletal calcification. Management of altered mineral metabolism in CKD and ESRD has focused on the control and prevention of sHPT by treating hyperphosphatemia and $1,25(OH)_2D_3$ deficiency.

Compared to our knowledge of Ca^{2+} and Pi metabolism in CKD, regulation of Mg^{2+} homeostasis in CKD is poorly understood. When renal function declines, the fractional excretion of Mg^{2+} is increased to maintain normal S[Mg] concentrations. Therefore, patients with stages 1–3 CKD generally have normal S[Mg]. In stages 4 and 5 CKD, raising fractional excretion eventually fails to compensate for reduced filtered Mg^{2+}, which can cause hypermagnesemia (Figure 41.1). Ultimately, in dialysis patients, S[Mg] is variable and often depends on the dialysate Mg^{2+} concentration.[58] The use of the Pi binder sevelamer hydrochloride has been associated with hypermagnesemia in CKD.[59] It may be caused by sevelamer binding to bile salts, leaving more free Mg^{2+} available for absorption. Contrary to common belief, hypomagnesemia is not a rare finding among CKD patients.[60] In addition to the CKD-related pathophysiology, drugs that cause hypomagnesemia are often prescribed to patients with kidney disease,[61] such as proton pump inhibitors. The changes in intestinal pH induced by PPIs can reduced bioavailability of Mg^{2+} and the activity of TRPM6, thus contributing to the development of hypomagnesemia. Hypomagnesemia is also associated with the use of diuretics,[62] antimicrobials, the immunosuppressive agent cyclosporine, and the anticancer drugs cetuximab and cisplatin, which mostly affect the renal reabsorption of Mg^{2+}.[61] Other factors such as low dietary Mg^{2+} intake and comorbidities such as diabetes type II, greatly affect S[Mg] in CKD patients. S[Mg] levels have been found to be lower in diabetics who are at high risk for CKD development compared to nondiabetics.[63] Whether low S[Mg] is causative or a consequence of diabetes is under debate. Epidemiologic findings are consistent with a potential causal role of low S[Mg] in the development of diabetes, possibly through increased insulin resistance, and/or inflammation.[64] Low S[Mg] levels also independently associate with incidence and progression of CKD in patients with or without diabetes, as well as CV events and mortality in patients with CKD or undergoing hemodialysis.[17] The molecular mechanisms underlying deleterious effects of low S[Mg] on renal function are largely unknown. Low S[Mg] levels aggravate hyperphosphatemia-induced kidney injury.[65,66] In a small group of nondiabetic CKD patients, subjects with high S[P] had a higher risk of ESRD when they had concomitant low S[Mg] levels at baseline.[65] This dramatic finding can be explained by multiple mechanisms. Firstly, low-dietary Mg^{2+} favors positive Pi balance by increasing intestinal Pi absorption and decreasing urinary Pi excretion.[66] Secondly, low Mg^{2+} and high Pi have interactive and synergistic deleterious effects directly on renal tubular cells. Increase in extracellular Mg^{2+} concentration *in vitro* suppressed Pi-induced apoptosis of cultured renal tubular cells by inhibiting the expression of profibrotic and proinflammatory cytokines.[65] Thirdly low Mg^{2+} and high Pi increase the CV burden, which in turn increase peripheral and intrarenal resistance.

Ca^{2+}, Pi, and Mg^{2+} and CKD-MBD

Disturbances in Ca^{2+}, Pi, and Mg^{2+} homeostasis, and their regulatory hormones are part of the pathogenesis of CKD-MBD, which encompasses impaired mineral metabolism biochemistries, bone abnormalities, extraskeletal calcification, and CVD.[67] Cardiomyopathy (hypertrophy and fibrosis) and vasculopathy (VC), contribute significantly to morbidity and mortality in CKD.[3,67] Understanding how Ca^{2+}, Pi, and Mg^{2+} disturbances affect the development and progression of CKD-MBD at the molecular level is essential for better patient management and the development of new therapeutic targets. Although the role of Pi is unequivocal in CKD-MBD, the role of Ca^{2+} and Mg^{2+} are less well defined.

Cardiomyopathy

Cardiomyopathy occurs in >90% of patients with CKD and contributes to mortality. Disturbances in Ca^{2+} and Pi balance in CKD may induce cardiac abnormalities through several mechanisms (Figure 41.3). First, direct effects on cells due to disturbances in intracellular Ca^{2+} and/or Pi secondary to changes in function and/or expression of Ca^{2+} and Pi transporters may occur. Secondly, induction of cardiomyocyte hypertrophy through abnormal levels of hormones and extraskeletal deposition of calcioprotein particles (CPPs) occurs. Thirdly, increased VCs result in an increase in peripheral resistance. Ca^{2+} regulates cardiomyocyte contraction, growth, and remodeling. Abnormal Ca^{2+}-dependent cardiac ion channels have been reported in animal models of hypertrophic cardiomyopathy, which predispose to arrhythmias.[68] Rat cardiomyocytes incubated with PTH have a rapid increase in intracellular Ca^{2+} and undergo apoptosis. Incubation with uremic serum reproduced these findings, but not if the animal had undergone parathyroidectomy.[69] Epidemiologic studies in humans confirm that high-plasma PTH and FGF-23 levels are associated with cardiac hypertrophy (Figure 41.3).[15,70,71]

Hyperphosphatemia is a risk factor for progression of CVD and mortality in CKD/ESRD (Figure 41.3).[72,73] In rodents with normal renal function, long-term high Pi intake induced cardiac remodeling and was associated with decreased renal and systemic α-Klotho, and increased levels of plasma PTH and FGF-23.[74] Elevations in FGF-23 in CKD patients are independently associated with progression of LVH.[15] FGF-23 can directly induce LVH and cardiomyocyte hypertrophy in mice through FGFR-dependent activation of the calcineurin-NFAT signaling pathway (Figure 41.3).[15] This effect is independent of transmembrane α-Klotho, which is not expressed in heart.[15] Circulating soluble α-Klotho protects against uremic cardiomyopathy independently of FGF-23 and Pi (Figure 41.3).[75] Dietary Pi restriction rescues premature aging and death in both *Fgf-23*$^{-/-}$ and *kl/kl* mice, but does not abrogate cardiac hypertrophy in *kl/+* CKD mice, suggesting an independent role of α-Klotho in cardiac remodeling.[36,75,76] *kl/kl* mice have elevated FGF-23 levels and develop LVH, whereas *kl/+* mice manifest FGF-23 levels and an LVH phenotype that are intermediate between those of wild-type and *kl/kl* mice.[15] Administration of soluble α-Klotho to *kl/+* or wild-type mice with CKD, or transgenic overexpression of α-Klotho ameliorate cardiac hypertrophy and fibrosis *via* suppressed phosphorylation of Smad2/3 and Erk (Figure 41.3).[74,75,77] Moreover, soluble α-Klotho protects against cardiac remodeling by inhibiting TRPC6 channel−mediated Ca^{2+} signaling in the heart and suppressing reactive oxygen species production (Figure 41.3).[78] α-Klotho also inhibits TGF-β1−, angiotensin II−, or high Pi−induced fibrosis in cardiac fibroblasts *in vitro* and abolishes TGF-β1− or angiotensin II−induced hypertrophy of cultured neonatal cardiomyocytes.[74] The collective evidence supports a direct protective role of soluble α-Klotho on cardiac tissue beyond effects on renal function and mineral parameters.

The role of Mg^{2+} in cardiomyopathy in CKD is not well characterized. Mg^{2+} plays an important role in cardiac function by influencing myocardial metabolism, Ca^{2+} homeostasis, vascular tone, peripheral vascular resistance, and cardiac output.[39] Mg^{2+} exerts its effects in three ways (Figure 41.3). First, Mg^{2+} regulates the activity of ion channels in cardiac cells, thereby affecting the electrical properties of the myocardium. Secondly,

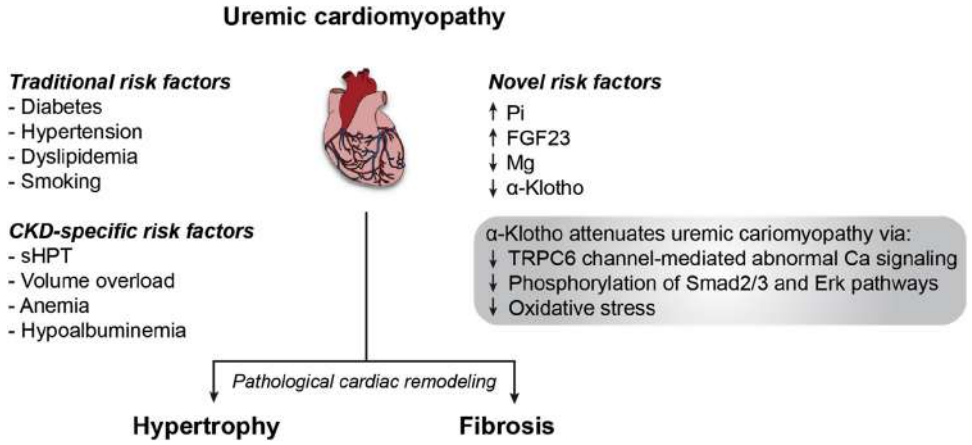

FIGURE 41.3 Risk factors for uremic cardiomyopathy. Mineral disorders along with high FGF-23 and α-Klotho deficiency are novel risk factor for uremic cardiomyopathy. Rodent models suggest that α-Klotho restoration is beneficial. The role of Mg supplementation on uremic cardiomyopathy is unclear. sHPT: secondary hyperparathyroidism; Pi: phosphate; FGF-23: fibroblast growth factor 23; Mg: magnesium; TRPC6: transient receptor potential canonical-6.

Mg^{2+} regulates myocardial contractility by influencing intracellular Ca^{2+} mobility. Finally, Mg^{2+} has anti-inflammatory and vasodilatory effects.[39] In the general population, low S[mg] is associated with higher risk of arrhythmias, coronary artery disease, myocardial infarction, congestive heart failure, and risk of sudden cardiac death.[79,80] Observational studies report that low S[Mg] is a significant predictor of CV events and CV death in patients with predialysis CKD or in patients treated with hemodialysis.[17]

Vascular Calcification

In CKD-MBD, elevated S[P], formation of CPP, and diminished levels of circulating inhibitors of VC, such as fetuin-A, matrix gla protein, and osteoprotegerin, initiate the trans-differentiation of vascular smooth muscle cells (VSMCs).[81] VSMC trans-differentiation is accelerated by the expression of osteogenic genes and amplified by the VSMCs through the release of exosomes and apoptotic bodies (Figure 41.4).[81]

Mounting evidence supports a protective role for soluble α-Klotho on VC that goes beyond its effect on amelioration of renal function and hyperphosphatemia.[44] Administration of exogenous recombinant α-Klotho, α-Klotho gene delivery, and increased endogenous circulating α-Klotho significantly reduced VC.[82–84] *In vitro* studies using endothelial cells and VSMCs show that α-Klotho improves endothelial function and suppresses uptake of Pi and mineralization induced by high S[P] (Figure 41.4).[46,85] The role of the FGF-23/α-Klotho signaling in endothelium and VSMC during CKD is still under investigation.

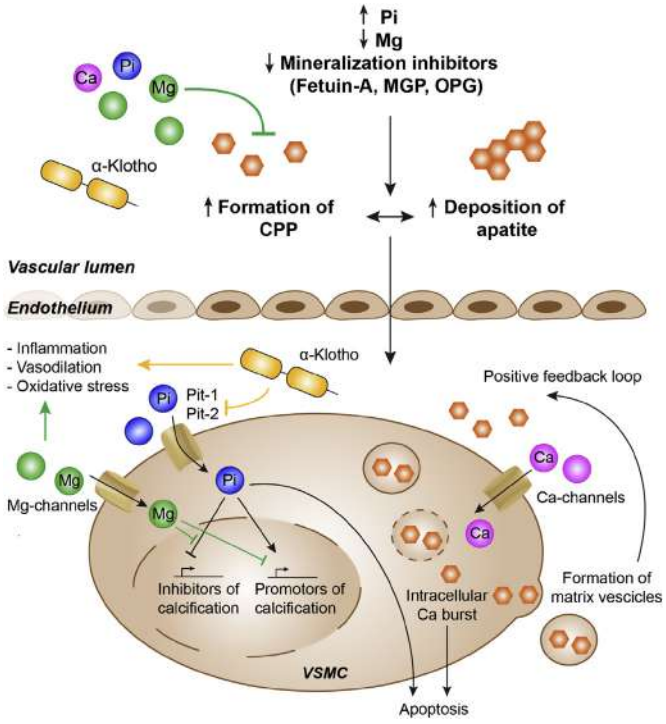

FIGURE 41.4 (Patho)physiology of vascular calcification during Ca, Pi, and Mg disturbances in CKD. Molecular mechanisms of vascular calcification in chronic kidney disease (CKD). The putative protective roles of Mg and α-Klotho on the endothelium and VSMC in the course of vascular calcification are depicted. MGP: matrix gla protein; OPG: osteoprotegerin; Pi: phosphate; Ca; calcium; Mg: magnesium; Pit-1: Na-Pi co-transporter-1; Pit-2: Na-Pi co-transporter-2; VSMC: vascular smooth muscle cells; CPP: calcioprotein particles.

There is increased circulating CPPs and serum calcification propensity in patients with CKD.[86,87] CPP are soluble colloidal protein−mineral nanoparticles, wherein Ca^{2+} and Pi are organized with various proteins with the main component being fetuin-A. CPP might initiate cardiomyopathy and VC[88] by inducing various cellular responses, including production of reactive oxygen species, mitochondrial dysfunction, cell cycle arrest, and cell death (Figure 41.4).[89] Serum CPP correlate positively with CV events,[86,90] worsening of kidney function,[86] and all cause and CV mortality in patients with CKD and renal transplant recipients.[91]

Low S[Mg] is independently associated with vascular disease in patients with CKD and treated with dialysis.[92,93] Low extracellular Mg^{2+} is proatherosclerotic in cultured endothelial cells, as it enhances the production of vasoconstrictor agents and cytokines, decreases the production of endothelial-derived vasodilators, and increases oxidative stress.[39] Mg^{2+} supplementation reverses these effects and reduces VC and osteogenic transdifferentiation of VSMC induced by high Pi both *in vitro* and *in vivo* (Figure 41.4).[94] Moreover, Mg^{2+} inhibits mineralization by directly suppressing apatite crystal formation or maturation in the extracellular space and maturation of CPP in uremic serum.[87,95] Increasing dialysate Mg^{2+} decreases calcification propensity in patients treated with maintenance hemodialysis.[96] Thus, Mg^{2+} seems to be useful to alleviate the Pi-induced calcification stress (Figure 41.4).

Renal Osteodystrophy

Fractures are more common in both predialysis CKD and stage 5D CKD compared to the general population, and the incidence increases with the progression of CKD.[97,98] The term renal osteodystrophy (ROD) is used to define alterations in bone morphology quantifiable by histomorphometry of bone biopsy.[99] Major classifications of ROD are based on histological findings. Osteitis fibrosa is associated with high turnover due to PTH stimulation of osteoblasts that are coupled to osteoclastic-mediated bone resorption. Osteomalacia is characterized by defective mineralization. Adynamic bone disease comprises low turnover due to low PTH and/or excessive treatment with vitamin D. The type of bone disease can influence S[Ca] and S[P] levels. High bone turnover contributes to elevated S[Ca] and

S[P] through increased release from bone. Low-turnover states can also make patients more susceptible to developing hypercalcemia after dietary loads or vitamin D therapy, due to the diminished buffering capacity for Ca^{2+} from the diminished bone remodeling.[100] Adynamic bone disease may increase the risk of vascular and soft tissue calcification, possibly due to limited Ca^{2+} buffering capacity or to a Ca^{2+} surfeit state.[101] Other examples of the impact of bone turnover on S[Ca] and S[P] in ESRD are hungry bone syndrome following parathyroidectomy, hypercalcemia observed with immobilization, and hypocalcemia following treatment with antiresorptive therapies. Osteoporosis may be observed with either high turnover or low turnover forms of ROD.

Whether FGF-23 acts directly on bone is a complex question to address because *in vivo* modifications of FGF-23 levels also disrupt S[P] and $1,25(OH)_2D_3$ levels. Direct action of FGF-23 on bone mineralization still remains to be clarified. *Fgf-23/NaPi2a* double knockout mice had completely normal S[P] levels compared with hyperphosphatemic *Fgf-23*$^{-/-}$ mice. Interestingly, these mice showed the same defects in bone mineralization, suggesting a direct action of FGF-23 on bone independent of S[P] levels.[102] It was proposed that increased osteopontin, a mineralization inhibitor, in bone is a pathogenic factor mediating the mineralization defect and alterations in bone metabolism observed in *Fgf-23*$^{-/-}$ mice.[103] However, *in vitro* experiments showed the opposite, with FGF-23 overexpression inhibiting matrix mineralization and osteoblast differentiation independent of its systemic effect on Pi metabolism,[104] while stimulating osteoclast activity.[105]

Recent investigations discovered α-Klotho in osteocytes.[106] Contrary to *kl/kl* mice that exhibit low-turnover osteoporosis, the deletion of *α-Klotho* from osteocytes resulted in a marked increase in bone formation and bone volume, along with the enhanced expression of osteoblastic marker genes.[107] The difference may be explained by the fact that the bone phenotype in *kl/kl* mice is not a direct result of the loss of α-Klotho in osteocytes, but of the inhibition of PTH secretion by hypercalcemia and hypervitaminosis D that leads to attenuated bone remodeling.

The role of Mg^{2+} in ROD is largely undefined. In bone, Mg^{2+} ions bind at the surface of hydroxyapatite crystals. Crystals are larger in Mg^{2+}-deficient bone, and the bone may be brittle and susceptible to fractures.[108] In a meta-analysis of population-based cohort studies, dietary Mg^{2+} intake was positively associated with the bone mineral density (BMD) of the femoral neck, total hip, and forearm.[109] Several studies showed that low S[Mg] is associated with osteoporosis.[110,111] Two large prospective cohort studies reported that both low serum and dietary Mg^{2+} levels are associated with increased risk of fractures.[112,113] Recently, it was found that patients undergoing hemodialysis with higher [Mg] levels have a lower risk of hip fractures.[114]

DIAGNOSIS

In adults, levels of S[Ca] (ionized Ca^{2+} or total Ca^{2+} corrected for albumin), S[P], PTH, serum bicarbonate, and alkaline phosphatase should be monitored in early stages of CKD (stage 3A). The frequency (every 1–3 to 12 months) should be based on the stage of CKD, the degree of abnormality, and the rate of CKD progression, with more frequent monitoring for patients with advanced CKD or rapid deterioration of eGFR.[115] As vitamin D deficiency (<10 ng/mL or 25 nmol/L) or insufficiency (10 to <20–32 ng/mL or 50–80 nmol/L) contributes to the pathogenesis of sHPT, levels of serum 25(OH) vitamin D should be routinely measured at baseline and to monitor therapeutic interventions.[116] The rate of change and severity of abnormalities in these analytes are highly variable among patients. Further, assay precision and accuracy may affect interpretation, specifically for PTH and 25(OH) vitamin D.[115] To diagnose CKD-MBD, one or more of these laboratory analytes should be abnormal. The interpretation of these abnormalities should also account for normal postprandial, diurnal, and seasonal variations. Laboratory tests should be performed at similar times of the day using the same assays whenever possible. The trend of changes rather one single measurement is also important for interpretation.

Calcium (Ca^{2+})

Measurement of S[Ca] is generally precise and reproducible, with minimal diurnal variation.[117] In patients with CKD, S[Ca] levels vary due to altered homeostasis and concomitant therapy. These fluctuations are more pronounced in CKD stage 5D (ESRD) patients due to dialysis-induced changes. Only 1% of total body Ca^{2+} is in the extracellular compartment. Serum ionized Ca^{2+} is physiologically active and constitutes 40–50% of total S[Ca]. Nonionized Ca^{2+} is bound to albumin and anions such as citrate, bicarbonate, and phosphate. Measurement of total serum Ca^{2+} concentration—even when corrected by S[Alb] levels—is less specific that ionized Ca^{2+} for the assessment of Ca^{2+} status, but it is more pragmatic.[118]

Phosphate (Pi)

The sum of bivalent (HPO_4^{-2}) and monovalent $(H_2PO_4^-)$ constitutes serum inorganic phosphate (Pi) concentration at pH 7.4, which is the compound measured in clinical practice by automated colorimetric

methods but commonly reported as "phosphorus" even though there is no elemental phosphorus in blood. Phosphate is mostly intracellular and serum levels are generally precise and reproducible. Diurnal and postprandial variations in S[P] and urinary phosphorus excretion have been documented (lower in the morning and higher late at night).[119]

Magnesium (Mg^{2+})

The assessment of Mg^{2+} status is complex as this cation is present mostly in the intracellular compartment, primarily in the skeleton and soft tissues. Only 1% of the total body Mg^{2+} is present in serum and the interstitium. Currently, measurement of S[Mg] by photometric methods is routine to evaluate Mg^{2+} status. However, levels of S[Mg] can be influenced by levels of S[Alb], other anions, and changes in blood pH.[120] Further, low levels of intracellular Mg^{2+} have been described in patients with diabetes, alcoholism, and malabsorption syndromes despite normal levels of S[Mg].[121] Overall, there is poor correlation between serum and intracellular Mg^{2+} levels.[122] Therefore, S[Mg] levels—although testing is readily available in clinical practice—is not the most reliable metric of total body Mg^{2+} status. Other measurements of Mg^{2+} status, such as serum free (ionized) Mg^{2+} or intracellular Mg^{2+} content by nuclear magnetic resonance and fluorescence probes are still under investigation. Functional tests such as the Mg^{2+} tolerance test to assess urinary excretion of Mg^{2+} in relation to parenteral load have been used in healthy subjects to assess magnesium deficiency but are of limited utility in patients with CKD due to the impaired renal functional excretory capacity.[123]

Parathyroid Hormone

PTH is stored in the parathyroid gland for pulsatile secretion and is cleaved at different sites (N-terminal, C-terminal, and mid-region fragments). The circulating 1−84 amino-acid protein has a half-life of 2−4 minutes. The extracellular ionized Ca^{2+} is a main determinant of minute-to-minute secretion of PTH. There are multiple PTH assays. Earlier assays measured C-terminal fragments lacking accuracy due to impaired renal excretion of these inactive peptides in CKD. N-terminal assays also detected inactive metabolites. Second generation PTH assays (two-site immunoradiometric capture at the amino- and carboxy-termini) can better detect active full-length PTH but can still pick up accumulated large C-terminal fragments, particularly in patients with advanced CKD.[124,125] Third generation bioactive PTH assays truly detect the 1−84-amino-acid, full-length PTH molecule.[126] Overall, the bioactive PTH assays yield lower PTH concentrations compared with intact PTH assays in CKD. Their use in clinical practice has not been fully implemented and further investigation is warranted.[127] The source of sample (serum vs. plasma) and sample handling also add variability to PTH assays.[128] Therefore, standardization in the methods of sample handling and processing is recommended. Analysis of trajectory of PTH levels rather than single-point interpretation and complementary CKD-MBD data should better guide the overall and comprehensive clinical management of patients with CKD-MBD.

Vitamin D and Metabolites

25-Hydroxyvitamin D

The term vitamin D collectively includes ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) compounds (Table 41.1). These compounds are lipophilic, have short half-life (~24 hours), and are not easy to quantify in serum or plasma. D_2 and D_3 are metabolized in the liver to 25(OH)D_2 (ercalcidiol) and 25(OH)D_3 (calcidiol) and are collectively named 25-hydroxyvitamin D or 25(OH)D, which has a longer half-life of ~3 weeks, and is considered the best clinical metric of vitamin D status from both nutritional and skin sources. The most common methods of measurement of 25(OH)D levels are automated chemiluminescence/radioimmunoassays for both 25(OH)D_2 and 25(OH)D_3 simultaneously, and liquid chromatography-tandem mass spectrometry, which can quantify 25(OH)D_2 and 25(OH)D_3 separately.[129] However, the utility of the latter in clinical practice has been questioned and may not necessarily guide management, as both metabolites have similar biological effects.[130]

1,25-Dihydroxyvitamin D

The dihydroxylated compounds 1,25$(OH)_2D_2$ and 1,25$(OH)_2D_3$ have a short half-life of approximately

TABLE 41.1 Vitamin D_2 and D_3 and Related Compounds

	D_2 Compounds	D_3 Compounds
Parent compound	Vitamin D_2 (ergocalciferol)	Vitamin D_3 (cholecalciferol)
After first hydroxylation	25-hydroxy D_2 (ercalcidiol)	25-hydroxy D_3 (calcidiol)
After second hydroxylation	1,25-dihydroxyvitamin D_2 (ercalcitriol)	1,25-dihydroxyvitamin D_3 (calcitriol)

4–6 hours and collectively constitute $1,25(OH)_2D$ (Table 41.1). Current commercial assays cannot distinguish between these two compounds. It is not known if these measurements—particularly in late stages of CKD—can substantially alter clinical decisions. Overall, circulating levels of $1,25(OH)_2D$ are approximately 1/1000 of total 25(OH)D levels. Furthermore, levels of $1,25(OH)_2D$ are influenced by substrate 25(OH)D storage and the enzymatic conversion of 25(OH)D to $1,25(OH)_2D$ by 25(OH)D-1α-hydroxylase renal enzyme (CYP27B1). CYP27B1 is stimulated by PTH, estrogen, calcitonin, growth hormone, prolactin, low Ca^{2+}, and low Pi and inhibited by FGF-23, metabolic acidosis, and its product $1,25(OH)_2D$.[131]

Alkaline Phosphatase

Alkaline phosphatases remove the phosphate moiety from phosphoproteins, phospholipids, nucleic acids, nucleotides, and other organic molecules and function optimally at alkaline blood pH. Total levels of alkaline phosphatases are measured by standardized automated colorimetric assays. These enzymes originate from the liver and bone but other organs such as the intestines, placenta, and kidneys are sources as well. Elevated levels of alkaline phosphatases are typically related to bone disease such as bone metastases, primary or secondary hyperparathyroidism, osteomalacia, and Paget's disease or liver dysfunction.[131] Therefore, liver function tests should be examined to exclude liver disease if elevated alkaline phosphatase is encountered. Bone-specific alkaline phosphatases can be isolated by an immunoradiometric assay, which further assists in the diagnosis of bone disease in the context of CKD-MBD, although the utility of this more specific test has not been fully elucidated for standardization in clinical practice.

Fibroblast Growth Factor 23

Initial studies showed *Fgf-23* mRNA expression in multiple organs[132] but later studies show osteocytes and osteoblasts to be the major source of elevated circulating FGF-23.[133] *Fgf-23* mRNA is still present in liver, kidneys, heart, spleen, and bone marrow.[132] In CKD patients, plasma FGF-23 levels are significantly elevated and inversely related to kidney function.[12,13] Measurement of circulating intact FGF-23—the biologically active form—is lower than levels reported using FGF-23 assays with C-terminal reagents (nondiscriminatory between full length and C-terminal fragments) in human CKD. Studies with simultaneous measurements of FGF-23 using both the intact and C-terminal assays are useful in assessing relative amounts of FGF-23 production and cleavage because cleavage will reduce circulating levels of intact FGF-23 but will not affect C-terminal FGF-23 levels. Currently, FGF-23 levels are not part of clinical assessments.

α-Klotho

α-Klotho expression is downregulated by inflammation, uremic toxins, hyperphosphatemia, low $1,25(OH)_2D$, oxidative stress, and by activation of the renin–angiotensin–aldosterone-system (RAAS), and upregulated by peroxisome proliferator-activated receptor gamma agonists, RAAS blockers, and statins.[44] The mechanisms by which α-Klotho expression is decreased include promoter hypermethylation and hyperacetylation.[134] Humans with lower eGFR also have lower circulating α-Klotho levels,[45] although some studies have reported no change in α-Klotho depending on level of kidney function.[50] These discrepancies are, in part, due to sample preparation errors and inaccurate measurement with commercial α-Klotho assays.[47,48,135] Serum α-Klotho is not currently measured in routine clinical practice.

Bone Health

Bone examination in patients with CKD stages 3 or above and evidence of CKD-MBD and/or risk factors for osteoporosis is now recommended for diagnosis and prognosis.[115] Dual-energy X-ray absorptiometry (DXA) measures of BMD—specifically femoral neck and total hip—predict pathologic fracture risk in CKD patients with stages 3 or above, particularly when levels of PTH are low or normal.[136] Other tools such as quantitative CT are available, but further research is needed to confirm their utility in fracture prediction. Overall, the observation of low or declining BMD can lead to timely interventions to improve outcomes in high-risk CKD patients. Noninvasive examination of bone disease is not fully informative for the classification of low, normal, and high bone turnover in some patients with CKD-MBD, yielding low negative predictive values and low positive predictive values for differentiating low-turnover vs. non low-turnover and high-turnover vs. nonhigh-turnover bone disease, respectively.[137]

Bone biopsy is not routinely performed for the evaluation of CKD-MBD. It is important to recognize that the ultimate pathologic diagnosis of ROD can only be achieved with a bone biopsy, the diagnostic gold standard. Bone biopsy should be strongly considered in patients with pathological fractures, suspicion of osteomalacia, refractory hypercalcemia, or erratic therapeutic response to standard CKD-MBD therapy.[115]

Vascular Calcification

In CKD patients, coronary artery and generalized VC are more prevalent, more severe, and more rapidly progressive than the general healthy population. Therefore, patients with CKD stages 3 or above and known vascular or valvular calcification should be considered at very high risk of cardiovascular morbidity and mortality. Other tests such as lateral abdominal radiograph, pulse wave velocity measurements of arterial stiffness, echocardiogram, or computed tomography-based imaging to estimate coronary artery calcification (CAC) metrics (CT-based CAC score) are alternatives.[131] CT-based CAC scores can be up to fivefold higher in patients on maintenance hemodialysis than in age-matched non-CKD controls.[138] Rather than indiscriminate testing of VC in all CKD patients, an individualized approach to assess severity, progression, and response to CKD-MBD therapy is recommended using noninvasive tests.[131]

THERAPY

Of the three ions under discussion, the one with the best data to support current therapeutic regimens is Pi. Pi restriction and Pi binding in the gut lumen are deployed routinely in clinical practice. The indications for Ca^{2+} and Mg^{2+} supplementation or restriction are much less clear, although both divalent cations are often given to CKD patients, primarily as Pi binders in the gut lumen. It is unknown whether the amount of Ca^{2+} and Mg^{2+} absorbed when given as Pi binders confers additional benefit. Practitioners largely rely on consensus guidelines that are based on expert opinion rather than randomized control trials with hard clinical outcomes. There is no reason why pathophysiology-driven consensus from experts in the absence of data on hard outcomes should not be acceptable in clinical practice.

Two points deserve mention. First, there are no single therapies that will work in CKD-MBD. There will always be integrated multiple therapies targeting more than one pathophysiologic factor—such as a specific type of Pi binder, calcimimetic, vitamin D replacement, and Mg^{2+} supplementation. The list of therapeutic agents will only increase as we learn more about the pathophysiology. Second, there will never be two patients that are identical, so treatment options will have to individualized for a given patient.

Calcium (Ca^{2+})

Ca^{2+} in acetate or carbonate form is still the most widely used Pi binder. Whether CKD and ESRD patients need more or less Ca^{2+} is a highly debatable subject. There is good consensus that osteoporosis in CKD should be treated.[139] Ca^{2+} supplementation has not received general support. In addition to its Pi-chelating properties in the gut lumen, some have argued that judicious Ca^{2+} absorption can contribute to suppression of PTH and also provides a Ca^{2+} load to counteract osteoporosis.[140] A counterpoint is an opposing view that ingested Ca^{2+} actually promotes soft tissue calcification (based mostly on acute balance studies) and hence is detrimental to health in CKD.[141] This is not a dichotomous situation as these models are not mutually exclusive. The skeleton of a CKD patient may indeed need Ca^{2+} for bone strength, but the problem is regulation of internal Ca^{2+} balance. The absorbed Ca^{2+} may undergo an ectopic destination. This is clearly a situation that will require tailored therapy for each patient. The Ca^{2+} preparations shown in Table 41.2 are designed for Pi binding. For more bioavailable oral Ca^{2+}, citrate will be more appropriate but currently, there is no indication for Calcium Citrate therapy in CKD.

Phosphate (Pi)

Phosphate is ubiquitous in the diet in the developed world. The impact of reduction of phosphotoxicity in preclinical animal models is excellent in showing causality. Human data are less strong, but high S[P] is clearly linked to VC, high FGF-23 and PTH, and cardiac remodeling; therapies to lower S[P] successfully ameliorate these intermediate phenotypes.[142] Randomized trials have documented the comparative efficacy between different protocols.[143,144] What is missing amidst these powerful data is the absence of assessments of hard clinical outcomes such as survival in well-designed randomized clinical trials. Nonetheless the beneficial effects of lowering Pi are still overall convincing. To achieve the goal, one can decrease Pi absorption or increase Pi excretion. Currently, we do not have practical means to achieve the latter in humans.

Intestinal Pi absorption can be reduced by several methods (Table 41.3). Dietary restriction is effective when properly executed but compliance is a formidable problem. A frequently ignored point is the highly diverse bioavailability of Pi ranging from highly easily absorbed (inorganic phosphate as food additives), to moderately absorbed (organic phosphate in its natural form needs to be hydrolyzed to free Pi), to phytates (found in plants and seeds) that are not absorbed by humans.[145] Ingested food with an equivalent amount of phosphate (e.g. 1000 mg of elemental phosphorus) delivers a vastly different amount of Pi to the circulation, depending on whether the Pi was ingested as inorganic, organic, or phytates. Therefore, in addition to restriction of the amount of dietary Pi, the modification of the type of dietary Pi is very important and often ignored.

Unfortunately, the conventional diet in the developed world is heavily laced with added inorganic Pi. Most patients are ingesting a high proportion of Pi as part of food additives, so the daily Pi load can be as high as twice the requirement.

There are many luminal binders of Pi that lower absorption (Tables 41.2 and 41.3). The principle is very similar despite different modes of action. The choice is largely driven by national guidelines, practice habit, cost, and accessibility. There is an array of bivalent (Ca^{2+}, Mg^{2+}, Fe^{2+}) and trivalent (Al^{3+}, La^{3+}) cations that function as anion exchangers to bind dietary and secreted Pi while releasing an anion such as carbonate or acetate. Synthetic polymeric cations such as sevelamer can bind Pi in exchange for chloride (sevelamer hydrochloride) or carbonate (sevelamer carbonate). Carbonate or metabolizable anions (acetate or citrate) when released also confers an alkali load. The perfect example is that sevelamer hydrochloride lowers serum bicarbonate concentration while sevelamer carbonate does not.

Pi binders reduce the available luminal Pi for absorption. Alternative methods modify the epithelial absorptive mechanisms that have evolved to be powerful means of extracting dietary Pi. Nicotinamide (niacin), which is already approved for human use for other indications, can inhibit the NaPi-2b transporter and transcellular transport.[146] Direct inhibition of the Na-coupled Pi transporter NaPi-2b is promising but may suffer from the large paracellular component that limits its efficacy.[147] In contrast, an unexpected downstream effect of an inhibitor of apical Na/H exchanger NHE3, originally designed to reduce gut Na^+ absorption, led to secondary effects of reduction of paracellular permeability to Pi and a substantial reduction of transepithelial Pi

TABLE 41.2 Phosphate Binders in Clinical Use

Cation	Formulation	Adverse Effects	Cost per Dose
Al^{3+}	Aluminum hydroxide	Osteomalacia Encephalopathy Microcytic anemia	$5
La^{3+}	Lanthanum carbonate	GI upset Unknown effect on bone	$12
Ca^{2+}	Calcium acetate Calcium carbonate	Hypercalcemia Ectopic calcification Adynamic bone disease	$1 $0.1
Mg^{2+}	Magnesium carbonate	Diarrhea Hypermagnesemia	$1.5
Fe^{2+}	Sucroferric oxyhydroxide Ferric citrate	Diarrhea Nausea	$11 $5
Sevalemar	Sevelamer hydrochloride Sevelamer carbonate	Diarrhea Constipation Metabolic acidosis	$7 $6

TABLE 41.3 Methods to Reduce Intestinal Pi Absorption

		Evidence	
Therapy	**Mode of Action**	**Preclinical**	**Humans**
Dietary modification	Reduce oral intake Reduce bioavailability	■	■
Gut lumen binder • Divalent/trivalent metal • Polymers	Binds dietary and secreted Pi in the gut lumen to be excreted in stool	■	■
NaPi-2b inhibitors	Inhibits transcellular absorption	■	
Nicotinamide (Niacin)	Inhibits transcellular absorption	■	■
NHE3 inhibitor	Inhibits paracellular absorption	■	■

absorption.[148] The reduction in intestinal Pi uptake will evolve very quickly to increasingly effective binders and inhibitors of both transcellular and paracellular Pi absorption, and treatment may be individualized.

Magnesium (Mg^{2+})

There is increasing appreciation regarding the potential deleterious effects of magnesium deficiency and the benefit of magnesium repletion in CKD. However, Mg^{2+} supplementation is not a routine practice, and there are no guidelines regarding how to achieve this goal. The data regarding the benefits of Mg^{2+} are well shown in animal models. Clinical epidemiologic data also support the detrimental effects of Mg^{2+} deficiency and the inferred beneficial effects of Mg^{2+} supplementation on diabetes, hyperparathyroidism, progression of CKD, cardiac arrhythmias, heart failure, hypertension, arterial calcification, and endothelial dysfunction.[17,149] Mg^{2+} is currently not routinely prescribed in the management of CKD, due mainly to lack of clinical guidelines, but other contributing factors include lack of clinically frank hypomagnesemia even in the presence of total body depletion, variations in interindividual and intraindividual longitudinal levels, variation in dialysis bath [Mg^{2+}], coexistence of compounding comorbid conditions, and side effects of therapy.

Oral Mg^{2+} supplementation is prescribed in various forms (oxide, chloride, lactate, gluconate, aspartate, citrate). Oxide has the lowest (<4%) and citrate the highest (~15%) absorption based on rise in S[Mg] and urinary Mg^{2+} excretion after an oral dose. The single factor most limiting Mg^{2+} therapy is diarrhea.

CONCLUSION

Disturbances in Pi, Ca^{2+}, and Mg^{2+} in CKD are part of the CKD-MBD syndrome, with grave cardiovascular complications that drive mortality, and skeletal complications that affect quality of life. The most important message is that there is not any automatic mobile phone-fit diagnostic algorithm or "one-size-fits-all" therapeutic regimen. There will be individualized treatments that are tailored to each patient's pathophysiology. Phosphate load to the organism should be restricted by dietary modifications and binders, and modifier of intestinal epithelial transport. Ca^{2+} supplements (or avoidance) should be prescribed only to those who will benefit from it based on individualized pathophysiology. Mg^{2+} therapy will have a similar scenario. We must have diagnostic capabilities to assess the Mg^{2+} status and guide whether to restrict or supplement Mg^{2+} to improve renal, cardiovascular, and metabolic outcomes.

QUESTIONS AND ANSWERS

Question 1

Which of the following statements about bone examination in CKD is false?

A. Bone examination in patients with CKD stages ≥3 and evidence of CKD-MBD and/or risk factors for osteoporosis is recommended for diagnosis and prognosis
B. In patients with advanced CKD and low or normal PTH, DXA measures of BMD predict pathologic fracture risk
C. Noninvasive examination of bone disease yields high negative predictive values for differentiating low-turnover vs. nonlow-turnover
D. Noninvasive examination of bone disease yields low positive predictive values for differentiating high-turnover vs. nonhigh-turnover bone disease
E. Bone biopsy should be considered in patients with pathological fractures, suspicion of osteomalacia, and refractory hypercalcemia

Answer: C

Bone examination in patients with CKD stages 3 or above and evidence of CKD-MBD and/or risk factors for osteoporosis is now recommended for diagnosis and prognosis. DXA measures of BMD—specifically femoral neck and total hip—predict pathologic fracture risk in CKD patients with stages 3 or above, particularly when levels of PTH are low or normal. Noninvasive examination of bone disease is not fully informative for the classification of low, normal, and high bone turnover in some patients with CKD-MBD, yielding low negative predictive values and low positive predictive values for differentiating low-turnover vs. nonlow-turnover and high-turnover vs. non high-turnover bone disease, respectively. Although bone biopsy is not routinely performed for the evaluation of CKD-MBD, it is important to recognize that the ultimate pathologic diagnosis of ROD can only be achieved with a bone biopsy, the diagnostic gold standard. Bone biopsy should be strongly considered in patients with pathological fractures, suspicion of osteomalacia, refractory hypercalcemia, or erratic therapeutic response to standard CKD-MBD therapy.

Question 2

Which of the following statements about PTH secretion and measurement is false?

A. Extracellular Pi is a main determinant of secretion of PTH
B. Third-generation bioactive PTH assays truly detect the 1− 84-amino-acid, full-length PTH molecule
C. Earlier PTH assays measuring C-terminal fragments lacked accuracy due to impaired renal excretion of these inactive peptides in CKD
D. Second-generation PTH assays can detect active full-length PTH but can still detect accumulated large C-terminal fragments, particularly in patients with advanced CKD

Answer: A

PTH is stored in the parathyroid gland for pulsatile secretion and is cleaved at different sites (N-terminal, C-terminal, and mid-region fragments). The circulating 1−84 amino-acid protein has a half-life of 2−4 minutes. The extracellular ionized Ca^{2+} concentration is a main determinant of minute-to-minute secretion of PTH. There are multiple PTH assays. Earlier assays measured C-terminal fragments, lacking accuracy due to impaired renal excretion of these inactive peptides in CKD. N-terminal assays also detected inactive metabolites. Second generation PTH assays (two-site immunoradiometric capture at the amino- and carboxy-termini) can better detect active full-length PTH but can still pick up accumulated large C-terminal fragments, particularly in patients with advanced CKD. Third-generation bioactive PTH assays truly detect the 1− 84-amino-acid, full-length PTH molecule.

Question 3

CKD is often considered a state of accelerated aging associated with α-Klotho deficiency and phosphate retention. Based on current knowledge, which one of the following events has not been linked to α-Klotho deficiency in CKD:

A. Cardiac remodeling
B. Increase in blood FGF-23 levels
C. Renal magnesium wasting
D. Increase in parathyroid hormone levels

Answer: C

Both α-Klotho deficiency and low serum magnesium levels have been associated with adverse outcomes in CKD. However, the crosstalk between α-Klotho and magnesium homeostasis is not currently defined. The principal role of α-Klotho is to form the specific receptor complex with FGFR1 that is required for FGF-23 signaling. As α-Klotho levels decline progressively in CKD, FGF-23 resistance develops, causing a compensatory increase in blood FGF-23 levels, high parathyroid hormone and S[P] levels, and low $1,25(OH)_2D_3$ accompany these changes. Preclinical studies showed that α-Klotho deficiency plays a role in the pathogenesis of uremic cardiomyopathy independently of FGF-23 and S[P].

Question 4

Select the molecular events that do not contribute to medial vascular calcification in CKD:

A. Production of reactive oxygen species by endothelial cells
B. Increase in circulating fetuin A levels
C. Transdifferentiation of vascular smooth muscle cells
D. Increased formation of calcioprotein particles in the blood

Answer: B

Fetuin A is circulating inhibitor of ectopic calcification. CKD-MBD is characterized by a decrease, not an increase, in circulating fetuin A levels, an event that promotes blood calcification propensity, formation of pathological secondary calcioprotein particles, and vascular calcification. Endothelial cells damaged by the uremic milieu or high phosphate show an increase in reactive oxygen species together with impaired nitric oxide production, and release of proinflammatory, profibrotic, and proangiogenic factors. These events not only induce endothelial dysfunction but also stimulate vascular smooth muscle cells transdifferentiation and vascular calcification.

Question 5

Which of the following statements about phosphate management in CKD is true?

A. The use of enteric phosphate binder lowers S[P] levels, parathyroid hormone, soft tissue calcification, and mortality in patient with CKD
B. Phosphate absorption from the gut can be decreased by dietary modification, inhibition of transcellular, and paracellular intestinal absorption
C. S[P] is usually increased in most patient with CKD stage 3
D. Dietary phosphate can be sequestered by oral administration of monovalent, divalent, or trivalent metallic ions.

Answer: B

Although phosphate binders correct a number of biochemical abnormalities in CKD, therapy with phosphate binders has not been shown in randomized control trials to lower mortality. The available methods to decrease phosphate absorption include lowering phosphate intake, changing the form of phosphate ingested, sequestering phosphate in the gut lumen, or decreasing transcellular or paracellular absorption. Frank hyperphosphatemia can occur in stage 3 CKD, but it rather unusual. There are no effective monovalent cations that can bind phosphate in the gut lumen.

Question 6

Based on both preclinical and clinical data, which one of the following is not a potential beneficial effect of magnesium supplementation in CKD?

A. Lowers phosphate absorption in the intestine
B. Prevents formation of calcioprotein particles in the blood
C. Acts directly on blood vessels to ameliorate uremic vasculopathy
D. Prevents hyperkalemia

Answer: D

Magnesium chelates phosphate in the gut lumen in an insoluble form and is a well-known phosphate binder. In the blood, magnesium can form soluble complexes with phosphate and prevent the formation of calcium phosphate precipitates and calcioprotein particles. There are many cell culture and *ex vivo* vascular experiments that show magnesium may protect the vasculature. The clinical data, albeit showing only association and not causality, clearly demonstrate a beneficial effect of higher S[Mg], particularly in the presence of hyperphosphatemia. Magnesium deficiency promotes renal potassium wasting and hypokalemia.

CHAPTER

Acid/Base Metabolism in Chronic Kidney Disease

Lee Hamm

Tulane University, New Orleans, LA, United States

Abstract

Chronic kidney disease (CKD) frequently causes metabolic acidosis. By stage 4 CKD approximately 40% of patients have metabolic acidosis. This is usually a hyperchloremic acidosis with a near-normal anion gap and normal S[K]. When the glomerular filtration rate (GFR) is less than 20 mL/min, a classic high anion gap metabolic acidosis ensues. Although a variety of defects in acid–base regulation have been reported, the predominant defect causing acidosis is an inadequate increase in ammonium excretion in the urine.

A variety of complications are caused by this acidosis in conjunction with the other consequences of CKD: loss of muscle mass, loss of bone mineral, insulin resistance, and faster loss of GFR. Increased mortality is associated with the acidosis as well.

Treatment of the acidosis may be with sodium bicarbonate, citrate, or diets high in fruits and vegetables. A few single-center trials have suggested that treatment of acidosis improves the progression of chronic kidney disease (CKD) and improves muscle function. Similar treatments have been evaluated in a few studies in patients with normal systemic pH and serum bicarbonate concentration. The rationale for such studies is based on some evidence of retained acid in selected patients with CKD.

SCOPE OF THE PROBLEM/PUBLIC HEALTH IMPLICATIONS

Metabolic acidosis is a common problem in patients with CKD, particularly as the CKD progresses beyond the earliest stages. Usually the acidosis is hyperchloremic with a normal anion gap when the glomerular filtration rate (GFR) is between 20 and 50 mL/min. As the GFR falls further below 20 mL/min, the acidosis frequently changes to a high anion gap type. Using a plasma bicarbonate concentration (HCO_3^-) of <22 mEq/L as the definition of acidosis, 2–13% of patients with stage 3 CKD and 19–37% of patients with stage 4 CKD have overt acidosis[1–3] (Figure 42.1).

This acidosis is not only a cause of a variety of complications but is likely also associated with further progression of the fall in GFR (Figure 42.2).

In addition to overt clinical acidosis reflected by a low plasma HCO_3^- or arterial pH, intrarenal (interstitial) acidosis or retained acid in CKD patients may be present when overt acidosis is not apparent.[4,5] This acid retention has been identified by administering boluses of bicarbonate and measuring the change in plasma HCO_3^-. Less than a normal increase in plasma HCO_3^- is assumed to represent retained acid.[4,5] Because this phenomenon of retained acid may be common,[5] even in early CKD, this may be an important target for future treatment. This retained acid may cause progressive renal damage, just as systemic acidosis does.

PATHOPHYSIOLOGY

Mechanisms of Metabolic Acidosis in CKD

Metabolic acidosis in CKD usually results from failure of the kidneys to adequately excrete the normal nonvolatile, endogenous acid load derived from typical diets and metabolism.[6] The acid load from a typical Western diet is normally 40–70 mEq per day in adults, with a vegetarian diet leading to lesser acid loads. This is usually reported as about 1 mEq/kg body weight in adults and 2–3 mEq/kg in children. The kidneys normally excrete this entire acid load with about 1/3 as titratable acid and 2/3 as ammonium excretion. Titratable acid excretion is the acid excreted along the nephron, lowering urine pH, and titrated by urinary buffers, predominantly phosphate moieties. Normally

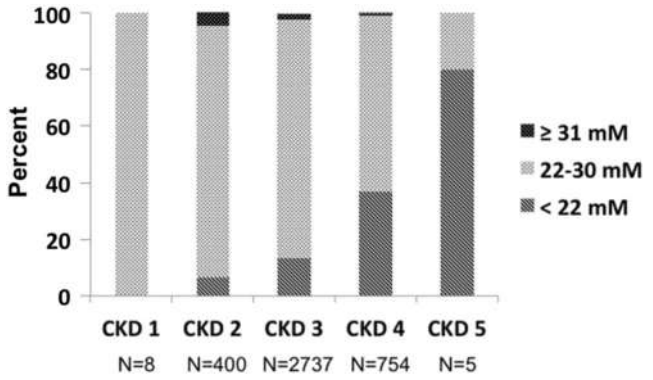

FIGURE 42.1 Prevalence of serum bicarbonate abnormalities by stage of chronic kidney disease (CKD) in the CRIC (Chronic Renal Insufficiency Cohort) study.[1]

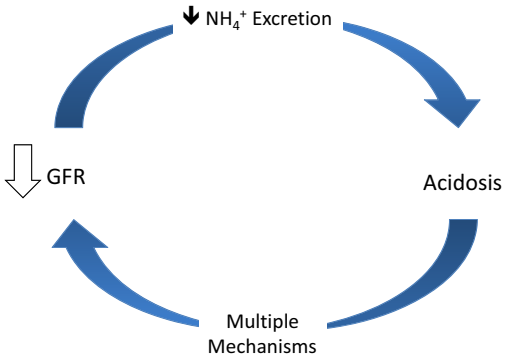

FIGURE 42.2 Schematic of the relationship of CKD and reduced glomerular filtration rate (GFR) and acidosis. Reduced GFR, particularly at levels below 30 mL/min is often associated with and causes metabolic acidosis. This is attributable predominantly to inadequate excretion of ammonium (NH_4^+). In recent years numerous studies have suggested that acidosis leads to further worsening of GFR.

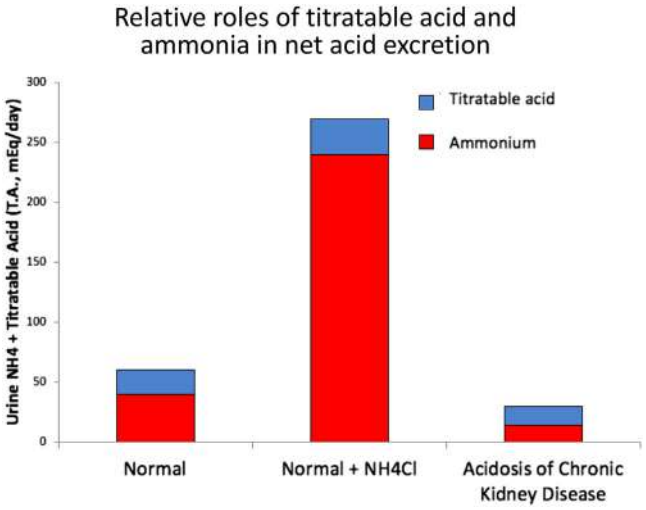

FIGURE 42.3 Acid excretion in normal individuals, normal individuals with an acid load induced with NH_4Cl (average plasma HCO_3^- 20 mEq/L), and individuals with acidosis accompanying CKD (average GFR 20 mL/min, average plasma HCO_3^- 17 mEq/L). In normal participants, increases in NH_4^+ excretion account for the predominant compensatory response to acidosis. In advanced CKD, NH_4^+ excretion fails to adequately increase with resultant acidosis. Abbreviations: *CKD*, chronic kidney disease; *GFR*, glomerular filtration rate; *T.A.*, urine titratable acidity. *Adapted with permission from reference 7.*

if daily acid load is higher, the predominant adaptation to excrete this acid load is an increase in ammonium excretion in the urine (Figure 42.3). The increased ammonium excretion occurs *via* both increased ammoniagenesis and increased transport of the produced ammonium into the tubular lumen and final urine.[8] With the acidosis of CKD, both increased titratable acid and increased urinary ammonium are observed (Figure 42.3), but the increases particularly in ammonium excretion are often inadequate to prevent or correct the acidosis. If one factors the increased acid excretion for the number of remaining nephrons, both titratable acid and ammonium excretion per nephron (or per mL of GFR) increase. The amount of increase, particularly in ammonium excretion, however, usually is insufficient to adequately compensate for the loss of nephrons or GFR.[7] Titratable acid excretion in CKD is aided by increased phosphate excretion per nephron, because of secondary hyperparathyroidism and increases in serum phosphate concentration as GFR declines.[6] Decreased protein intake and use of phosphate binders will usually lessen urinary phosphate excretion. There is evidence that there is some defect in outer medullary ammonium accumulation and trapping.[9] Most patients with CKD can appropriately lower the urine pH, and titratable acid excretion is relatively well preserved.[9] In some CKD patients, hyperkalemia may also suppress ammoniagenesis and ammonium excretion.[10]

Bone buffering may account for much of the relative stability of plasma HCO_3^-.[11] Retained acid, however, even in the absence of a decreased plasma HCO_3^- can also be detected in the renal interstitium and muscles of experimental animals with reduced renal mass.[12–14] The same retention of acid, even in the absence of a reduced plasma HCO_3^-, is postulated to occur in at least some patients with CKD.[4,5] In humans, this acid retention has been assessed using the response of plasma HCO_3^- 2 hours after giving 0.5 mEq/kg body weight oral $NaHCO_3$[5] (Figure 42.4).

CONSEQUENCES OF METABOLIC ACIDOSIS IN CKD

Metabolic acidosis in CKD causes or contributes to many secondary deleterious complications (Table 42.1). As delineated below, the acidosis worsens bone demineralization, contributes to loss of muscle function and

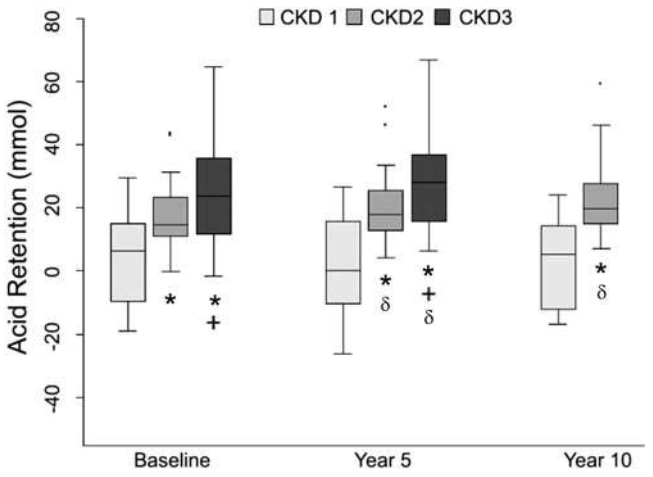

FIGURE 42.4 Acid retention for CKD stages 1, 2, and 3 calculated from the increment in plasma HCO_3^- after oral HCO_3^- loads. The figure displays boxplots showing acid (H+) retention for individuals with stage CKD 1, CKD 2, and CKD 3 at baseline (*year 0*), *year 5*, and *year 10* of follow-up. *$p < 0.05$ vs. respective CKD 1; $^{+}p < 0.05$ vs. respective CKD 2; $^{\delta}p < 0.05$ vs. respective baseline value. *From reference 5; see reference for details of methods.*

TABLE 42.1 Consequences of Acidosis of CKD

Worsening bone disease
Impaired growth in children
Increased protein catabolism, decreased synthesis with decreased muscle mass, and decreased plasma albumin concentration
Impaired glucose tolerance and insulin resistance
Increased inflammation
Progression of renal disease
Increased mortality

mass, causes hypoalbuminemia, and is associated with glucose intolerance. In addition, over the past decade, many studies have associated acidosis or acid retention with progression of CKD. Most importantly, acidosis in CKD is associated with increased mortality.[15–18]

CKD is associated with loss of muscle mass,[19] and metabolic acidosis in CKD decreases muscle mass, lessening activity, and therefore probably contributes to increasing morbidity and mortality.[20–24] The mechanisms involve interactions with cortisol, inflammatory cytokines, activation of the ubiquitin–proteasome pathway, impaired insulin/IGF-1 signaling, and activation of caspase-3 proteolysis.[20–22,24,25] There is some evidence of improvement of muscle strength and mass with treatment of acidosis with bicarbonate.[26–28] Similarly, acidosis in CKD is associated with lower serum albumin concentration, which improves with treatment.[2,27]

Metabolic acidosis, including that associated with CKD, causes bone demineralization.[11,24,29] Although hyperparathyroidism and vitamin D abnormalities are the main factors in the bone and mineral disease with CKD, acidosis contributes. Acidosis increases the activity of osteoclasts and decreases that of osteoblasts.[30] Clinically, bone disease is worse in CKD patients with acidosis.[24,31] The interactions of acidosis with other factors (such as PTH, 1,25-dihydroxyvitamin D, and fibroblast growth factor 23) contributing to bone disease in CKD are complex.[24] In children, acidosis is associated with impaired growth.

Metabolic acidosis in CKD can worsen glucose tolerance and increase insulin resistance. Both states improve with treatment of the acidosis.[32–36] Metabolic acidosis is also associated with abnormalities in the growth hormone-IGF-1 axis, decreased leptin levels, and reduced T4 levels,[24,37] but the clinical impact of these is not yet known with certainty. There is also some evidence that cognitive function is worse in patients with acidosis.[38]

Several studies have shown an association between acidosis in CKD and faster progression of CKD.[18,39–44] Is this causation or just association? The experimental and clinical studies, which demonstrate that treatment of acidosis slows the deterioration of GFR, are the most compelling evidence of a causal relationship between acidosis and further declines in GFR. Experimental animal studies have demonstrated that acid loads or a more acidic or higher protein diet accelerate GFR decline and that alkali loads prevent this decline.[12–14,45,46]

Mechanisms for CKD Progression

The mechanisms that account for acidosis or retained acid causing progressive kidney injury and further reduction in GFR are not completely established (Figure 42.1) but have been investigated to some extent (Table 42.2). Early studies suggested that acidosis, by inducing medullary accumulation of ammonia, activates complement and subsequently increases interstitial fibrosis.[47] More recent studies have shown increased interstitial endothelin, angiotensin II, and

TABLE 42.2 Proposed Mechanisms of Acidosis Causing Progressive Renal Damage

Ammonium activation of complement leading to fibrosis
Increased proinflammatory cytokines
Increased endothelin
Increased angiotensin II, aldosterone

aldosterone are major factors underlying this pathophysiology.[12–14,45,46] These hormones may be part of the mechanisms whereby a homeostatic increase in acid excretion occurs in response to systemic acidosis. The renal damage is an unfortunate side effect of the increase in these hormones.

DIAGNOSIS

Metabolic acidosis is recognized by a reduced arterial pH as a consequence of a decreased plasma HCO_3^-. Respiratory compensation lowers the pCO_2. In the setting of known CKD of appropriate magnitude (sufficiently reduced GFR), an arterial blood gas is not usually necessary to establish a diagnosis. A reduced venous plasma HCO_3^- or total CO_2 is sufficient to make the diagnosis of metabolic acidosis secondary to CKD (assuming nothing else to suggest another cause, such as respiratory alkalosis).

Metabolic acidosis in CKD patients often begins with a hyperchloremic, normal anion gap acidosis. As the CKD gets more severe, a high anion gap metabolic acidosis ensues. Retention of phosphate, sulfate, urate, and other anions accounts for the elevation in anion gap. The increase in anion gap may be seen earlier when the anion gap is fully adjusted for albumin.[48] A higher anion gap independent of the plasma HCO_3^- may correlate with progression of CKD.[44]

Some patients with CKD do not have overt metabolic acidosis (reduced plasma HCO_3^-) but have apparent retained acid or an acidotic renal interstitium and a normal plasma HCO_3^- and arterial pH. This has been referred to as subclinical acidosis, preclinical acidosis, or eubicarbonatemic acidosis and may be present in patients with CKD.[29,49,50] For research purposes in humans, this acid retention has been identified using the response of plasma HCO_3^- after giving oral $NaHCO_3$.[5] Reduced urine citrate excretion may also indicate retained acid.[51] Urinary citrate excretion is regulated predominantly by acid–base status, as urinary citrate decreases significantly with acid loads or acidosis.[52] Reduced urinary citrate excretion is associated with increased incidence of calcium kidney stones, as citrate is among the most important inhibitors of calcium stone formation.[53]

In contrast to the typical acidosis of CKD, some patients with CKD may have an early hyperchloremic, hyperkalemic acidosis that is disproportionate to the degree of decrement in GFR. This is often called type 4 renal tubular acidosis or hyporeninemic, hypoaldosteronism, associated with diabetes, obstructive uropathy, sickle cell disease, or other interstitial kidney diseases. Often in these patients the hyperkalemia is actually more pronounced than the acidosis. In fact, the hyperkalemia contributes to the acidosis. Hyperkalemia suppresses ammoniagenesis and ammonium secretion, and it is an important contributor to the acidosis in these patients.[10] This hyperkalemia contrasts with the usual acidosis of CKD, which is typically normokalemic, due to adaptations in both renal collecting duct and colonic K+ secretion as GFR declines.[9]

TREATMENT

The clinical evidence that treatment of acidosis in CKD slows the progression of GFR decline has been recently summarized[29,54] (Figure 42.5). Several single-center studies strongly suggest that treating acidosis slows progression of CKD.[26,27,54,55,57] These studies have used sodium bicarbonate (0.3–0.5 mEq/kg per day), sodium citrate, or a diet high in fruits and vegetables to treat acidosis. Another positive study used a keto-analog-supplemented low-protein vegetarian diet to treat CKD and the associated acidosis.[56] A low-protein diet has been shown to raise plasma HCO_3^-.[58] Although most of these studies have addressed patients with reduced plasma HCO_3^-, some studies used patients with normal plasma HCO_3^- levels.[59] Other studies are underway.[29] There are limited data regarding whether treatment of acidosis in CKD improves mortality.[60]

Current guidelines for therapy of the acidosis of CKD by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative and others is to monitor total CO_2 (or HCO_3^-) and maintain plasma HCO_3^- above 22 mEq/L.[61,62] Many now question whether this is sufficient, or whether others with higher plasma HCO_3^- should be treated. A so-called subclinical acidosis, preclinical acidosis, or eubicarbonatemic acidosis may be present in many patients with CKD.[29,49,50] At the present time, there are no large randomized trials that address this question.[54] Which

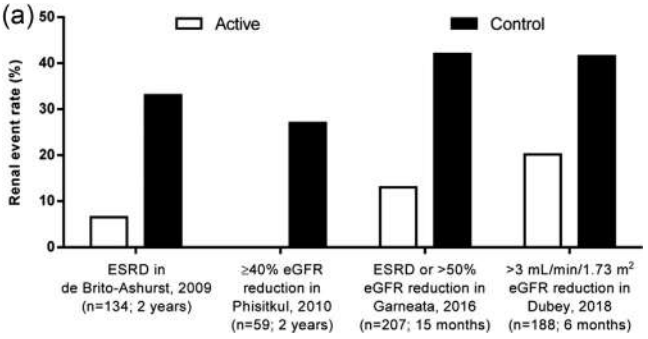

FIGURE 42.5 Renal event rate in some of the trials of treating acidosis of CKD. Active refers to treatment with (from left to right) sodium bicarbonate,[27] sodium citrate,[55] very low protein diet with ketoanalogue supplementation,[56] or sodium bicarbonate,[26] respectively. *From reference 54.*

patients with normal acid–base status should be treated has not been defined. Lower urinary ammonium excretion, possibly indicating inability to adequately excrete acid, has been associated with worse outcomes in some populations.[63–65] However, lower urinary ammonium could also result from a low dietary and metabolic endogenous acid load, which may be beneficial.[66]

Reduced urinary citrate excretion may indicate those patients who have retained acid, and those that may therefore benefit from alkali treatment or other means of treating acidosis or retained acid.[51] Urinary citrate is regulated predominantly by acid–base status of individuals, such that urinary citrate excretion declines remarkably with even modest acid loads.

Alkali or HCO_3^- can be given as Shohl's solution (Citric Acid—Sodium Citrate), other forms of citrate, or sodium bicarbonate tablets. The dose can initially exceed the daily endogenous and dietary acid load (typically 40–70 mEq/kg body weight per day). New therapies with a H^+ binding agent are under development.[67,68] Neither alkali supplementation or adding fruits and vegetables in the diet require dietary protein restriction, but this may have added benefit. Alkali therapy not only slows progression of CKD but also improves bone and skeletal muscle effects of CKD.[69] Citrate (such as Shohl's solution) has been shown to enhance the absorption of aluminum from the gastrointestinal tract and therefore should be used with caution or not at all in patients receiving aluminum-containing antacids, because of the risk of aluminum intoxication.[70]

Potential negative side effects of treating acidosis have been raised[29,71] but do not seem significant with the present data.[72] Hypertension with sodium loads has not occurred during most studies with sodium bicarbonate. There is some association of higher serum HCO_3^- with congestive heart failure, but this is not necessarily the result of treatment of acidosis[73] and has not been consistently found.[74] There is a theoretical risk of worsened vascular calcification with treatment of acidosis, but this has also not been clinically confirmed.[29]

CONCLUSIONS

Metabolic acidosis in CKD is very common, particularly as GFR declines and patients reach stage 4 CKD. The acidosis results predominantly from inadequate ammonium excretion. This acidosis clearly contributes to several complications, including loss of muscle mass and bone mineral, accelerated decline in GFR, and increased mortality. There is also some evidence that some patients with CKD and normal plasma HCO_3^- have retained acid, particularly in the renal interstitium, and that this contributes to progressive GFR decline. Although there have not been any large randomized trials, several single center trials of moderate size suggest that treatment of acidosis slows the progression of CKD. Treatment of acidosis in patients with CKD may be with sodium bicarbonate, citrate, or diets high in fruits and vegetables.

QUESTIONS AND ANSWERS

Question 1

What is the main cause of metabolic acidosis in CKD?

A. Inability to acidify the urine
B. Decreased HCO_3^- reabsorption in the distal nephron
C. Inadequate HCO_3^- reabsorption in the proximal tubule
D. Decreased titratable acid excretion
E. Inadequate NH_4^+ excretion

Answer: E

Although many defects in acid–base metabolism are present in kidney disease, the main factor causing acidosis is inadequate NH_4^+ excretion.

Question 2

Which of the following is not usually a complication of acidosis in CKD?

A. Loss of bone mineral
B. Cardiomyopathy
C. Hypoalbuminemia
D. Progression of CKD
E. Insulin resistance

Answer: B

Cardiomyopathy is not a specific complication of the acidosis of CKD. Although a significant spectrum of complications has been found, cardiomyopathy is not included. Increased muscle catabolism and loss of skeletal muscle mass is a known complication. The other complications, such as loss of bone mineral, progression of CKD, hypoalbuminemia, and insulin resistance are known.

Question 3

Which type of acidosis is most common in early CKD?

A. Hyperchloremic normal anion gap metabolic acidosis
B. Respiratory acidosis
C. High anion gap metabolic acidosis
D. Mixed high anion gap and hyperchloremic acidosis
E. Hyperkalemic hyperchloremic metabolic acidosis

Answer: A

Although other patterns can be seen, particularly in later stages of CKD, a hyperchloremic acidosis (with normal serum potassium concentration [S[K]]) is the most common, if overt acidosis is present.

Question 4

What is the potassium level in most early CKD?

A. Low
B. Normal
C. High

Answer: B

Potassium levels are usually normal until very late in CKD due to a number of adaptations. Some patients, particularly with diabetic nephropathy, are hyperkalemic and have hyporeninemic hypoaldosteronism.

Question 5

Which approaches to treatment of metabolic acidosis have been studied and reported to improve progression of CKD?

A. Citrate
B. Sodium bicarbonate
C. Diet high in fruits and vegetables
D. A and B
E. A, B, and C

Answer: E

All of the approaches above have been reported to improve the progression of CKD.

Question 6

What is the most typical pattern of electrolytes for a patient with an estimated glomerular filtration rate of 65 mL/min/1.73m^2 ? The kidney disease is from hypertension with minimal proteinuria.

A. Na 140, Cl 105, K 4.0, HCO_3^- 17
B. Na 140, Cl 107, K 5.5, HCO_3^- 22
C. Na 140, Cl 105, K 4.0, HCO_3^- 25
D. Na 140, Cl 100, K 3.0, HCO_3^- 30
E. Na 140, Cl 108, K 4.0, HCO_3^- 22

Answer: C

Normal electrolytes including a normal HCO_3^- is statistically the most likely electrolyte pattern in patients with stage 2 CKD. If an acidosis were present, it would most likely be hyperchloremic (e) with normal S[K]. Other patterns are not typical for relatively mild CKD: (a) high anion gap; (b) hyperkalemic hyperchloremic metabolic acidosis, and (d) likely metabolic alkalosis.

Abstract

Hyperuricemia and gout are common in chronic kidney disease (CKD) patients. This relationship has been noted since the 1800s. Over the years there has been great controversy over the biologic significance of hyperuricemia, with some individuals arguing it is a major cause of CKD, and others viewing the rise in serum urate concentration (S[Ur]) as strictly an epiphenomenon. During the last 10–15 years, interest in uric acid has reawakened with the realization that an elevated S[Ur] can predict the development of CKD and by experimental studies that document a causal role for uric acid in both the development and progression of CKD. Today there is great interest in the potential that uric acid may represent a remediable risk factor for CKD. We provide an update on uric acid and the kidney, focusing both on uric acid metabolism and a critical evaluation of the current evidence base for uric acid as a risk factor for CKD.

INTRODUCTION

Hyperuricemia and gout are common in chronic kidney disease (CKD) patients. This relationship has been noted since the 1800s.[1] Over the years there has been great controversy over the biologic significance of hyperuricemia. Some argue hyperuricemia is one of the major causes of CKD,[2] whereas others view the rise in serum urate concentration (S[Ur]) as strictly an epiphenomenon.[3] During the last 10–15 years, interest in uric acid has reawakened with the realization that an elevated S[Ur] can predict the development of CKD,[4,5] and by experimental studies that document a causal role for uric acid in both the development and progression of CKD.[6–9] Today there is great interest in the potential that uric acid may represent a remediable risk factor for CKD. We provide an update on uric acid and the kidney, focusing both on uric acid metabolism and a critical evaluation of the current evidence for uric acid as a risk factor for kidney disease.

URIC ACID METABOLISM

Generation of Uric Acid

Uric acid is generated from metabolic conversion of either exogenous (dietary) or endogenous purines, primarily in the liver and intestine. The immediate precursor of uric acid is xanthine, which is metabolized to uric acid by either xanthine oxidase or by its isoform, xanthine dehydrogenase. Approximately two-thirds of total body urate is produced endogenously, while the remaining one-third is accounted for by dietary purines.[10] Purine-rich foods include beer, meat, poultry, seafood, mushrooms, spinach, asparagus, and cauliflower.[11] Uric acid can also be generated by fructose, which is produced both from nucleotide turnover and from increased synthesis from amino acid precursors.[12,13] Alcohol can also increase uric acid levels from increased nucleotide turnover and reduced urinary excretion.[14,15] In healthy men, the urate pool averages about 1200 mg with a mean turnover rate of 700 mg/day.[16]

In humans, uric acid represents the final enzymatic degradation product in purine metabolism. In most mammals a liver enzyme, uricase, degrades uric acid to 5-hydroxyisourate and eventually allantoin.[17] However, in humans, and great and lesser apes, uricase was mutated approximately 10–15 million years ago, and as such, serum urate levels are higher in these species compared to other mammals.[18,19] Nevertheless, much of uric acid is still metabolized in humans. First, uric acid is an antioxidant and can react with a variety of substances, resulting in the formation of allantoin

Chronic Renal Disease, Second Edition

(from superoxide), triuret (from reaction with peroxynitrite), or 6-aminouracil (from reaction with nitric oxide).[20,21] These products account for less than 1% of uric acid metabolism, but it can be elevated in patients with CKD and those treated with maintenance dialysis. However, as much as one-third of uric acid enters the gut *via* transporters (ABCG2 and SLC2A9) where it is metabolized by gut bacteria and can be excreted in the stool as uric acid or downstream products.

Excretion of Uric Acid

One-third of the total uric acid excreted is *via* bacterial metabolism in the gut, with two-thirds excreted by the kidneys. Normal urinary urate excretion ranges between 250 and 750 mg a day. Urate, the form of uric acid in the circulation, is freely filtered at the glomerulus, followed by both reabsorption and secretion in the proximal tubule. The fractional urate excretion is 8–10% in the healthy adult. Some adaptation occurs in people with impaired renal function, in whom the fractional excretion increases to the range of 10–20%[22] along with an increased intestinal excretion of uric acid. An increase in the gut transporter ATP-binding cassette superfamily G member 2 (ABCG2) mRNA expression in an animal model of CKD has also been reported, consistent with a compensatory increase in uric acid elimination from the intestine.[23]

During the last decade there have been great advances in our understanding of urate transport by the kidney, largely due to the characterization and isolation of transporters mainly or exclusively restricted to urate transport. Membrane vesicle studies have suggested the existence of two major mechanisms modulating urate reabsorption and secretion, consisting of a voltage-sensitive pathway and a urate–organic anion exchanger.[24,25] Several of these transporters/channels have been identified (Figure 43.1).[26] Organic anion transporters 1–10 (OAT1–10) and the urate transporter-1 (URAT-1) belong to the SLC22A gene family, which facilitate the movement of a variety of chemically unrelated endogenous and exogenous organic anions including uric acid.[27] URAT-1, which is encoded by SLC22A12, is the major organic anion exchanger for uric acid on the apical (luminal brush border) side of the proximal tubular cell.[28] In the human kidney, urate is transported *via* URAT-1 across the apical membrane of proximal tubular cells, in exchange for anions being transported back into the tubular lumen to maintain electrical balance. URAT-1 has a high affinity for urate together with lactate, ketones, α-ketoglutarate, and related compounds. Pyrazinamide, probenecid, losartan, and benzbromarone all inhibit urate uptake in exchange for chloride at the luminal side of the cell by

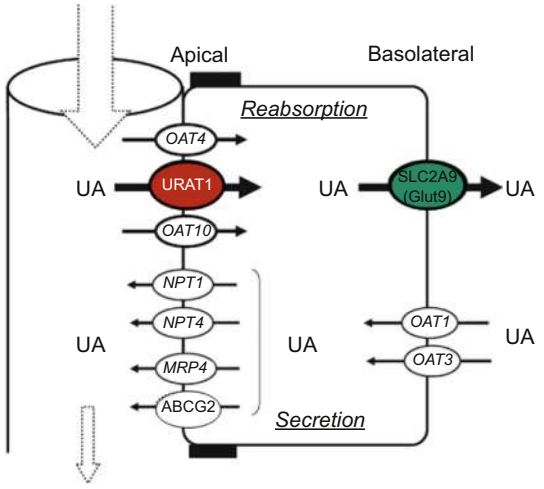

FIGURE 43.1 Renal urate transport. Renal urate transport is thought to occur primarily, if not exclusively, in the proximal tubule. The two most important transporters involved in reabsorption are URAT1 (on the apical membrane) and SLC2A9 (on the basolateral membrane). Important transporters for urate secretion include ABCG2, MRP4, and others. *Adapted from reference 26.*

competition with the urate exchanger. OAT-4 exhibits 53% amino acid homology with URAT1. After uptake into cells, urate then moves across the basolateral membrane into the blood by other organic anion transporters, of which the most important is SLC2A9 (also known as GLUT9).[29,30] SLC2A9 is highly expressed in the kidney, gut and liver. Individuals with mutations in either URAT1 or SLC2A9 have severe hypouricemia with marked uricosuria.[31,32]

Urate secretion appears to be mediated principally by a voltage-sensitive urate transporter, which is expressed ubiquitously and localizes to the apical side of the proximal tubule.[33] One candidate is MRP4, which is a novel human renal apical organic anion efflux transporter. MRP4 is a member of the ATP-binding cassette transporter family. MRP4 mediates secretion of urate and other organic anions such as cAMP, cGMP, and methotrexate across the apical membrane of human renal proximal tubular cells.[34] Another important voltage-sensitive transporter for uric acid is ABCG2. ABCG2 is expressed in both the proximal tubule and gut and appears to have a critical role in the movement of uric acid into the gut.[35]

Another protein involved in renal transport of urate is Tamm–Horsfall protein (THP), also known as uromodulin. THP is exclusively expressed and secreted by epithelial cells of the thick ascending limb.[36] THP has antibacterial effects. THP also colocalizes with the Na, K, 2Cl transporter in lipid rafts in the apical cell membrane, suggesting a functional interaction.[37] Mutations in the human uromodulin gene have been identified in people with type 2 medullary cystic kidney disease and familial juvenile hyperuricemic nephropathy.[38,39]

THP polymorphisms have also been associated with hyperuricemia,[40] which is inconsistent with the conventional wisdom that uric acid handling is restricted to the proximal tubule. However, there is some evidence that some urate secretion in the rat can occur distal to the proximal tubule. Furthermore, the THP mutation may lead to sodium wasting and diuresis,[41] possibly resulting in stimulation of urate reabsorption proximally.

CAUSES OF HYPERURICEMIA AND HYPOURICEMIA

Hyperuricemia

Hyperuricemia is arbitrarily defined as a S[Ur] greater than 7.0 mg/dL in men and greater than 6.5 mg/dL in women.[42] S[Ur] levels in the population appear to be increasing throughout the last century, likely as a consequence of changes in diet.[43] Uric acid levels tend to be higher in certain populations (such as African Americans and Pacific Islanders), with certain phenotypes (such as obesity and metabolic syndrome) and with special diets. Uric acid also has a circadian variation, with the highest levels in the early morning.[44]

The S[Ur] is determined by the balance between urate production and elimination. Hyperuricemia may occur from excessive production of urate (overproduction) or decreased elimination (underexcretion). Frequently a combination of both processes occurs in the same patient. Furthermore, uric acid levels may vary in the same individual by as much as 1−2 mg/dL during the course of a day, due to the effects of diet, hydration, and exercise.

Genetic mechanisms mediating hyperuricemia include overproduction due to a lack of hypoxanthine−guanine phosphoribosyltransferase (HGPRT) or overactivation of phosphoribosyl pyrophosphate synthetase. People with Lesch−Nyhan syndrome (due to a mutation of HGPRT on the X chromosome) present with neurologic manifestations (mental retardation, choreoathetosis, and dystonia) in childhood and have an increased risk for nephrolithiasis, renal failure, and gout. A partial deficiency of HGPRT may manifest later in life as recurrent gout and/or nephrolithiasis (Kelley−Seegmiller syndrome).[45] Other genetic mechanisms include people with the uromodulin mutation, who develop hyperuricemia (due to underexcretion) with early and progressive renal disease. Certain populations such as indigenous peoples living in Oceania also have higher uric acid levels than Caucasian populations.[46] Finally, African Americans also have higher uric acid levels, and a twofold higher incidence of gout compared to Caucasian or Asian populations.[47] However, this could reflect diets higher in fructose-containing sugars rather than genetic mechanisms.[48]

Hyperuricemia may also result from diets high in purines, ethanol, or fructose. The effect of alcohol is in part related to increased urate synthesis, which is due to enhanced turnover of ATP during the conversion of acetate to acetyl-CoA as part of the metabolism of ethanol.[14] In addition, acute alcohol consumption causes increased lactate production. Because lactate is an antiuricosuric agent, it reduces renal urate excretion and exacerbates hyperuricemia.[15] Fructose (a simple sugar present in sucrose, table sugar, high fructose corn syrup, honey, and fruits) can also induce a rapid rise in S[Ur], due in part to its rapid phosphorylation in hepatocytes with ATP consumption, intracellular phosphate depletion, and the stimulation of AMP deaminase with the generation of uric acid.[49] Chronic fructose consumption also stimulates the synthesis of uric acid from amino acid precursors. The marked increase in fructose intake may have a role in the rising levels of S[Ur] and obesity worldwide.[50]

In addition, uric acid levels may be affected by exercise, with moderate exercise reducing urate levels (probably by increasing renal blood flow) and severe exercise causing a rise in S[Ur] (probably due to ATP consumption with adenosine and xanthine formation). Urate levels vary between genders. Premenopausal women have lower S[Ur] than men due to the uricosuric effect of estrogen.[51] S[Ur] tends to increase in the setting of low blood volume and/or low salt diet due to its increased reabsorption in proximal tubules. Hyperuricemia is particularly common in patients with obesity and/or metabolic syndrome (thought to be secondary to the effect of insulin to stimulate uric acid reabsorption) and in those with untreated hypertension (in association with reduced renal blood flow). Thiazides also increase uric acid reabsorption in the proximal tubule by decreasing blood volume and *via* a direct interaction with the organic anion exchanger.

Other drugs, such as cyclosporine, pyrazinamide, and low-dose aspirin increase S[Ur], primarily by interfering with renal urate excretion. In addition, the generation of organic anions by lactate or β-hydroxybutyrate may interfere with urate secretion in the proximal tubule and cause a rise in serum urate levels. Chronic lead ingestion can also cause hyperuricemia by reducing urate excretion. In contrast, acute toxicity with extremely high lead concentrations may cause hypouricemia, due to proximal tubular injury and the induction of a Fanconi syndrome.[52,53]

Uric acid production is also increased in the setting of tissue hypoxia or with cell turnover. With tissue hypoxia, ATP is consumed and the isoform, xanthine oxidase, is induced, resulting in increased local uric acid concentrations. Circulating uric acid levels are thus high in

subjects with congestive heart failure, acute and chronic high altitude hypoxia, congenital cyanotic heart disease, and with obstructive sleep apnea.[54,55] Uric acid levels are commonly elevated with certain malignancies, especially leukemia and lymphoma, and levels may sharply rise following chemotherapy. Finally, S[Ur] has a tendency to be elevated in patients with polycythemia vera and other myeloproliferative disorders.

In the setting of reduced renal function, the fractional excretion of urate increases, but not enough to fully compensate for the reduction in GFR. As a consequence serum urate levels rise in CKD patients. In an animal model of CKD, the expression of URAT1, GLU9, ABCG2, and NPT4 in proximal tubules uniformly decreased possibly due to tubular injury.[23] Therefore, the mechanism for an elevation of uric acid in CKD is not clear yet, and simply may be because of the decreased GFR. In CKD, uric acid excretion by the gastrointestinal tract is also enhanced.[56] Therefore serum urate levels tend to be only mildly elevated in patients with CKD, and gout is relatively rare. However, by the time dialysis is initiated, half of CKD patients are hyperuricemic.[57,58]

Hypouricemia

Low uric acid levels (levels less than 2.0 mg/dL) can occur *via* a variety of mechanisms, including with liver disease (due to decreased production), Fanconi syndrome (due to impaired reabsorption by the proximal tubule) and diabetic glucosuria (which causes uricosuria). There is also a hereditary renal hypouricemia syndrome, particularly common in East Asia, due to a mutation in the URAT-1 gene.[59] A similar hypouricemia syndrome has also been observed with mutations in SLC2A9.[31] Patients carrying these mutations are particularly prone to develop acute kidney injury (AKI) following vigorous exercise.[32]

Drugs such as probenecid, high-dose salicylates, sulfinpyrazone, benziodarone, benzbromarone, the new class of glifozin SGLT2 inhibitors, and losartan are uricosuric. Allopurinol, febuxostat, and oxypurinol lower S[Ur] by blocking xanthine oxidase. Some statins also lower S[Ur].[60] Recombinant uricase (rasburicase) can markedly reduce S[Ur] and is approved for use in patients with tumor lysis syndrome. Pegloticase is a recombinant uricase that has polyethylene glycol attached to increase the circulating half-life and is used to treat refractory gout.[61]

URIC ACID AND RENAL DISEASE

There are two types of renal disease induced by uric acid. One is mediated by urate crystal deposition, and the other is unrelated to crystals, but is mediated by soluble uric acid, which causes or aggravates renal disease. Acute uric acid nephropathy, chronic urate nephropathy, and uric acid nephrolithiasis are the diseases induced by urate crystals. Among them, the identity of chronic urate nephropathy as a disease entity fell into question due to the focal nature of urate crystal deposition, the presence of intrarenal crystalline deposition in patients without renal disease, and because the kidney disease could often be attributed to coexisting risk factors such as hypertension and vascular disease in gout patients. We focus on the kidney disease associated with an elevation of soluble uric acid levels.

Hyperuricemia as a Primary Cause of CKD

Hyperuricemia is common in CKD patients. Although in some cases the hyperuricemia is due to specific disease entities, uric acid excretion is impaired in patients with reduced GFR. Therefore, in many cases the rise in S[Ur] may be simply secondary to CKD, although this does not rule out the possibility that uric acid may still have a role in modifying progression of renal disease.[62]

Gout was considered a cause of CKD, dating back to the mid-19th century. Natural history studies prior to the availability of uric acid–lowering drugs reported that as many as 25% of gouty patients developed proteinuria, 50% developed renal insufficiency, and 10–25% developed ESRD.[2] Renal histologic changes in patients with gout include arteriolosclerosis, glomerulosclerosis, and tubulointerstitial fibrosis, often with focal deposition of monosodium urate in interstitial areas, especially the outer medulla.[63] This led to the supposition that the disease "gouty nephropathy" or "chronic urate nephropathy" might be due to urate crystal deposition in the kidney. However, studies in the late 1970s challenged this hypothesis, as the intrarenal crystal deposition was focal and could not explain the diffuse disease that was commonly observed. In addition, the renal lesions observed in gout were similar to the findings one observes in patients with hypertensive renal disease (nephrosclerosis) or with aging, suggesting these latter conditions might be responsible for the diffuse renal scarring.[3] Studies using uric acid–lowering therapy to improve renal function in gout patients also showed variable results, leading to skepticism regarding whether the disease truly exists.[3,64]

New Insights Regarding the Entity of Primary Hyperuricemic Nephropathy

Renewed interest in the role of gout and/or asymptomatic hyperuricemia in the pathogenesis of CKD

began when it was realized that it was inappropriate to ascribe hypertension to explain every case of renal insufficiency in the gouty patient, because most subjects with essential hypertension have relatively preserved renal function.[65] Another implicit assumption was that gouty nephropathy had to be due to crystal deposition, and the possibility that uric acid might mediate effects through crystal-independent mechanisms was not considered.[65] Furthermore, the analysis also assumed that the presence of hypertension was a separate cause of renal disease and that it had to be independent of the uric acid.[66] This led to a proposal to reinvestigate the role of uric acid in CKD.

Subsequently numerous epidemiological studies have shown that serum urate is an independent risk factor for developing CKD (Table 43.1).[62] Most observational studies suggested hyperuricemia as an independent risk factor for new onset CKD or progression to end-stage renal disease (ESRD). In one Japanese study, hyperuricemia conferred a 10.8-fold increased risk in women and a 3.8-fold increased risk in men for the development of CKD, compared to those with normal uric acid levels. This higher relative risk in subjects with hyperuricemia was independent of age, body mass index, systolic blood pressure, total cholesterol, serum albumin, glucose, history of smoking, alcohol use, exercise habits, hematuria, and even proteinuria. An elevated S[Ur] was also independently associated with a markedly increased risk of ESRD in another study of more than 49,000 male railroad workers.[67] Meta-analysis of 13 observational studies including 190,718 patients demonstrated that an increase in S[Ur] was an independent risk factor for newly diagnosed CKD.[68] The association was stronger in Western countries compared to that in Asian populations. The population with longer follow-up was associated with the greater risk of CKD, indicating that hyperuricemia may aggravate the progression of renal injury over the long term. In addition, a GLUT9 polymorphism, which determines level of S[Ur] in healthy populations with normal kidney function, predicted the progression of CKD in a cohort of 755 CKD patients.[69] However, not all studies showed

a significant association of hyperuricemia with kidney disease. *Post hoc* analysis of the Modification of Diet in Renal Disease study, enrolling 838 patients with stage 3 and 4 CKD showed that hyperuricemia was associated with mortality and cardiovascular disease, but not with renal progression.[70]

A second insight came from experimental studies in which chronic mild hyperuricemia was induced in rats, which developed hypertension and progressive renal disease without intrarenal crystal deposition.[6,8] The primary mechanism appeared to be due to the ability of increased levels of S[Ur] to induce glomerular hypertension and renal vasoconstriction.[71] Early in the course the rats developed arteriolar thickening and rarely hyalinosis of the preglomerular arterioles, often accompanied by glomerular hypertrophy.[7] Proteinuria appeared subsequently with the development of worsening vascular disease, glomerulosclerosis, and interstitial fibrosis. The lesion was identical to that observed with nephrosclerosis of hypertension, with aging-associated glomerulosclerosis, and with gouty nephropathy, except for the absence of crystal deposition that had been observed in the latter condition.[6–9] This finding suggests that chronic hyperuricemia may cause renal disease and hypertension *via* a crystal-independent pathway (Figure 43.2).

Further studies showed that uric acid was able to induce endothelial dysfunction *in vitro*. Several mechanisms appear to be operative, including the ability of uric acid to block uptake of the substrate (L-arginine) for nitric oxide, increased degradation of intracellular L-arginine, and a scavenging of nitric oxide by uric acid or uric acid-induced oxidants.[72–75] Indeed, uric acid inhibits endothelial release of nitric oxide, blocks endothelial cell proliferation, and induces senescence *via* activation of the local renin–angiotensin system and induction of oxidative stress.[72,76,77] Uric acid also stimulates vascular smooth muscle cell proliferation *in vitro via* uptake of urate into the cell with activation of MAP kinases, nuclear transcription factors (including NF-κB and AP-1), and inflammatory mediators (including monocyte chemoattractant protein-1 and C-reactive protein).[9,78–80] Uric acid also inhibits tubular cell proliferation and induces epithelial-to-mesenchymal phenotype transition of renal tubular cells with the production of extracellular matrix.[81] Hyperuricemic rats displayed evidence of endothelial dysfunction (with low serum nitrites reflecting low NO) and increased intrarenal renin expression.[8,72] The *in vivo* renal changes could be reversed by lowering circulating uric acid levels with uric acid–lowering drugs such as allopurinol and febuxostat.[6,9,82–84] In addition, micropuncture

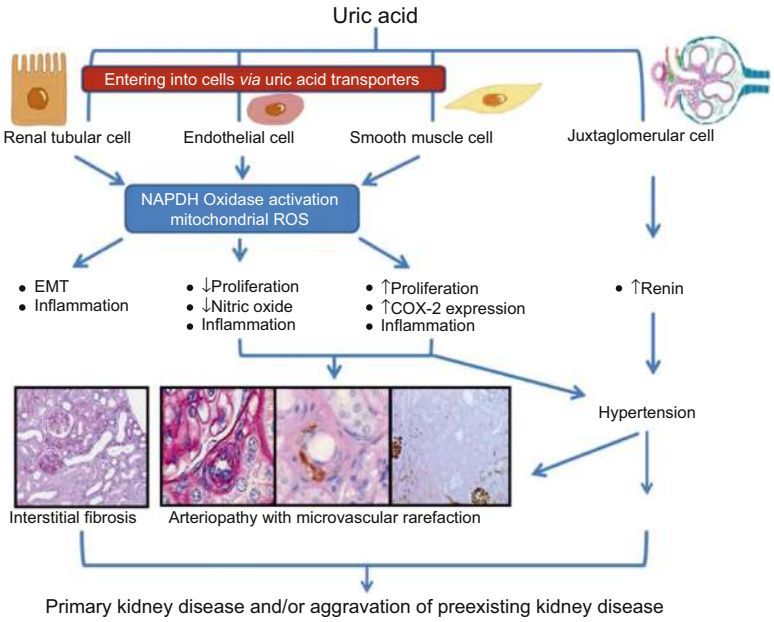

FIGURE 43.2 Proposed mechanism for uric acid–induced renal disease. Uric acid can have direct effects on cells and may also induce hemodynamic changes in the kidney. Some of the effects include the stimulation of oxidative stress in the cell, including stimulation of NADPH oxidase and oxidative stress in mitochondria. The oxidative stress is associated with tubular changes (epithelial mesenchymal transition, EMT). Endothelial cells show impaired nitric oxide bioavailability and reduced proliferation. Vascular smooth muscle cells produce growth factors, thromboxane, and inflammatory mediators. Renin is also stimulated. Glomerular hypertension and reduced renal blood flow result, and over time vascular changes (arteriolosclerosis), glomerulosclerosis, and tubulointerstitial fibrosis develop. *COX*, cyclooxygenase; *ROS*, reactive oxygen species.

studies performed on the hyperuricemic rats demonstrated glomerular hypertension with a reduction in renal plasma flow. All these mechanisms can lead to renal injury.

One of the key mechanisms by which uric acid appears to work is by inducing intracellular oxidative stress and inflammation.[77,85–88] (Figure 43.2) This is paradoxical, in that uric acid is an antioxidant that can bind and inactivate superoxide and peroxynitrite, and some studies suggest that uric acid may represent one of the more important antioxidants in the circulatory system.[89,90] However, the binding of uric acid with peroxynitrite generates radicals (aminocarbonyl radical and triuretcarbonyl radical) as the peroxynitrite is inactivated, and the urate–peroxynitrite reaction also generates alkylating species.[20,91] In addition, when uric acid enters cells it stimulates NADPH oxidase, leading to both intracellular and mitochondrial oxidative stress. Indeed, uric acid induces oxidative stress in a large variety of cell types, including vascular endothelial and smooth muscle cells, renal tubular epithelial cells, hepatocytes, islet cells, and adipocytes.[77,85–88] Taken together, uric acid may induce primary kidney disease or accelerate the progression of CKD by effects on the renal microvasculature, renal tubules, and interstitium.

Clinical Manifestations of Hyperuricemic Nephropathy

Most patients with longstanding gout have asymptomatic renal involvement with either normal or only mild renal insufficiency.[2,92] The majority have hypertension.[93] Renal blood flow is usually disproportionately low for the degree of decrement in renal function.[94] Fractional excretion of uric acid is usually less than 10%. Proteinuria occurs in the minority of cases, and, when present, is usually in the nonnephrotic range. The urinary sediment is also usually benign. However, hypertension is frequent, occurring in 50–60% of patients, and increasing in prevalence as renal function worsens. Renal biopsy shows chronic changes indistinguishable from chronic hypertensive nephropathy, with chronic glomerulosclerosis, tubulointerstitial fibrosis, and renal microvascular disease.[2] Intrarenal crystals may occasionally be observed, but their presence or absence does not rule out a role for uric acid in the pathogenesis of the kidney disease.[65] Nonetheless, a disproportionately elevated S[Ur] in relation to impaired renal function (such as S[Ur] greater than 9 mg/dL for a S[Cr] of less than 1.5 mg/dL, S[Ur] greater than 10 mg/dL for a S[Cr] of 1.5–2.0 mg/dL, and S[Ur] greater than 12 mg/dL when S[Cr] is greater than 2.0 mg/dL) would suggest there is a primary process raising S[Ur] besides reduction in GFR.

Role of Hyperuricemia in Progression of CKD

Although there is extensive epidemiological evidence that an elevated S[Ur] is an independent risk factor for the development of CKD (Table 43.1), it remains controversial whether an elevated S[Ur] is a risk factor for progression of kidney disease in patients with preexisting CKD. This is because patients with CKD may have elevated S[Ur] simply due to the reduction in urate excretion that accompanies reduced GFR. For example, neither the Modification of Diet in Renal Disease Study nor the Mild to Moderate Kidney Disease Study could show S[Ur] to be an independent risk factor for progression in patients with preexisting CKD.[70,95] A study in middle-aged and old Taiwanese subjects found an elevated S[Ur] increased the risk of renal disease, after adjustment for other metabolic risk factors such as gender, BMI, cholesterol, triglyceride, blood pressure, and blood sugar. An interesting finding from this study was that S[Ur] was independently associated with estimated glomerular filtration rate (eGFR) only in stage 3 CKD but not in stage 4 or 5 CKD patients.[96]

There may be a variety of reasons why an elevated S[Ur] may not predict CKD in subjects with established CKD. One potential explanation is that factors associated with reduced GFR itself may have major effects on driving renal progression that dwarf the biological mechanisms by which uric acid may cause renal disease. Thus, impaired renal function results in hypertension from impaired salt excretion, causes endothelial dysfunction, and is associated with inflammation.[97] Many people with severe CKD also suffer from malnutrition, and these patients may have low S[Ur] due to a reduction in food intake (because uric acid levels are driven in part by diet). It is also possible that in the setting of a prooxidant state such as CKD, the antioxidant benefits of uric acid may outweigh its proinflammatory and prooxidant effects. More studies need to be performed to better understand the complexity of uric acid and its potential pathogenic role in established CKD.

Role of Uric Acid–Lowering Therapy in CKD

Allopurinol

There have been a limited number of studies to examine the effect of uric acid–lowering in the development or progression of CKD. Kanbay et al. reported that treatment of healthy subjects with asymptomatic hyperuricemia improved renal function.[98] Siu et al. also reported that the treatment of asymptomatic hyperuricemia delayed disease progression, with a lesser increase in blood pressure following a 12-month treatment of allopurinol in patients with stage 3 CKD.[99] Shi et al. evaluated the effects of allopurinol in subjects with

IgA nephropathy and mild CKD, but because the control group did not progress, it was not possible to judge whether allopurinol was protective or not.[100] In another prospective study of 113 patients with stable CKD with eGFR less than 60 mL/min/1.73 m^2, Goicoechea et al. demonstrated that 100 mg/day allopurinol significantly slowed the progression of renal disease after 23.4 ± 7.8 months of treatment compared to controls, although the relative benefit was mild (difference in GFR of 4.6 mL/min/1.73 m^2).[101] However, follow-up with an extension study over 7 years confirmed a significant benefit of allopurinol treatment on renal survival.[102] One recent meta-analysis of eight randomized controlled trials (RCTs) reported that allopurinol did not improve renal survival compared to controls in five trials (n = 346), but did slow renal progression in three trials (n = 130).[103] However, a problem with the negative studies in this analysis was that there was no change in eGFR in the control group, and hence it was not possible to assess if allopurinol was protective because renal function remained stable. In another meta-analysis of 19 RCTs including 992 stage 3−5 CKD patients, allopurinol reduced S[Ur] and blood pressure with a preserved eGFR compared to control groups.[104] One problem with meta-analysis is the substantial heterogeneity among the trials regarding study design, populations enrolled, duration of follow-up, and level of baseline renal function.

Although early studies suggest some potential benefit of lowering S[Ur] on renal function, one of the more striking benefits appears to be on heart disease. In the study by Goicoechea et al., there was a significant reduction in cardiovascular events in patients with CKD.[101] Terawaki et al. also noted a nearly 50% reduction in cardiovascular events by allopurinol in people with hypertensive nephrosclerosis.[105] Furthermore, Kao et al. noted that allopurinol could improve left ventricular mass and endothelial dysfunction in CKD patients.[106] These studies suggest that lowering uric acid may be of benefit to reduce cardiovascular events in CKD.

Febuxostat

Febuxostat is a potent nonpurine-selective inhibitor of xanthine oxidase, which is metabolized in the liver, with only 1−6% of the dose being excreted through the kidneys. Hence, impaired renal function has little impact on the pharmacokinetic profile of febuxostat, allowing its safe administration to CKD patients.[107] In one RCT enrolling 93 stage 3 and 4 CKD patients, febuxostat slowed the decline in eGFR compared to placebo.[108] The mean eGFR in the febuxostat group showed a nonsignificant increase from a baseline of 31.5 ± 13.6 to 34.7 ± 18.1 mL/min/1.73 m^2 at 6 months. With placebo, mean eGFR decreased from 32.6 ± 11.6 to 28.2 ± 11.5 mL/min/1.73 m^2 (p = 0.003). Of the 45 (38%) participants in the febuxostat group, 17 had >10% decline in eGFR over baseline, compared with 26 of 48 (54%) from the placebo group (p < 0.004). A recent RCT including 467 stage 3 CKD patients with asymptomatic hyperuricemia demonstrated that febuxostat did not slow renal progression.[109] However, a problem with this study was that the control group only progressed 0.5 mL/min/1.73 m^2, making it difficult to show that the treatment arm was protective. However, subgroup analysis showed a benefit of febuxostat treatment in patients without proteinuria or with S[Cr] lower than the median.

Uric Acid and ESRD

In subjects with normal renal function, an elevated S[Ur] is almost always associated with increased cardiovascular risk, and a smaller rise in cardiovascular risk occurs in subjects with low S[Ur] levels ("J curve" of mortality).[110] However, in ESRD patients, the high risk for mortality is generally in those subjects with the lowest S[Ur] (reverse J curve).[57,58] The reason for this finding is unknown, but it is important to note that the lower quartile for S[Ur] in the ESRD population is still quite high compared to normal subjects. One potential explanation for the association of lower S[Ur] with increased mortality in dialysis patients may relate to the fact that subjects in the lowest S[Ur] category are those with the poorest nutrition, such as subjects who are bedridden or suffering from stroke.[58] A cohort study in 4298 incident HD patients showed an increased mortality risk of low S[Ur] (<5.0 mg/dL) among patients with low normalized protein catabolic rate (nPCR) (<0.9 g/kg/day; HR 1.73, 95% CI 1.42−2.10) but not with high nPCR (≥0.9 g/kg/day; HR 0.99, 95% CI 0.74−1.33).[111] It is also possible that S[Ur] might act similarly to obesity or hypertension as a risk factor associated with improved survival in ESRD patients. Further studies are necessary to better understand this complex relationship.

Hyperuricemia, Hypertension, and Metabolic Syndrome

Hyperuricemia is commonly associated with other conditions, including obesity, metabolic syndrome, fatty liver, and hypertension. For decades the increase in S[Ur] in these conditions has been thought to be secondary, and due to effects of hyperinsulinemia or obesity to alter uric acid excretion or metabolism. However, more recent studies have raised the exciting possibility that uric acid may have a causal role in these conditions.[112] For example, experimentally induced hyperuricemia has been shown to result in hypertension.[6] In various

models of metabolic syndrome and fatty liver, lowering uric acid with allopurinol has been reported to be protective.[113,114] Epidemiological studies demonstrate that an elevated S[Ur] is a consistent independent risk factor for hypertension, metabolic syndrome, diabetes, fatty liver, and obesity.[112,115] Pilot clinical interventional studies also report some benefit of lowering S[Ur] on blood pressure, insulin resistance, and systemic inflammation.[116–118] Clearly more studies need to be performed, but there is increasing evidence that uric acid may be a true risk factor not only for CKD but also for metabolic syndrome, hypertension, and fatty liver.

Challenges to the Uric Acid Hypothesis

The uric acid hypothesis is not without controversy. For example, some continue to argue that uric acid is actually a pure antioxidant and that the benefits of lowering serum urate with allopurinol are due to the ability of xanthine oxidase inhibitors to also block oxidants generated during the production of uric acid from xanthine. In support of this hypothesis, it has been repeatedly observed that allopurinol therapy improves endothelial dysfunction in humans, yet treatment with a uricosuric agent was reported to have no effect.[119,120] However, the mechanism by which uric acid causes cardiovascular disease appears to be due to the intracellular effects of uric acid, so treatments that block uric acid synthesis (such as allopurinol) would likely be more effective than uricosuric agents. Furthermore, in some cell culture studies the benefit of allopurinol can be prevented if uric acid is added to the media,[121] suggesting it is the uric acid that is responsible for the effect. In addition, in a recent clinical trial, both allopurinol and probenecid (a uricosuric drug) lowered blood pressure significantly in obese prehypertensive adolescents.[117]

The other major challenge is that genome wide association studies have found several polymorphisms in urate transport that predict hyperuricemia and gout, but they do not appear to predict hypertension or diabetes.[122,123] This has been interpreted as meaning that it is unlikely that S[Ur] is a true risk factor for these conditions. However, the polymorphisms alter the transport of uric acid in and out of cells, so it is unclear how these polymorphisms affect intracellular uric acid levels where the uric acid is working. We need more studies on this complex topic before any conclusions can be made firmly.

Should People with CKD and Hyperuricemia Be Treated?

Hyperuricemia is common in CKD patients, but it remains unclear if lowering uric acid is beneficial. Certainly the experimental, epidemiological, and pilot clinical studies raise the possibility that lowering S[Ur] may benefit both renal function and the cardiovascular risk in these patients, but we need larger, randomized trials before such therapy should be routinely embraced. We must also remember that allopurinol can induce a Stevens–Johnson syndrome, and rarely AKI. Although the serious reactions from allopurinol may be minimized by testing the HLA status of patients and excluding treatment in those who are HLA-B58 positive,[124] we still need to be careful to do no harm. We have another option in the use of febuxostat. The US FDA, however, issued a warning about the increased risk for mortality with febuxostat compared to allopurinol. Although it was not confirmed in many clinical trials using febuxostat, one study showed an increased cardiovascular and all-cause mortality in patients treated with febuxostat.[125] As such, we recommend treatment only for those patients with severe hyperuricemia (S[Ur] greater than 10 mg/dL in men and greater than 9 mg/dL in women), and only after discussing the pros and cons of such therapy with the patient.

CONCLUSIONS

Serum urate levels are determined by the balance of uric acid generation and excretion by the kidney. Decreased GFR and altered expression/function of uric acid transporters in renal tubules and the gastrointestinal tract can lead to elevations of S[Ur]. Hyperuricemia is epidemiologically associated with increased risk for kidney disease, and experimental studies suggest uric acid may have a contributory role. There is also accumulating evidence supporting hyperuricemia as a true risk factor for CKD, based on recent epidemiologic, clinical, and experimental observations. Nonetheless, there are still controversies regarding the causative role of uric acid in kidney disease. As such, we recommend a large randomized clinical trial be conducted to determine if uric acid–lowering therapy provides benefit in hyperuricemic subjects with CKD before routine lowering of uric acid levels is recommended.

QUESTIONS AND ANSWERS

Question 1

A 22-year-old medical student presents to the emergency room with nausea and vomiting. He has a BUN 24 mg/dL, S[Cr] 2.4 mg/dL. S[Ur] was 1.4 mg/dL. He states he ran a 10K race yesterday. The most likely diagnosis is:

A. Rhabdomyolysis. The patient needs a CPK evaluation
B. Cocaine-induced AKI. This is common in medical students
C. Acute renal failure associated with SLC2A9 mutation
D. Dehydration-induced prerenal azotemia

Answer: C
A, B, and C are associated with a high S[Ur]. SLC2A9 mutation causes uricosuria and is associated with increased risk for exercise-induced AKI.

Question 2

Which of the following is not associated with hyperuricemia?

A. Hiking in the Andes
B. Jogging around the park
C. Pyrazinamide therapy in a patient with tuberculosis
D. Medullary Cystic Kidney Disease

Answer: B
Hyperuricemia can be observed with the hypoxia at high altitude, with pyrazinamide therapy and in medullary cystic disease. Moderate exercise tends to lower S [Ur], not raise it.

Question 3

Current Drugs used to Lower S[Ur] include all of the following except:

A. Febuxostat
B. Pegloticase
C. Losartan
D. Probenecid
E. Enalapril

Answer: E
Enalapril does not reliably lower S[Ur]. All other compounds do—losartan acts by directly inhibiting urate transport in the renal tubule independent of its angiotensin receptor blocking activity.

Question 4

All are true regarding CKD patients except:

A. An elevation in S[Ur] may be secondary to the renal disease
B. An elevated S[Ur] correlates with increased risk for cardiovascular events
C. S[Ur] is a better predictor for the progression of CKD than for the development of CKD
D. Pilot studies have shown benefit of lowering uric acid on cardiovascular events in subjects with CKD

Answer: C
Uric acid is better at predicting development of CKD, not progression. All other statements are true.

Question 5

All of the following are Risk Factors for Hyperuricemia Except:

A. Calcineurin inhibitor use
B. Thiazide use
C. Low-dose aspirin
D. Furosemide
E. Atorvastatin

Answer: E
Atorvastatin use is associated with lower S[Ur] levels. All other statements are true.

Question 6

All are true regarding the entity "Gouty Nephropathy" except

A. "Gouty Nephropathy" is observed in people with longstanding gout, who often have tophi
B. A primary finding in "Gouty Nephropathy" is a greater reduction in renal blood flow compared to GFR
C. "Gouty Nephropathy" is strongly associated with hypertension
D. "Gouty Nephropathy" is characterized by diffuse deposition of urate crystals in the renal medulla and cortex
E. "Gouty Nephropathy" results in ESRD in about 25% of patients untreated with Allopurinol

Answer: D
Renal histologic findings in patients with "Gouty Nephropathy" do not typically demonstrate focal deposition of urate crystals in the renal medulla. All other statements are true.

CHAPTER

Trace Elements in Chronic Kidney Disease

Andrew Davenport

UCL Centre for Nephrology, University College London, Royal Free Hospital, London, United Kingdom

Abstract

Essential trace elements play a vital role in cellular metabolism and the maintenance of homeostasis, by acting as key cofactors for enzymes. Their intracellular and plasma concentrations are regulated by gastrointestinal absorption and renal and gastrointestinal excretion to prevent deficiency and toxicity. Patients with chronic kidney disease (CKD) are potentially at risk of both essential trace element deficiencies and toxicity due to the failure to excrete other nonessential elements, leading to accumulation within the kidney which may cause chronic kidney damage, resulting in hypertension, proteinuria, and progression of kidney disease. Environmental exposure to chemical elements varies throughout the world due to differences in the composition of topsoil and surface water. Epidemiologic studies suggest possible linkages between environmental contaminations and increased local populations.

INTRODUCTION

Both a deficiency of essential trace elements and conversely an excess of trace elements are well recognized to cause harm in the general population.[1,2] The patient with chronic kidney disease (CKD) may be at greater risk of both deficiencies, due to the combination of dietary restrictions and increased urinary losses (in particular loss of binding proteins associated with heavy proteinuria), and, on the other hand, accumulation due to failure of renal excretion.

Exposure to trace elements varies from geographic region to region, due to differences in the chemical composition of topsoil. Minerals and other elements are washed from topsoil into rivers, and so can potentially enter the drinking water system. Similarly, plants take up nutrients and elements from the topsoil, allowing them to enter the normal human food chain. In industrialized areas, patients are exposed to airborne sources of chemicals, and contamination of land by industrial waste, with subsequent leaching into water tables and potentially into the domestic water supply. Although water companies aim to "purify" domestic water supplies, this is not universal worldwide. In addition, most systems are designed to remove low-level contaminants and not large industrial waste spills. Historically, lead piping was used to transport domestic water, allowing lead to leach into the water. Water companies also add chemicals to domestic water, not only to prevent bacterial growth but also precipitate small particles, so improving the clarity of drinking water. In some countries, fluoride is added to reduce dental decay as part of a public health policy.

TRACE METALS AND CHRONIC KIDNEY DISEASE

Not every element in the periodic table is vital to sustain human life. Exposure to some elements may result in pathology. As the kidney is one of the main routes of excretion, the kidney may become a target organ for damage by nonessential metals, including mercury, lead, cadmium, chromium, and platinum and metalloids such as arsenic. Depending on the level of acute or chronic exposure, and how the metal is handled within the kidney, a spectrum of renal pathologies ranging from acute kidney injury (AKI) to Fanconi-like proximal tubular syndromes, chronic interstitial fibrosis, and CKD may ensue. Patients with preexisting CKD may be more susceptible to toxicity. Environmental or other exposure to these elements may lead to progressive CKD.

RENAL TRANSPORT OF CATIONIC METALS

The biologically important divalent metals, zinc, copper, and iron, operate at micromolar levels and are carefully regulated by gastrointestinal absorption and renal

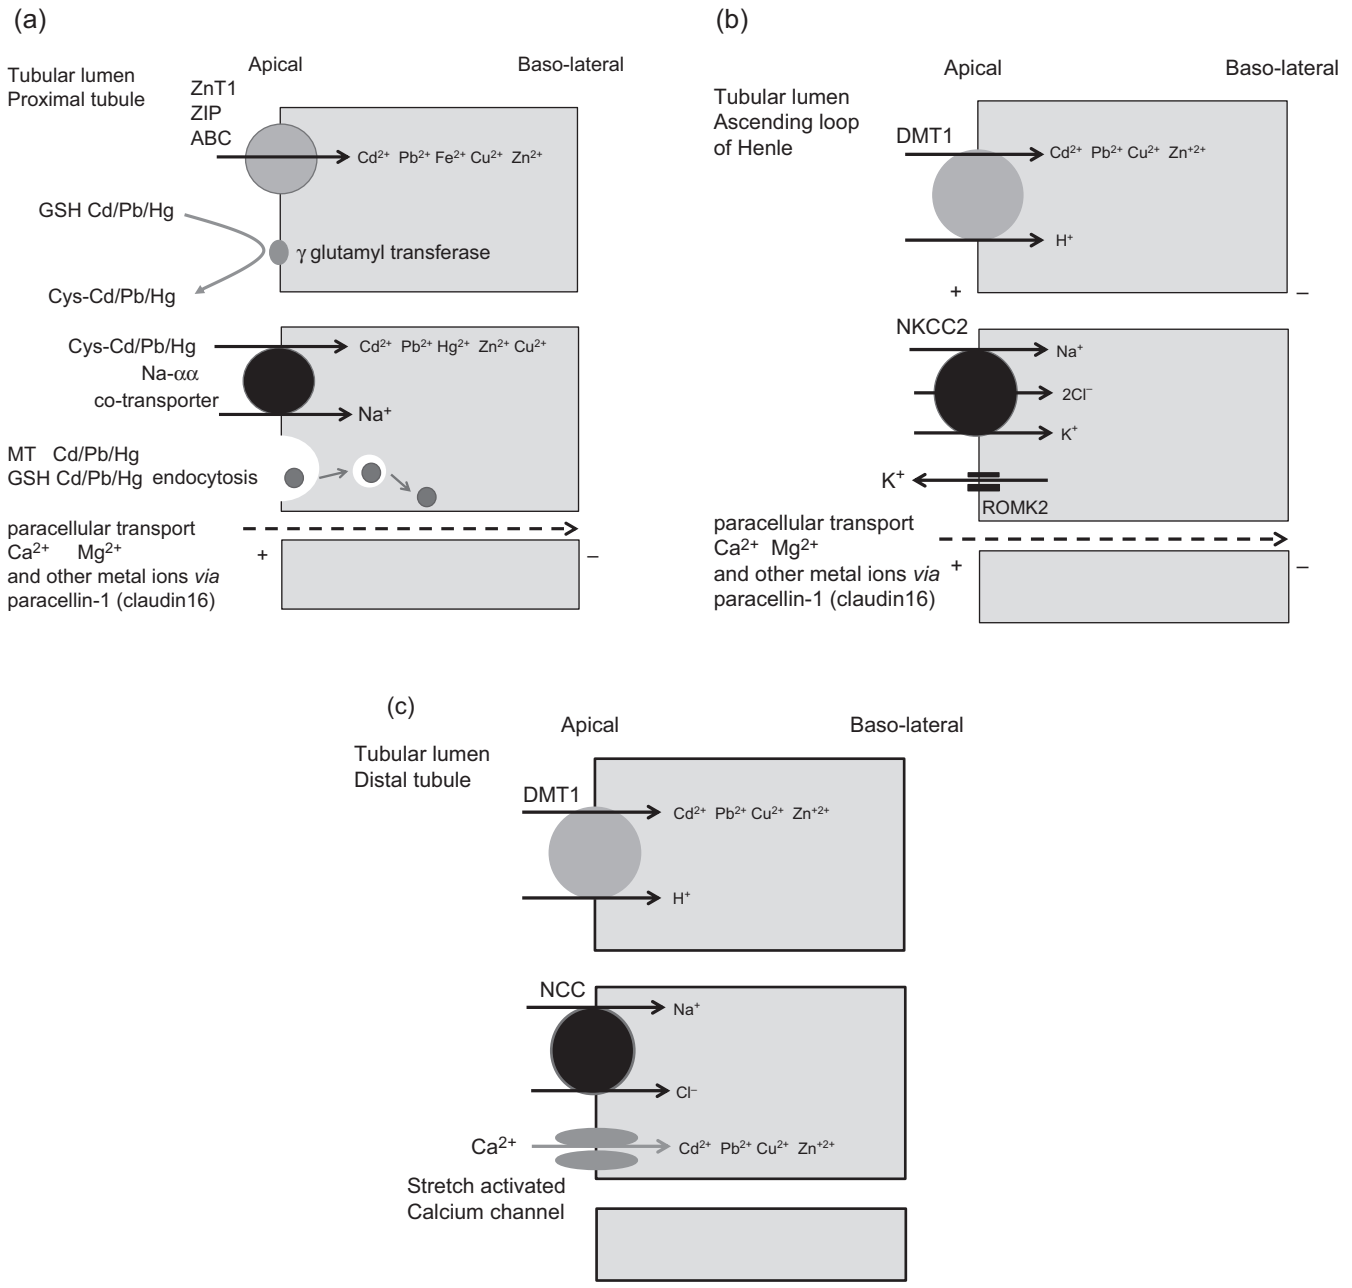

FIGURE 44.1 Ionized metal reabsorption in the proximal tubule (a), ascending loop of Henle (b), and distal tubule (c). (a) A variety of ionized metal transporters are present in the proximal tubule in addition to the DMT1, including zinc transporter 1 (Znt1), Zrt/Irt-like protein (ZIP), and ATP-binding cassette transporters (ABC). Metals which can bind glutathione can be cleaved by apical brush boarder γ-glutamyl transferase to cysteine bound metals which can then be reabsorbed by sodium-amino acid (αα) cotransporters. In addition, ionized metals can also be reabsorbed by endocytosis of metallothionein (MT) and glutathione (GSH) complexes, along with some paracellular transport. (b) In the ascending loop of Henle, reabsorption of metal ions takes place by DMT1 and paracellular transport. Paracellular transport is greater due to the electrical gradients generated by the sodium potassium 2 chloride transporter (NKCC2) and inwardly rectifying potassium channel (ROMK2). (c) In the distal tubule, ionized metals can be reabsorbed by the DMT1 transporter and also through stretch-activated cation channels. Sodium potassium cotransporter (NCC).

and gastrointestinal elimination, to tightly control intracellular and body fluid concentrations. Pathology may equally occur due to either low or high intracellular concentrations.

Although the normal renal handling of divalent cations has not been fully elucidated, approximately 70% of the transport occurs within the proximal tubule,[3] *via* the endosomal divalent cation transporter (DMT1) (Figure 44.1), which is also present in the gastrointestinal tract. DMT1 is also involved in the transport of highly toxic divalent cations, including cadmium, lead, cobalt, nickel, and platinum. Competition for DMT1

transporter can lead to both uptake of the toxic cation into the renal tubular cell and failure to reabsorb essential divalent metals. DMT1 is not the only reabsorption pathway for renal divalent cations, as zinc can be taken up into proximal tubules complexed with cysteine or histidine *via* sodium-amino acid cotransporters.[4] Toxic metals, particularly mercury and cadmium, which form cysteine conjugates, may potentially compete with zinc by binding these amino acids.

Toxic or essential plasma heavy metals exist either as nondiffusible protein-bound or diffusible complexed and ionized forms. Accidental intoxications usually result in gastrointestinal absorption, with the majority of the divalent metal ions absorbed binding to circulating plasma proteins, predominantly albumin, with only a relatively small amount (<10%) of the free ionized metal remaining in plasma water. As some plasma albumin is filtered by the glomerulus, the filtrate entering the proximal tubule may contain both the divalent metal bound to albumin and other protein transporters and the ionized form. Thus, proximal tubular uptake following acute intoxication is a combination of both the albumin-bound and free forms of the metal. Chronic low-level intoxication leads to a compensatory increase in circulating metal-binding plasma proteins, and metallothionein and glutathione in the liver and kidney. These latter compounds protect against heavy metal toxicity by forming conjugates which trap the metal inside.[5]

In vivo animal experimental studies suggest 99% of filtered divalent metal ions in free ionized form are taken up by tubular absorbption.[6] However, there are then differences regarding how divalent metals are transported out across the basolateral membrane. There is relatively rapid transport of essential metals, such as iron, zinc, and copper, whereas mercury, lead, and cadmium accumulate in the proximal tubular cell, with less than 10% transported out of the cell, due to slower basolateral transport.[5]

A series of heavy metal ion transporters, besides DMT1, have been isolated, including zinc transporter 1 (ionized zinc, iron, copper, cadmium), and ATP-binding cassette transporters (nickel, manganese, iron, molybdenum). Stretch-activated cation channels may also be involved. The binding affinities for ionized metals differ between transporters. The relative role of these transporters and channels has yet to be fully elucidated.

Although the majority of metal cations are reabsorbed in the proximal part of the tubule, reabsorption also occurs in the loop of Henle, distal tubule, and collecting duct through DMT1. During passage through the loop of Henle, local electrical gradients generated also allow paracellular reabsorption of cations. Additional metal ion transporters may be present in the distal tubule and collecting duct.

Cations bound to proteins are reabsorbed in the proximal tubule by the luminal multiligand receptor complex megalin:cubilin:amnionless. These include metalloproteins, such as iron bound to transferrin and cadmium bound to metallothionein. Many of the iron-binding proteins, such as transferrin, neutrophil gelatinase-associated lipocaclin (NGAL)/24p3/lipocalin-2, lactoferrin, albumin, hemoglobin, myoglobin, and hepcidin are filtered by the glomerulus, yet normally there is little or no iron lost in the urine. The proximal tubule megalin:cubilin:amnionless is important for transferrin and albumin reabsorption. Transferrin is also reabsorbed by the transferrin receptor, located in the proximal tubule and collecting duct. Other iron-containing proteins are reabsorbed *via* the NGAL/24p3/lipocalin-2 receptor (distal tubule, collecting duct), ferroportin (proximal tubule), the Zrt, Irt-related proteins ZIP 4 and 14 (proximal tubule), the epithelial Ca2+ channel 1 (TRPV5 Ca2+ channel) (distal tubule), and transient opening type Ca2+ channel $Ca_v3,1$ (distal tubule). Cadmium can compete with iron for all of these transporters. Similarly, these transporters will transport calcium, barium, strontium, and manganese and are inhibited by several di- and trivalent cations. In cases of iron deficiency, the renal tubule reabsorbs more of these divalent metals. In cases of metal toxicity, such as cadmium poisoning, cadmium competes with iron for reabsorption, leading to renal iron losses, and losses of other divalent cations.[7] Thus, toxicity with one metal or divalent cation can be exacerbated by losses of another metal.

In cases of chronic exposure to toxic cations, liver damage releases metals bound to metal-metallothionein and glutathione. These complexes are filtered by the glomerulus. In animal experimental models, around 50% is reabsorbed in the proximal tubule by endocytosis.[8] Enzymatic cleavage can occur, releasing Cys-metal conjugates which can then be reabsorbed by sodium-amino acid cotransporters.

RENAL TOXICITY OF CATIONIC METALS

Albumin and protein-bound and conjugated cationic metals are not directly toxic to the kidney, but when released in ionized forms, they can cause renal tubular epithelial pathology. The actual pathological injury will depend on the individual metal, the amount delivered to the kidney, and whether exposure is acute or chronic. For example, a single exposure to cadmium may simply cause calciuria and polyuria. More extensive proximal tubular necrosis may lead to an acquired Fanconi-like

syndrome. A single exposure to lead or mercury in an animal model can lead to reduced glomerular filtration rate, glycosuria, proteinuria, and tubular obstruction due to sloughing of tubular cells.

Typically, chronic exposure to toxic metal ions will result in an acquired Fanconi syndrome, with reduced glomerular filtration rate, increased urinary flow, proteinuria, glycosuria, and amino aciduria. In addition, because of competition for metal ion reabsorption systems within the tubules, patients may have increased urinary loss of essential metals such as iron, copper, and zinc.

TRACE METALS AND CHRONIC KIDNEY DISEASE

Zinc

Zinc is an essential micronutrient, incorporated into many metalloenzymes and proteins which are involved in cell metabolism, production of neurotransmitters, and regulatory pathways controlling oxidative stress.[1] Zinc deficiency has been reported to be a major cause of disease in developing countries.[9] Zinc deficiency is associated with delayed wound healing[10] and an immune deficiency characterized by defective phagocytosis and abnormal lymphocyte function,[10,11] which may contribute to suboptimal response to vaccinations reported in CKD patients.[12] Zinc deficiency may also cause or contribute to a number of relatively nonspecific conditions including dysgeusia and anorexia and may exacerbate anemia.[13]

Dietary sources of zinc are widespread, as zinc is present in meats, whole grains, legumes, and shell fish. However, zinc may bind to phytates and oxalate within the gut, leading to the formation of insoluble complexes, preventing absorption.[14] Zinc can also potentially bind to ion exchange resins prescribed to the CKD patient as phosphate binders. As zinc is mainly excreted in feces, urinary losses usually have little impact on zinc balance. In patients with severe nephrotic syndrome, plasma zinc concentrations may appear to be low, due to the associated hypoalbuminemia, as zinc is predominantly transported by albumin. Plasma zinc levels reflect current zinc status, whereas zinc in red blood cells and hair provide an estimate of longer-term zinc nutritional status. Competition for divalent transporters in the renal tubule, for example, by chronic cadmium toxicity, can lead to urinary loss of zinc.[15]

Generally, plasma zinc levels are normal or slightly reduced in CKD patients,[16] although reports suggest that as CKD progresses, patients are more likely to have lower levels of plasma zinc.[17] Whether this relates to a reduction in red meat consumption remains to be determined. As zinc is predominantly excreted by the gastrointestinal tract, CKD patients are at no greater risk of zinc toxicity than the general population. Zinc toxicity has been reported with zinc-denture adhesives and can lead to a neuropathy with bone marrow failure, especially in the presence of reduced serum copper concentration.[18] As several of the serine proteases in the clotting cascade are zinc dependent, there have been reports of increased risk of thrombosis with high levels of zinc. Conversely, increased risk of bleeding with platelet dysfunction has been reported with zinc deficiency.[19]

Copper

Copper is also an essential micronutrient, incorporated into many metalloenzymes and proteins involved in cell metabolism, and regulatory pathways controlling oxidative stress.[20] Because of its ubiquitous distribution among food sources and low daily requirement, acquired copper deficiency is rare in humans. Copper is predominantly excreted into the bile, so patients with CKD are not at increased risk of copper-related disorders.[21,22] Copper mainly binds not only to circulating ceruloplasmin but also to albumin. Therefore, increased urinary copper losses in patients with nephrotic syndrome and heavy proteinuria can occur. Children with Fanconi syndrome, particularly secondary to cystinosis, may also become copper deplete when treated with cysteamine.[23] Acquired copper deficiency may occur after bariatric surgery, typically presenting with a progressive myelopathy with spastic paraparesis, paraesthesias, and ataxic gait,[113] similar to that observed in subacute combined degeneration, as in cases of Vitamin B_{12} deficiency. Rarely, central nervous system demyelination, optic neuritis, and neuropathies have been reported.[23]

Acute release of copper, as in Wilson disease, or acute copper toxicity, can lead to met-hemoglobinemia, and red cell hemolysis with hemoglobinuria, resulting in AKI. Chronic copper toxicity can lead to renal proximal tubular damage, as copper is taken up by proximal tubular cells *via* the Ctr1 transporter.[24,25]

Manganese

Manganese is an essential cofactor for the metalloenzyme superoxide dismutase, and enzyme activity is decreased in manganese-deficient animals.[26] Whether subtle manganese deficiency contributes to the increased oxidative stress remains unknown.

Manganese is present in meat, fish, nuts, and dried fruit, but less than 5% is absorbed in the small bowel. Absorption can be reduced by concurrent high dietary intake of fiber, calcium, and phosphate. Manganese is stored primarily in the skeleton and mitochondria.[26] Most reports suggest patients with CKD have normal or low manganese levels.[16,22]

Manganese toxicity is typically secondary to water contamination and industrial exposure. Manganese toxicity causes neurological damage resulting in memory loss, ataxia, and a Parkinsonian-like neurological disturbance.[27] In cases of chronic toxicity, both serum and urine often show high levels of manganese, but there are no reports of kidney damage. In patients with CKD, manganese accumulation can contribute to anemia.[28]

Cadmium

Cadmium can be ingested by eating shell fish, liver, and kidney meats, and fish that live in cadmium-exposed water. However, most cadmium toxicity occurs from industrial exposure. Smokers have around twice as much cadmium in their body as nonsmokers, due to traces of cadmium in tobacco plants. Cadmium can compete with calcium for gastrointestinal absorption and is then taken up by the liver and kidney. Cadmium can be released by the liver during episodes of acute liver failure, possibly contributing to acute renal tubular damage.[29] Chronic cadmium exposure results in renal tubular toxicity, and proximal tubular cell necrosis, initially affecting the pars convoluta of the proximal tubule, then progressing to more distal regions of the tubule leading to chronic renal tubulointerstitial fibrosis with glomerular drop out,[30] and progressive CKD with hypertension.[15,31]

Cobalt

Cobalt is a key component of vitamin B_{12} and is required for the synthesis of hemoglobin. Food sources rich in cobalt include fish, nuts, leafy green vegetables, such as broccoli and spinach, and cereals, including oats.

Dietary deficiency is unusual, but more recently concerns have arisen over cobalt toxicity due to cobalt release from metal on artificial hips, resulting in neurological (hand tremor, incoordination, cognitive decline, depression, vertigo, hearing loss, and visual changes), cardiac (arrhythmias and cardiomyopathy), and endocrine (hypothyroidism) symptoms. Cobalt is strongly bound to albumin and readily excreted in the urine. It has been suggested that patients with CKD may be at greater risk of arthroprosthetic cobaltism and toxicity from cobalt containing coronary artery stents.[32,33]

Gadolinium

Gadolinium is used as a contrast agent for magnetic resonance imaging techniques. Gadolinium is filtered by the glomerulus and initially taken up into proximal renal tubular cells, stored, and then resecreted, similar to aluminum. Early clinical studies reported that high dosages could cause kidney damage.[34] Much lower gadolinium dosages are now used in clinical practice. However, of greater concern is the risk of nephrogenic systemic fibrosis[35] for patients with CKD stages 4 and 5 (glomerular filtration rate <30 mL/min/1.73 m^2) and renal dysfunction due to the hepatorenal syndrome or in the perioperative liver transplantation period, where the risk applies to any severity of renal dysfunction.[36,37] Although the majority of reports have been linked with linear gadolinium chelates, these contrast agents were introduced into clinical practice some time before the newer cyclical chelates. It is currently unclear whether the different forms of gadolinium contrast media have different risks for the development of nephrogenic systemic fibrosis.[38]

Strontium

Strontium is not recognized as being essential for life. The majority of strontium absorbed from the gastrointestinal tract is eliminated by the kidney. However, in patients with CKD, strontium can accumulate and be deposited in bone, causing osteomalcia. This has been reported in CKD patients living in areas with strontium in the drinking water and topsoil,[39] as well as those prescribed strontium supplements for the treatment of osteoporosis. Strontium supplements should be avoided or dosages must be reduced in elderly patients with CKD.[40]

Platinum

Platinum-based drugs are used in the treatment of several solid organ malignancies, including testicular and ovarian cancer, transitional cell bladder cancer, and small cell lung cancer.[41] Besides the acute side effects of cisplatin, gastrointestinal toxicity, and moderate myelosuppression, reduction in glomerular filtration rate occurs in 20%–30% of patients, despite prophylactic-intensive hydration and forced diuresis. Such changes in glomerular function are essentially irreversible.[42] Persistent effects on tubular renal function occur less commonly, but classically hypomagnesemia due to hypermagnesiuria is often seen due to distal tubular toxicity.[43] The risk of renal tubular injury is increased by concomitant prescription of nonsteroidal antiinflammatory drugs, diuretics, and inadequate hydration, coupled with administration of high dose cisplatinum.[44] Neurotoxicity, mainly sensory peripheral neuropathy, may occur during treatment, but typically disappears in the majority of patients after completion of the chemotherapy course. Persistent paresthesias are reported in 20%–60% of patients. Bilateral loss of

hearing at 4–8 kHz is seen in around 50% of patients. Several studies have reported a direct correlation between the cumulative cisplatin dose administered and the frequency of both neuro- and nephrotoxicity.[43] Chemotherapy schedules using single-day infusions have also been associated with increased neural and renal toxicity, possibly due to the higher peak plasma levels of cisplatin achieved. Renal toxicity potentially becomes cumulative with the increasing number of chemotherapy cycles.

Uranium

Uranium-induced AKI in animal models is typically associated with a reduction in outer renal cortical blood flow and glomerular perfusion.[45] Decreased glomerular perfusion may occur without decreased renal plasma flow, perhaps consequent on increased tubular hydraulic pressure secondary to impaired tubular solute and fluid reabsorption or tubular blockage due to cellular debris. In animal models of acute uranium nephrotoxicity, glomerular endothelial damage may also be marked. However, in man, chronic exposure leads to renal tubular damage, typically affecting the ascending limb and the proximal tubule. Renal injury is cumulative and related to chronic uranium exposure in mine and quarry workers. Proteinuria typically develops with tubular damage, but cannot reliably be used as a marker of renal damage. Low levels of uranium in drinking water do not appear to lead to clinically significant renal damage.[46]

Nickel

Industrial contamination with nickel typically leads to inhalation of nickel particles. Nickel settles in the topsoil and contaminates plants and water sources. Drinking water contaminated with nickel has been reported to cause hemolysis, hemoglobinuria, and kidney damage.[47] Patients with CKD have been reported to have elevated serum nickel concentrations.[22] Whether this is consequent to CKD or a cause of progressive renal damage or both is unclear.[48]

Thallium

Thallium is used as a rodenticide and has been included in some herbal remedies for skin conditions. Although thallium is mainly excreted *via* the fecal route, around 35% is renally excreted. Thallium poisoning typically presents with abdominal pain, nausea, and vomiting occurring within a few hours of an acute exposure. A few days later, alopecia often develops, along with a painful sensory neuropathy, typically involving the soles and palms, which may be followed by leg weakness, ataxia, confusion, psychosis, convulsions, and even coma. Liver function is often abnormal and patients may develop AKI.[49] Chronic low-level exposure may lead to CKD.

Thallium is used as an isotope for myocardial perfusion scans, and thallium cardiac washout times are prolonged in patients with CKD.[50]

Lanthanum

Lanthanum is prescribed to patients with CKD as a phosphate binder. Although lanthanum is predominantly excreted by the biliary system, it has been reported to be taken up into bone, and more recently into the gastric mucosa and upper gastrointestinal tract in both animal experimental models and patients with CKD.[51]

Bismuth

Besides industrial uses, bismuth containing compounds are used in surgical dressings, cosmetics, and for the treatment of gastric and duodenal ulcers, and some cancers. In cases of acute toxicity due to ingestion of bismuth salts, such as tripotassium dicitrato bismuthate (DeNol liquid), patients present with nausea, vomiting, and abdominal pain, and then may develop AKI and neurotoxicity. Patients chronically exposed to bismuth typically present with encephalopathy which has progressed from incoordination, loss of memory, and psychiatric symptoms. Other manifestations of chronic bismuth toxicity include CKD, thrombocytopenia, spontaneous fractures of the thoracic vertebra, and a paralytic ileus-like syndrome. Bismuth binds to sulfhydryl detoxification sites, inactivates enzymes, and affects methylation, leading to proximal tubular cell death by destabilizing the cell membrane.[52]

TOXICITY DUE TO METALS IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Lead

Lead is the 19th most common element in the earth's surface, but has no essential biological role in man. Although lead has been recognized to cause toxicity for many centuries, lead piping has been used for domestic water supplies until relatively recently. Legislation was only recently introduced to curb lead emissions from gasoline-powered cars. Even so, current exposure generally occurs from air pollution or occupational exposure. Around 40% of inorganic lead inspired is absorbed through the lungs. Only 10–15% is absorbed

via the gastrointestinal tract, although the exact proportion depends on the presence of competition from other divalent cations. Organic lead from gasoline can also be absorbed through the skin. Lead workers are not the only group at risk of lead toxicity, as toxicity has also been reported in automobile mechanics.[53] Whereas many other cation metals bind to plasma proteins and albumin, lead and aluminum are predominantly transported in red blood cells. Ionized lead is filtered by the glomerulus and reabsorbed in the proximal tubule. Lead tends to be retained in the proximal tubular cell due to reduced basolateral secretion and thus accumulates causing renal tubular cell damage by free radical production, resulting in cell death.

Chronic exposure to lead leads to minor elevations in whole blood lead levels, resulting in impaired cognitive function, anemia (as lead competes for σ-aminolevulinic acid dehydratase and heme synthase, so reducing heme synthesis), and ultimately hypertension and CKD.[54,55] There is debate regarding whether lead accumulation is a consequence of CKD or whether lead exacerbates and accelerates the progression of CKD.[56–60] This may depend on the amount of lead exposure. There is clearer evidence for a role of lead in the progression of CKD from geographical areas with greater lead exposure.[59] In addition to renal damage, lead accumulation also affects the nervous and cardiovascular systems. Acute or acute and chronic exposure may result in colicky abdominal pain and general nonspecific symptoms of nausea, constipation, arthralgia and myalgia, headaches, and difficulty concentrating may occur. Lead may cause a peripheral motor neuropathy, classically causing wrist drop. Hypertension may increase the risk of stroke.[60]

There have been concerns that even low-level exposure to lead, especially in children, may result in developmental delay and brain damage, as well as anemia in infants and young children.[61]

As lead is carried in red blood cells, lead levels should be corrected for hematocrit. Whole blood lead levels may markedly underestimate total body lead stores.[62] To prevent industrial overexposure to lead, industrial workers often undergo provocation tests designed to mobilize tissue stores, and urine lead is measured in a timed urine collection. Newer alternatives to screening include X-Ray fluorescence techniques.[63,64]

Mercury

Toxicity from mercury may be caused by exposure to elemental, organic, and inorganic compounds. Organic mercury poisoning may result from industrial exposure to methyl and ethyl mercury compounds. Although inorganic mercury poisoning may be associated with occupational exposure, it has also been reported with medicinal products, including teething powders, skin whitening creams, and laxatives. Elemental mercury causes toxicity by releasing a mercury vapor which is inhaled.

Mercury is highly reactive with selenium, which is a key element in a series of intracellular enzymes. Selenium-containing enzymes prevent and reverse oxidative damage,[65] and these enzymes are irreversibly inhibited by mercury. For example, mercury inhibits thioredoxin reductase, the key enzyme which restores vitamins C and E, as well as a number of other important antioxidant molecules, back to their reduced forms, enabling them to counteract oxidative damage within cells. The proximal renal tubular epithelial cells have a high energy requirement and are vulnerable to mercury toxicity. Historically, mercury was used as a diuretic, as its toxic effects reduced renal tubular sodium reabsorption. In addition, mercury inactivates catecholaminei-o-methyltransferase, which increases serum and urinary epinephrine, norepinephrine, and dopamine, resulting in the development or worsening of hypertension.[66]

Organic mercury intoxication typically presents with a progressive neurologic illness, characterized by mental deterioration, leading progressively to paresthesia, ataxia, spasticity, deafness, and finally coma and death.[67] Inorganic mercury poisoning more often presents insidiously, sometimes only after many years of exposure, with chronic kidney damage, gastroenteritis, dermatitis, and in the latter stages dementia and tremor.[68–70]

Although mercury toxicity typically affects the renal tubular epithelium, resulting in cell death and chronic interstitial fibrosis, acquired Fanconi syndrome is rarely reported.[71] Mercury has also been reported to cause a number of glomerular pathologies, including nephrotic syndrome due to minimal change,[72] membranous[73] and possibly focal segmental sclerosis.[74] However, as with lead, mercury accumulates in patients with CKD,[22] but clinical studies failed to prove causation with progressive CKD.[75]

Aluminum

Aluminum is the third most common element in the earth's crust, yet it has no biological function in humans. Aluminum filtered by the glomerulus is taken up into the proximal tubule cells and accumulates due to slower basolateral transport. Aluminum can generate free radical oxygen species,[76] but does not appear to cause direct renal toxicity. Aluminum accumulates in patients with CKD due to reduced renal clearance. Other than aluminum-containing antacids and buffered aspirin, food is the primary source of exposure for most healthy people. Systemic uptake of aluminum after ingestion of

the monomeric salts is somewhat greater from drinking water (0.28%) than from food (0.1%). Aluminum exposure may result from contamination of domestic water due to treatment with aluminum salts, used to precipitate particulate matter to improve water clarity and appearance,[77] and from leaching from aluminum-coated cooking utensils.[78] In addition, some patients with CKD may be prescribed aluminum-containing medicines, not only as phosphate binders but also as antacids.

Aluminum accumulation leads to aluminum deposition in bone, resulting in reduced bone mineralization and osteomalacia.[79] Rarely, occupational aluminum exposure has been reported to cause multifocal osteonecrosis.[80] Aluminum can compete for key enzymes (delta aminolevulinic acid dehydratase and heme synthase), involved in the synthesis of hemoglobin, resulting in the development of anemia.[81,82] In severe cases of aluminum toxicity, patients can present with memory loss, a pseudo-Parkinsonian gait, tremor, which may progress to seizures, dementia, and death.[83] Aluminum is taken up into macrophages and leukocytes and has been suggested to affect immune function in CKD patients.[84–86]

METALLOIDS IN CHRONIC KIDNEY DISEASE

Arsenic

Arsenic contamination of groundwater is a problem that affects millions of people across the world. Other sources of arsenic include occupational industrial exposure and traditional medicines.[87] Arsenic poisoning usually causes headaches, confusion, severe diarrhea, and drowsiness and can progress to convulsions. Chronic poisoning leads to leukonychia and pigmentation of the hands. Acute arsenic poisoning is associated with abdominal pain, vomiting, and diarrhea, hematuria, myalgia, hair loss, convulsions, and ultimately death.[88]

Arsenic disrupts cell energy production by inhibiting the pyruvate dehydrogenase (PDH) complex in the Kreb cycle, resulting in apoptosis. Chronic low-level exposure inactivates endothelial nitric oxide synthase, leading to reduction in the generation and bioavailability of nitric oxide, and increases free radical production, with resultant increased oxidative stress. In addition, chronic arsenic exposure induces high oxidative stress, which may affect the structure and function of the cardiovascular system. Moreover, arsenic exposure may cause arrhythmias by altering voltage-gated potassium channels, increasing the QT interval and accelerating intracellular calcium overload.[89]

Low levels of arsenic exposure are associated with hypertension and peripheral vascular disease.[90] Population studies report an association between increased blood and urine arsenic levels and hypertension,[91] but whether chronic arsenic exposure *per se* leads to hypertension remains debatable, as there is no clear correlation between increasing arsenic levels and systolic hypertension.[92] However, chronic exposure to arsenic does result in chronic kidney damage and proteinuria,[92,93] and hypertension may be a consequence of chronic kidney damage. Occasionally arsenic can cause AKI.[94]

Polonium

Polonium is a radioactive metalloid which causes AKI and multiple organ failure when ingested.[95] Whether low-dose exposure results in CKD similar to uranium remains unknown.

Other Trace Elements in CKD

Other trace elements which have been implicated in causing CKD secondary to tubular damage include boron,[96] chromium,[97] and inhalation of silica dust.[98] One study in hemodialysis patients from Canada reported that tungsten and beryllium concentrations were commonly reduced, whereas vanadium, barium,

TABLE 44.1 Suggested Daily Intake of Trace Elements for Normal Adults

Element	Dietary Intake
Bismuth	25–50 μg
Chromium	Men 30 μg, women 20 μg
Cobalt	0.006′μg
Copper	0.9 mg
Fluoride	Men 4 mg, women 3 mg
Iodine	0.1–0.15 μg
Magnesium	Men 300 mg, women 270 mg
Manganese	≤4 mg but older subjects ≤0.5 mg
Molybdenum	45 μg
Nickel	0.4–0.6 mg
Selenium	Men 0.075, women 0.06 mg
Silicon	<700 mg
Strontium	Not determined
Sulfur	Not determined
Zinc	Men 5.6–9.5 mg, women 4–7 mg

antimony, molybdenum, and chromium concentrations were increased.[22] Whether these results are generalizable to other countries remains to be determined, as they may reflect the specific composition of local soil and water and exposure to industrial pollution.

Fluoride

Fluoride is a chemical element that is found most frequently in groundwater and has become one of the most important toxicologic environmental hazards globally.[99] Although when ingested in small quantities fluoride helps prevent dental caries, at higher concentrations (>1.5 mg/L) fluorosis may develop. It has been questioned whether increased fluoride exposure in parts of Sri Lanka is linked to the high rate of CKD reported in these areas,[100] as fluoride exposure has been linked to a chronic tubular interstitial nephritis.[101] Studies have reported that fluoride has direct toxic effects on the renal tubule, leading to apoptosis.[114]

Fluoride exposure from anesthetic gases including methoxyfluorane has been reported to reduce renal urate excretion.[102] In some parts of the world, fluoride is added to domestic water to reduce dental caries. Patients with CKD are more likely to retain fluoride[103] and be at risk of fluorosis.[104]

TABLE 44.2 Suggested Adult Reference Levels for Monitoring Deficiency of Essential Trace Elements and Toxicity of Nonessential Elements[1]

Element	Sample	SI Unit	Conventional Unit
Aluminum	Serum	<0.3 μmol/L	<8 μg/L
		Toxic[1] >7.4 μmol/L	Toxic[1] >200 μg/L
Arsenic	Whole blood[2]	0.03–0.08 μmol/L	0.2–6.2 μg/dL
	24-hr urine	Toxic >0.67 μmol/L	Toxic >50 μg/L
Bromide	Serum	≤0.15 mmol/L	<11 mg/L
		Toxic >20 mmol/L	Toxic >1500 mg/L
Cadmium	Whole blood	2.7–10.7 mmol/L[3]	0.3–1.2 μg/L[3]
		5.6–37 mmol/L[4]	0.6–3.9 μg/L[4]
Chromium	Serum	<10 nmol/L	<0.25 μg/L
Cobalt	Serum	1.7–6.8 nmol/L	0.1–0.4 μg/L
Copper	Plasma	11–22 μmol/L	72–164 μg/dL
Fluoride	Serum	0.3–2.2 μmol/L	0.57–4.2 μg/dL
Gadolinium	Serum	<1.0 nmol/L	<0.5 μg/L
Lanthanum	Serum	<10 nmol/L	<1.0 μg/L
Lead	Whole blood	<0.98 μmol/L	<20 μg/dL
		>2.4 μmol/L[5]	>50 μg/dL[5]
Manganese	Serum	9–24 nmol/L	0.5–1.3 μg/dL
Mercury	Whole blood	<20 nmol/L	<4 μg/L
		Toxic >500 nmol/L	Toxic >100 μg/L
Selenium	Plasma	0.89–1.65 μmol/L	70–130 μg/L
Silver	Whole blood	<0.28 nmol/L	<0.3 μg/L
Thallium	Whole blood	<5 nmol/L	<1 μg/L
Uranium	Serum	<10 nmol/L	<20 ng/L
Zinc	Serum	11–24 μmol/L	0.7–1.6 μg/L

Some samples must be taken into specially prepared specimen tubes to prevent environmental contamination.
[1]*Serum and whole blood samples do not readily correlate with tissue stores. As such, provocation testing should be considered in cases of suspected toxicity, for example, desferioxamine testing in cases of suspected aluminum toxicity.*
[2]*Whole blood taken in EDTA.*
[3]*Nonsmoker.*
[4]*Smoker.*
[5]*Industrial workers to be removed from occupational exposure.*

Selenium

Although the biological significance of low blood selenium concentrations in patients with CKD[105,106] is less clear, severe selenium deficiency is associated with sudden death and cardiomyopathy in the general population.[107–110] Selenium is vital for the function of a series of selenomethionine enzymes, which regulate immunity, redox state, and inflammation, including glutathione peroxidase, thioredoxin reductase, and selenoprotein P. Selenium deficiency leads to increased free radical activity and cell damage. The effect of mercury is to produce a selenium deficiency state. Therefore, some of the toxicity of mercury is due to selenium deficiency.[111] Lower levels of serum selenium without severe deficiency have been associated with hypertension,[106] heart failure,[107] and coronary artery disease[108] in the general population, and with cardiomyopathy among dialysis patients.[106] Although selenium is a vital micronutrient, too much selenium from contaminated soil or water can be toxic resulting in hair loss, sloughing of nails, neurodegenerative diseases, increased cancer risk, and death.[112]

SUMMARY

CKD patients are more susceptible to the consequences of trace element deficiencies and toxicity. The intracellular and plasma concentrations of trace elements are carefully regulated by the gastrointestinal tract and kidney to maintain homeostasis. Loss of regulation by the kidney typically leads to deficiency of key biological trace elements, including zinc and selenium, but accumulation and potential toxicity of elements with no normal physiological role, such as lead and arsenic. Exposure to trace elements varies throughout the world due to differences in the chemical composition of topsoil and drinking water. However, in industrial societies, mining and manufacturing processes not only potentially increase the risk of exposure to workers but also release of contaminated water and gases into the environment also exposes those living in neighboring areas to toxicity (Tables 44.1 and 44.2).

QUESTIONS AND ANSWERS

Question 1

A 35-year-old man presented with increasing peripheral edema over a two-month period. He had been working in a factory making fluorescent light tubes for the last three years. On examination, he was hypertensive, blood pressure 160/95 mm Hg, with pitting edema in the lower legs. Urine dipstick testing revealed 4+ proteinuria, blood negative.

The most likely diagnosis is

A. Minimal change glomerulonephritis secondary to neon exposure
B. Membranous glomerulonephritis secondary to argon exposure
C. Focal segmental glomerulosclerosis secondary to fluorosis
D. Membranous glomerulonephritis secondary to mercury exposure
E. Lead-induced glomerulonephritis

Answer: D

Mercury exposure is an occupational hazard for workers in the light bulb industry. Mercury has been reported to cause minimal change and membranous glomerulonephritis, and, less frequently, focal segmental glomerulosclerosis and other forms of proliferative glomerulonephritis. The presence of hypertension suggests membranous glomerulonephritis rather than minimal change.

Question 2

A 28-year-old man was admitted to start his fourth course of cis-platinum-based chemotherapy for testicular carcinoma. Four days after starting chemotherapy he was found seizing in his bed by the nursing staff. The seizure was initially terminated with diazepam. Blood tests showed hemoglobin of 9.7 g/dL, BUN 25 mg/dL, and serum creatinine (S[Cr]) 3.5 mg/dL. Two hours later, he suffered a further grand mal tonic-clonic seizure.

The cause of the seizures was

A. Hypoglycaemia
B. Hypomagnesemia
C. Hypocalcemia
D. Hyponatremia
E. Hypokalemia

Answer: B

Although many metals predominantly cause proximal renal tubular damage, platinum-based compounds typically affect the distal tubule. Repeated courses characteristically cause distal tubular damage, excessive magnesuria, and hypomagnesemia. This patient has significant renal impairment, presumably secondary to the repeated renal damage caused by cis-platinum. The patient is most likely to be hypokalemic, despite the impaired renal function, but this is not the cause of the seizures. Typically hypokalemia does not repond to simple potassium repletion, and only starts to normalize once magnesium supplements have been administered.

Question 3

A 28-year-old woman with type 2 diabetes, nephrotic range proteinuria, and CKD stage 4 had a BMI of 45. She underwent gastric bypass surgery to lose weight. The operation was successful. She lost weight, from 135 kg to 95 kg over 4 months. She presented to the clinic with a two-week history of difficulty getting out of bed and chairs and had difficulty walking. On examination, she had an ataxic gait and some cerebellar signs.

Her neurological state was due to

A. Hypothyroidism
B. Vitamin B_{12} deficiency
C. Selenium deficiency
D. Zinc deficiency
E. Copper deficiency

Answer: E

Nephrotic range proteinurial reduces ceroplasmin levels. Therefore, this patient may be at risk of copper deficiency, due to increased urinary copper losses. Copper deficiency is a well-recognized complication of gastric bypass surgery, due to a combination of reduced appetite and reduced dietary copper intake. Small bowel bacterial intestinal overgrowth following removal of the acidic stomach barrier, which restricts bacterial entry into the small bowel, results in reduced copper absorption from the gastrointestinal tract. Although it is possible that some of the symptoms and signs could be secondary to vitamin B_{12} deficiency, body stores would be unlikely to become depleted and cause these symptoms within a few months of the operation.

Question 4

A 75-year-old man was brought to the outpatient clinic by his wife. He was unable to give a history. His wife explained that he had become demented over the previous 2 months. He had complained of difficultly reading and watching television, which had not improved with new glasses. He had also become somewhat hard of hearing. On examination, his blood pressure was 145/95 mm Hg. He had a tremor, worsening when his arms were outstretched, and had difficulty picking up small objects due to the tremor. He had a past medical history of hypertension, type 2 diabetes,

and CKD stage 3. Eighteen months earlier he had undergone successful left hip replacement. Blood tests showed a hemoglobin of 11.0 g/dL and S[Cr] 2.2 mg/dL.

What was the cause of his neurological decline?

A. Binswanger's disease
B. Alzheimer's dementia
C. Cobalt toxicity
D. Pick's disease
E. Cadmium toxicity

Answer C

Cobalt toxicity due to cobalt release from metal from metal artificial hips has been termed arthroprosthetic cobaltism. It results in neurological (hand tremor, incoordination, cognitive decline, depression, vertigo, hearing loss, and visual changes) and cardiac (arrhythmias and cardiomyopathy) abnormalities. As this patient had underlying CKD, he was likely to excrete cobalt released from the metal on the metal prosthetic hip joint. The tremors and difficulty with vision and hearing point away from Alzheimer's and Pick's dementias. Although cadmium can cause neurological damage, the movement disorder again would be somewhat atypical.

Question 5

A 66-year-old man was seen in the outpatient clinic complaining of recurrent generalized abdominal pain and constipation, nausea, and headaches. He continued to work in a glass factory specializing in stained glass windows. On examination, he was hypertensive, blood pressure was 170/105 mm Hg. He was anemic with hemoglobin 10.3 g/dL. S[Cr] was 2.6 mg/dL. Urine dipstick testing revealed 2+ protein, but no blood. A blood smear showed basophilic stippling.

The cause of his renal impairment was

A. Arsenic poisoning
B. Hypertension
C. Cadmium toxicity
D. Lead toxicity
E. Aluminum toxicity

Answer: D

The nonspecific gastrointestinal symptoms and abdominal pain are consistent with lead toxicity. Lead toxicity typically causes anemia and CKD, along with hypertension. Although CKD could simply be associated with hypertension, the presence of basophilic stippling on the blood smear, and the degree of anemia in light of the S[Cr] suggest lead, especially in view of industrial exposure to lead work in the making of stained glass. If he had gum discoloration, this would have clinched the clinical diagnosis.

Question 6

A 72-year-old Chinese woman was brought to the emergency department complaining of sudden onset of shortness of breath. She was dyspneic at rest, with a respiratory rate of 20 per minute. Her blood pressure was 170/110 mm Hg. She had atrial fibrillation at a rate of 140 beats per minute, confirmed on ECG. She also had pitting peripheral edema and pulmonary rales. She had generalized hair loss, brown spots on the palms of her hands, and leukonychia. Urine dipstick testing noted 2+ protein and 1+ blood. She was not known to take any regular prescription medicines but had regularly consulted a traditional Chinese medical practitioner.

The most likely cause of her atrial fibrillation was

A. Arsenic toxicity
B. Syphilis
C. Hypertensive heart disease
D. Thyrotoxicosis
E. Thallium poisoning

Answer: A

Thallium can cause cardiac toxicity with atrial fibrillation and hair loss. Thallium has occasionally been reported to contaminate some alternative medicines, but poisoning has usually been accidental when patients have taken rodenticide tablets in error or with contamination of foodstuffs. However, the combination of leukonychia and brown pigmentation on the palms is classically associated with low-level chronic arsenic toxicity. Arsenic exposure, probably from taking traditional medicine preparations, could account for her atrial fibrillation, hypertension, and CKD with proteinuria.

CHAPTER

Approach to the Patient with Chronic Glomerular Disease

Scott D. Cohen[a], *Gerald Appel*[b]

[a]Division of Kidney Diseases and Hypertension, Department of Medicine, George Washington University, Washington, DC, United States; [b]Division of Nephrology, Columbia University Medical Center, New York, NY, United States

Abstract

Glomerular diseases are a leading cause of chronic kidney disease (CKD). However, most treatment protocols for glomerulonephritis center on acute management. There are far less data on the treatment of CKD specifically caused by glomerular diseases. Most forms of glomerulopathy can progress to CKD, especially if not treated early when the disease process is most active. Risk factors for progression of glomerular disease to CKD include the presence of proteinuria especially in the nephrotic range or greater, decreased estimated glomerular filtration rate at baseline, and histologic evidence of crescentic glomerulonephritis, glomerulosclerosis, and tubulointerstitial fibrosis. The conservative treatment of all chronic renal diseases secondary to glomerulopathy includes blood pressure control, especially with medications of the renin–angiotension–aldosterone system inhibitor class, control of edema with diuretics and a low-sodium diet, avoidance of nephrotoxins, and moderation of dietary protein intake. Some therapies, such as control of dyslipidemia, will ameliorate the cardiovascular risk so common in CKD patients. Therapies to prevent tubulointerstitial fibrosis are currently being studied. This chapter will present an overview of management considerations for CKD secondary to glomerular diseases.

INTRODUCTION

Glomerular diseases are a frequent cause of morbidity and end-stage renal disease (ESRD) in the US.[1] In the 2017 report of the US Renal Data System "glomerulonephritis" (GN) accounted for between 15 and 20% of all prevalent cases of ESRD.[1] There have been significant advances made in the treatment of acute GN.[2,3] Perhaps because of better survival in ESRD secondary to glomerular disease as opposed to diabetic nephropathy and hypertensive nephrosclerosis, there remains less focus on the subset of patients with progressive GN leading to chronic kidney disease (CKD).[4] Even with successful treatment of the acute phase of GN or with partial remission of the nephrotic syndrome, glomerular diseases of diverse pathogenesis can transform into a phase of chronic progressive renal insufficiency with histologic changes consistent with secondary focal segmental glomerulosclerosis (FSGS) and increasing tubulointerstitial fibrosis.[5,6] Glomerular damage associated with hypertension and hyperfiltration are likely mediators of the disease process at this point (Figure 45.1).

There is compelling evidence that control of hypertension is essential in slowing the progression of all types of CKD, including those secondary to glomerular diseases. Moreover, for patients with glomerular diseases, elevated blood pressure should be treated with inhibitors of the renin–angiotensin–aldosterone system (RAAS), as clinically tolerated, to ameliorate the chronic effects of hyperfiltration. RAAS inhibitors have several effects on glomerular hemodynamics that make this class of medication especially beneficial in patients with chronic GN. Inhibition of RAAS leads to efferent arteriolar vasodilatation with a subsequent decrease in glomerular hyperfiltration, decreased aldosterone secretion, antifibrotic effects, reduced oxidative stress on the glomerulus, and preservation of the glomerular filtration barrier. There is little evidence for the appropriate target blood pressure in patients with glomerular disease and CKD, but lower goal blood pressures to less than 125/75 (or $<$ 130/80) mm Hg should be considered in those patients with proteinuria greater than 1 g/day.[7,8] The use of angiotensin-converting enzyme inhibitor (ACEI)/angiotensin receptor blocker (ARB) combinations has been associated with more cardiovascular events and episodes of AKI in two populations of

Chronic Renal Disease, Second Edition

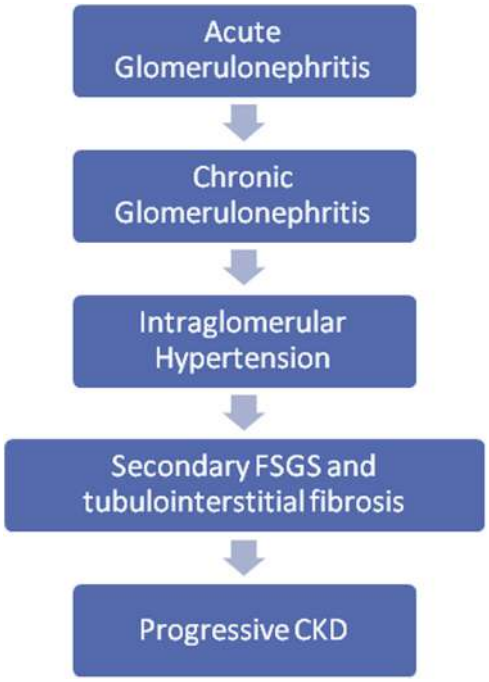

FIGURE 45.1 Development of chronic kidney disease (CKD) secondary to glomerular diseases: glomerular diseases can lead to CKD through increased glomerular hyperfiltration and secondary glomerular sclerosis leading to tubulointerstitial fibrosis. *FSGS*, focal segmental glomerulosclerosis.

patients at high risk for cardiovascular disease.[9,10] Combining ACEI and ARB has fallen out of clinical favor. Whether this should prohibit use of combination RAAS inhibitors in young individuals at high risk for progressive renal damage but lower risk for immediate cardiovascular disease is debated. There is increased interest in combining RAAS inhibitors with a mineralocorticoid receptor antagonist for enhanced antiproteinuric effects.

There are mixed results regarding the effects of dietary protein restriction to slow the progression of CKD secondary to glomerular diseases.[8,11,12] There are increasing data to support the use of sodium bicarbonate supplementation to treat the metabolic acidosis of CKD. In several small trials, patients with CKD and hypobicarbonatemia treated with sodium bicarbonate had a decrease in the rate of decline in estimated glomerular filtration rate (eGFR) compared to patients who did not receive sodium bicarbonate therapy.[13–15] Newer trials are also focusing on methods to prevent tubulointerstitial fibrosis and renal progression in CKD patients with glomerular diseases. There is interest in the role of transforming growth factor receptor-beta (TGF-β) inhibitors (pirfenidone and fresolimumab) to decrease the formation of glomerulosclerosis and tubulointerstitial fibrosis.[16,17] Bardoxolone, a new agent that may increase glomerular filtration rate (GFR) without affecting proteinuria through activation of the Nrf2 pathway and inhibition of the NF-kb pathway, is being studied in a variety of glomerular diseases including the genetic disease Alport's syndrome. This chapter will review the data on chronic glomerular diseases and risk factors for progression to CKD, and will focus on therapeutic strategies to halt the progression of chronic GN to ESRD.

NEPHROTIC SYNDROMES AND CHRONIC RENAL DISEASE

The nephrotic syndrome is classically defined by the triad of proteinuria greater than 3.0–3.5 g/day, edema, and hypoalbuminemia.[18] If the nephrotic syndrome is untreated, it can progress to CKD and ESRD. Other complications of the disease include hyperlipidemia, protein malnutrition, acute kidney injury (AKI), thromboembolic events, infections, vitamin D deficiency with associated osteomalacia, and decreases in thyroxine-binding globulin.[18–20] There are three common primary causes of adult nephrotic syndrome—minimal change disease (MCD), membranous nephropathy (MN), and FSGS.

Minimal Change Disease

MCD is felt to have an excellent long-term prognosis and little risk of progression to CKD. When worsening renal impairment is evident, a repeat renal biopsy should be considered to evaluate for possible misdiagnosis of FSGS or transformation to FSGS or other disease variants such as IgM and C1Q nephropathies.[21,22] It was previously felt that MCD and FSGS were part of the same disease process. However, advances in pathogenesis support the notion that MCD and FSGS are two separate entities. Approximately 25% of adult patients with MCD may present with or develop AKI.[22] AKI is a known major risk factor for the development of CKD.[23] Patients with AKI in the setting of MCD should initially be treated with steroids.[22] In some patients who develop severe episodes of AKI, there may be residual renal impairment that leads to CKD.[22,23] Once the AKI resolves, an ACEI or ARB should be used as the antihypertensive medication of choice for its antiproteinuric effect and to slow the progression of any residual renal impairment. Surveillance for recurrence of MCD should continue as the disease tends to have a relapsing and remitting course.[2,21,22] Patients with frequently relapsing or steroid-dependent MCD may benefit from steroid-sparing agents such as cyclosporine, cyclophosphamide (CYC), rituximab (RTX), or mycophenolate mofetil (MMF).[24,25]

Membranous Nephropathy

MN progresses to ESRD in approximately one-third of cases over 10 years, although the rates vary in different epidemiologic studies.[26–29] Risk factors for progressive CKD secondary to MN include nephrotic range proteinuria of greater than 8 g/day for more than 6 months, increased age, male gender, hypertension, and elevated serum creatinine concentration (S[Cr]) at baseline.[26–29] The presence of sclerotic glomeruli and tubulointerstitial fibrosis are also associated with progression to CKD. However, the pathology does not add additional independent risk beyond the clinical features mentioned above.[30] Likewise, a pathologic staging system for MN based on the location of electron dense deposits has not correlated with clinical outcomes.[30]

Initial management of patients with MN and CKD should focus on "conservative therapy" including diuretics to treat edema, low-sodium diet and moderation of protein intake, treatment of hyperlipidemia, and control of blood pressure with use of RAAS inhibitors where appropriate[26–29] (Figure 45.2). Use of ACEI or ARBS in patients with MN can slow the progression of CKD.[26–30] Use of statins was also shown in one study to reduce the risk of progression to ESRD in patients with MN. However, these data have not been confirmed by other studies.[30]

CKD patients with worsening renal insufficiency and evidence of persistently active immunologic injury on renal biopsy or by elevated levels of antiphospholipase A2 receptor antibody should receive immunomodulatory therapy as deemed clinically appropriate by the treating clinician.[31] Antiphospholipase A2 receptor antibody levels were shown to be present in approximately 70% of all patients with primary MN.[32] The ability to measure these antibody levels in patients with MN has revolutionized treatment. Persistent elevations in these antibody titers can assist in clinical decision-making to use additional immunosuppression to bring the disease into remission[31,33] Patients with low PLA2R antibody titers and lower levels of proteinuria may not be candidates for immunosuppression therapy, and treatment should focus on modifying risk factors for progressive CKD.

Immunosuppression treatment options for patients with MN include use of alkylating agents in combination with steroids, calcineurin inhibitors with or without steroids, mycophenolate MMF, RTX, and adrenocorticotropic hormone (ACTH).[26–29,34] CKD patients without evidence of immunologic activity either by a biopsy showing advanced glomerulosclerosis and severe tubulointerstitial fibrosis, and/or undetectable antiphospholipase A2 receptor antibody titers, should not receive immunomodulatory therapy.[31,33] The risks of

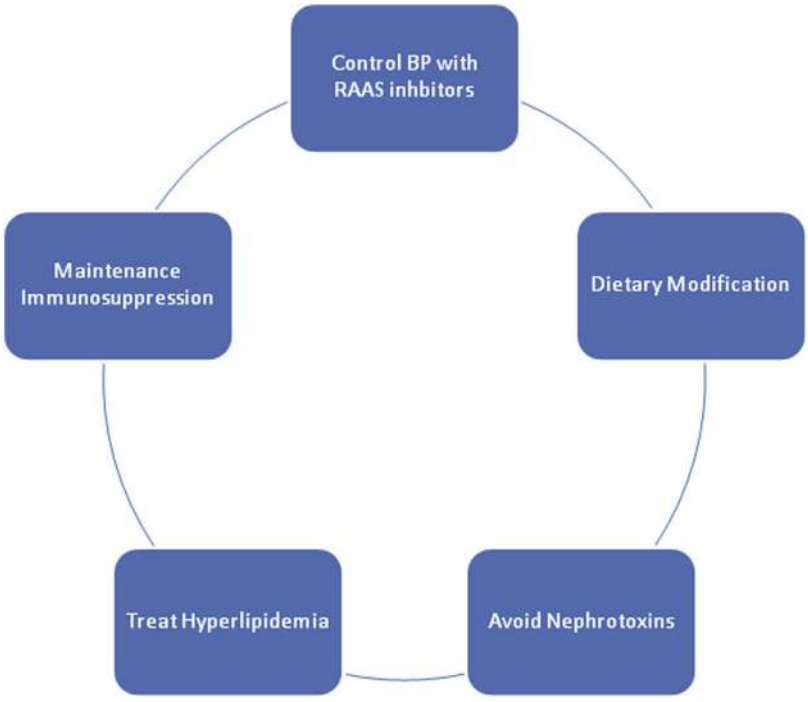

FIGURE 45.2 Treatment of chronic kidney disease (CKD) secondary to glomerular diseases: treatment includes control of blood pressure with renin–angiotensin–aldosterone inhibitor (RAAS) inhibitors unless otherwise contraindicated, dietary modification, avoidance of nephrotoxins, control of hyperlipidemia, and maintenance immunosuppression if there is active disease.

immunosuppression in this setting outweigh any remote benefits in patients with more advanced stages of CKD secondary to MN.

Patients with MN and advanced CKD with eGFR less than 20 mL/min/1.73 m^2 are candidates for renal transplantation. The risk of recurrent disease in this patient population ranges from 10 to 44%.[35,36] Until the past decade, there were little data on the optimal treatment for recurrent MN. Studies now support the use of RTX added on to standard maintenance immunosuppression protocols for the treatment of nephrotic range proteinuria in the setting of recurrent MN.[36]

Focal Segmental Glomerulosclerosis

FSGS represents a histologic glomerular injury pattern that is caused by diverse etiologies, including circulating permeability factors, genetic variants, viruses (including HIV and Parvovirus B19), medications (including interferon, bisphosphonates, sirolimus, and lithium) and secondary causes attributed to adaptive structural–functional responses.[37–39] FSGS is the most frequent glomerular disease to lead to progressive CKD and ESRD. Determining the etiology of FSGS, including whether the lesion represents a primary or secondary form, is essential because the rate and risk of progression to CKD and ESRD can be quite variable and dependent on the specific subtype of FSGS. Treatment differs for primary and most secondary forms of FSGS.[38,39] Research has continued into potential circulating permeability factors that can lead to primary FSGS but have produced mixed results. Circulating levels of the soluble urokinase receptor (suPAR) have been shown to be elevated in some patients with FSGS.[40,41] However, in other studies elevated suPAR levels have not distinguished between primary and secondary FSGS. Moreover, levels are elevated in many other disease states with CKD, making assay of circulating levels of little value in distinguishing FSGS with CKD from other proteinuric glomerular diseases.[42–44]

Untreated primary FSGS progresses to CKD and ESRD in the majority of cases.[45,46] In contrast to MN, rates of spontaneous remission are significantly lower.[45] Approximately 50% of patients who do not respond to therapy with a complete or partial remission will progress from CKD to ESRD over 10 years.[38,45,46] Patients with FSGS that are at greater risk for progressive CKD include those presenting with nephrotic range proteinuria and the full nephrotic syndrome, reduced eGFR at baseline; African Americans; and those with collapsed glomerular capillary tufts (the "collapsing variant") and tubulointerstitial fibrosis on biopsy and failure to achieve either a complete or partial remission.[38,39,45–47]

Until recently it was unclear why African Americans had a higher rate of progression to CKD and ESRD and increased rates of FSGS compared to Caucasians. A genetic breakthrough was made with the identification of unique apolipoprotein 1 (APOL1) genotypes on chromosome 22.[48–50] Certain allelic variants of apoL1 are able to lyse the pathogen *Trypanosoma brucei rhodesiense*, thereby conferring protection against African sleeping sickness.[48–50] Through natural selection, individuals of African descent have up to a 35% frequency of these allelic variants of APOL1.[48] Individuals with two mutant alleles of APOL1 have significantly higher rates of FSGS and progression to ESRD compared to those with one or no mutant alleles.[48–50] The exact mechanism whereby APOL1 mutants predispose to FSGS and renal disease is unclear and is undergoing further evaluation.[48–50] Mutated APOL1 gene products may predispose to podocytopathies through alterations in membrane ion flux, dysregulation of endolysosomal, mitochondrial and autophagic function, and increased cellular inflammatory pathways.[51] There is also recent evidence that suPAR interacts with APOL1 to activate integrin receptors, which can potentially lead to podocyte injury.[51]

Patients with FSGS and CKD should be treated with conservative therapy, including blood pressure control with maximization of RAAS inhibitors as clinically tolerated, statins to treat hyperlipidemia, low-sodium diet and moderation of animal protein intake, and diuretics as needed to control edema.[2,38] In animal models of FSGS, dietary protein restriction has been shown to reduce glomerular scarring through reductions in profibrotic cytokines including transforming growth factor-beta and platelet derived growth factor. Long-term protein restriction in humans with severe nephrotic syndrome remains controversial. The data are mixed regarding whether there is a beneficial impact of dietary protein restriction in slowing progression of glomerular diseases such as FSGS.[11,12]

It is not clear if adding additional immunosuppression therapy will slow progression of disease once advanced tubulointerstitial scarring and global glomerulosclerosis is present. Risks of immunosuppression should be balanced against any potential benefits. However, patients with severely reduced levels of eGFR are not likely to benefit from additional immunosuppression. Patients with secondary forms of FSGS should receive treatment directed at the underlying condition as opposed to immunosuppression with steroids. For example, observational studies show that patients with HIV-associated FSGS benefit from therapy with antiretroviral therapy to slow the progression of CKD.[52–55] Likewise, patients with obesity-induced glomerulomegaly and adaptive hyperfiltration secondary FSGS may benefit from weight reduction.[56]

In patients with primary FSGS and mild or moderate degrees of interstitial fibrosis and minimal glomerular sclerosis, immunosuppression options include a trial of corticosteroids. If the patient remains unresponsive after an adequate treatment trial, then second line therapies should be considered.[37,38,57] Calcineurin inhibitors can be considered as another option in patients with preserved GFR and steroid-resistant or steroid-dependent disease.[37,57] There is a direct effect of cyclosporine to stabilize the actin cytoskeleton in podocytes, thereby reducing proteinuria.[58] However, cyclosporine is contraindicated in patients with moderate or advanced CKD because constriction of the glomerular afferent arteriole can exacerbate the decline in GFR. MMF has been shown to be noninferior to cyclosporine at inducing remissions in corticosteroid-resistant FSGS.[59] There has also been research supporting a direct effect of RTX and ACTH on podocytes, potentially elucidating other mechanisms to decrease proteinuria.[60,61] There are clinical trials supporting the use of these agents in inducing remisssions of proteinuria in some but not all patients.[62,63] Additional studies are warranted to determine the precise role of calcineurin inhibitors, MMF, RTX, and ACTH as options for the treatment of patients with steroid-resistant disease.

NEPHRITIC SYNDROMES AND CHRONIC RENAL DISEASE

The nephritic syndrome is characterized by hypertension, proteinuria of usually less than 3.5 g/day, an active urine sediment including dysmorphic red blood cells (RBCs) and RBC casts, with or without AKI, and edema. There are a number of glomerular diseases associated with the nephritic syndrome that can progress to CKD and ultimately ESRD. Among others, these include postinfectious GN, IgA nephropathy, pauci-immune GN, antiglomerular basement membrane (anti-GBM) disease, and system lupus erythematous (SLE) nephritis. Another pattern of glomerulopathy that may present with either the nephritic syndrome, a nephrotic picture or asymptomatic urinary findings is membranoproliferative glomerulonephritis (MPGN). MPGN can be idiopathic or associated with a variety of secondary causes and pathogenetic mechanisms including immune complex renal disease with hepatitis C virus infection, SLE, paraproteinemias and lymphoproliferative disorders, thrombotic microangiopathies, and disorders of the alternative complement pathway system. Nephritic syndromes clearly make a contribution to the burden of CKD imposed by glomerular diseases.

Postinfectious Glomerulonephritis

Poststreptococcal glomerulonephritis (PSGN) was previously felt to be a relatively benign disease, especially in children with resolution of clinical findings and minimal clinical sequelae once treated with appropriate antimicrobial therapy.[64,65] However, a study in 1519 Australian Aboriginal residents living in a rural community found significantly higher levels of albuminuria and reduced eGFR <60 mL/min/1.73 m^2 in the 200 individuals who had at least one episode of PSGN.[66] This study highlights the importance of regular follow-up of patients once an episode of postinfectious GN resolves to assess for the clinical consequences of CKD. CKD in this patient population likely results from residual glomerular scarring leading to secondary FSGS with subsequent glomerular hyperfiltration and glomerulomegaly in the remaining functioning nephrons. This subset of patients should receive treatment strategies focused on slowing the progression of CKD and reducing extent of albuminuria, including treatment of hypertension with RAAS inhibitors where clinically appropriate.

Staphylococcus aureus-associated GN with or without endocarditis is surpassing PSGN as the most common cause of postinfectious GN in the US and other developed countries.[67] This is largely the result of widespread effective antistreptococcal antimicrobial therapy. There are little data on the risk of progressive CKD in the postinfectious staphylococcal population. Renal outcomes largely depend on the early eradication of infection, which will help ameliorate any ongoing immune complex-mediated glomerular injury. A particular subset of IgA dominant postinfectious GN, more common in patients with diabetes, may have a more treatment-resistant course with higher rates of progressive renal impairment.[68]

IgA Nephropathy

IgAN is the most common form of idiopathic GN worldwide.[2,69] Previously felt to have low risk for progression to CKD, epidemiologic studies show that IgAN can lead to ESRD in approximately 25% of cases at 10 years and up to 50% of cases at 25 years of follow-up.[70–72] Therefore, particular attention must focus on strategies to reduce CKD progression in this patient population.

The Renal Pathology Society developed the Oxford classification of IgA nephropathy based on key histologic criteria to provide an assessment of renal prognosis independent of clinical variables.[73] It was updated in 2016 to include the presence of crescents.[74] Renal histopathologic findings associated with a higher risk for progression include crescents, mesangial hypercellularity, segmental glomerulosclerosis, endocapillary hypercellularity, and tubular atrophy/interstitial fibrosis.[73,74] Clinical risk factors for progression of IgAN are similar to other forms of renal disease and include decreased eGFR at baseline, higher degrees of proteinuria, and

the presence of hypertension.[2,70–72] Even an increase of proteinuria from 500 mg daily to over 1 g daily, which may be clinically insignificant in FSGS or MN, is highly prognostic of progressive disease in IgAN.[75] Reduction of heavier amounts of proteinuria to less than 1 g daily has been associated with improved prognosis.[76–78]

Decreased eGFR or CKD at initial presentation or during the disease observation period has been associated with significantly higher rates of progression to ESRD. Wakai et al.[71] evaluated 2270 Japanese patients with IgAN and found an almost 70% incidence of ESRD over seven years in patients who had S[Cr] greater than 1.68 mg/dL. Multiple studies have shown increased rates of proteinuria to be associated with worse renal outcomes. The incidence of CKD is highest in IgAN patients who present with nephrotic range proteinuria >3.5 g/day. The best prognosis was in those patients who had proteinuria of less than 1000 mg/day.[2,70–78] Hypertension is also associated with worse renal outcomes. Berthoux et al.[72] prospectively evaluated 332 patients with IgAN and found the incidence of ESRD and mortality to be significantly higher in those patients with hypertension (defined as blood pressure >140/90 mm Hg) at the time of initial diagnosis compared to normotensive patients. The incidence of dialysis was 15% at 10 years in those patients whose blood pressure was >140/90 mm Hg compared to 3% in patients whose blood pressure was well controlled. Because control of hypertension is essential to slowing the progression of CKD, much attention has focused on the dual benefit of RAAS inhibitors to reduce proteinuria and control blood pressure.

There are limited studies evaluating the effects of RAAS inhibitors in patients with IgAN. In addition to their antihypertensive effect, this class of medications is believed to decrease glomerular hyperfiltration and enhance the size-selectivity of the glomerular filtration barrier.[79] Several trials have shown a benefit to RAAS inhibitors in the setting of IgAN.[80–83] Use of ACEIs or ARBs has become the standard of care for all IgAN patients who present with more than 500 mg of proteinuria per day.

The use of combination RAAS inhibitor therapies including ACEI, ARB, and direct renin antagonists is significantly more controversial. Studies of dual RAAS inhibitor therapies in non-IgAN patients, including the ONTARGET[9] and ALTITUDE[10] trials, showed negative outcomes from combined RAAS inhibitors, including increased incidence of cardiovascular adverse outcomes, AKI, and hyperkalemia. However, these studies occurred largely in older patient populations at higher risk for major cardiovascular events, rather than younger individuals where reduction of proteinuria and slowing progressive renal disease may be paramount. At present, it appears safest to individualize combination use of ACE inhibitors and ARBs and only consider it in nondiabetic patients at low risk for cardiovascular events.

TABLE 45.1 Potential Therapeutic Options for Chronic Kidney Disease (CKD) Secondary to IgAN

Renin–angiotensin–aldosterone inhibitors
Nondihydropyridine calcium channel blockers
Statins to treat hyperlipidemia
Low sodium diet +/− diuretics
Fish oil
Tonsillectomy
Immunosuppression (unlikely to be effective with advanced CKD eGFR <30 mL/min/1.73 m^2)

eGFR, estimated glomerular filtration rate.

Other therapeutic options to reduce proteinuria and possibly slow CKD progression include use of nondihydropyridine calcium channel blockers such as diltiazem or verapamil, mineralocorticoid receptor antagonists such as spironolactone or eplerenone, low-sodium diet in combination with diuretics, and use of statins to treat significant hyperlipidemia (Table 45.1).[84] There is increased evidence supporting the pleiotropic effects of statins. Several reports support a role for statins to reduce proteinuria and slow the decline in eGFR.[85–88] On the basis of current evidence, statins should only be initiated when patients have poorly controlled hyperlipidemia and not for any potential unproven effect on slowing CKD progression.

There has been a longstanding interest in the use of fish oil to slow the progression of CKD secondary to IgAN. Donadio et al.[89] performed a randomized controlled trial of 12 g/day of fish oil supplementation or placebo in 106 patients. At 4 years of follow-up, there was a significantly lower incidence of mortality and progression to ESRD in patients who received fish oil. However, fish oil therapy had no effect on blood pressure or proteinuria. Subsequent studies have failed to show a beneficial effect of fish oils on IgAN.[90] Nevertheless, KDIGO guidelines recommend the use of fish oil in patients at high risk for progressive disease.[2] If used, fish oils should not replace other therapies such as RAAS blockade. Likewise, although there is some evidence to support a role for tonsillectomy in slowing the progression of IgAN, most studies are retrospective and imbalanced for use of ACEI and corticosteroids.[91–93] Thus, it is not clear if tonsillectomy provides additional benefits above standard of care to slow the progression of IgAN.

IgAN patients with advanced CKD are often resistant to immunosuppression treatments. Immunomodulatory therapies should not be offered to patients with later stages of CKD who have extensive glomerulosclerosis

or tubulointerstitial fibrosis on renal biopsy. When immunosuppression is offered, options include corticosteroids, cyclosphosphamide plus corticosteroids, MMF, ACTH, and RTX. Corticosteroids are the best studied. Although the conclusions of several studies are controversial, it appears that most studies have shown a significant decrease in proteinuria. The evidence is not conclusive. The data support a role for corticosteroids, particularly in patients with earlier stages of CKD (stages 2–3) with persistent proteinuria greater than 750 mg daily, despite maximum use of RAAS blockade.[94–99] There are mixed results using alkylating agents in combination with steroids, but this regimen should be considered in those IgAN patients with evidence of progressive disease manifested by crescentic GN on biopsy.[98,100] There are also inconclusive results with MMF in the setting of IgAN.[101–103] The risks of immunosuppression often outweigh any potential benefits in IgAN patients with advanced stage CKD. There is also an increased risk of adverse events including infections in those patients who receive immunosuppression.[98,99]

Lupus Nephritis

Approximately one-third to one-half of all patients with new onset SLE have evidence of GN.[104–106] The ISN/RPS classification categorizes SLE nephritis into six major subtypes including Class I–VI.[107,108] If there is a pure active inflammatory lupus nephritis (LN) lesion, this is denoted with (a), whereas purely chronic lesions are denoted with a (c). A mix of active and chronic lesions on biopsy will be labeled as (a/c). Classes III and IV are histologically characterized as focal and diffuse proliferative GN respectively. Clinically, Class III and IV SLE nephritis are characterized by the nephritic syndrome with or without nephrotic syndrome, whereas Class V SLE MN often presents only with proteinuria and/or the nephrotic syndrome. Classes I and II mesangioproliferative SLE nephritis usually have only mild clinical manifestations and are not associated with progressive nephropathy leading to advanced CKD.[108] Class VI LN patients are those with extensive glomerulosclerosis who are already progressing to ESRD.

Between 8–15% of patients with SLE nephritis display progressive CKD leading to ESRD.[109–111] The degree of activity and chronicity on renal biopsies (percent with glomerulosclerosis and degree of tubulointerstitial fibrosis) plays a key role in therapeutic decision-making.[108] The NIH activity and chronicity index scores reported by some renal pathologists can help the clinician in deciding if immunosuppression is warranted. It is common for SLE nephritis to transform from one class to another.[107,108] Therefore, prior to any potential intensification of immunosuppression, a repeat renal biopsy should at least be considered. In patients with proliferative LN, the risks of induction immunosuppression protocols outweigh the benefits in patients with evidence of chronic SLE GN without active inflammation.[108]

Decreased eGFR at baseline and increased proteinuria are associated with faster rates of CKD progression in SLE patients. African Americans, Hispanics, males, younger age at onset of SLE, and lower socioeconomic status all have previously been shown to be associated with worse clinical outcomes.[112–114] SLE patients with proteinuria benefit from optimizing blood pressure control with antagonism of RAAS where clinically feasible. As with other causes of CKD, SLE nephritis patients are at increased risk of developing cardiovascular disease. Reich et al. found that dyslipidemia was a risk factor for progression of CKD in LN patients.[115] Prescription of statins, where clinically appropriate, should be strongly considered in this patient population.

Immunosuppression for patients with chronic SLE nephritis with CKD should focus on maintenance therapies designed to prevent flares of this relapsing–remitting autoimmune disease. Maintaining a remission will control inflammation and slow CKD development and progression. MMF has become a first-line therapy for maintenance of remission in patients treated with SLE nephritis.[106,111] The Aspreva Lupus Management Study (ALMS)[110] was a multicenter trial of 227 patients comparing the outcomes of patients who received 36 months of treatment with azathioprine (AZA) compared to MMF. Those patients who received MMF were more likely to remain in remission from SLE nephritis compared to those on AZA. However, the results of the MAINTAIN trial in 105 patients who received induction therapy with CYC failed to show a statistically significant difference in flare rate over 4 years between those who received MMF and those on AZA.[116] It should be noted that differences in study design may well explain these differences. The ALMS trial was a multiethnic, multicontinental study with endpoints of renal failure and doubling of S[Cr]. The MAINTAIN trial had predominantly Caucasian patients with a study endpoint of time to renal flare. The duration of therapy required to keep patients in remission is unclear, but many clinicians will continue low-dose immunosuppression therapy with MMF with or without corticosteroids for at least 3–5 years or longer. Relapse rates of SLE nephritis range from 35 to 60% depending on the clinical study.[117,118] Recent studies of multitargeted therapy with steroids, tacrolimus, and mycophenolate, and the use of RTX have shown benefit in this population.[119–121] Transplantation remains a viable option for SLE patients. Outcomes are equivalent to other ESRD patients without SLE as their primary diagnosis.[122]

Pauci-Immune Glomerulonephritis

Pauci-immune GN is a form of small vessel vasculitis classically associated with rapidly progressive glomerulonephritis (RPGN).[123] On renal biopsy the hallmarks of the disease are the presence of crescents and segmental necrosis on light microscopy, and absence of immune deposits on immunofluorescence microscopy. The usual clinical presentation is that of a relapsing and remitting disease. If untreated, this form of GN often rapidly progresses to ESRD. There are also extrarenal manifestations depending on the disease process that may involve the upper and lower respiratory tract, nerves, skin, and musculoskeletal system. There is a subset of patients with pauci-immune GN who have a more indolent presentation for many years, with subtle findings on urinalysis characterized by microscopic hematuria and proteinuria.

Pauci-immune GN includes microscopic polyangiitis, granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, and drug-induced antineutrophil cytoplasmic antibody (ANCA)—associated vasculitis.[123] There is scant literature focused on specific aspects of CKD management in this patient population. Induction therapies for acute flares of pauci-immune GN have been well studied and include use of CYC for at least 3 months, with a corticosteroid taper followed by maintenance immunosuppression for up to 2 years with AZA or MMF.[124] The RAVE[125] and RITUXIVAS[126] trials showed RTX can be an effective induction therapy for pauci-immune ANCA-associated GN, with equivalent outcomes to CYC induction. RTX may be particularly effective in patients with relapsing disease. Because prevention of relapses and maintenance of remission are critical to slow CKD progression to ESRD in this group of patients, a number of trials have focused on repeat doses of RTX at set 6 month intervals or alternate agents to prevent relapse.

Predictors of relapse in the setting of ANCA-associated vasculitis include an initial clinical presentation with upper or lower respiratory tract involvement and presence of PR3-ANCA titer.[127] A prospective randomized trial, IMPROVE,[128] showed AZA was superior to MMF at maintenance of remission in this particular disease. Other forms of GN seem to respond better to MMF. Longer-term data on the RAVE trial[129] show initial RTX alone is as effective as CYC followed by further AZA in the maintenance of remission over an 18 month follow-up period. However, both groups had an unacceptable relapse rate leading to the maintenance studies mentioned above. The MAINRITSAN trial[130] showed a significantly higher number of patients who received RTX maintained a complete remission of ANCA vasculitis compared to those randomized to standard AZA-based maintenance immunosuppression.

Risk factors for progression to ESRD include an increased initial S[Cr] or decreased eGFR at baseline, older age, presence of pulmonary hemorrhage, and dialysis-dependent AKI.[131,132] The presence of glomerulosclerosis and tubulointerstitial fibrosis and atrophy on these renal biopsies is associated with worsened clinical outcomes.[131,132] As with other forms of CKD, patients with stable but decreased eGFR usually benefit from blood pressure control with long-term inhibition of RAAS axis to reduce glomerular hyperfiltration, low-sodium diet, and moderation of protein intake.

Antiglomerular Basement Membrane Disease

Antiglomerular Basement Membrane (anti-GBM) disease is another form of RPGN, which if untreated quickly progresses to ESRD. Unlike ANCA-associated vasculitis, anti-GBM disease usually does not recur once treated, and there is no need for long-term maintenance immunosuppression protocols. A subset of patients presenting as anti-GBM disease will be positive for both ANCA and anti-GBM antibodies. These patients are likely to be older, more likely to recover from severe renal failure, have a high relapse rate (about 50%), and a mortality similar to either the single ANCA and anti-GBM positive patients.[133] Thus, in this group of patients, long-term maintenance immunosuppression is required because they can follow a relapsing—remitting course similar to those with pauci-immune ANCA-associated GN.

Membranoproliferative Glomerulonephritis

The revised classification system for MPGN has changed the diagnostic approach to this disease. Previously classified by the location of immune deposits by electron microscopy, the updated system based on immunofluorescence (IF) staining for IgG and complement 3 (C3) is more representative of the heterogeneous nature of MPGN.[134] MPGN is similar to FSGS or MN in that it represents histologic patterns of glomerular injury caused by diverse etiologies. When the IF staining is positive for both C3 and immunoglobulins, this may be secondary to immune complex damage with infections such as Hepatitis C virus (HCV) or endocarditis, monoclonal gammopathies, lymphoproliferative disorders, or autoimmune diseases such as SLE. If there is only staining for C3 or the staining for C3 is two orders of magnitude greater than other immunoreactants, this supports a disorder of the alternative complement system pathway or C3 glomerulopathy.[135,136] Here, electron microscopy helps differentiate dense deposit disease from C3 GN. A MPGN pattern by light microscopy with negative IF staining for IgG and C3 is suggestive of chronic thrombotic microangiopathy.

Preventive CKD management is directed toward the underlying cause of the MPGN. If HCV infection has caused MPGN, then treatment of the virus should be considered. Interferon-based therapy regimens for HCV are no longer recommended. There is growing evidence of the efficacy of direct acting antiviral therapy with sustained virologic response rates in excess of 95% at 12 weeks.[137] Regimens containing sofosbuvir should be avoided in patients with eGFR <30 mL/min/1.73 m^2.[137] In patients with stage 4 or 5 CKD or treated with dialysis, guidelines recommend 12 weeks of elbasvir−grazoprevir for HCV genotypes 1, 1b, or 4 and an 8−16 week course of glecaprevir−pibrentasvir for HCV genotypes 1−6.[137] RTX may also play a role in treating HCV-infected patients with cryoglobulinemia.[138]

Treatment of immune complex forms of the disease such as LN has been discussed. Treatment of endocarditis with appropriate antimicrobial therapy may help ameliorate the course of MPGN. Treatment of the underlying lymphoproliferative disorder, whether related to chronic lymphocytic leukemia or plasma cell dyscrasia, may also improve renal outcomes of patients with MPGN.[139] Monoclonal gammopathies of unknown significance are increasingly recognized to be associated with MPGN and have been reclassified as monoclonal gammopathies of renal significance (MGRS).[139] Earlier initiation of therapy directed at the MGRS, which may be clinically significant, can be beneficial in slowing any potential progression to CKD.[139] Studies using a humanized monoclonal antibody against the fifth component of complement, eculizumab, have shown mixed results in C3 glomerulopathies.[140,141] MMF with corticosteroids for the treatment of C3 glomerulopathy showed some benefit particularly in the subset of patients with higher membrane attack complex levels.[142,143]

Although the prognosis of MPGN depends on the underlying pathogenesis, many forms of MPGN have a poor prognosis, with up to 50% of untreated patients progressing to ESRD over 5−10 years. Factors associated with a worse prognosis include evidence of CKD with decreased eGFR at baseline, nephrotic range proteinuria, poorly controlled blood pressure, evidence of crescentic GN (>50% crescents), and severe tubulointerstitial fibrosis. Blood pressure control with RAAS inhibitors if tolerated and dietary modifications including low sodium intake and moderation of protein intake may slow the progression of CKD secondary to MPGN.

Thrombotic Microangiopathies

A variety of glomerular and vascular diseases have been associated with pathophysiologic mediators of coagulation. Although in the past they were all combined diagnostically, they are now defined separately by pathophysiologic mechanisms.[144] Thus, thrombotic thrombocytopenic purpura is defined by a severe deficiency of ADAMTS 13, the von Willebrand cleaving enzyme, whereas the presence of Shiga toxin defines STEC + hemolytic uremic syndrome and antiphospholipid antibodies define the anticardiolipin syndrome. Atypical hemolytic syndrome is due to defects in the alternative complement pathway.[144] Each disease should be treated for the specific coagulation defect to prevent progressive CKD. Use of eculizumab, a humanized monoclonal blocker of the fifth component of complement (C5), has led to striking remissions of renal failure and the requirement for plasmapheresis in the patient population with complement-mediated TMA.[145]

Inherited Glomerulopathies

Alport syndrome (AS) can display X-linked, autosomal dominant, and autosomal recessive inheritance patterns.[146] AS is characterized as a disorder due to mutations that affect type 4 collagen proteins. Clinical manifestations in males are often more severe than in females. Males with X-linked AS due to a deletion mutation of the alpha 5 chain of type IV collagen usually progress to ESRD by the second or third decade of life. Likewise, patients with autosomal recessive AS due to mutations affecting alpha 3 or 4 chains of type IV collagen tend to progress to ESRD by age 30. Autosomal-dominant AS with heterozygous mutations of COL4A3 or COL4A4 usually has a slower progression of CKD. Treatment of CKD centers on blood pressure control with RAAS inhibitors where clinically appropriate.[146] Cyclosporine may be helpful in some patients with stage I and II CKD with significant proteinuria. Caution using calcineurin inhibitors is indicated in all patients with more advanced CKD stages due to potential nephrotoxicity.[146]

Thin Basement Membrane Nephropathy (TBMN) is caused by mutations in COL4A3 and COL4A4 and usually follows an autosomal dominant pattern of inheritance.[147] Previously termed "benign familial hematuria" because it was thought to have no risk for progression to renal failure, it is now recognized that this condition can in some instances be associated with CKD and can lead to secondary forms of FSGS.[147] The treatment of TBMN is conservative and includes blood pressure control with use of RAAS inhibitors as necessary.

Fabry disease is an X-linked disorder characterized by alpha-galactosidase A deficiency (alpha-Gal A). There is intracellular accumulation of neutral glycosphingolipids leading to glomerular injury from damage to visceral epithelial cells and ischemia due to impaired glomerular capillary flow from enlarged endothelial

cells. Patients with Fabry disease can develop proteinuria and microscopic hematuria by the third decade of life. There is typically slow CKD progression with ESRD by the fourth or fifth decade of life. Use of recombinant alpha-Gal A has been shown to stabilize eGFR and potentially reduce CKD progression.[148]

CONCLUSION

There have been significant advances in the diagnostic and therapeutic approaches to patients with the nephrotic syndrome and those with acute GN. There are fewer data on the optimal strategy for patients with chronic glomerulopathies to slow the progression of CKD. Maximization of conservative therapy with blood pressure control including use of RAAS inhibitors, low-sodium diet with or without diuretics to control edema, statins to treat hyperlipidemia, moderation of animal protein intake, and avoidance of nephrotoxins should be employed in patients with CKD secondary to glomerular diseases (Table 45.2). Randomized controlled trials are needed to determine optimal immunosuppressive therapies for patients with CKD secondary to glomerular diseases. With more effective strategies to diagnose and treat acute GN, the incidence of CKD secondary to glomerular disease should begin to decrease. A major challenge will be preventing progressive tubulointerstitial fibrosis in patients with glomerular diseases.

TABLE 45.2 Summary of Glomerular Diseases, Risk of Progression to End-Stage Renal Disease (ESRD), and Potential Therapeutic Options

Glomerular Disease	Risk of Progression to ESRD	Therapeutic Options
Minimal change disease (MCD)	Minimal risk	- Corticosteroids or other second-line therapies including cyclosporine, MMF, CYC, or RTX for acute flare-up - Consider ACEI or ARB for patients with hypertension and stable renal function without AKI
Membranous nephropathy	Approximately 1/3 over 10 years	- Consider ACEI or ARB as antihypertensive agent of choice - Consider statin therapy for significant hyperlipidemia - Low-sodium diet - Diuretics as needed to control edema - Moderation of protein intake - Immunomodulatory therapy should be considered only if there is evidence of continued immunologic activity based on the review of patient's renal pathology
Focal segmental glomerulosclerosis	Approximately 50% of patients who do not respond to therapy will progress to ESRD over 10 years	- Blood pressure control with RAAS inhibition as clinically tolerated - Statins to treat hyperlipidemia - Low-sodium diet and moderation of animal protein intake - Diuretics as needed to control edema - Caution is advised with immunosuppression protocols in patients with chronic and severely reduced eGFR (see text for additional details)
Postinfectious glomerulonephritis	Higher risk of progression in adults and the subset with IgA dominant disease	- Treatment of underlying infection - RAAS inhibition for BP control in those patients who develop CKD and proteinuria
IgA nephropathy	25% risk of ESRD at 10 years	See Table 45.1
SLE nephritis	Between 8–15% of patients with SLE nephritis progress to ESRD	- Optimize BP control with RAAS inhibitors - Maintenance immunosuppression therapies to consider include MMF vs. AZA - Treat hyperlipidemia with statins - Low-sodium +/− low-protein diet

TABLE 45.2 Summary of Glomerular Diseases, Risk of Progression to End-Stage Renal Disease (ESRD), and Potential Therapeutic Options—cont'd

Glomerular Disease	Risk of Progression to ESRD	Therapeutic Options
Pauci-immune glomerulonephritis	Untreated forms can rapidly progress (RPGN) to ESRD	- Prevention of relapse and maintenance of remission is critical to slow progression to CKD - Maintenance immunosuppression for patients in remission includes azathioprine for patients who received cyclophosphamide-based induction regimens - RAAS inhibition to optimize BP control where clinically feasible
Antiglomerular basement membrane disease	Untreated forms rapidly progress to ESRD (RPGN)	- Prompt initiation of induction therapy for acute disease with cyclophosphamide, corticosteroids, and plasmapheresis
Membranoproliferative glomerulonephritis	Approximately 50% of untreated patients progress to ESRD over 5–10 years	- Treatment of the underlying etiology such as infection, autoimmune disease, or lymphoproliferative disorder is essential

ACEI, angiotensin-converting enzyme inhibitor; *AKI*, acute kidney injury; *ARB*, angiotensin receptor blocker; *AZA*, azathioprine; *CKD*, chronic kidney disease; *CYC*, cyclophosphamide; *eGFR*, estimated glomerular filtration rate; *MMF*, mycophenolate mofetil; *RAAS*, renin–angiotensin–aldosterone inhibitors; *RTX*, rituximab; *RPGN*, rapidly progressive glomerulonephritis; *SLE*, system lupus erythematous.

QUESTIONS AND ANSWERS

Question 1

A 37-year-old woman with a history of SLE nephritis Class IV received successful induction therapy with intravenous CYC and steroids. She is currently in remission. Her S[Cr] is 1.2 mg/dL. Her most recent urinalysis shows no proteinuria and no hematuria. Based on the most current evidence, which of the following medications is best for this patient to maintain a remission of her LN?

A. RTX
B. CYC
C. MMF
D. Belimumab
E. ACTH

Answer: C

MMF is the best choice of the answers provided. Quarterly pulse CYC (Choice B) was shown to be inferior to MMF and AZA for maintenance of remission from SLE nephritis. There is a lack of evidence to support maintenance immunosuppression with RTX (Choice A), ACTH (Choice D), or belimumab (Choice E) at this time.[111,116,149]

Question 2

A 55-year-old man with CKD stage 4 secondary to IgA nephropathy presents to your office for an opinion on management. His S[Cr] is stable at 2.8 mg/dL. His most recent urine protein:creatinine ratio (UPCR) is 1500 mg/g creatinine. His blood pressure is 145/89 mm Hg and his examination is otherwise normal.

Which of the following therapies would be most effective in slowing the progression of his chronic kidney disease?

A. Lisinopril
B. MMF
C. CYC
D. Azathioprine
E. Amlodipine

Answer: A

Lisinopril would be most effective at slowing the progression of advanced CKD secondary to IgA nephropathy. There is a lack of evidence for immunosuppression in IgA patients with severe CKD (Choices B, C, and D). A trial of MMF at this level of renal function showed no beneficial effect (Choice B). Amlodipine (Choice E) is not the correct choice since ACEI (Choice A) is the preferable antihypertensive agent to slow the progression of CKD.[79–82]

Question 3

A 38-year-old woman with thin basement membrane disease presents to your office for advice regarding her risk of developing progressive CKD. Her S[Cr] is 0.8 mg/dL. Her UPCR is 350 mg/g creatinine, and blood pressure is 118/70 mm Hg. Which of the following statements is true regarding thin basement membrane disease?

A. There is no risk for progression to ESRD
B. There is a high risk for progression to ESRD in the next 5 years
C. There is a potential risk for progression to ESRD over the next 25 years
D. This is most commonly the result of a genetic defect in the alpha 5 chain of type IV collagen

Answer: C

There is a small risk for progressive CKD in the setting of thin basement membrane disease, with reports of secondary FSGS developing later in the disease course. The progression to CKD is far less likely than other forms of glomerulopathy. Therefore, Choices A and B are incorrect. The disease results from mutations in alpha chains type 3 and 4 of type IV collagen, therefore Choice D is incorrect.[146,147]

Question 4

A 41-year-old man is diagnosed with primary FSGS. His S[Cr] has remained stable at 1.9 mg/dL over the past 3 months. His UPCR decreased from 6000 mg/g creatinine to 800 mg/g creatinine after 6 months of steroid therapy. His medications include lisinopril 20 mg daily and simvastatin 20 mg daily. His blood pressure is 124/75 mm Hg and his examination is otherwise normal with no peripheral edema. Which of the following statements is true regarding this patient's risk of progression to ESRD?

A. This patient's partial remission places him at decreased risk for progression to ESRD
B. The presence of subnephrotic but persistent proteinuria places him at a high risk for progression to ESRD over the next five years
C. Absence of partial or complete remission from FSGS has no impact on this patient's risk for progressive CKD
D. RTX should be administered following completion of the corticosteroids

Answer: A

A partial or complete remission in the setting of primary FSGS confers a significantly more favorable renal prognosis and lower likelihood of progressive CKD compared to those patients who fail to respond to

immunosuppressive therapies. Therefore, Choice B and C are incorrect. Addition of RTX (Choice D) is not indicated in this patient who has had a significant response to corticosteroid therapy.[38,39,45,46]

Question 5

A 55-year-old woman with a history of CKD stage 4 secondary to PR3 ANCA positive pauci-immune GN presents to your office for an opinion on optimal management. Her S[Cr] has been stable at 2.7 mg/dL for the past 6 months, UPCR is 2500 mg/g creatinine, and PR3−ANCA titer is negative. The most recent urinalysis showed 3+ protein with no hematuria. The patient otherwise feels well, with no extrarenal manifestations of vasculitis. The patient had a peak S[Cr] of 4.8 mg/dL on presentation 2 years ago with renal-limited disease and no evidence of pulmonary involvement. Her medications for the past 18 months include azathioprine 100 mg daily, lisinopril 40 mg daily, and simvastatin 10 mg daily. Which of the following regimens is indicated to help to prevent progression of CKD?

A. Treatment with CYC 2.5 mg/kg/day for an additional six months followed by methotrexate for an additional 18 months
B. Continuation of the current medication regimen
C. Treatment with RTX 375 mg/m^2 weekly for 4 weeks
D. Discontinuation of lisinopril

Answer: B

This patient has CKD secondary to pauci-immune GN and is currently in remission. She is on appropriate treatment at this time, including maintenance immunosuppression with AZA and RAAS inhibition. RTX (Answer C) and CYC (Answer A) are incorrect choices because they are used in induction treatment of patients with active flares of disease. It is not appropriate to discontinue the lisinopril in this patient with stable CKD (Answer D).[124−126,128,129]

Question 6

A 52-year-old Hispanic woman, permanent resident of Honduras, presents to the office with a history of CKD stage 3 secondary to poststreptococcal GN, after renal biopsy 10 years ago. Her most recent S[Cr] is stable at 1.5 mg/dL. She has a UPCR of 1100 mg/g creatinine. Her urinalysis shows 3+ protein, no hematuria, and no cellular casts visualized. Blood pressure is 122/65 mm Hg and examination is normal without peripheral edema. Which of the following histologic lesions is most likely to be found on a repeat renal biopsy?

A. Diffuse endocapillary GN with subepithelial humps on EM
B. MN
C. Secondary FSGS
D. Collapsing focal and segmental glomerulosclerosis
E. MCD

Answer: C

The most likely histologic lesion in this patient with CKD caused by postinfectious GN is secondary FSGS. CKD from chronic GN with no residual active inflammation can appear as a form of focal glomerular scarring or as a form of secondary FSGS. Diffuse endocapillary GN with subepithelial humps on EM (Choice A) would classically be seen during the acute presentation of postinfectious GN. MN (Choice B), follapsing FSGS (Choice D), and MCD (choice E) are unlikely histologic renal lesions based on the clinical history provided.[66]

Approach to the Patient with Hypertensive Nephrosclerosis

Aldo J. Peixoto[a], *George L. Bakris*[b]

[a]Section of Nephrology, Yale School of Medicine, and Hypertension Program at the Yale New Haven Hospital Heart and Vascular Center, New Haven, CT, United States; [b]Comprehensive Hypertension Center, Department of Medicine, The University of Chicago Medicine, Chicago, IL, United States

Abstract

Hypertensive nephrosclerosis (HN) is defined as chronic kidney disease caused by nonmalignant hypertension (HTN). HN is the presumed underlying disease in 10–30% of patients with end-stage renal disease worldwide. HN typically presents without proteinuria or any abnormalities in the urine sediment. The mechanisms of injury in HN are heterogeneous. In areas with preserved arteriolar myogenic responses (i.e. autoregulation), there is ischemic glomerular tuft collapse and interstitial fibrosis. In other areas with impaired autoregulation, the lesions reflect glomerular HTN leading to podocyte loss and glomerulosclerosis. Apolipoprotein-L1 gene mutations are associated with increased susceptibility to HN. The management of HN should focus on blood pressure control (target <140/90 mm Hg) using a blocker of the renin–angiotensin system as base therapy.

INTRODUCTION

The term nephrosclerosis refers to a morphologic diagnosis, while hypertensive nephrosclerosis (HN) is broadly defined as chronic kidney disease (CKD) caused by nonmalignant primary hypertension (HTN). Because relatively few patients in whom this diagnosis is entertained undergo a renal biopsy, HN is often a diagnosis applied to patients who present with CKD carrying a long-standing diagnosis of HTN, relatively low levels of albuminuria (i.e. <300 mg/day), and no other apparent cause for CKD.[1,2] Acknowledgment of this limitation and the frequent uncertainty of the diagnosis have led to use of the term "hypertension-attributed kidney disease." In this chapter, we will use the term "hypertensive nephrosclerosis" to refer to this broader category of HTN-attributed kidney disease despite the recognition that the histological features are confirmed only in a minority of cases. Our discussion will not cover acute/subacute renal injury in the setting of malignant HTN.

Scope of the Problem and Public Health Implications

According to estimates of the World Health Organization, HTN affects ~40% of the world population over the age of 25 years. Recently published guidelines from the American College of Cardiology and the American Heart Association proposed lower BP levels to define HTN (130/80 mm Hg vs. 140/90 mm Hg) and have, thereby, increased the relative prevalence of HTN among US adults by 43% (from 32% to 46%).[3] It is the most important modifiable cardiovascular risk factor, responsible for more than 50% of strokes and coronary artery disease events worldwide.[4,5] In fact, its overall impact on death and disability is impressive. HTN accounts for ~13.5% of all deaths and ~6% of all disability-adjusted life years lost.[4] While end organ damage attributable to HTN is most remarkable in the brain (strokes, transient ischemic attacks), heart (coronary artery disease, left ventricular hypertrophy [LVH], congestive heart failure), and peripheral arterial system, hypertensive vascular injury also occurs in the kidney and may result in the development of CKD.

An ongoing debate over many years focuses on whether nonmalignant HTN causes CKD or not, with some spirited opinions available in the literature. This is primarily driven by the lack of data from randomized clinical trials that the treatment of uncomplicated HTN leads to a reduction in CKD endpoints.[6] Other

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00046-2

considerations include the possible coexistence of a primary kidney disease as the driver of both the HTN and the loss of renal function during follow-up, the development of microvascular renal lesions acting as the primary driving factor, resulting in both HTN and loss of renal function,[7] and the frequent misclassification of patients as having HN while the actual diagnosis is an alternative one, such as ischemic nephropathy, atheroembolic kidney disease, or chronic interstitial nephritides.[2,8,9]

Although there is no question that renal injury is most remarkable in patients with malignant HTN, we believe that the current evidence supports nonmalignant HTN as the primary etiologic factor in many patients with stage 3 and 4 CKD. The first line of evidence came from a single center cohort of 500 untreated hypertensive patients followed until their death: 42% developed proteinuria and 18% had complications related to "nitrogen retention."[9] That study was followed by a series of small cohort studies that differed in their findings, with some demonstrating an association between higher blood pressure (BP) levels and increased risk for loss of renal function over time,[10,11] whereas others were unable to link BP and CKD.[12] The analysis of placebo-controlled trials of the treatment of nonmalignant HTN that reported renal outcomes reveals, most importantly, an absence of events.[6] Very few subjects in these trials with up to 7 years of follow-up developed "renal events" (investigator-defined increases in S[Cr] or end-stage renal disease (ESRD)). More than 90% of these events consisted of modest alterations in serum chemistries, and no apparent difference between active treatment or placebo.[6] It is important to recognize that because the incidence of ESRD is so low, all studies have been underpowered to address this issue. In fact, due to the other demonstrable benefits of antihypertensive therapy, a definitive study to test whether treatment of HTN prevents CKD or ESRD would be unethical to perform today.

Therefore, we must rely on observational studies to address the "chicken or egg" between HTN and CKD. Indeed, many recent large cohort studies have more definitively linked HTN and its severity to renal risk. Table 46.1 summarizes the salient features of each of these studies.[10,11,13–29] In aggregate, they indicate that, while the rates of severe renal dysfunction related to uncomplicated HTN are low (e.g. ESRD rates of ~0.2% over 10–25 years), they are strongly influenced by BP levels in a dose-dependent fashion, particularly in African-American individuals, where the overall risk is increased, likely due to genetic susceptibilities that are now being better understood (see below, under *Pathophysiology*). A meta-analysis of 16 observational cohorts including more than 315,000 patients with baseline BP in the prehypertensive and hypertensive range (>120/80 mm Hg) and normal renal function at baseline demonstrated a dose-dependent increase in risk of incident CKD (defined as estimated glomerular filtration rate <60 mL/min/1.73 m^2) with increasing BP levels. For every 10 mm Hg increase in BP, there was an increase in CKD of 8% (relative risk 1.08 [1.04–1.11]) for systolic BP and 12% (relative risk 10.12 [1.04–1.20]) for diastolic BP).[30] Therefore, based on observational studies that performed systematic screening for kidney disease (renal function and urinalysis) at baseline in large cohorts, we believe there is good evidence supporting nonmalignant HTN as a cause of progressive CKD and ESRD.[30]

The global burden of presumed HTN-related CKD is large. Despite substantial geographic differences, registries from more than 22 countries representing all continents indicate that HN is listed as the primary diagnosis in about 10–30% of cases of advanced CKD requiring dialysis. In the US, the prevalence of the diagnosis of presumed HN among patients on dialysis is overrepresented among African-American patients. While African Americans represent about one-third of all US patients receiving dialysis for ESRD, they account for 46% of those whose primary diagnosis is HN.[31] No other ethnic group is overrepresented among dialysis patients. Unfortunately, extension of these observations to other areas of the world is not straightforward.

It is often difficult to ascertain the prevalence of HN as a function of ethnicity, as there are very few well-organized registries in Africa, where the leading etiology of CKD is glomerulonephritis.[32] There is marked variability in the prevalence of HN even in Western Europe[33] where most countries have small populations of African descent.

PATHOPHYSIOLOGY

Mechanisms of Renal Injury in Hypertension

The mechanisms resulting in renal injury in nonmalignant HTN are many, and yet not completely understood. Detailed reviews have been published elsewhere.[34–38] Figure 46.1 provides a schematic depiction of the processes discussed below.

The initial key element involved in parenchymal injury relates to changes in the regulation of afferent arteriolar tone in response to changes in pressure (myogenic reflex) and sodium excretion (tubuloglomerular feedback).[35,36,39] These abnormalities can have opposite effects resulting in potentially different types of vascular and glomerular lesions. For example, an increase in sensitivity of these mechanisms can result in excessive arteriolar vasoconstriction and ischemic glomerular injury. Arterioles with normal myogenic

TABLE 46.1 Summary of Studies Evaluating the Link Between Hypertension and Progressive Kidney Disease

Author, Year	Country	N	F/U (years)	Population	Comments
Lindeman, 1984[13]	US	446	>8	General population	MAP correlated with fall in CCr ($r = 0.32$, $p < 0.001$) on serial measurements over 10 years. Rate of CCr decline was 0.52 mL/min/year faster for every 10 mm Hg higher baseline MAP. Relationship not significant in group with MAP <107 mm Hg.
Rostand, 1989[11]	US	94	4.9	HTN	All subjects with HTN under treatment and preserved renal function at baseline. 15% had an increase in S[Cr] ≥0.4 mg/dL during follow-up, most (10/14) occurring in patients with controlled DBP (<90 mm Hg, average 84 mm Hg). AA subjects (32%) had twice the rate of development of increased S[Cr] (23% vs. 11% for whites).
Shulman, 1989[14]	US	8683	5	HTN	Hypertension Detection and Follow-Up Program. 2.3% developed S[Cr] ≥2 mg/dL and a rise by >25% above baseline. Average 5-year rise in S[Cr] was higher in black men (0.67 mg/dL) than white men (0.14 mg/dL) and all women (0.0 mg/dL). Baseline DBP and S[Cr] were the strongest predictors of rise in S[Cr] concentration during follow-up.
Rosansky, 1990[10]	US	115	9.8	Male veterans, both HTN and non-HTN	Historical cohort study of patients with normal baseline renal function, 49% with HTN. Adjusted increase in S[Cr] was 0.02 mg/dL/year higher among patients with HTN ($p = 0.03$). Development of S[Cr] >1.4 mg/dL was 13% among hypertensives, 7% among normotensives ($p = NS$).
Perneger, 1993[15]	US	1399	12–15	General population	16% of men and 11% of women developed abnormal S[Cr] concentration during follow-up (>1.3 mg/dL in men, >1.1 mg/dL in women). OR = 1.6 (per 20 mm Hg SBP) and 2.1 (per 20 mm Hg DBP) in men (both significant). OR = 1.5 and 1.6 in women (significant only for SBP). Associations significant only for baseline, not follow-up BP.
Perry, 1995[16]	US	11,912	9.4–14.2	Male veterans with HTN	2.1% of patients developed ESRD. Risk of ESRD significant for SBP 165–180 mm Hg (adjusted RR = 1.9) and >180/118 mm Hg (adjusted RR = 4.6). Any decrease in SBP during follow-up was associated with decreased risk of ESRD, most prominent for SBP fall >20 mm Hg (adjusted RR = 0.39).
Madhavan, 1995[17]	US	2125	5.3	HTN, males only	All patients treated. 2% progressed to S[Cr] >2 mg/dL. Baseline, not treated DBP was independently associated with the final S[Cr]. Black race was also an independent predictor of final S[Cr].
Iseki, 1996[18]	Japan	104,331	10	General population	0.18% developed ESRD. DBP was an independent predictor of ESRD development (adjusted OR = 1.39 per 10 mm Hg).
Klag, 1996[19] and Klag, 1997[20]	US	332,554	16	General population, males only	Multiple Risk Factor Intervention Trial screenees. 0.22% developed ESRD. RR for ESRD was 2.0 per SD of SBP [16 mm Hg], 1.6 per SD of DBP [11 mm Hg]. RR increased progressively according to HTN stage compared with normotensive levels (adjusted RR = 3.1 for 140–159/90–99 mm Hg, RR = 6.0 for 160–179/100–109 mm Hg, RR = 11.2 for 180–219/110–119 mm Hg, RR = 22.1 for >220/120 mm Hg). AAs had almost twice the risk as whites (adjusted RR = 1.87).

TABLE 46.1 Summary of Studies Evaluating the Link Between Hypertension and Progressive Kidney Disease—cont'd

Author, Year	Country	N	F/U (years)	Population	Comments
Siewert-Delle, 1998[21]	Sweden	686	20	HTN, males only	All patients treated. 8.9% of subjects developed S[Cr] >1.45 mg/dL on follow-up, 1.7% possibly due to HTN. Highest observed S[Cr] was 2.1 mg/dL; no cases of ESRD. No clinical differences between patients with and without a rise in S[Cr].
Hsu, 2005[22]	US	316,675	25	General population	Kaiser Permanente of Northern California. All subjects with preserved eGFR and normal urinalysis at baseline. 0.4% developed ESRD. Compared with normotensives (BP <120/80 mm Hg), increasing baseline BP resulted in dose-dependent increases in RR for ESRD (1.62 in the prehypertensive group, 4.25 in those with BP of 180–219/110–119 mm Hg). The association was not only stronger in AAs but also significant in whites.
Hanratty, 2010[23]	US	528	3.8	General population	Small fraction (5%) of Denver Health cohort with baseline BP. No independent effect of BP on incident CKD (new eGFR <60 mL/min/1.73 m^2 or albuminuria >30 mg/g). Linear analysis showed a trend toward faster loss of eGFR in patients with higher baseline BP (0.58 mL/min/year per 10 mm Hg SBP, $p = 0.09$).
Hanratty, 2011[24]	US	43,305	3.7	HTN	Kaiser Permanente Colorado. 12% developed new CKD (eGFR<60 mL/min/1.73 m^2 or albuminuria>30 mg/g). Adjusted HR for incident CKD was significant for SBP (1.06 per 10 mm Hg, both at baseline and in time-varying, updated models).
Chang, 2013[25]	US	123,058	4.8	General population	Kidney Early Evaluation Program. Increased risk of ESRD in both albuminuric and nonalbuminuric patients (HR 1.18–1.19 per 10 mm Hg SBP).
Cao, 2014[26]	China	1703	4.5	General population	Pre-HTN and HTN associated with incident CKD (HR 1.25 for pre-HTN, HR 1.62 for undiagnosed HTN, HR 1.98 for known HTN).
McMahon, 2014[27]	US	1323	30	General population	Framingham Offspring Study. Case-control study (441 cases of incident CKD, 882 controls). OR for HTN prior to the diagnosis of incident CKD was 1.76 at 30 years. Association also present at the 10- and 20-year marks.
Lohr, 2015[28]	US	15,221	4.8	Elderly veterans >70 years old (98% men)	VA cohort. Time-dependent SBP >140 mm Hg associated with progressive risk of incident CKD. However, time-dependent achieved SBP <130 mm Hg was associated with increased mortality.
Erikson, 2016[29]	Sweden	1299	5.6	General population	Repeat iohexol GFR evaluation, on average 5.6 years apart. HTN or baseline BP did not result in loss of renal function. In fact, higher BP resulted in less steep loss of GFR.

responsiveness can be slightly hypertrophic but do not have hyaline lesions.[40] Decreased sensitivity, on the other hand, allows direct transmission of the pressure load to the glomerulus resulting in intraglomerular HTN, glomerular hypertrophy, and progressive glomerulosclerosis.[34,40,41] Arterioles associated with these glomerular changes are dilated and show significant hyalinosis. This morphometric evidence is further supported by animal models of HTN indicating that glomerular injury occurs only after autoregulation is lost.[42] In models where the myogenic reflex remains intact, such as the spontaneously hypertensive rat, renal injury seldom occurs despite significant BP elevations. In other models where autoregulation is lost, such as the renal ablation model, the Dahl salt-sensitive rat, and the fawn-hooded hypertensive rat, renal injury

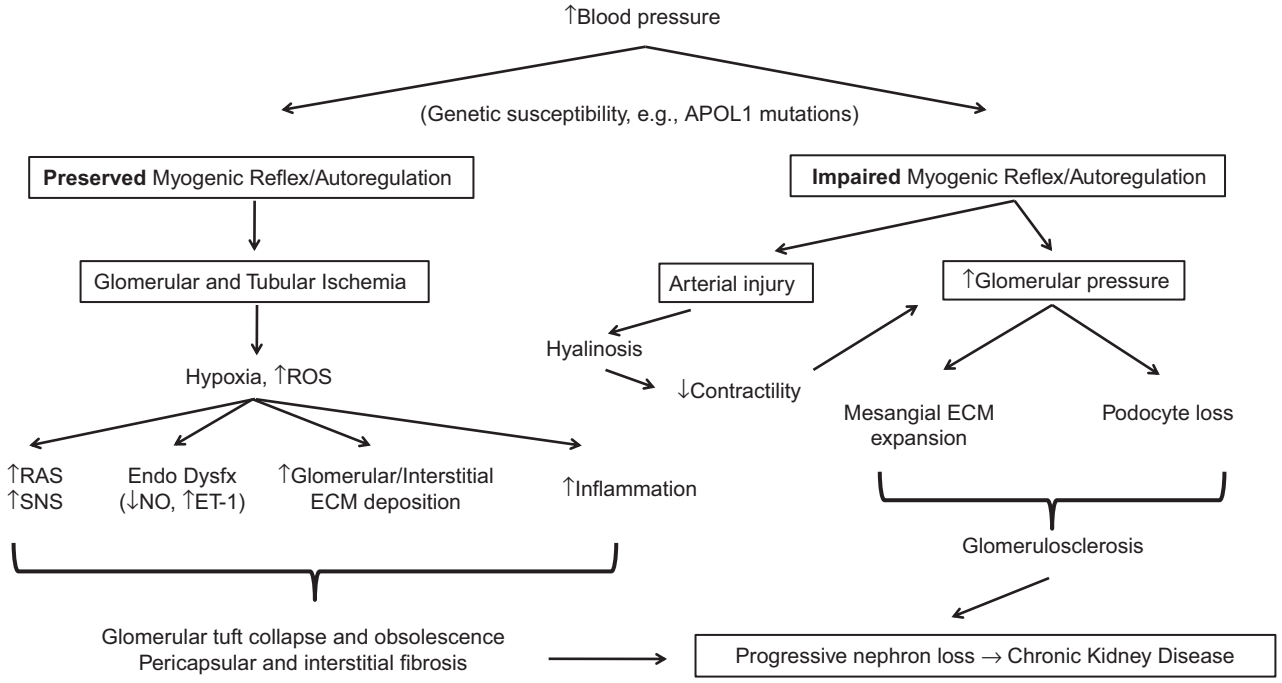

FIGURE 46.1 Mechanisms of blood pressure-induced kidney injury in hypertension. There are differences in the pattern of injury according to the presence or absence of an intact afferent arteriolar myogenic reflex (i.e. autoregulation). If autoregulation is normal, glomerular and tubular ischemia activates pathways that result in glomerular obsolescence and interstitial fibrosis. If autoregulation is abolished, arterial injury and glomerular hypertension result in glomerulosclerosis (or "solidification"). Both processes can occur in the same patient and both contribute to progressive nephron loss and kidney disease. *APOL1*, apolipoprotein-L1; *ECM*, extracellular matrix; *ET-1*, endothelin-1; *NO*, nitric oxide; *RAS*, renin–angiotensin system; *ROS*, reactive oxygen species; *SNS*, sympathetic nervous system.

occurs at much lower BP levels.[42] Similarly, interventions that lead to decreased afferent myogenic tone, such as high protein diet or administration of calcium channel blockers (CCBs), result in glomerular injury at relatively low BP levels. The mechanisms responsible for the abnormal myogenic reflex are not known. The fact that vessels retain their responsiveness to exogenous vasoconstrictors such as phenylephrine indicates that the problem is not related to the contracting apparatus, but more likely resides at the level of mechanotransduction of the pressure stimulus.[43] Finally, another mechanism of BP-induced renal injury is arterial stiffness, which amplifies the transmission of a pressure wave to the renal microvasculature.[39]

In the case of glomerular ischemia, decreased flow itself leads to glomerular tuft retraction. Chronic glomerular ischemia leads to production of reactive oxygen species and hypoxia-induced factors that generate increased expression of many proinflammatory and profibrotic factors.[44] Chronic glomerular ischemia also results in activation of the renin–angiotensin system, with resultant angiotensin II-mediated inflammation, oxidative stress, extracellular matrix production, and fibrosis,[36–38] which occur through the effects of several proinflammatory (MCP-1, osteopontin, endothelin-1) and profibrotic (TGF-β, endothelin-1) chemokines that are upregulated by angiotensin II.[36–38] Increased activity of the sympathetic nervous system and endothelial dysfunction (decreased nitric oxide availability, increased endothelin-1) add to this injury environment.[34,36–38]

Nonischemic injury, conversely, is mediated by both pressure-related and unrelated mechanisms. Increased intraglomerular pressure results in glomerular capillary endothelial cell injury and loop collapse with attendant podocyte injury and segmental sclerotic lesions.[38,45] The process of endothelial damage triggers further non-BP-mediated injury to the nephron unit through similar mediators as listed above for the ischemic process. Interestingly, there is marked nephron heterogeneity in the pattern of lesions. Both ischemic and nonischemic lesions often coexist in the same kidney,[7,40,46] are not the result of progression from one type to another,[7] and ischemic lesions appear to have a faster course toward glomerular destruction than the sclerosing, nonischemic lesions.[36]

Genetic Susceptibility

ESRD attributable to HTN is 2.5- to 20-fold more common among African Americans than whites based on

unadjusted data from the US Renal Data System. In models with multiple relevant adjustments, the excess risk is about twofold.[20] The discovery of apolipoprotein-L1 (APOL1) gene variants and their association with ESRD in African Americans has been an exciting development in the understanding of this relationship. Previous genome-wide analyses had mapped a strong signal to the area of chromosome 22 that includes the gene coding for APOL1. Exploring associations with focal and segmental glomerulosclerosis (FSGS) in African-American individuals, Genovese et al. identified two closely related and mutually exclusive mutations (G1 and G2) in the APOL1 gene that are associated with a 10.5-fold increased risk of FSGS and a 7.3-fold increase in risk of "hypertensive ESRD" in African-American individuals.[47] Further studies have identified increased risk of HIV nephropathy, lupus nephritis, albuminuria, diabetic kidney disease progression, and earlier age of onset of ESRD among black individuals.[48,49] A report of the African American Study of Kidney Disease (AASK) study examined the relationship between APOL1 mutations and clinical endpoints. Compared with African-American patients from another cohort without kidney disease, the presence of two APOL1 mutant alleles was associated with an overall 2.3-fold increase in the odds of having a clinical diagnosis of HN.[50] These odds increased to 6.3 to define a phenotype of HN with proteinuria>0.6 g/g on spot urine, and to 4.6 when the phenotype was defined by baseline S[Cr] >3 mg/dL.

APOL1 is a trypanolytic serum factor that protects against several *Trypanosoma* species that cause sleeping sickness. Serum from patients carrying the G1 or G2 mutations has lytic activity against *Trypanosoma brucei rhodesiense*. These mutations are common among Western Africans and may have occurred as a survival factor that, as a side effect, conferred increased risk of kidney disease.[51] Unfortunately, the mechanistic links between APOL1 and kidney injury remain incompletely understood.

APOL1 is normally expressed in glomeruli, tubular, and vascular endothelium in the kidney, and the expression pattern is abnormal in patients with FSGS as well as HIV nephropathy.[52] In transgenic mice, conditional overexpression of APOL1 in podocytes results in loss of podocyte integrity, foot process effacement, glomerulosclerosis, proteinuria, and progressive kidney failure.[53]. Based on early available evidence, APOL1 expression in podocytes mediates injury through mechanisms that include abnormal anion and cation fluxes that induce osmotic cell swelling and defective endolysosomal and autophagosome maturation. This results in autophagy block and accumulation of endocytic vacuoles that activate intracellular pathways including stress-activated protein kinase signaling, mitochondrial and endoplasmic reticulum damage, and inflammasome activation, resulting in caspase 1-mediated inflammatory cell death (pyroptosis).[49]

Because only about 20% of carriers of high-risk alleles develop clinical kidney disease, it is likely that a "second hit" is necessary for disease development.[7] Interferon induces APOL1 expression, so it has been postulated that interferon induction in the setting of viral infections, such as HIV or parvovirus B19, may be the link to mediate APOL1 toxicity.

Another possible second hit is chronic immune activation leading to increased production of soluble urokinase-type plasminogen activator receptor (suPAR).[54] suPAR interacts with the gene products of the abnormal G1 and G2 genes leading to enhanced activation of podocyte integrins that ultimately lead to the formation of autophagosomes, dysregulation of the actin cytoskeleton, and podocyte detachment. In patients with HN in the AASK study, the coexistence of high suPAR levels and high-risk APOL1 alleles resulted in faster rates of CKD progression.[54]

Because of the likely role of oxidative stress in the development of HN, a report in the AASK cohort identified increased risk of CKD progression in null carriers of the GSTM1 gene.[55] The GSTM1 gene codes for a glutathione-S-transferase that metabolizes reactive oxygen species and reactive aldehydes. Null allele homozygosity leads to complete lack of enzyme activity and is associated with increased cardiovascular risk and risk of development of several malignancies. Another report of the AASK study evaluated the relevance of interactions in APOL1 and GSTM1 genotypes in black patients with HN.[56] The study showed that the combination of high-risk APOL1 alleles with GSTM1 null carrier status was associated with higher levels of protein excretion and lower glomerular filtration rate (GFR) at baseline and the highest rates of progression of CKD during follow-up, thus possibly adding increased oxidative stress, in this case genetic in nature, as a possible second hit to APOL1.

Morphological Features of Hypertensive Nephrosclerosis

While several clinical characteristics define the disease for practical purposes, a renal biopsy is needed to confirm the diagnosis of suspected HN.[57] Findings on biopsy include typical vascular hypertrophic changes, interstitial fibrosis, and glomerulosclerosis (Figure 46.2). Glomerular density is decreased in biopsy-proven HN (2.0 vs. 3.2 glomeruli per mm^2 in comparison with samples from kidney donors), a finding that is more prominent among HN patients with proteinuria >1g/day than

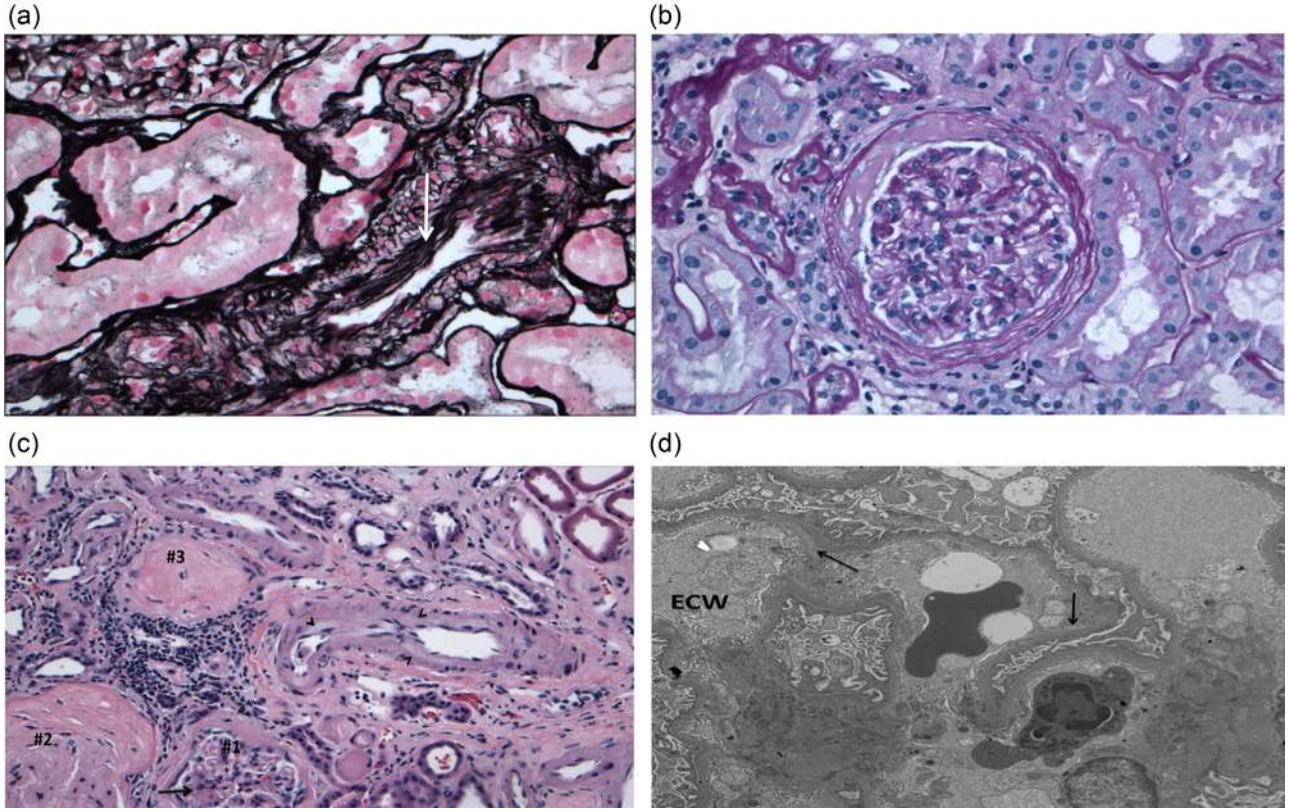

FIGURE 46.2 Histological findings in hypertensive nephrosclerosis. (a) Cross section of an arteriole showing vessel tortuosity and intimal fibrosis (*arrow*). Jones silver stain, 400×. (b) Glomerulus with pericapsular fibrosis and accumulation of collagenous material in Bowman's space. The capillary walls are diffusely thickened and the glomerular basement membrane is wrinkled with luminal collapse. PAS, 400×. (c) Arteriolar wall thickening with intimomedial mucoid degeneration (*small arrowheads*) and diffuse interstitial fibrosis and tubular atrophy. There are three glomeruli in different stages of injury: all have pericapsular fibrosis and some degree of collagen deposition in Bowman's space; #1 has early capillary loop thickening and mesangial sclerosis (*arrow*); #2 has more advanced global sclerosis and marked loss of capillary lumina; and #3 is completely obsolescent. H&E, 200×. (d) Typical electron microscopy findings with endothelial cell swelling (ECW), diffuse wrinkling of the glomerular basement membrane, expanded subendothelial space (lamina rara interna) (*arrows*), and focal collapse of foot processes. *Slides courtesy of Gilbert Moeckel, MD, PhD (Department of Pathology, Yale School of Medicine).*

those without it (1.8 vs. 2.2 glomeruli per mm^2, respectively).[58] The lobar and arcuate arteries are seldom visualized in renal biopsies, but when examined show typical signs of atherosclerosis, such as fibrous intimal thickening which, in conjunction with the frequently observed medial thickening, may produce luminal narrowing. The small interlobular arteries and afferent arterioles are tortuous and show hyalinization, fibroelastic intimal thickening, and reduplication of the internal elastic lamina.[36,57,59] In some chronic cases, there is mucoid degeneration of the arterial wall. This is typical of malignant HTN, but can be seen in the chronic phase even in patients who have never behaved clinically as having malignant HTN. The severity of arteriolar changes matches the severity of abnormalities in larger vessels, and there is an inverse relationship between the severity of these microvascular changes and renal function, but no consistent association with BP levels.[40,57,60] The interstitium shows diffuse widening due to ischemic tubular atrophy. The severity of interstitial atrophy is directly correlated with the severity of both arteriolar and glomerular changes (see below).

Approximately three-quarters of cases show evidence of glomerular ischemia as evidenced by tuft collapse.[59,61] The glomerular capillary loops appear to have increased wall thickness and decreased lumen diameter, a process that is due to wrinkling of the glomerular basement membrane.[61] Periglomerular fibrosis and thickening of Bowman's capsule are often observed.[36] When the process is long-standing, there is progressive glomerular shrinking and retraction toward the vascular pole as an eosinophilic "pink ball."[61] In addition, there is collagen accumulation in Bowman's space, thus filling the space left by the shrunken tuft, leading to glomerular obsolescence. In approximately one-quarter of the cases, the pattern of injury observed on light microscopy is different, consisting of segmental or global sclerosis, mesangial widening, and absence of collagen deposition in Bowman's space.[59,61] This pattern

is distinct from glomerular obsolescence and is called glomerular solidification. Patients with predominance of glomerular solidification have higher baseline BP and proteinuria and lower renal function than patients with predominant obsolescence.[62] In the US, this pattern is more common in African Americans with biopsy findings consistent with HN (53%),[46] but is also observed, in variable proportions (typically ~20–25%) among nonblacks in the US[46,59,63] and other countries.[59,63] Moreover, the percentage of solidified glomeruli in African Americans (25%) is three-fold higher than in Caucasians (8%), whereas the numbers of obsolescent glomeruli correlate with age but do not differ according to ethnicity.[46]

In most cases, immunofluorescence and electron microscopy (EM) add little to the pathological diagnosis of benign HN. On EM, there is conspicuous wrinkling and thickening of the glomerular basement membrane accompanied by widening of the subendothelial space as a result of subtle endothelial cell injury.[61] In patients with segmental glomerular sclerosis, the identification of focal foot process effacement is an important factor in the distinction between HTN-associated secondary glomerulosclerosis, as opposed to the diffuse effacement seen in primary FSGS.[46]

DIAGNOSIS

Establishing the Diagnosis of HN

CKD is defined as the presence of abnormalities of kidney structure or function, present for greater than 3 months, with implications for health. HN should be suspected in patients presenting for the evaluation of CKD who carry a diagnosis of HTN, especially in the absence of albuminuria, hematuria, or significant abnormalities on renal imaging. A long-standing history of HTN marked by prolonged periods of suboptimal control observed while renal function was still normal is an important characteristic of the disease. Because HTN is present in almost 90% of patients with advanced CKD, it is imperative to demonstrate the presence of uncontrolled HTN prior to the loss of kidney function. If this timeline cannot be ascertained, which is often the case in clinical practice,[2] the diagnosis of HN remains questionable. Further support for the diagnosis occurs if there is evidence of hypertensive injury to other target organs, particularly the heart.[64] Because of the common association of HTN with LVH, the presence of LVH on ECG or echocardiography is a useful correlate of hypertensive renal injury as it reflects duration of poor BP control. Retinal damage was also associated with renal injury in older studies, but this association was largely represented by patients with retinal features of malignant HTN.[65] Current evidence shows poor associations between retinal abnormalities and degree of renal injury in HN.[63,66–68] The presence of certain retinal findings, venous dilation in particular, is associated with the development of cardiovascular events in patients with CKD,[69] thus suggesting prognostic value of retinal examinations regardless of diabetic status; however, these were not findings of hypertensive retinopathy, so the relevance to hypertensive patients with HN is uncertain.

Analysis of renal imaging, typically ultrasound, although computed tomography (CT) and magnetic resonance (MR) imaging are also used, is essential in the diagnostic evaluation of patients with suspected HN, as it allows exclusion of other causes of nonproteinuric CKD, such as polycystic kidney disease and obstructive uropathy. Patients with HN often have kidneys of decreased size, lobulated contour, and atrophic cortices that are hyperechogenic on ultrasound. These are nonspecific abnormalities related to chronic small vessel damage. Because renovascular disease and ischemic nephropathy are commonly entertained diagnoses in patients with HTN and CKD, renovascular imaging with duplex ultrasound, CT angiography, or MR angiography may be necessary to discriminate between the two.

Proteinuria, albuminuria, and hematuria, often seen in malignant HTN, are not common in HN, which in its classic definition requires proteinuria to be low grade (i.e. levels no greater than 500–2000 mg/day based on 24-hour urine collection or spot urine protein:creatinine ratio <0.5–2 mg/g) and hematuria to be absent.[62–64] When these clinical parameters are applied to African-American patients, >90% have the histological features of HN on biopsy,[57] but we are not aware of any similar studies in other ethnic groups.

Among African Americans with presumed HN enrolled in the AASK trial, ~70% had proteinuria less than 300 mg/day.[70] Although most patients have minimal proteinuria, several series demonstrate variable rates of proteinuria in patients with biopsy-proven HN, many of whom have nephrotic-range proteinuria.[63,67,68,71–75] In a large series of 185 patients with biopsy-proven benign nephrosclerosis in the United Kingdom, ~70% had at least 300 mg of daily protein excretion, while 22% excreted >3 g/day.[73] Biopsy series, unfortunately, are skewed typically toward higher levels of proteinuria, as this finding often prompts a search for a primary glomerulopathy. However, we must recognize that a small subgroup of patients with pure HN on biopsy can present with very high levels of proteinuria.

Hematuria frequency in biopsy-proven cases of HN is 25–30%.[71,73] However, just as applicable to proteinuria, confounding by indication may be the reason explaining this high proportion, which may be as high as half of the

cases when high-grade proteinuria is also present.[74] Most patients with HN, however, have little or no proteinuria and no hematuria. When accompanied by long-standing HTN and evidence of other target-organ injury, a diagnosis of HN can be made with reasonable certainty, especially in African-American patients.[57] However, proteinuria, sometimes in the nephrotic range, and/or hematuria will be present in a minority of patients, in which case a renal biopsy should be considered to define the diagnosis.

In the absence of proteinuria, hematuria, or abnormalities on renal imaging, the differential diagnosis of HN is limited to chronic interstitial nephritides of any etiology (drugs, infections, autoimmune, etc.), atheroembolic renal disease, renovascular disease/ischemic nephropathy, and functional states of chronic renal hypoperfusion, such as the chronic forms of cardiorenal or hepatorenal syndromes. Identification of these conditions should be readily apparent based on other clinical, laboratory, and imaging features, although the assessment of their clinical relevance is often problematic, as in the case of renal artery stenosis as a cause of CKD, especially if unilateral.

Evaluation of Hypertension

Patients with HN typically have long-standing HTN and have undergone a detailed evaluation of secondary causes of HTN. As part of the approach to these patients, the nephrologist should revisit this issue with particular focus on conditions that are common and/or can be affected by specific treatment, such as primary aldosteronism, renovascular disease, sleep apnea, thyroid disorders, and pheochromocytoma. Appropriate diagnostic tests should be pursued according to level of suspicion.

Assessment of established extrarenal organ damage is essential in the management of patients with HN. This assessment helps confirm the presumptive diagnosis of HN and identifies comorbid conditions that may affect treatment choices related to HTN and cardiovascular risk management, choice of renal replacement modality, and—if applicable—vascular access creation. We perform a detailed cardiovascular, neurological, and peripheral vascular history and examination looking for findings suggestive of coronary artery disease, congestive heart failure, stroke, and peripheral arterial disease. Aside from "kidney-specific" tests such as serum chemistries, urinalysis, albuminuria, and/or spot protein:creatinine ratio, and some form of imaging, we uniformly evaluate the heart not only with an ECG but also with an echocardiogram to provide more precise measures of LVH, systolic and diastolic function, as they may have both prognostic and therapeutic implications.

BP Measurement and Monitoring

Office measurements should be performed with close attention to the American College of Cardiology/American Heart Association[3] guidelines and with routine performance of orthostatic measurements, particularly in older patients, given the high prevalence of orthostatic hypotension.[3] There is substantial evidence that BP monitoring outside of the office is a stronger predictor than office BP of cardiovascular events in essential HTN.[76] Home and 24-hour BPs provide a better overall assessment of average BP (i.e. closer proximity to one's "true BP") and BP variability, the characterization of BP in the ambulatory environment, and, in the case of 24-hour BP monitoring (ABPM), assessment of BP during sleep, all of which are stronger predictors of risk than clinic BP. The recent report of a registry-based, multicenter, Spanish cohort study of 63,910 adults who had 24-hour ABPMs and followed for a median of 4.7 years demonstrated a 58% increase in all-cause mortality among those with white coat and masked HTN. Masked HTN was more strongly associated with all-cause mortality (hazard ratio, 2.83; 95% CI, 2.12−3.79) than sustained HTN (hazard ratio, 1.80; 95% CI, 1.41−2.31) or white coat HTN (hazard ratio, 1.79; 95% CI, 1.38−2.32). Thus, ABPM is a stronger predictor of all-cause and cardiovascular mortality than clinic blood pressure measurements.[77]

The United Kingdom National Institute for Health and Care Excellence (NICE) BP guidelines recommend the use of 24-hour ABPM as the primary tool for *initial* diagnosis of primary HTN. This will result in cost savings as ~15% of patients do not require treatment due to a white coat effect (i.e. BP high in the office but normal at home) and ~10% require more stringent treatment due to a masked effect (i.e. BP normal in the office but high at home).[78] When ABPM is not available, home BP is a good alternative.[3,78] Similar recommendations now exist in the US. The US Preventive Services Task Force recommends the use of out-of-office BP to confirm the diagnosis of HTN prior to treatment initiation (https://www.uspreventiveservicestaskforce.org/Page/Document/RecommendationStatementFinal/high-blood-pressure-in-adults-screening), and the ACC/AHA guidelines recommend the use of out-of-office BP both for diagnosis and treatment adjustments.[3]

The prevalence of masked and white coat effects is high in CKD. An analysis of 960 patients in 6 separate studies of out-of-office BP (home BP in 4 studies, ABPM in 2) showed that 40% of individuals with adequate office BP were high at home, and 31% of those with elevated office BP were controlled based on ambulatory values.[79] These observations have major implications regarding the assessment of HTN control and treatment monitoring and justify the recommendation

of integration of ABPM and/or home BP readings in the routine management of HTN. Additionally, an ABPM substudy performed in the AASK cohort demonstrated that 36% had masked HTN with office BPs in an acceptable range. A recent report presented data on 7518 patients from 5 cohorts from 4 different countries (two from the US and one each from Italy, Spain, and Japan).[80] In this analysis, the overall prevalence of white coat and masked HTN was 20% and 16%, respectively. However, there were significant differences in prevalence across cohorts. White coat HTN ranged from 3% to 30% (lower in the US, higher in other cohorts), whereas masked HTN ranged from 6% to 35%, with higher prevalence in the US and lower elsewhere.

In addition, as in primary HTN, studies supporting improved prognostication with ABPM or home BP in CKD are available.[81–83] All studies show better characterization of renal and cardiovascular risk using 24-hour, daytime and night-time BP levels. However, there is inconsistent evidence that the dipping status (i.e. whether BP falls by >10% during sleep or not) provides additional prognostic information that is independent of average BP levels. In the specific case of HN, the 5-year observation of 617 subjects enrolled in the AASK cohort study revealed that ABPM was a significant predictor of cardiovascular and renal events.[82] In fully adjusted models that included baseline clinic BP, each 10 mm Hg increase in 24-hour systolic BP was associated with 26% (12–41%, $p < 0.001$) increased risk of cardiovascular events (hospitalization for myocardial infarction, revascularization procedure, heart failure, or stroke), an effect that was more robust in patients with uncontrolled clinic BP. There was no independent predictive advantage of ABPM over clinic BP when the entire cohort was analyzed for the CKD endpoint (composite of doubling of S[Cr], ESRD, or death). However, among the 267 subjects with controlled clinic systolic BP (<130 mm Hg), each 10 mm Hg increase in 24-hour systolic BP was associated with a 33% (4–70%, $p = 0.02$) increase in risk of the CKD endpoint. This advantage over clinic BP was not noted among patients with uncontrolled clinic BP. In this study, dipping status was not an independent predictor of any of the outcomes. However, the high incidence of masked HTN may have played a role contributing to the negative outcome.

The severity of nocturnal HTN in HN was evaluated using baseline data from the 617 African-American patients with HN enrolled in the AASK cohort study.[84] In this cohort, 80% were nondippers using the definition of <10% BP decline during the night. Surprisingly, however, of the 377 with controlled office BP, 70% had a diagnosis of masked HTN, largely represented as nocturnal HTN (i.e. adequate office BP <135/85 mm Hg, adequate daytime ambulatory BP <140/90 mm Hg, but high night-time BP >120/70 mm Hg). This had clinical relevance as there was a graded relationship between the level of nocturnal HTN and the severity of organ damage, such as higher levels of proteinuria and LVH. Nocturnal BP was significantly higher in the AASK population than in patients from four other CKD studies (135 mm Hg in AASK vs. 122–124 mm Hg in the other cohorts), thus postulating a significant effect of black race and possibly the etiology of kidney disease on the prevalence on uncontrolled nocturnal HTN.[80] The possible value of nocturnal dosing of pharmacological therapy is discussed below.

TREATMENT

To appreciate fully how to treat HTN in HN, one needs to value the cornerstone of therapy for HTN in general, i.e. the importance of lifestyle intervention, especially sodium restriction to <2400 mg/day, reduced alcohol consumption, and aerobic exercise.[3] Studies evaluating the effect of sodium intake on BP control in people with stage 4 CKD show that for approximately every 400 mg above a sodium intake base of 3000 mg day requires an additional BP medication to maintain BP control.[85] Additionally, other than aerobic exercise, alternative therapies used by patients have no evidence to support their use.[86]

Blood Pressure Goals

Consensus guidelines regarding BP targets in patients with CKD are currently underway and have been the subject of substantial controversy. The recommended BP goal by the 2012 Kidney Disease: Improving Global Outcome (KDIGO) guidelines for patients with nephropathy, regardless of etiology, is <140/90 mm Hg.[87] Data to support this goal are derived from three prospective trials that randomized groups to different BP goals with the primary endpoint being CKD progression. The three trials were the Modification of Dietary Protein in Renal Disease (MDRD),[88] AASK,[70] and the Ramipril Efficacy in Nephropathy-2.[89] All three trials failed to show a slower decline in estimated GFR (eGFR) in the lower BP group.

The AASK study had similar BP targets to the MDRD study (mean arterial pressure [MAP] <92 mm Hg vs. 102–107 mm Hg) and failed to show a difference in eGFR decline after 5 years of follow-up.[70] The trial continued as a cohort study for five additional years maintaining BP at levels <130/80 mm Hg with the hypothesis that the duration of follow-up was too short.[90] However, even with this level of control, up to 65% of the cohort had progressive nephropathy.

The results of the Systolic Blood Pressure Intervention Trial (SPRINT)[91] spurred recommendations for a target <130/80 mm Hg by the ACC/AHA guidelines.[3] In SPRINT, nondiabetic patients with HTN and high cardiovascular risk were randomized to a systolic BP target of <140 or <120 mm Hg. Those randomized to the low target developed significantly fewer cardiovascular events and death.[91] SPRINT was enriched by a large number of CKD patients (N = 2646) and a separate analysis of CKD patients confirmed the same pattern of 19% fewer cardiovascular endpoints and 28% fewer deaths among those randomized to the lower target after 3.3 years of follow-up.[92] There were no differences in CKD progression or need for dialysis. Because of the improvements in nonrenal outcomes, these results led the ACC/AHA guidelines to recommend tighter BP targets (<130/80 mm Hg) among CKD patients.[3] KDIGO guidelines are being updated, with planned release in 2019.

There have been concerns about increased rates of acute kidney injury in patients subjected to more intensive BP lowering, both in patients with normal and abnormal baseline renal function.[91,92] In the SPRINT renal substudy, intensive therapy was associated with a 46% greater risk of hospitalization for acute kidney injury, though the overall rate was low (2.8% vs. 1.9%, HR 1.46, p = 0.01). Two recent publications looked at the long-term risk of ESRD and death in patients randomized to lower BP targets in AASK and MDRD. With respect to ESRD, early (within 3−4 months of randomization) fall in GFR >20% was associated with increased risk of ESRD, but there was no difference between intensive or usual BP target.[93] A fall in GFR between 5% and 20% was only associated with increased ESRD risk in the usual group. As it pertains to death risk, those with an early loss of GFR less than 20% had decreased mortality risk if randomized to the intensive BP arm, whereas no such protection was noted in the usual BP arm.[94] A fall in GFR >20% was associated with increased risk of death in the usual BP group only. These data indicate that, while significant loss of GFR is associated with increased risk of ESRD, this is not related to BP goals. Furthermore, in the intensive group, the death risk was lower among those randomized to intensive therapy even if there was an early GFR loss between 5% and 20%.

One explanation for the observation of high rates of progressive CKD despite lower BP targets in AASK is the inability to capture masked or nocturnal HTN with routine clinic BP measurements, as suggested by the AASK ABPM substudy where more than 33% of people had masked HTN.[84] Of relevance to this point, the manipulation of nocturnal HTN and abnormalities in the circadian BP rhythm by bedtime dosing of antihypertensive agents has been evaluated in HTN. In 21 randomized studies involving 1993 patients with HTN, evening dosing (6 p.m.−12 a.m.) of antihypertensive drugs resulted in a nominal but statistically significant advantage in 24-hour BP reduction (1.7/1.2 mm Hg) compared with morning dosing (6 a.m.−12 p.m.).[95] Bedtime dosing led to a significant 67% risk reduction in cardiovascular events compared with morning dosing among 2156 hypertensive patients treated for 5.6 years in a large single center randomized clinical trial.[96] The same investigators demonstrated a similar cardioprotective effect in the subgroup of patients enrolled in the study who had stage 2 or stage 3a CKD.[97] In another study of 32 nondipper CKD patients (22 with a diagnosis of HN), modification of the administration time of at least one agent from the morning to bedtime resulted in conversion from nondipper to dipper in 28 of 32 subjects, reduction in nocturnal BP by 7/4 mm Hg (p < 0.001) with an opposing increase in daytime BP by 3/1 mm Hg, p = not reported, and a concomitant association between degree of nocturnal BP fall and reduction in proteinuria.[98]

Most drugs are effective in achieving this effect, though the most consistent are blockers of the renin−angiotensin system, CCBs, and alpha blockers, whereas beta blockers are not effective in lowering night-time BP, except in patients with sleep apnea.[99] Despite the success of some investigators in lowering nocturnal pressure in nondipper CKD patients with this strategy,[98,100] a study of African Americans with HN (stage 4 CKD) was unsuccessful in lowering nocturnal BP with bedtime dosing.[101] Therefore, although promising, further data are necessary before we can recommend changes in therapy with the goal of reducing night-time BP, especially until we can define which patients should have ABPM prior to the change, if only nondippers should undergo the modifications, and if follow-up ABPM is indicated after each treatment change.

Taken together, prospective evidence supports a BP goal of <140/90 mm Hg to slow HN progression. Moreover, while nephropathy progression is slowed, it is not stopped as indicated by the clinical trial evidence of the long-term (10-year) AASK follow-up. However, based on data from SPRINT, cardiovascular events and death risk may be minimized by a tighter target (<120−130 mm Hg SBP), thus making these lower targets desirable, as long as well tolerated.

Overall Management Approach and Drug Choices

We refer the reader to Chapter 21 for a detailed discussion of drug choices in the treatment of HTN in CKD. Most of the data driving treatment choices in

HN come from people with advanced nondiabetic kidney disease having more than 300 mg of albuminuria per day. While only one trial randomized drug classes, i.e. AASK, the others randomized BP levels and also used ACE inhibitors (ACEIs) because angiotensin receptor blockers (ARBs) were not available when they were done. Mindful of the limitations of generalizability of these results to all HN patients, all results among these participants indicate that ACEIs are the preferred agents to be used for treatment. In AASK, ramipril was superior to either amlodipine or metoprolol for slowing the rate of progression of HN.[70] However, no other ACEIs have been tested in HN and a systematic review and meta-analysis by the Cochrane group found that there are not enough data to make claims that ACEIs prevent or delay any nephropathy in its early stages (CKD stage 1 or 2).[102] ARBs are often used interchangeably with ACEI, but the data on ARBs are restricted to diabetic nephropathy with no outcome data in nondiabetic HN CKD. However, given the mechanism of action and the benefit seen in diabetic nephropathy, there is no reason to think these agents would not be as effective in HN, as supported by studies in diabetic kidney disease.[103,104]

Thiazide-like diuretics (chlorthalidone and indapamide) have a strong evidence base for reducing cardiovascular risk even in patients with stages 1–3b CKD. However, their role in CKD outcome studies is unclear. *Post hoc* analyses of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) demonstrated that chlorthalidone was as good as ACEIs for slowing CKD progression in stage 3 CKD.[105] This *post hoc* analysis of ALLHAT included both those with HN and diabetic nephropathy so the data are not definitive.

When used in patients with HN, both dihydropyridine (DHP) and nondihydropyridine CCBs are effective in lowering BP and CV events in high-risk populations. These agents are particularly efficacious for CV risk reduction when combined with an ACEI as shown by the results of the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH).[106] In this trial, patients at high risk for CV events and CKD progression treated with a single pill combination of an ACEI (benazepril) with amlodipine had a 20% relative risk reduction in CV events and slower CKD progression when compared with those assigned to the benazepril/hydrochlorothiazide combination.

In addition, a prespecified *post hoc* analysis of ACCOMPLISH evaluated CKD outcomes showing that the DHP CCB plus ACEI decreased CKD progression to a greater extent than the ACEI and diuretic (hazard ratio 0.52, $p < 0.001$).[107] About 60% of the patients in this substudy were thought to have HN.

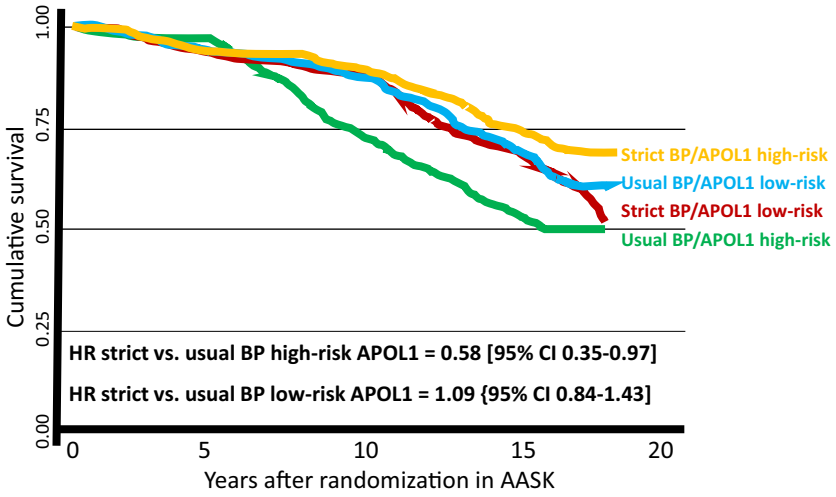
Beta blockers are no longer a first-line option to lower BP in the most treatment guidelines.[3] Some patients with HN have an increase in sympathetic activity and a high CV event rate and could benefit from β blockers. In the AASK study, subjects randomized to metoprolol had intermediate outcomes, better than amlodipine but worse than ramipril.[70] Therefore, in black patients with HN, metoprolol is a useful choice, in particular for patients who cannot tolerate an ACEI well, or who need additional therapy to achieve BP control.

None of the other drug classes has been systematically evaluated for treatment of HN in CKD. Their use in HN is acceptable as combination therapy to achieve BP control in patients with resistant HTN.

FUTURE HORIZONS: APOL1 GENOTYPE AND TREATMENT DECISIONS

In the AASK long-term follow-up study, compared with patients with none or 1 high-risk allele, those with 2 high-risk APOL1 alleles had 88% greater risk of doubling of S[Cr] or ESRD over 9 years of follow-up (HR 1.88, 95% CI 1.46–2.41).[48] Patients with proteinuria had faster progression than those without, but APOL1 genotype predicted risk similarly among patients with or without proteinuria at baseline. Finally, BP target assignment (MAP <92 [intensive] vs. 92–107 mm Hg [usual] and drug assignment [ramipril vs. metoprolol or amlodipine]) did not modify the impact of APOL1 genotype on renal outcomes.

Interestingly, a separate report of AASK that focused on nonrenal endpoints over 14.5 years of follow-up showed that patients with high-risk APOL1 genotypes (23% of the entire cohort) had the same risk of death than those with low-risk genotypes.[108] However, among high-risk APOL1 subjects, assignment to the intensive BP target group during the study resulted in 52% decrease in adjusted mortality risk (HR 0.48, 95% CI 0.28–0.84) (Figure 46.3). This effect became noticeable after ~5 years of follow-up and was not observed among patients with low-risk APOL1 genotypes. In addition, among high-risk APOL1 subjects, there was also a nonsignificant trend toward fewer cardiovascular events (HR 0.72, 95% CI 0.34–1.53). Therefore, it is plausible that, once APOL1 genotyping becomes more widely available, patients with two phenocopies of G1 or G2 APOL1 alleles should be treated more intensively than those with low-risk genotypes with the goal of preventing nonrenal events despite the apparent absence of renal benefit from such intervention. The prospective benefit of this approach has yet to be demonstrated.



Number at risk					
Usual BP/APOL1 low risk	264	261	235	192	59
Usual BP/APOL1 high-risk	78	78	65	50	12
Strict BP/APOL1 low-risk	261	256	235	186	57
Strict BP/APOL1 high-risk	79	79	71	62	20

SUMMARY

HN is defined as CKD attributed to HTN. Morphologically, HN is characterized by arteriolar sclerosis, glomerulosclerosis, and interstitial fibrosis. Clinically, HN presents as progressive loss of renal function in a patient with previously uncontrolled HTN, accompanied by minimal proteinuria, and normal urinary sediment and renal imaging. This condition is responsible for ~30% of cases of ESRD in the US and is more common in African Americans, a genetic susceptibility that is identified through mutations in the APOL1 gene, although the mechanistic implications of these mutations remain only partly understood. Treatment recommendations based largely on data from the AASK trial and observational studies include preferential use of a blocker of the renin–angiotensin system (ACEI or ARB) as the primary component of drug treatment to achieve a BP goal of <130/80 mm Hg.

Approach to the Patient with Chronic Kidney Disease and Renovascular Disease

Stephen C. Textor, Lilach O. Lerman

Division of Nephrology and Hypertension, Mayo Clinic, Rochester, MN, United States

Abstract

Renovascular disease (RVD) results most commonly from atherosclerotic vascular occlusion. Although clinically significant loss of glomerular filtration rate develops with its more severe forms, RVD is often complicated by widespread cardiovascular manifestations and preexisting microvascular injury, making management of these patients challenging. The kidney adapts to moderate reductions of blood flow and oxygenation, but severe arterial occlusion eventually leads to tissue hypoxia and loss of kidney function. Recent studies demonstrate proinflammatory changes in the renal vasculature preceding kidney injury, which are followed by rarefication of renal microvessels. Tissue inflammation and fibrosis ensue and eventually produce irreversible structural injury that precludes recovery of glomerular filtration. Medical treatment of hypertension, comorbidities, anemia, and electrolyte disorders is fundamental to the management of these patients. Renal revascularization is beneficial for selected patients with progressive decline in kidney function, refractory hypertension, and/or recurrent circulatory congestion or pulmonary edema. Experimental studies indicate that evolving adjunctive measures, including cell-based therapy and mitochondrial protection, may attenuate injury or facilitate renal repair mechanisms for preservation of kidney function.

SCOPE OF THE PROBLEM

Occlusive vascular disease of the main renal arteries gained attention as an important cause of chronic renal failure—and one that could be potentially reversed—only as recently as the 1970s and 1980s.[1] Until then, beginning in the 1930s, renovascular disease (RVD) was recognized primarily as a "secondary" cause of hypertension. Most diagnostic tests until the 1980s were focused on identifying renovascular hypertension that effectively might be "cured" by revascularization. As medical therapy of renovascular hypertension has become more effective, many more kidneys are exposed to prolonged periods of reduced blood flow to the poststenotic kidney. The clinical focus has shifted to preserving and restoring glomerular filtration rate (GFR) by revascularization for carefully selected patients with chronic kidney disease (CKD) and RVD. Recognizing the transition from a hemodynamic process limiting GFR to an active injury with inflammatory, oxidative stress, and profibrotic processes represents an important and evolving paradigm shift in RVD.[2] Preventing irreversible kidney injury thereby can relieve the need for renal replacement therapy (RRT) in some patients and provide major clinical benefits.

Most clinical RVD derives from atherosclerosis and, therefore, is complicated by widespread associated cardiovascular disease and preexisting microvascular injury. The combination of reduced GFR, progressive hypertension, and atherosclerotic disease makes management of these patients exceptionally complex. Clinicians caring for such individuals often include cardiovascular specialists, internists, vascular surgeons, and others. Patients often present to nephrologists with advanced disease, near the time RRT, or maneuvers to manage fluid retention, such as dialysis or ultrafiltration, are being considered. Several prospective trials evaluating the additional role of endovascular stenting for RVD have failed to identify compelling benefits for large groups over the short term, when added to medical therapy. Although these trials have been controversial, the clinical application of renal revascularization has declined in many countries. One result has been the emergence of more patients identified later in the course of chronic renal disease related to vascular occlusion.

This chapter will summarize current and emerging concepts of the role of RVD in the development of

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00047-4

CKD. Although the kidney ordinarily has more blood flow than required for basic viability, critical loss of perfusion remains an important, reversible process nephrologists should understand and plan to identify and treat when indicated. A well-defined approach to a difficult clinical problem will result in better care for patients.

DEFINITION AND PREVALENCE

The term "ischemic nephropathy" was coined to identify patients with a loss of GFR associated with RVD, based on the assumption that reduced blood flow induced a deficit in oxygen supply resulting in kidney injury.[3] More than 80% of patients with occlusive RVD in the US have atherosclerosis. Other disorders including inflammatory vasculitides, such as Takayasu's arteritis, are more common in Southeast Asia where they may account for as many as 60% of cases.[4,5] Some patients develop progressive loss of kidney function with advancing RVD, sometimes leading to total occlusion. The degree of vascular occlusion required to produce these effects has been controversial. Physiologic studies of graded vascular occlusion indicate that development of a measurable pressure gradient, reductions in blood flow, and release of pressor materials such as renin require at least 60% lumen occlusion, and often require 75–80% occlusion (Figure 47.1).[6,7] Hence, biplane imaging studies utilizing estimates of 50% stenosis regularly include individuals with "incidental" or trivial disease without measurable hemodynamic effect. Some authors argue that subtle effects of lesser degrees of occlusion may be important, but this has been difficult to prove.

Community-based population screening studies using high-resolution Doppler ultrasound in the US indicate that up to 6.8% of individuals above age 65 have more than 60% occlusive RVD.[8] This is supported by the identification of visible renovascular lesions by CT angiography in nearly 5% of individuals presenting as potential kidney donors, with the prevalence highly related to age.[9] Most of these lesions are incidental and have minimal hemodynamic or clinical importance for many years. Not surprisingly, atherosclerotic RVD is associated with other vascular disease, such as coronary, aortic, and peripheral vascular disease. Numerous studies over the past two decades suggest that screening high-risk patients will identify coexistent RVD in 14–20% of those undergoing coronary angiography, rising to more than 35% of those with clinical manifestations of aortic and peripheral vascular disease.[10] A review of Medicare claims data indicated that individuals developing identifiable RVD were at substantially higher risk of cardiovascular disease complications, including stroke, new coronary disease, congestive heart failure (CHF), and death over the subsequent few years[11] (Figure 47.2). Such individuals are also at higher risk for progressive renal failure, although this is far less likely than other cardiovascular manifestations. As a result, several treatment trials, including the Angioplasty and STenting for Renal Artery Lesions (ASTRAL) and Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL), seeking to examine the role of revascularization in preserving kidney function have been complicated by high rates of non-renal events.[12,13]

Does atherosclerotic RVD contribute to the rising incidence of end-stage renal disease (ESRD) in older individuals? It is widely recognized that stated "causes" of ESRD from the US Renal Data System

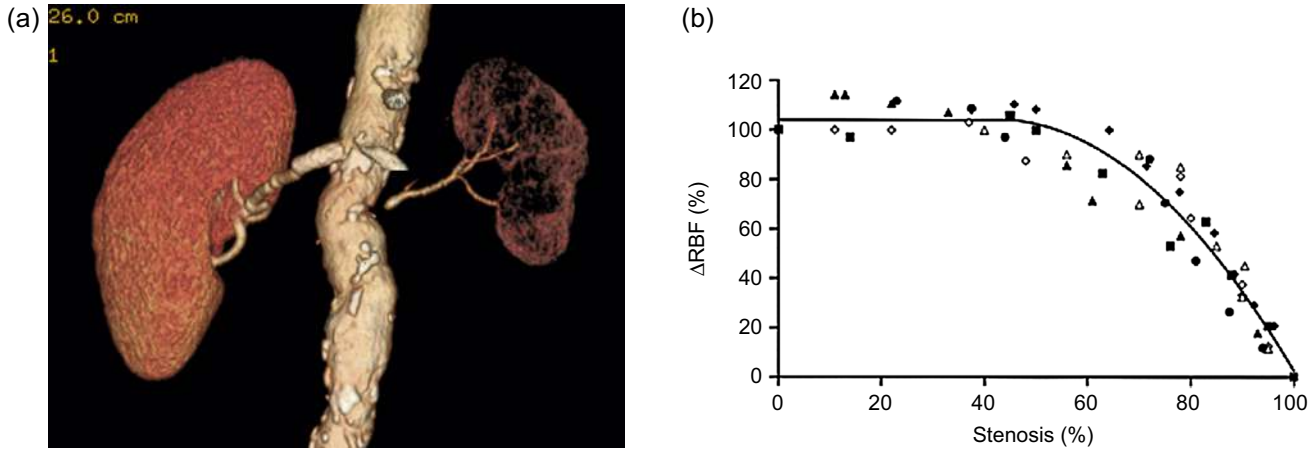

FIGURE 47.1 (a) Atherosclerotic RVD with evident loss of flow and volume. CT angiogram demonstrating vascular occlusion to the left kidney leading to loss of volume, cortical and medullary blood flow reductions, and impaired renal function due to ischemic nephropathy. (b) Measured changes in blood flow in relation to severity of stenosis. Studies of blood flow and metabolic function indicate that lumen occlusion up to 60–70% have little hemodynamic effect in the kidney. Stenoses beyond this degree produce major decrements in blood flow, eventually leading to insufficient perfusion to maintain function.

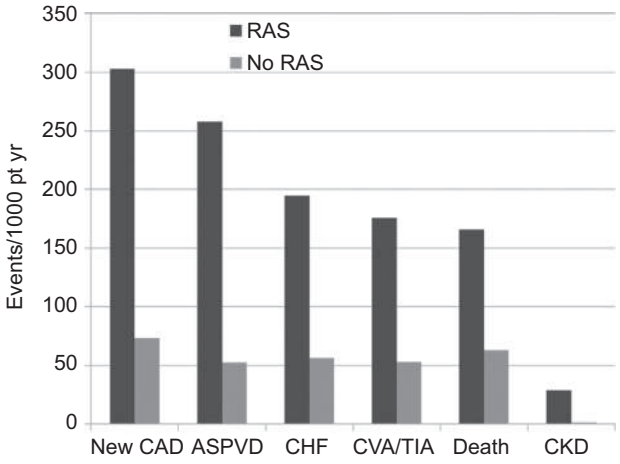

FIGURE 47.2 Relative risks for cardiovascular disease in patients with identified RAS in Medicare Claims data: Patients with newly identified atherosclerotic RAS in the Medicare claims group (*dark bars*) generate substantially more medical event claims over the subsequent 2 yr than those without RAS (*light bars*). These data highlight associated cardiovascular risks, including stroke, death, and congestive heart failure associated with RAS. Although progression to renal failure is more common with RAS than without this claim, it is far less likely than cardiovascular disease events. *ASPVD*, atherosclerotic peripheral vascular disease; *CAD*, coronary artery disease; *CHF*, congestive heart failure; *CKD*, chronic kidney disease; *CVA*, cerebrovascular accident; *TIA*, transient ischemic attack. *After Kalra.*[11]

are highly subjective and rarely reflect precisely determined etiology. Rates of identifiable RVD in newly started dialysis patients without other diseases in small series range as high as 20–40%.[10,14,15] Medicare claims data for more than 160,000 individuals indicate that up to 9.7% of new ESRD patients have identified atherosclerotic RVD, but fewer than half were designated with this as the primary cause of renal disease. Hence, some authors estimate that about 5% of otherwise unexplained ESRD may be driven by occlusive RVD in the US.[16] Isolated case reports identify some individuals with substantial recovery of kidney function and/or stabilization of blood pressure and cardiovascular status after restoring blood flow to the kidney, although this is not common.[17] Retrospective series of azotemic patients undergoing renal revascularization indicate that between 25 and 30% of such individuals have meaningful recovery of kidney function, defined in one series as a fall in serum creatinine (S[Cr]) of more than 1.0 mg/dL.[18] Follow-up studies of patients whose GFR improves after revascularization indicate distinctly better survival and reduced morbidity as compared with those with deteriorating kidney function.[19,20] Enthusiasm for widespread renal revascularization has been tempered, however, by the fact that some patients have adverse events. No prospective treatment trial to date has demonstrated reduced overall rates of either renal or cardiovascular endpoints associated with renal revascularization. More than ever, careful selection is paramount for patients considered for either vascular or reparative intervention (see below).

PATHOPHYSIOLOGY OF CKD WITH RENOVASCULAR DISEASE

Atherosclerotic RVD can accelerate hypertension by multiple mechanisms that do not necessarily require reduction of GFR, including activation of the renin–angiotensin–aldosterone system (RAAS) and sympathetic adrenergic system. RVD also complicates sodium homeostasis by impairing sodium excretion, leading both to resistance to antihypertensive drug therapy and to worsening circulatory congestion associated with heart failure. These features lead to multiple clinical manifestations separate from the loss of kidney function and are beyond the scope of this discussion.[21,22] We focus on specific mechanisms by which kidney function is threatened in this disorder.

Hemodynamic Features Specific to the Kidney

The kidney vasculature is complex and heterogeneous, consistent with localized functions of glomerular filtration in the cortex and active solute transport in deeper regions, particularly within the medulla. Whole kidney estimates indicate that less than 10% of blood flow is required strictly for the metabolic demands of the entire organ.[23] Cortical blood flow is several-fold higher than that to medullary regions, consistent with its function as a filtering site. The medulla is primarily the site of descending and ascending tubular structures associated with transepithelial electrolyte transport and developing concentration gradients that require ATP-dependent energy. As a result, oxygenation follows a gradient with high levels in the cortex decreasing to distinctly hypoxic levels in deeper medullary segments, leaving these regions continually near the brink of "hypoxia."[23] The normal kidney tolerates this oxygenation gradient remarkably well, and tissue oxygen levels within each region remain stable over a wide range of maneuvers that alter whole kidney blood flow[24] (Figure 47.3).

Studies using Blood Oxygen Level Dependent (BOLD) magnetic resonance in humans demonstrate that despite chronic reductions in renal blood flow averaging 25–30% beyond a stenotic lesion, tissue oxygenation within both cortex and medulla remain well preserved and similar to those of subjects with essential hypertension.[25] Preservation of oxygen supply appears partly due to reduced glomerular filtration and thereby reduced medullary oxygen consumption from active

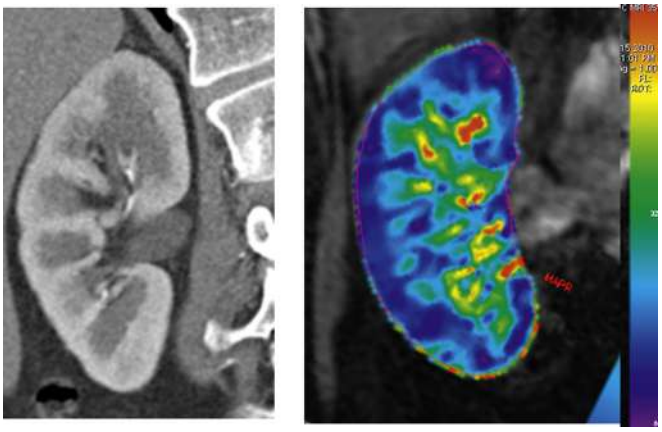

FIGURE 47.3 Coronal view of CT angiogram of a normal kidney (left panel) illustrating cortical and medullary contrast distribution associated with differential blood flows. The right panel contains an R2* parametric map from a Blood Oxygen Level Dependent MR image depicting levels of deoxyhemoglobin (scale on far right). Cortical levels of deoxyhemoglobin are low, reflecting high blood flows and abundant oxygenation. Deeper segments develop a gradient with progressively increasing deoxyhemoglobin in medullary segments with lower blood flow and high oxygen consumption (see text). These characteristics reflect the normal kidney's complex configuration of capillary beds in series, first to the cortex and glomerular filtration sites, then to post-glomerular capillaries extending into the medullary region.

transport. These observations provide reassurance that antihypertensive drug therapy to lower perfusion pressures and blood flows to many poststenotic kidneys may not directly induce or worsen hypoxic injury. Hence, medical therapy of renovascular hypertension as conducted in prospective trials for moderate RVD has been tolerated without identifiable kidney injury, sometimes for many years. Similar studies in patients with more advanced renovascular occlusion (identified by higher degrees of stenosis on duplex ultrasound and more severely reduced GFR) identify obvious limits to this point. Severe arterial occlusion eventually reduces blood flow, and tissue oxygenation, in both cortex and medulla[26,27] Hence, there are clearly limits of the kidney's ability to "adapt" to reduced blood flow and oxygenation beyond arterial occlusion.

EMERGING PARADIGMS OF KIDNEY INJURY BEYOND ARTERIAL OCCLUSIVE DISEASE

Large Vessel Pathology

Because of its dense vascular supply, the kidney is subject to alterations of vascular endothelial function, recognized as a prodromal phase associated with systemic atherosclerotic disease. Elevations of cholesterol, aging, and smoking induce limitations in the availability of nitric oxide (NO) and increase local production of endothelins.[28] These changes are associated with altered endothelial regulation of inflammatory cytokines, chemokines, and nuclear factor-kappa B throughout the systemic vasculature. Studies in the main renal artery segments from human subjects demonstrate that proinflammatory changes are evident before measurable renal dysfunction ensues.[29] These changes lead to alterations of T-cell function and distribution in circulatory lymphocytes. When vessels from such patients are examined at autopsy, the main renal arteries demonstrate intimal inflammatory changes as part of the atherosclerotic lesion proximal to the kidney. Histologic changes in the renal arterial wall resemble those occurring in other vascular beds during atherogenesis, and the ultimate plaque constituents are similar to coronary arterial lesions.[30]

Small Vessel Changes

The kidney is unique in having capillary beds in series, as the efferent glomerular vessels become the inflow to the vasa recta descending into medullary segments alongside renal tubules. These vessels are especially sensitive to changes in the microvascular milieu that can be affected by alterations in vasoactive substances, including NO, prostaglandins, endothelins, vascular endothelial growth factor (VEGF), and other factors that modify endothelial function. Modifications in endothelial function associated with dyslipidemia, smoking, diabetes, and aging alter vessel dimensions and remodeling that predispose to local fibrosis.[31] Short-term ischemia often leads to upregulation of growth factor expression and new vessel formation, yet this compensatory mechanism seems to be lost during exposure to chronic ischemia, particularly in the kidney. Furthermore, newly formed vessels are often fragile, hyperpermeable, and prone to dropout. Superimposing repeated episodes of reduced perfusion has the capacity to magnify functional rarefication of these vessels, effectively impairing local blood supply[31] (Figure 47.4a).

In the microenvironment of renal ischemia, microvessels are exposed to noxious insults like reactive oxygen species (ROS), which increase renal vascular tone and impair endothelial cell integrity, contributing to endothelial dysfunction.[32] The most prominent vascular changes associated with chronic RVD involve remodeling (e.g. wall thickening) and loss of intrarenal microvessels (<500 μm in diameter),[33] including interlobar, arcuate, interlobular arteries, and small arterioles (<200 μm), which are responsible for intrarenal distribution of blood. The spatial density of small outer cortical microvessels (<40 μm) in RVD correlates directly with GFR, implicating them in renal dysfunction.[34] Renal

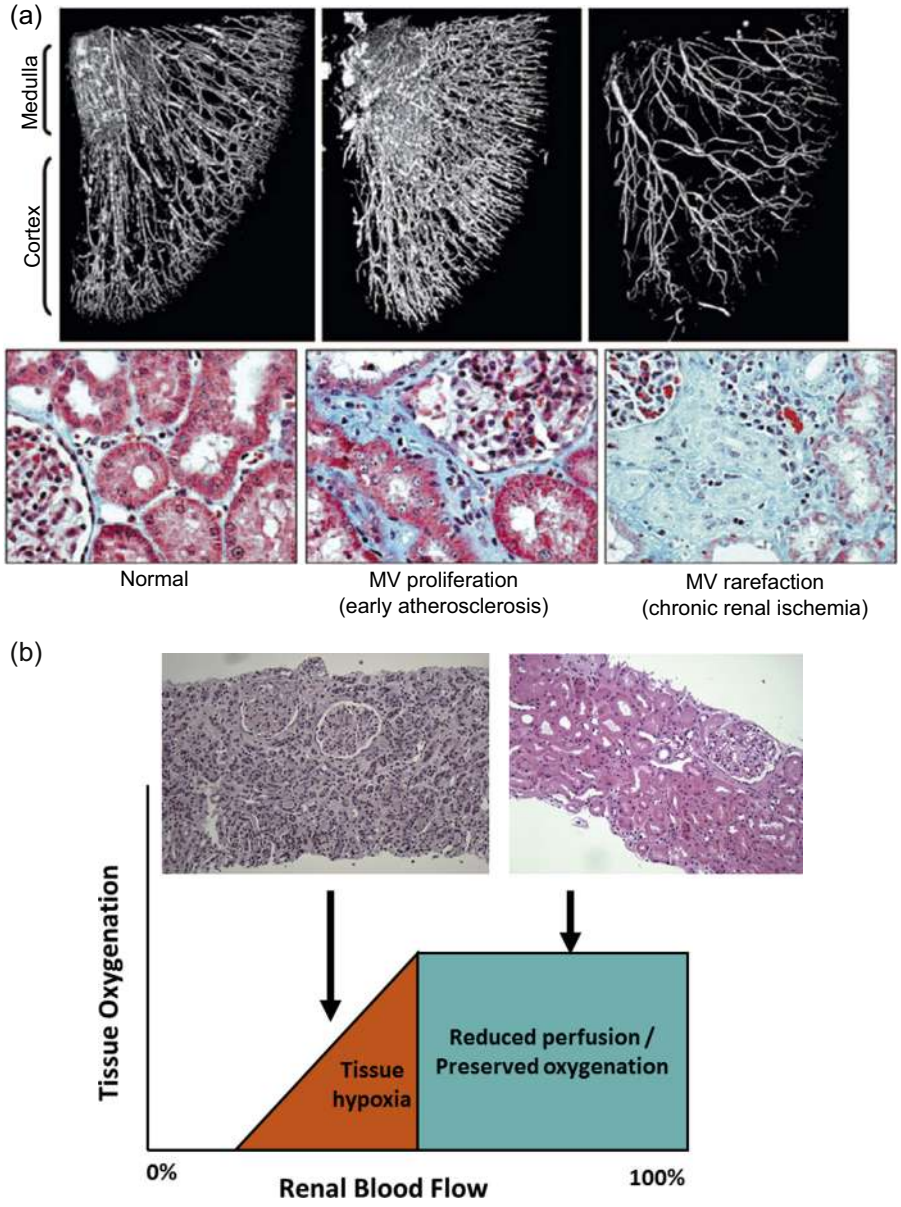

FIGURE 47.4 (a) Vascular rarefication developing beyond a stenotic lesion in experimental atherosclerotic RAS as shown by a postmortem micro-CT image. The complex vascular arrangements within the cortex and medulla are susceptible to both functional and structural "rarefication" during sustained reductions in perfusion, particularly when additional microvascular injury is present (see text). (b) Tissue oxygenation as a function of renal blood flow to the kidney. Unlike brain or heart muscle, tissue oxygenation is well preserved despite substantial decrements (up to 30–45%) in blood flow with relative preservation of tubular and glomerular structures. With more severe decrements in blood flow, tissue oxygenation falls and active inflammatory processes ensue, leading to loss of tubular structures in interstitial fibrosis (above). At some point, restoration of main vessel patency no longer abrogates this process and has little effect on restoring tissue integrity and/or function.

microvascular disease is also associated with decreased expression of angiogenic proteins, like VEGF, which promote cell functions essential to sustain and repair the renal microvasculature.[33]

Some authors emphasize the distinction between "functional" rarefication of these microvessels, in which perfusion is diminished but the vascular structures remain intact, and "structural" rarefication, in which the vessels are eliminated by progressive fibrosis.[35] This may be an important distinction, insofar as "functional rarefication" may have greater potential for vascular repair under the influence of local reparative mechanisms known to be active, particularly in the renal medulla.[36] Experimental studies demonstrate the capacity for infusions of VEGF or extracorporeal ultrasound shock wave therapy,[37] for example, to restore functional perfusion in renal microvessels in a swine model of RVD.[38]

Mitochondrial Dysfunction and Injury

RVD is associated with structural and functional abnormalities of renal mitochondria.[39] Prolonged hypoperfusion triggers oxidative stress and inflammation, impairing mitochondrial bioenergetics and compromising the integrity of the inner mitochondrial membrane. Rapid restoration of blood flow during angioplasty may also amplify inflammation and oxidative stress in the poststenotic kidney (ischemia-reperfusion injury), contributing to mitochondrial injury and inadequate recovery following percutaneous renal angioplasty (PTRA). Patients with RVD present with elevated urinary levels of mitochondrial DNA, surrogate markers of mitochondrial injury.[40] Urinary mitochondrial DNA correlates with markers of renal injury and dysfunction and varies as a function of estimated GFR (eGFR) after therapy, underscoring the role of this organelle in renal damage in human RVD.

Transition from Hemodynamic to Inflammatory Injury

A striking feature from pathologic examination of both experimental and human studies of atherosclerotic RVD is the presence of inflammation in advanced disease (Figure 47.4b). Nephrectomy samples from patients with total occlusion demonstrate clusters of T cells and enhanced transforming growth factor-beta (TGF-β) in many subjects, which are somewhat less prominent in patients treated with statins.[41] Experimental studies in Smad3 knockout animals missing the downstream effector pathway for TGF-β indicate a major degree of protection from tubular atrophy and interstitial fibrosis despite high-grade vascular occlusion.[42] Transjugular poststenotic kidney biopsies from humans demonstrate widespread tissue immunostaining for TGF-β and a stepwise increase in both T cells and macrophages (CD68+ cells), compared with implantation biopsies obtained from normal kidney donors.[43] Both experimental models of RVD and human studies indicate robust cytokine release, including net secretion of tumor necrosis factor (TNF)-alpha and IL-6, from the poststenotic kidney, consistent with the activation of inflammatory pathways.[44] Once these injury pathways have been activated, restoration of vessel patency has only limited effectiveness on restoring kidney function. Repeat measurements of renal vein cytokines three months after technically successful revascularization and resolution of evident tissue hypoxia measured by BOLD magnetic resonance techniques indicate ongoing release of inflammatory cytokines, suggesting that restoring vessel patency alone does not reverse this process.[45] Experimental studies confirm that high renal vein cytokine release in a swine model of RVD predicts blunted renal recovery after revascularization.[46]

Fibrogenesis

Ultimately, profibrotic pathways become activated and lead to interstitial fibrosis. As this process ensues, microvascular occlusion leads to structural breakdown of tubules and a high prevalence of atubular glomeruli. Even if fibrosis were reversed, the lack of structural nephron components effectively limits recovery of meaningful glomerular filtration. Taken together, CKD associated with RVD undergoes a gradual transition from a hemodynamic disorder induced by impaired blood flow (to which the kidney partially can adapt) to a disorder eventually characterized by activation of tissue inflammation and fibrosis that no longer depends mainly on hemodynamic compromise. Hence, while restoring vessel patency and blood flow may be critical to restore function at some time points, it is equally clear that revascularization alone is ineffective under conditions when CKD is no longer primarily a hemodynamic problem. This is an important point for nephrologists to recognize during clinical management of patients with RVD. Identifying this transition and developing tools to reverse parenchymal injury remain areas where improved diagnostic tools and adjunctive therapy are sorely needed.

CLINICAL SYNDROMES WITH RVD AND CKD

Table 47.1 summarizes clinical manifestations most commonly associated with atherosclerotic RVD. Most of these are nonspecific, and also associated with other causes of CKD. Hence, recognizing clinical features more specific to RVD depends on clinical suspicion and perhaps most importantly, the clinician's

TABLE 47.1 Clinical Manifestations of Atherosclerotic Renovascular Disease (RVD)

Incidental Renal Artery Stenosis: normal renal function and blood pressure
Renovascular Hypertension: *de novo* or accelerated phase of treated essential HTN
Chronic Kidney Disease: "ischemic nephropathy"
Unilateral asymmetric or atrophic kidney
Bilateral RVD and/or solitary functioning kidney
Deteriorating GFR during antihypertensive drug therapy
Acute "functional renal insufficiency" during ACEI/ARB therapy
Circulatory congestion with impaired sodium/volume control
Refractory congestive heart failure
Rapidly developing ("flash") pulmonary edema

commitment to intervene if high-grade RVD is identified. Much of this commitment depends on the perceived balance of risk vs. benefit for an individual patient. Hence, defining the actual severity of each of the following manifestations is the first step in evaluating RVD.

Hypertension

Hypertension is nearly universal in this disorder, although occasional cases of ischemic renal atrophy occur with normal blood pressures. Most often, patients have a background of essential hypertension and other cardiovascular risk factors, including smoking and dyslipidemias.[47] In the age group at risk for atherosclerotic disease, preexisting hypertension sometimes worsens with rapid development of target-organ injury (such as a stroke or encephalopathy). Such a rapid or recent change often leads to diagnostic studies that reveal the presence of RVD. How long it has been present or how directly it participated in the blood pressure change is often unclear. Previous studies of renovascular hypertension focused on cases of severe, refractory hypertension for which medical therapy was intolerable or ineffective.[48] With the widespread use of agents that block the RAAS and other potent antihypertensive drugs, refractory hypertension is less commonly encountered from RVD than before. Other factors including obesity, sleep apnea, medication adherence, and other forms of CKD likely are more commonly encountered. Several small prospective trials in the 1990s comparing drug therapy to renal revascularization (primarily with angioplasty) failed to demonstrate major differences for all but a small fraction of patients with renovascular hypertension.[49] Crossover rates from medical therapy to renal revascularization ranged from 26 to 44% in these trials conducted over 6 months to 2 yr,[50–52] but have been substantially lower in recent prospective trials (6% in ASTRAL). Based on the observation that many patients "adapt" to reduced blood flow without major loss of kidney function or demonstrable tissue hypoxia, many argue that RVD with hypertension should be treated primarily with drug therapy. If BP and renal function are stable, little is to be gained by further diagnostic studies and specific vascular intervention, as long as the degree of vascular occlusion and kidney function remain stable.

Rapidly Developing Circulatory Congestion

Rapidly developing or refractory circulatory congestion, sometimes designated "flash pulmonary edema," is an increasingly recognized syndrome associated most often with bilateral RVD.[53] This disorder has complex elements related to the impaired sodium and volume excretion associated with RVD and poor kidney perfusion. The syndrome also appears to be related to relatively rapid rises in blood pressure that produce sudden impairment of left-ventricular function.[53] Patients are often caught between extremes of hypertension with CHF followed by intensive diuresis leading to volume depletion and azotemia. Mortality rates for patients with CHF and RVD are higher than those with CHF alone.[19,54] Renal revascularization has been associated with dramatic improvement in symptoms of CHF and reduced hospitalizations.

Deterioration of Kidney Function

Deterioration of kidney function related to RVD is a major clinical issue. Moderate hemodynamic reduction of filtration appears to be within the range of adaptation of the normal human kidney. For such patients, restoring vessel patency can increase GFR and lead to "recovery" of renal function, even for some patients with reduced GFR for a long period of time.[17] It may be argued that essentially all patients with otherwise unexplained loss of GFR should undergo some evaluation to exclude reversible disease (such as obstructive uropathy and/or RVD). Such diagnostic studies frequently identify some degree of vascular occlusion. The challenge is to define (1) to what extent RVD is primarily responsible for the loss of GFR and (2) whether restoring renal vessel patency is likely to result in recovery or stabilization of function.

Loss of GFR with Renin–Angiotensin System Blockade

Loss of GFR associated with renin–angiotensin system blockade merits specific consideration. Physiologic studies in the dog established that under conditions of normal sodium intake and normal blood flow, filtration pressures throughout the length of the glomerulus are maintained without angiotensin.[55] As perfusion pressures and afferent blood flows are reduced, however, activation of the renin–angiotensin system becomes essential to support filtration by increasing efferent arteriolar resistance.[56] Blockade of this effect can lead to abrupt loss of transcapillary filtration pressures and reduced GFR, even at levels of blood flow that are sufficient to maintain the kidney parenchyma. Hence, this has been termed "functional" acute renal failure associated clinically first with ACE inhibitors, but thereafter with nearly all agents that block the renin–angiotensin system, including angiotensin-receptor blockers.[57] The first clinical reports of this phenomenon were from patients with bilateral renal artery

stenosis or stenosis to a solitary functioning kidney.[58] Later reports suggest that similar changes could occur in patients with microvascular disease, particularly under conditions of volume depletion and/or diuretic use. As a result, identifying an acute loss of GFR after starting ACEIs/ARBs merits strong consideration as a signal that RVD approaching a critical level is present. Some authors recommend routinely withholding RAAS blockade as patients develop advancing CKD for the same reason.[59]

Recent Development of Progressive CKD without Other Explanation

Many, if not most, causes of CKD in older patients follow a relatively indolent rate of progression, including those attributed to nephrosclerosis and diabetes. Average loss of GFR was −2 mL/min/1.73 m^2/yr in the AASK trial and approximately −4 mL/min/1.73 m^2/yr in the MDRD trial. Loss of GFR in patients with RVD can appear to be especially variable, particularly when changes appear to be associated with adjustment of blood pressure levels and therapy.[57,60,61] A series of prospectively studied patients subjected to renal revascularization indicates that the likely change in renal function, specifically whether the slope of change in GFR would be positive, was related directly to the rate of loss of GFR in the months preceding revascularization[62] (Figure 47.5).

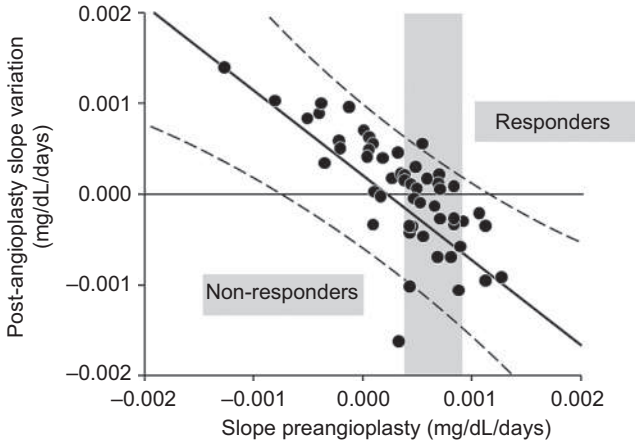

FIGURE 47.5 Plot of the rate of change in GFR (slope) before renal revascularization vs. the slope observed after revascularization. The likelihood of achieving a positive slope, i.e. recovery of kidney function, was strongly related to the rate of deterioration prior to undergoing renal revascularization. Other criteria, such as renal resistive index, biopsy characteristics, proteinuria, and evidence of tissue oxygenation, may provide insight as to the degree of reversibility but have not been studied in large populations prospectively. *Data from Muray et al.,[62] with permission.*

Loss of Kidney Function in Patients after Endovascular Stent Grafting

In recent years, endovascular grafts have gained widespread application to limit the risk of expanding abdominal aortic aneurysms. These aneurysms commonly are located adjacent to one or more renal arteries. Recent stent-graft designs sometimes migrate or are placed deliberately over the renal artery origins leading to an acquired iatrogenic form of renovascular occlusion.[63,64] Loss of renal function after endovascular aneurysm repair is a recognized risk associated with this therapy and carries measurable long-term risk for morbidity and mortality.[64,65] Recognition and restoration of blood flow can limit the loss of function and materially improve outcomes related to survival and avoidance of CKD.

DIAGNOSTIC CONSIDERATIONS IN CKD ASSOCIATED WITH RVD

The issues surrounding RVD are complex and include both characterizing the state of the vasculature and the state of the kidney. Implicitly, these questions must address both the severity of hemodynamic compromise and the viability of the poststenotic kidney, with particular emphasis on whether or not restoring blood flow will provide a net benefit or not.

The renal macro-vasculature is most commonly evaluated using noninvasive imaging modalities, including renal artery duplex ultrasound (RADUS), computerized tomographic (CT) angiography, and/or magnetic resonance (MR) angiography. Invasive contrast angiography remains the "gold standard" for most clinicians but is usually reserved for patients undergoing therapeutic intervention, usually with PTRA with stenting.

RADUS currently is the least expensive method of evaluating the renal vessels, primarily by evaluating Doppler velocities. Peak systolic velocities (PSVs) above 180−200 cm/sec and/or a renal to aortic ratio above 3.5 are thought to usually reflect a "significant" stenotic lesion. The correlation between PSV and severity of stenosis is variable, however, and the clinical significance rises with higher velocities. The CORAL trial set 300 cm/sec as a threshold for RADUS criteria to be considered for randomization.[66] This technique remains operator and center dependent and can demand both ultrasonographer expertise and time. In our center, these imaging values are most useful when "positive," as accessory vessels can sometimes be missed and areas of high velocity can be overlooked if the entire course of each renal artery is not imaged. Imaging segmental

vessels in both systole (end systolic velocity, or ESV) and diastole (end diastolic velocity or EDV) allows calculation of a "resistive index" defined as (1-(EDV/ESV)) × 100%. Higher levels of resistive index (nominally set above 80%) are associated with parenchymal fibrosis and a lower likelihood of recovering GFR after technically successful revascularization.[67] This has been questioned in other series,[68] but overall consensus has been that lower resistive index is associated with higher likelihood of preserved function.[69] Imaging the kidneys with ultrasound also provides measurements of kidney size, parenchymal thickness, cystic disease, and outflow tract obstruction.

CT angiography (Figure 47.1) provides ever higher resolution and precise characterization of main vessel anatomy, small vessel aberrations including fibromuscular dysplasia and renal arterial aneurysms, in addition to identifying vascular calcification, parenchymal thickness, perfusion, and structural integrity. Radiation exposure continues to fall as a function of multiple detector and rapid acquisition technology, as does contrast exposure.

MR angiography avoids radiation exposure and can provide excellent vascular imaging with gadolinium contrast. Its use in CKD patients with contrast has declined after reports of nephrogenic systemic fibrosis in patients with reduced GFR and repeated exposure. As a result, newer imaging techniques attempt to achieve vessel and perfusion measurements without contrast. BOLD MR has been proposed as a method to evaluate tissue oxygenation within both cortex and medulla, using the properties of deoxyhemoglobin as a paramagnetic modifier of local magnetic dipole polarization.[70–72] Analytical techniques for interpreting deoxyhemoglobin maps remain investigational, but these tools clearly are suited for identifying expanding hypoxic zones within kidneys severely affected by RVD.[73–75] They hold enormous promise for identifying hypoxic kidneys and for evaluating the effects of modifying blood flow and/or oxygen consumption in nearly "real time" without contrast or radiation exposure. Other experimental techniques using MR, such as diffusion-weighted imaging or MR elastography, offer the potential to examine development of kidney fibrosis *in vivo.*

The State of the Kidney

Remarkably little attention has been focused on the degree of parenchymal injury and potential for recovery in discussing CKD associated with RVD. Individuals with atherosclerotic RVD are typically older and have a long exposure history to the atherosclerotic milieu, often complicated by hypertension, obesity, and smoking. Histologic characterization of parenchymal injury in such patients is associated with reduced function and progressive CKD,[76] although these features are not closely related to the degree of stenosis.[61] Pathologic estimates of the degree of fibrosis and atherosclerotic disease from nephrectomy specimens vary widely.[41] Implantation biopsies from kidney donors demonstrate substantial preexisting interstitial fibrosis and changes attributed to "nephrosclerosis" as a function of age that are not closely related to blood pressure.[77,78] Intraoperative biopsy samples during renal revascularization identify evidence of atheroemboli in many patients (36%) that predicted poor long-term survival.[79] The presence of both interstitial inflammatory and fibrotic changes in these patients led some to suggest that vascular occlusive disease is only one of several contributors to the CKD in this setting.[80]

Recent studies emphasize the role of inflammatory changes, both in the renal vessels and in the kidney parenchyma. Kotliar et al. identified T-cell infiltrates within the vascular wall of early atherosclerotic RVD that corresponded to alterations in T-cell populations in peripheral blood.[29] These cell populations were vastly expanded in autopsy samples obtained in a different group of subjects, suggesting to the authors that early inflammatory changes within the renal vasculature precede both severe occlusion and clinical CKD. Gloviczki et al. reported findings obtained from transjugular biopsies of the poststenotic kidney in atherosclerotic RVD.[43] When compared to implantation biopsies from normal kidney donors or nephrectomy specimens from RVD with total occlusion, the moderate RVD patients had severely elevated tissue levels of TGF-β. Groups with more severe vascular occlusion demonstrated ever higher cellular infiltrates of T cells and macrophages (defined as CD68+ cells). Sampling of the renal veins demonstrated substantial increases in inflammatory cytokines, including monocyte chemoattractant protein-1, IL-6, and TNF-α, in addition to elevated circulating neutrophil gelatinase-associated lipocalin.[44] Although renal revascularization did improve cortical blood perfusion and reversed hypoxia in a group of patients with high-grade atherosclerotic RVD, it generally failed to reverse these inflammatory cytokine signatures or restore GFR.[45] Taken together, we interpret these data to indicate that vascular occlusive disease may initiate and/or provoke CKD and inflammatory injury, but once in progress, revascularization alone fails to reverse many of these processes.

TREATMENT OF CKD ASSOCIATED WITH RVD

Medical Therapy for CKD Associated with RVD

The mainstay of treating CKD in this instance is similar to that employed for most other causes, specifically achieving blood pressure control, limiting atherosclerotic risk and complications, treating anemia and electrolyte disorders, and monitoring progressive disease. Normally, these maneuvers will be essential both for initial and ongoing therapy, regardless of other interventions. Antihypertensive drug therapy with RAAS-blocking drugs in RVD has a particular predilection for unmasking "near critical" vascular occlusion by producing a functional fall in filtration. Remarkably, a clinically detectable rise in S[Cr] after RAAS blockade is uncommon even in patients with known bilateral RVD.[81] A prospective registry of 621 patients treated over a decade in the United Kingdom indicated that 357/378 (92%) of patients treated with RAAS blockade experienced no adverse events, including 54/69 (78%) of those with known RVD above 60% lumen occlusion. On a statistical basis, those treated with ACEI/ARB therapy had lower mortality during follow-up, an observation consistent with other reports.[82–84] 16 of 21 patients that were "intolerant" to RAAS blockade were rechallenged after revascularization and treated successfully with ACEIs. Hence, application of RAAS blockade should be part of medical therapy in this condition, albeit with awareness of the potential changes in both serum potassium (S[K]) and S[Cr] that sometime occur. These are usually evident within a few days after starting therapy, arguing for clinicians to recheck laboratory values sometime in the first week. Targeted therapy to withdraw tobacco use and administer statin-class therapy should be attempted—both for the likely reduction in atherosclerotic risk and for additional effects that appear to reduce inflammatory injury within the kidney parenchyma.

As with other vascular occlusive diseases, periodic reevaluation of the vascular stenosis generally is warranted. Prospective RADUS studies in the 1990s indicated that high-grade (>60%) occlusion from atherosclerotic disease progresses in severity in more than half the cases (defined as a rise in velocity by more than 100 cm/sec).[85] Remarkably, these changes are often barely detectable clinically, with a fall in kidney length by more than 1 cm developing in 5.5–20% depending on initial severity, and a measurable rise in S[Cr] in less than 10%.[86] As a practical matter, the clinical issue resides primarily in whether progressive disease now affects the entire functioning renal mass, i.e. both kidneys or stenosis to a solitary functioning kidney.

Some authors argue that progressive deterioration in GFR—from nearly any cause—merits withdrawal of RAAS blockade.[59] For CKD associated with RVD, this approach makes especially good sense and may allow recovery of renal function on a hemodynamic basis. Such a development may signal the potential benefit of revascularization as noted above.

Renal Revascularization for CKD Associated with RVD

Removing vascular obstruction would seem to be an obvious step in treating RVD. From the perspective of interventionalists and vascular surgeons, this has immediate face validity, although multiple series and several small, prospective trials until now fail to identify consistent or clinically significant recovery of function. An important element in this discussion is the heterogeneity of outcomes for all forms of revascularization, including angioplasty, endovascular stenting, and surgical bypass. Results from more than 300 azotemic patients (pretreatment S[Cr] >2.0 mg/dL) subjected to surgical revascularization indicate that nearly 28% had a "significant" fall in S[Cr] (i.e. more than 1.0 mg/dL).[18] Most (52%) experienced essentially no change, whereas 20% actually had important worsening of kidney function (rise of S[Cr] by more than 1.0 mg/dL). As a result, overall group average levels of S[Cr] did not change. Similar results have been seen in numerous series, regardless of the specific revascularization procedure or level of change in function defined as "worthwhile."[87,88] There is little doubt that the group with improved renal function in this series had a major clinical benefit, with improvement in function and blood pressure control evident for years. Those with no change, it may be argued, were unlikely to develop progressive disease. The group with deterioration of kidney function, however, commonly developed ESRD within the year and/or died. Similar outcomes have been reported in surgical series from Wake Forest, in which long-term survival improved only in those with increased eGFR after successful surgical revascularization.[89]

In recent years, endovascular stenting has become the initial and preferred procedure for renal revascularization in atherosclerotic RVD,[64] with surgical reconstruction being limited to failed stenting and/or complex aortic surgical reconstructions. The results of surgical series have been expanded within the context of recent prospective trials conducted over relatively short terms. In the STAR trial, reductions in creatinine clearance occurred in 16–22% but were not different between those treated with stents or medical therapy only.[90] Results from the ASTRAL trial indicate progression to a "renal endpoint" in 20–22% after 5 yr, but outcomes

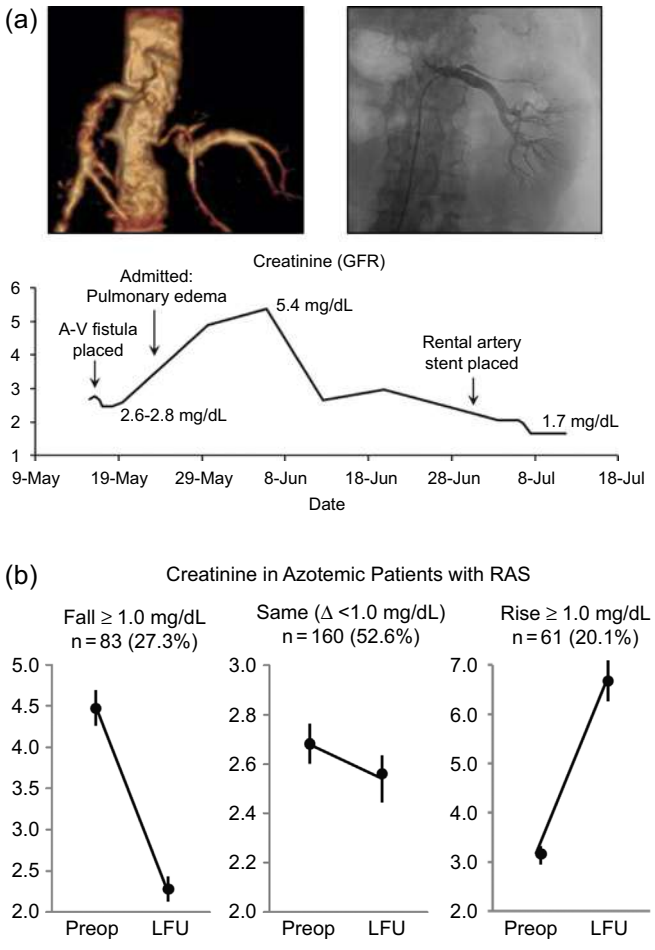

FIGURE 47.6 (a) S[Cr] levels during progression of RVD in a 62-yr-old woman with a solitary functioning kidney. Gradual development of azotemia led to creation of an arteriovenous fistula and preparation for dialysis. An episode of pulmonary edema, severe hypertension, and worsening kidney function prompted identification of a high grade lesion with RVD. Temporarily withholding RAAS blockade and renal artery stenting led to recovery of kidney function. Blood pressure control and kidney function have now been stable for more than 5 yr without requiring dialytic support. (b) Follow-up values of S[Cr] in more than 300 patients with S[Cr] levels above 2.0 mg/dL subjected to renal revascularization. Although 27% of these individuals had major clinical improvements in GFR, these were offset by 20% whose function deteriorated soon afterward. As a result, mean values for the entire group did not change. These results are consistent with numerous other reports and prospective trials indicating heterogeneous outcomes after all forms of revascularization to date. *From reference 10, with permission.*

did not differ, on average, between those with stenting and those without.[12] Overall cardiovascular outcomes did not differ in CORAL, for which progressive renal dysfunction (16–20%) was the single most common outcome in both stented and nonstented patients.[13] Such group averages obscure the differences between those with clinical improvement and those whose renal dysfunction progressed. In the latter two trials, reported overall cardiovascular endpoints were two- to threefold more common than renal events.[91] As a result, heterogeneity among patients and their comorbid diseases has been so great as to make clinical benefits from restoring the blood supply to the kidney in RVD unpredictable.

Do the negative results from these trials indicate that revascularization of the kidney is of no benefit? Figure 47.6 illustrates one case in which progressive CKD was identified in a woman with a solitary functioning kidney and a nonfunctioning kidney related to multiple cysts. With the development of rising S[Cr], preparation for RRT was made with creation of dialysis access. After an episode of worsening hypertension and azotemia, the responsible clinicians identified high-grade RVD to the functioning kidney. Renal function improved slightly after removing the ACEI in her drug regimen. Renal artery stent placement lowered blood pressures and restored kidney function to baseline levels consistent with her solitary kidney. This individual now has done well for more than 5 yr after revascularization. Observational series from "high-risk" subsets with rapidly deteriorating GFR and severe hypertension, as well as episodes of circulatory congestion, demonstrate major improvements in survival as compared with medical therapy alone.[19] In such instances, the net benefit of identifying and treating RVD has major outcome and mortality consequences that should not be overlooked. Table 47.2 summarizes a recent review of renal artery stenting and the recommendations that might be applied in considering the relative merits of medical therapy and surveillance only vs. medical therapy and revascularization. Development of additional tools to identify "viable" or "hibernating" kidneys that can benefit from revascularization and recover GFR is a high priority in this field (Table 47.3).

Adjunctive Therapy: Role of Mitochondrial Protection, Cell-Based Therapy, and Other Protective Measures

The aforementioned clinical data indicate that CKD associated with RVD often does not reverse after restoring vessel patency alone. The processes of injury within the kidney are dynamic and undergo a transition from a hemodynamic to inflammatory/profibrotic processes. It is also possible that suddenly flooding the kidney with highly oxygenated blood after a period of prolonged flow reduction may induce "ischemia/reperfusion" injury, analogous to that observed in muscle and

TABLE 47.2 Functional Classification for Atherosclerotic Renal Artery Stenosis

Grade	Manifestations
Grade I	Renal artery stenosis present, but no clinical manifestations (normal blood pressure and normal renal function)
Grade II	Renal artery stenosis present, but patients have medically controlled hypertension and normal renal function
Grade III	Renal artery stenosis present and patients have evidence of abnormal renal function, medically refractory hypertension, or evidence of volume overload

TABLE 47.3 Major Features That Influence Revascularization vs. Surveillance Therapy for Occlusive Renovascular Disease

FACTORS FAVORING MEDICAL THERAPY AND REVASCULARIZATION FOR RENAL ARTERY STENOSIS
Progressive decline in GFR during treatment of hypertension
Failure to achieve adequate blood pressure control with optimal medical therapy
Rapid or recurrent decline in the GFR in association with a reduction in systemic pressure
Decline in GFR during therapy with ACEIs or ARBs
Recurrent congestive heart failure in a patient in whom the adequacy of left ventricular failure does not explain the cause
Absence of other primary kidney disease and/or proteinuria
FACTORS FAVORING MEDICAL THERAPY AND SURVEILLANCE OF RENAL ARTERY DISEASE
Controlled blood pressure with stable renal function
Stable renal artery stenosis without progression on surveillance studies (e.g. serial duplex ultrasound)
Advanced age and/or limited life expectancy
Extensive comorbidities that make revascularization too risky
High risk or previous experience with atheroembolic disease
Other concomitant renal parenchymal diseases that cause progressive renal dysfunction (e.g. diabetic nephropathy)
Proteinuria

Modified from the writing group for Atherosclerotic Peripheral Vascular Disease Symposium.[100]

many other tissues.[92,93] In these cases, abundant oxygen may be delivered into tissue with damaged mitochondrial electron transport chains that generate toxic ROS.[94] Studies in an experimental swine model and human subjects indicate that preinfusion with an agent that stabilizes the mitochondrial transition pore produces improvements in microvascular recovery and GFR after renal artery angioplasty.[95,96]

An additional strategy for recovering renal function derives from the observation that microvascular rarefication and inflammatory injury pathways persist after restoring renal perfusion. Experimental work with endothelial progenitor cells indicates that such vessels can be repaired with intrarenal cell therapy targeted at angiogenesis,[97] even without revascularization. Further work using autologous, adipose-derived mesenchymal stem cells (MSCs) delivered into the kidney indicates that microvessels can be repaired, along with reduction in inflammatory signaling, oxidative stress, and macrophage activation[98] (Figure 47.7a and b). Initial studies in human subjects with atherosclerotic RVD demonstrate a rise in cortical blood flow and reduced tissue hypoxia three months after infusion of autologous MSC.[99] These studies indicate that adjunctive, cell-based maneuvers targeted to local injury mechanisms may provide important supplemental pathways that allow repair and restoration of microvascular structures.

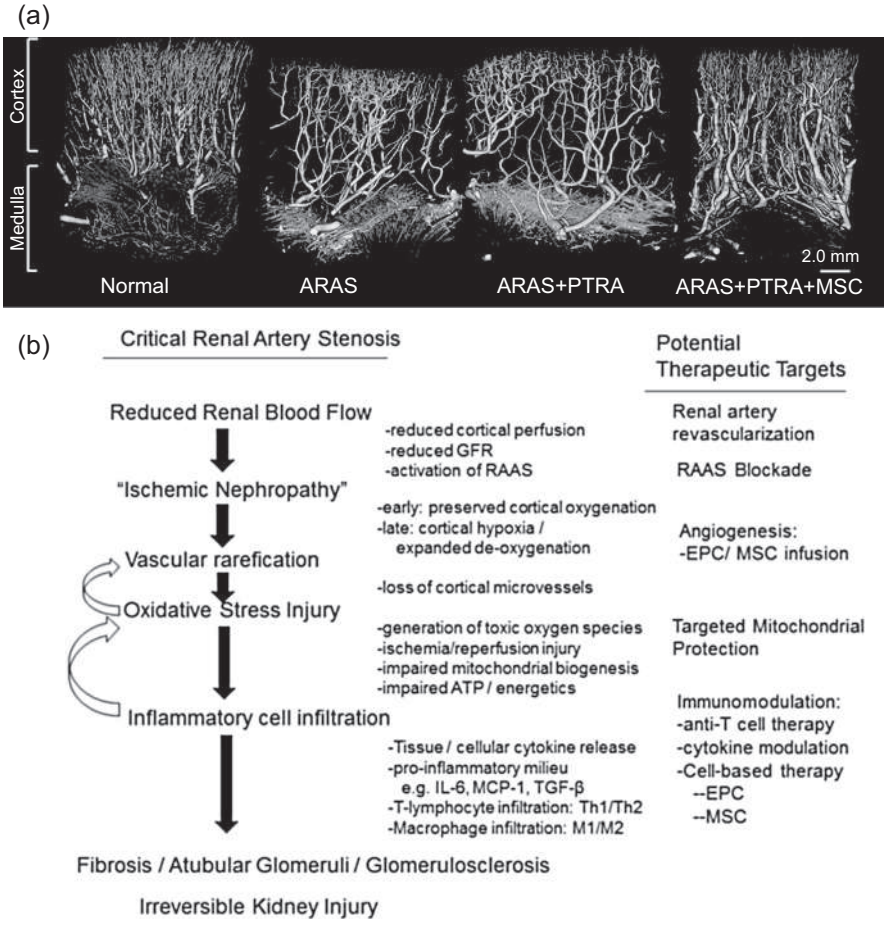

FIGURE 47.7 (a) Cell-based therapy as an adjunct to renal revascularization: Micro-CT images from experimental atherosclerotic RVD treated with PTRA with or without intrarenal administration of adipose-derived MSC. Loss of microvessels within the stenotic kidneys is only partially restored with PTRA alone, whereas addition of MSC to PTRA allowed restoration of microvessels associated with improvements in blood flow and GFR. *PTRA*, percutaneous renal angioplasty. (b) Injury pathways and potential targets in atherosclerotic RVD. This schematic highlights pathways of vascular rarefication, oxidative stress injury, and inflammatory mechanisms in the poststenotic kidney. The right panel identifies specific therapeutic targets that may alleviate these injury pathways, over and above restoring blood flow. *EPC*, endothelial progenitor cells; *MCP*, monocyte chemoattractant protein; *MSC*, mesenchymal stem cells. *(a) Reproduced from reference 98, with permission. CONCLUSION

Large vessel RVD is a common manifestation of atherosclerosis, particularly in aging populations. Under some conditions, RVD functions as the critical pathway that reduces blood flow and eventually worsens hypoxia within the kidney, associated with vascular rarefaction. Eventually, these processes activate tissue injury with cytokine release, mitochondrial dysfunction, activation of TGF-β, and accumulation of cellular inflammatory infiltrates with both T cells and macrophages. Tissue fibrosis ensues. The time course for these events appears widely variable and reflects additional factors such as age, atherosclerotic milieu, diabetes, and smoking, among others. Although restoring vessel patency and improving tissue perfusion would seem to be a rational approach, the net benefit of revascularization alone is limited and appears to depend on the state of the poststenotic kidney regarding ongoing inflammatory injury. Both the timing and achieved benefit of renal revascularization depend on experienced clinicians recognizing the hemodynamic severity of RVD and the variability in determinants of recovering function, including kidney size, duration of occlusion, vascular rarefaction, and inflammatory injury. Successful management of RVD in the future will depend on developing more precise evaluation of these factors, and likely will require adjunctive maneuvers to reverse ischemia/reperfusion and induce reparative pathways.

QUESTIONS AND ANSWERS

Question 1

A 73-yr-old man is identified having a 70% stenosis of his right renal artery during CT angiography for abdominal pain. The left was normal. He has two-vessel coronary disease, for which stents were placed a month earlier. His cardiologist recommends that he must undergo renal artery stenting after six months of clopidogrel therapy.

He has hypertension for 15 yr and now feels well. His current medications include an ACE inhibitor, a beta blocker, an alpha blocker, a diuretic, clopidogrel, and aspirin.

BP: 145/74 mm Hg, P: 65
Chest clear, no edema
Labs: CBC normal, S[Cr] 1.4 mg/dL (eGFR: 49 mL/min/1.73 m^2), sodium 140 mEq/L, and potassium 4.6 mEq/L

Which of the following most accurately describes the likely results of renal artery stenting for this individual?

A. Lower antihypertensive drug requirements
B. Improved kidney function
C. Reduced angina
D. Regression of left ventricular hypertrophy
E. Lower mortality

Answer: A

Several studies demonstrate that antihypertensive medication requirements are lower, but usually not withdrawn after revascularization, making (A) most likely. Other potential benefits including changes in kidney function rarely occur, especially with unilateral disease (making (B) incorrect). Most importantly, no mortality benefits have been observed (E). (C) and (D) sometimes are benefits with effective BP control but are not directly related to stenting. These points have been underscored in several trials including ASTRAL, STAR, and CORAL.[12,13,90]

Question 2

A 69-yr-old woman returns after a recent hospitalization with congestive heart failure (EF 40%) and a rise in creatinine from 1.2 to 2.6 mg/dL. An ultrasound examination identifies a small right kidney (7.4 cm) and normal sized left kidney (10.8 cm). Doppler ultrasound demonstrates no flow to the right kidney. The left has a PSV of 425 cm/sec and estimated more than 70% stenosis.

Blood pressure was 180/80 mm Hg initially, but fell to 130/80 after treatment with ramipril, amlodipine, and furosemide. Creatinine 2.7 mg/dL, sodium 139 mEq/L, and potassium 4.9 mEq/L.

Which of the following is most likely to stabilize kidney function and fluid status for this patient?

A. Laparoscopic nephrectomy of the right kidney
B. Withdrawal of ramipril
C. Addition of spironolactone
D. Transition to an angiotensin receptor blocker
E. Endovascular stent placement

Answer: E

This individual has both impaired cardiac pump function and reduced GFR with a solitary functioning kidney. In this situation, hospitalization for recurrent CHF can be reduced by renal revascularization[19,54] taking (E) the best choice. Option (A) would have no effect on kidney function. One might withdraw ramipril (B), but this would impair cardiac function and allow higher BP, making it less correct. No benefits in this situation to a transition to ARB (same effect as doing nothing) or spironolactone (C).

Question 3

Which of the following is most probable for an 81-yr-old man with recently identified, high-grade renal arterial stenosis (S[Cr] 1.5 mg/dL) and a small abdominal aortic aneurysm (3.2 cm) over the next 2 yr?

A. Cerebrovascular event (stroke, TIA)
B. Congestive cardiac failure
C. End-stage kidney disease
D. Aneurysm rupture
E. Development of angina

Answer: E

Patients with atherosclerotic renal artery stenosis are at highest risk for developing new cardiovascular symptoms. New angina and coronary symptoms (E) are most common, as directly reflected from Figure 47.2 from the Medicare Claims review of Kalra et al.[11] End-stage disease (C) and aneurysm rupture (D) are distinctly less probable, whereas congestive heart failure (B) and CNS symptoms (A) are intermediate.

Question 4

A 65-yr-old woman is referred for CKD stage 3. Two years ago, she developed a rise in blood pressure to 170/95 mm Hg during a routine examination. Previous BP levels always had been below 140/90. Current medications include losartan, amlodipine, and indapamide.

BP: 134/70 mm Hg, P: 74 bpm trace edema. BMI: 27 kg/m^2

S[Cr] 1.5 mg/dL (CKD EPI eGFR: 36 mL/min/1.73 m^2)

Doppler ultrasound identified high velocities (310 cm/sec) to the left kidney (9.0 cm) and normal velocities (85 cm/sec) to the right kidney (10.8 cm).

Which of the following MOST accurately describes the state of the left kidney?

A. Despite reduced blood flow, cortical oxygenation is preserved
B. Progressive medullary hypoxia is inevitable
C. Reduced GFR magnifies medullary oxygen deprivation
D. Angiotensin receptor blockade limits renin release
E. Restoring renal blood flow will reverse cortical inflammation

Answer: A

Experimental and human studies indicate that moderate RVD is associated with a loss of blood flow and volume, but well-preserved cortical oxygenation, in part because the cortex receives a large excess of oxygenated blood, making (A) correct.[25] Functional and tissue biopsy information indicates that medullary hypoxia can be stable, in part because reduced GFR lowers oxygen consumption related to solute transport, making (B) and (C) incorrect.[101] Blockade of the renin–angiotensin system tends to stimulate renin release (opposite of (D)), and when inflammatory pathways become activated, restoring blood flow alone fails to abrogate that process, making (E) incorrect.

Question 5

You are asked to evaluate resistant hypertension and azotemia in a 56-yr-old woman with atherosclerotic RVD. S[Cr] had been 1.7 mg/dL during therapy with losartan, which had lowered BP to 130/70 mm Hg. She had undergone renal artery angioplasty a year previously, after which her angiotensin receptor blocker had been withdrawn.

Current medications: carvedilol, amlodipine, and furosemide.

BP: 180/98 mm Hg. Well-appearing. Audible epigastric bruit.

Urinalysis: normal, S[Cr]: 1.4 mg/dL (CKD EPI eGFR: 42 mL/min/1.73 m^2)., S[K]: 3.4 mEq/L.

CT angiography demonstrates two normal sized kidneys with residual stenosis in both renal arteries.

Which of the following MOST accurately describes the role of renin–angiotensin blockade in this patient?

A. ACE inhibition should be avoided due to bilateral RVD
B. A direct renin inhibitor (aliskiren) would be the preferred agent
C. Administration of losartan would likely lower BP
D. An angiotensin receptor blocker should be started only after repeat angioplasty

Answer: C

The vast majority of patients (92%) with RVD (either atherosclerotic or fibromuscular in origin) tolerate blockade of the renin–angiotensin system, including bilateral disease (78%).[81] The finding of recurrent hypertension and lower S[K] is consistent with activation of the renin–angiotensin system and likely would respond to blockade, making (C) the preferred answer. It is incorrect to infer that these agents should be avoided, as long-term outcomes and mortality appear to be improved with RAAS blockade,[83] making (A) incorrect. The role of aliskiren is not precisely defined, but has no advantage. If azotemia worsens, repeat revascularization may be considered, but should not be a necessary first step to therapy, making (D) less correct.

Abstract

Polycystic kidney disease (PKD) results from single-gene defects transmitted as either autosomal dominant or autosomal recessive traits. Different ages of onset, variability in kidney disease progression, and a diverse array of extrarenal manifestations distinguish these disorders. In autosomal dominant PKD (ADPKD), defects in either of two causative genes, *PKD1* or *PKD2*, can initiate cyst formation resulting from a germline mutation in one allele and a somatic mutation in the second allele. The respective protein products, polycystin-1 and polycystin-2, form a receptor-channel complex that is variably expressed in the plasma cell membrane, as well as in the primary apical cilia membrane. Autosomal recessive PKD (ARPKD) results from mutations in the *PKHD1* gene, which encodes the protein product, fibrocystin/polyductin, which is also expressed in primary cilia. Recent studies have identified atypical forms of ADPKD and ARPKD that result from mutation of other genes. This chapter considers PKD genetics, clinical and genetic diagnosis, management of organ-specific complications, and future directions for disease monitoring and potential therapies.

SCOPE OF THE PROBLEM

Polycystic kidney disease (PKD) describes a heterogeneous set of disorders that result from single-gene defects transmitted as either autosomal dominant or autosomal recessive traits. Although the development of fluid-filled cysts and progressive impairment of renal function is a common feature, these disorders are distinguished by different ages of onset, variable rates of renal disease progression, and a diverse array of extrarenal manifestations.

Autosomal dominant polycystic kidney disease (ADPKD; MIM 601313, MIM 613095) is by far the most common form of PKD, affecting between 1/500 and 1/2000 individuals. The disease is characterized by age-dependent occurrence of bilateral, multiple renal cysts, and a variety of extrarenal manifestations. The latter include cysts in the liver bile ducts, pancreatic ducts, seminal vesicles, and arachnoid membrane, as well as noncystic manifestations, such as intracranial aneurysms (ICA) and dolichoectasias, aortic root dilatation and aneurysms, mitral valve prolapse, and abdominal wall hernias[1] (Figure 48.1). Autosomal dominant polycystic liver disease (ADPLD; MIM 177060, MIM104160, MIM 611341) is a similarly common, related condition in which individuals have an age-dependent presentation of phenotypically identical liver cysts but few, if any renal cysts.[2] There are rare families that have genetically distinct, atypical forms of ADPKD that had initially been mistaken for the more common forms of the disease. One cohort has variably cystic kidneys and livers, but the kidneys are not enlarged and the disease does not progress to end-stage renal disease (ESRD).[3] Another set of families had chronic interstitial fibrosis and mild, variably cystic kidneys that also were not enlarged, but in which the cystic disease progressed to ESRD.[4]

Autosomal recessive polycystic kidney disease (ARPKD; MIM 606702) is less common but typically has a more severe, early onset form of cystic disease affecting 1/26,500 live births.[5] Affected patients have a spectrum of clinical phenotypes arising from cystic involvement of the renal collecting ducts and biliary tract.[6] Their parents may have mild liver cystic disease, which can be mistaken for mild forms of PLD.[7,8] The basic defects observed in ARPKD suggest defects in the terminal differentiation of the renal collecting duct and intrahepatic biliary ducts (Figures 48.2 and 48.3). There is also a very rare form of ARPKD that presents in childhood with enlarged kidneys and progressive

renal dysfunction, but which is both clinically and genetically distinct in that there is no clinical evidence of hepatic fibrosis. The disease results from mutations in *DZIPL1* (MIM 617570).[11]

Major advances in understanding the pathogenesis of human polycystic diseases have included the discovery of the mutated genes and their novel protein products by positional cloning, the understanding that multiple somatic mutations are implicated in the molecular pathogenesis of ADPKD, the recognition that there are a number of recessively transmitted disorders that can mimic the renal expression of ARPKD, and the emergence of a once disregarded organelle, the primary apical cilium, as the focus of investigation not just in renal cystic diseases but in a broad spectrum of biological processes (reviewed in reference 1); and recent evidence indicating that alterations in cell metabolism are a hallmark of the disease.[12] These specific advances, coupled with broader investigations in the field, have led to improved understanding of the clinical disease and the phenotypic variations; resulted in a steady increase in the number of therapeutic clinical trials in patients; and culminated in the first therapy approved by regulatory authorities (the US Food and Drug Administration [FDA] and the European Medicines Agency [EMA]) that may slow progression of disease in those most at risk.[13] And yet, the goal of identifying targeted treatment that arrests disease progression remains a work in progress.

PATHOPHYSIOLOGY

ADPKD

Molecular Basis of Disease: PKD1 and PKD2

Mutations of *PKD1* account for approximately 85% of ADPKD cases and mutations of *PKD2* for most of the remainder.[1] *PKD1* mutations are more common because *PKD1* is much larger than *PKD2*, and its sequence is more mutable. DNA testing methods can identify mutations in up to approximately 93% of affected individuals.[14] *De novo* mutations account for up to 10% of cases, although at least one study suggests a lower frequency.[15] The high mutability of *PKD1* likely explains

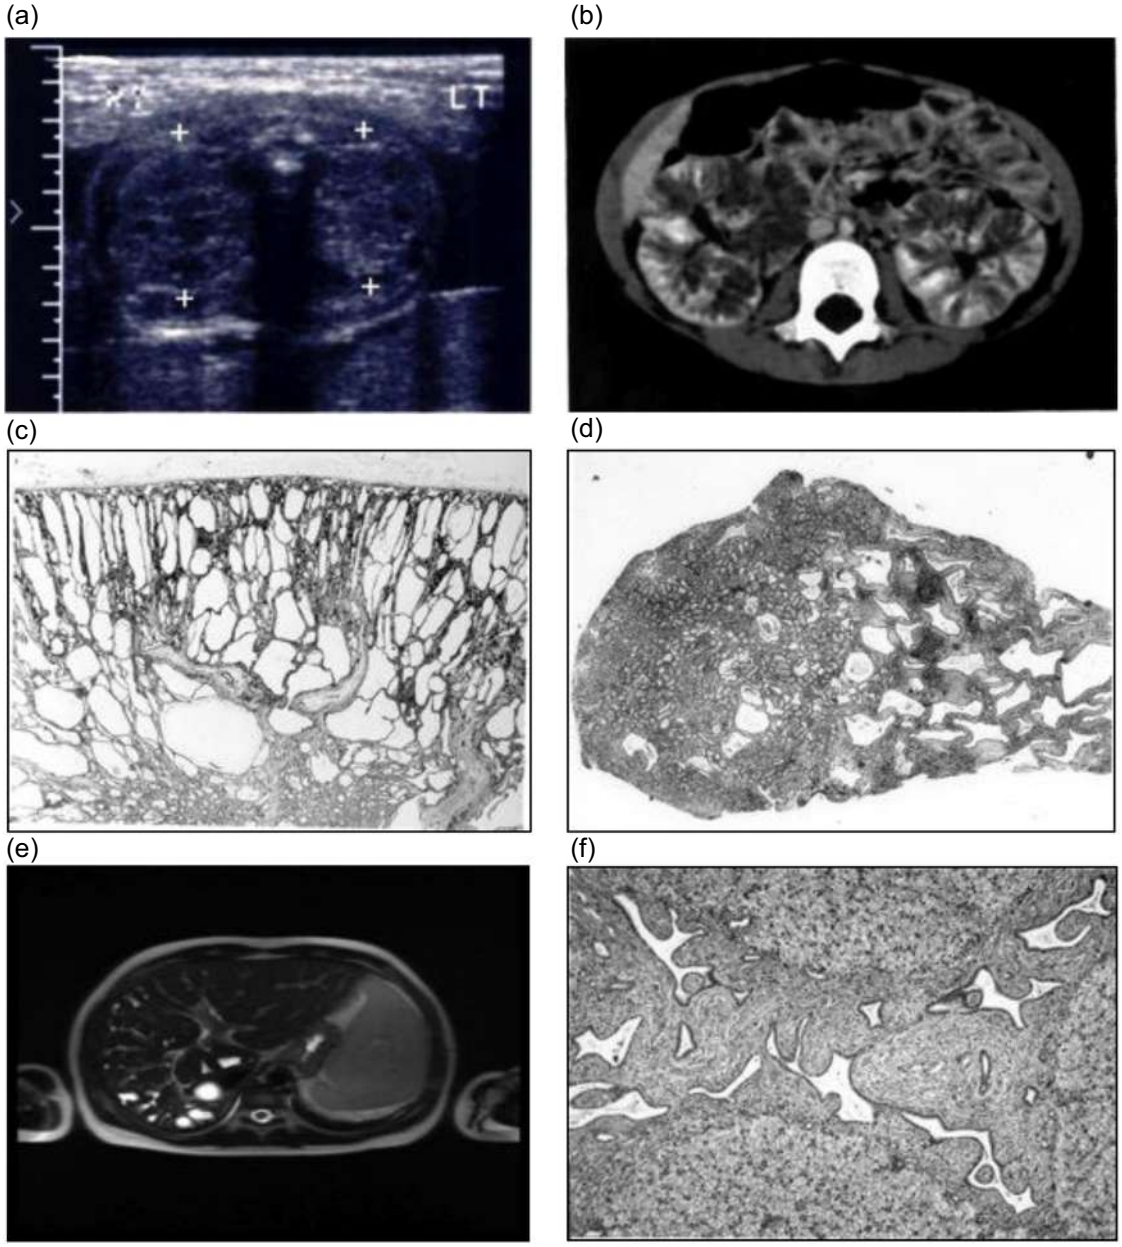

FIGURE 48.2 **Radiologic findings and pathologic features associated with autosomal recessive polycystic kidney disease (ARPKD).** (a) Neonatal sonography with nephromegaly and increased echogenicity. (b) Contrast-enhanced CT in a symptomatic 4-year-old girl reveals a striated nephrogram and prolonged corticomedullary contrast retention. (c) Light microscopy: ARPKD kidney from a 1-year-old child reveals discrete medullary cysts and dilated collecting ducts, H&E × 10. (d) Light microscopy: later-onset ARPKD kidney with prominent medullary ductal ectasia, H&E × 10. (e) Coronal heavily T2-weighted image of the abdomen in an 8-year-old boy reveals marked cystic and fusiform dilatation of the intrahepatic biliary system. why *de novo* mutations arise much more frequently in *PKD1* than in *PKD2* and why private mutations (i.e. unique to a single family) in *PKD1* are more abundant than in *PKD2*.[16,17]

One characteristic feature of ADPKD is its clinical variability. Even within a family, the pattern or presence of extrarenal manifestations and the severity of cystic liver and kidney disease can vary markedly. The hypervariability is perhaps most dramatic on an individual level, since only a small fraction of renal and biliary tubules within a PKD patient's organs give rise to cysts (Figure 48.4). This characteristic provided a clue to the molecular basis of disease. Although the disease is transmitted as an autosomal dominant trait, it is recessive on a cellular level.[18,19] In other words, ADPKD is genetically a "two-hit" disease analogous to what has

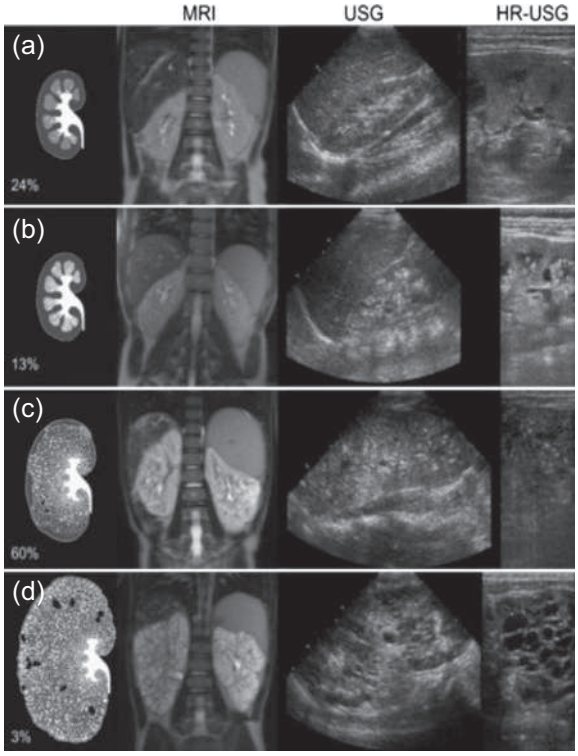

FIGURE 48.3 **Spectrum of kidney abnormalities in Autosomal recessive polycystic kidney disease (ARPKD).** Artist's rendering, MRI, standard ultrasound (USG), and high-resolution ultrasound (HR-USG) images showing the spectrum of kidney abnormalities in a cohort of 62 patients with ARPKD. Percentages refer to the frequency of each pattern within their population. (a) Normal-sized kidneys with medullary hyperechogenicity and some visibly dilated ducts; (b) Mildly enlarged kidneys with more extensive medullary hyperechogenicity and ductal dilations, with cortical sparing; (c) Enlarged kidneys with diffuse hyperechogenicity and ductal dilatation, with only partial cortical sparing and few macrocysts; (d) Massively enlarged kidneys with complete involvement of medulla and cortex and multiple macrocysts. *From Gunay-Aygun et al.[20] with permission from the American Society of Nephrology.*

been described for tumor suppressor genes like *Rb* (retinoblastoma). Cysts form only when both copies of the gene are mutated or the activity level of the complex somehow otherwise compromised.

The molecular recessive nature of ADPKD indicates that *PKD1* and *PKD2* mutations reduce gene function. This observation suggests a threshold model to explain cyst initiation[21–23] (Figure 48.5). Cysts arise when the combined effects of a germline and acquired PKD mutation reduce PKD gene activity below the threshold. The cellular threshold is not known but likely differs in cells of different nephron segments and may even change over time depending on developmental stage or other genetic or cellular factors. Genetic modifiers or other stimuli that alter the activity of critical upstream or downstream factors also could change the threshold.[23]

With this information, one can explain much of the observed clinical variability. Intraindividual variability occurs because cysts arise only from cells where PKD gene function has fallen below the threshold. Intrafamilial variability is explained in part by the same mechanism. Somatic mutation is a stochastic process. The timing, location, and frequency of the second hits determine the severity of disease. Other genetic modifying loci segregating randomly within a family also may alter the cyst-initiation threshold or the rate of cyst growth/fluid secretion once the threshold is breached.[23] Interfamilial differences mostly can be explained by the nature of the germline mutation. Families with particularly severe germline mutations are more likely to have multiple individuals with more severe clinical disease. Conversely families with germline mutations of *PKD2* generally have less severe disease than those with mutation of *PKD1*, probably because *PKD2* is less mutable.[24] Variants at modifying loci also likely play a role.[25]

It is likely that the same "two-hit" process accounts for the high prevalence of simple cysts in the general population as it ages. Although no studies have directly examined this thesis, the large population of cells at risk (all renal epithelial cells), the long duration of risk (lifetime), and the documented somatic instability of the loci make the probability of acquiring two somatic hits in either *PKD1* or *PKD2* very high.

ADPKD, ADPLD, and ADTKD—Overlapping Phenotypes and Genotypes

In individuals with classic ADPKD and ADPLD, there usually is little question about the underlying diagnosis, as renal cysts are the predominant manifestation in one and liver cysts in the other. With increased availability of genetic testing, however, it has become clear that there is a very small number of families with slightly atypical presentations who initially had been diagnosed as having ADPKD but instead were found to have mutations in genes other than *PKD1* or *PKD2*. In one example, seven families were reported with variably cystic kidneys and livers in which the cystic renal disease met the clinical criteria for ADPKD, but in them, the kidneys did not become enlarged or the disease progress to ESRD. DNA studies identified heterozygous pathogenic missense or truncating mutations in *GANAB*, which encodes the catalytic alpha subunit of glucosidase II (GII), an endoplasmic reticulum (ER)–resident enzyme involved in glycosylation.[3] Mutations of the same gene were additionally found in families with a more typical presentation of ADPLD.[3,8] Mutations of *PRKCSH*, which encodes the noncatalytic β subunit of GII, also cause ADPLD. In another example of ADPKD/ADPLD overlap, where some family members had typical ADPLD but others presented with mostly renal cysts, inactivating mutations were found in *ALG8*, which encodes α-1,3-glucosyltransferase, an ER integral membrane protein involved in glycosylation.[8]

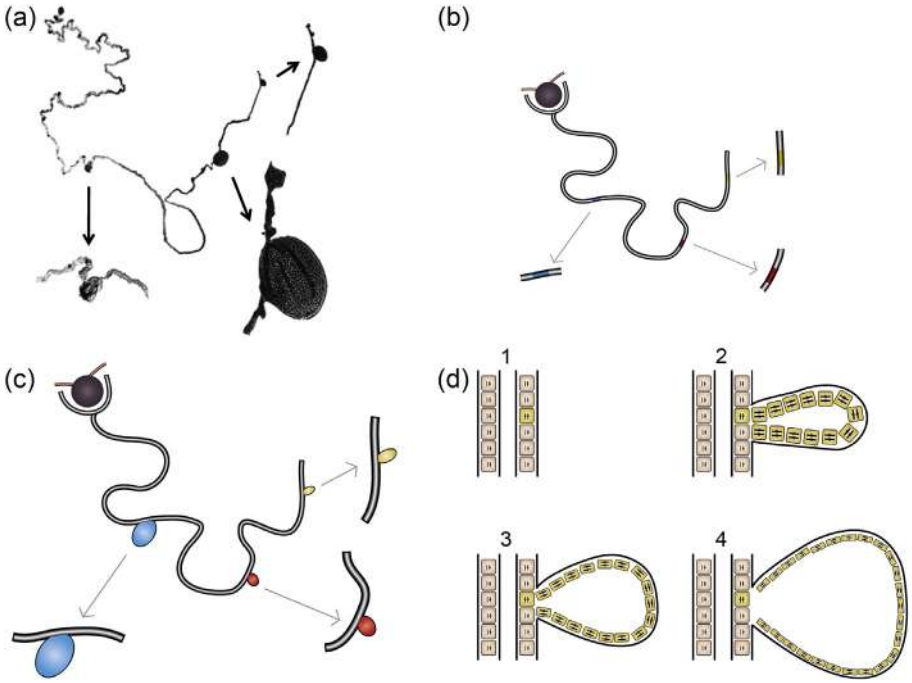

FIGURE 48.4 **Autosomal dominant polycystic kidney disease (ADPKD) cysts are focal.** (a) Microdissected nephron from a woman in her 30s with early ADPKD. The section contains a glomerulus, proximal tubule, and the loop of Henle and shows three small cysts. This elegant study clearly showed that cysts arise as localized outgrowths, initially connected[26] to nephrons, from all parts of the nephron and the collecting ducts. (b) Schematic of the same nephron but how it would have appeared prior to cyst growth. The colored areas identify locations where tubule epithelial cells will acquire a somatic mutation and initiate future cyst growth. (c) The nephron after cells with "two-hits" has begun clonal expansion. (d) Schema illustrates the different stages of cyst initiation and growth as predicted by the "two-hit" model. The first event is an acquired somatic mutation that reduces the activity of the previously normal allele (1). The "second hit" activates growth pathways which result in clonal expansion (2). As the clone expands, the cells begin to flatten and at late stages they pinch off from the tubule and lose some of their nephron-segment specific properties (3,4). *(a) Adapted from reference 26 and used with the permission of Elsevier.*

The mechanism by which mutations of *GANAB* and *ALG* cause disease has not been definitively established, but it is likely to be similar to what has been reported for *PKD1*, *PKD2*, and the ADPLD genes, *PRKCSH* and *SEC63*.[27,28] As in these other conditions, families with *GANAB* and *ALG* mutations have heterozygous variants that are either pathogenic missense substitutions or protein-truncating. The latter suggest loss of function effects.

A recent report described another small set of families initially mistaken for ADPKD that was found to have mutations in *DNAJB11* instead of *PKD1* or *PKD2*.[4] On closer inspection, the ADPKD was somewhat atypical, with variably cystic kidneys that were not enlarged and in fact often became atrophic over time, with histologic evidence of interstitial fibrosis. One family was also noted to have recurrent gout in association with the condition. Together, the presentation was more similar to Medullary Cystic Kidney Disease (OMIM 162000), a form of Autosomal Dominant Tubulointerstitial Kidney Disease (ADTKD) that is clinically and genetically distinct and caused by mutations in *UMOD*, the gene that encodes Tamm–Horsfall protein (uromodulin).

Pathobiology

The decades-long interval between diagnosis and ESRD affords ample opportunity for therapeutic intervention based on a firm understanding of the pathobiology of disease. It is well established that increased cell proliferation, fluid secretion, and loss of normal renal parenchyma are key elements that together contribute to loss of renal function. The genetic origin of disease offers a unique opportunity to determine the altered signaling pathways responsible for these properties. Much of the effort over the past two decades has been focused on understanding how loss of either *PKD1* or *PKD2* triggers these changes. With the genes in hand, investigators have characterized the proteins in tissues and cell culture systems and have made genetically faithful murine models that recapitulate many aspects of the disease as well as revealing new, unsuspected functions of the proteins. A comprehensive review of this topic is beyond the scope of this chapter and is a fast-evolving science. Interested readers are referred to several recent reviews for more detailed discussions.[12,21,29–31]

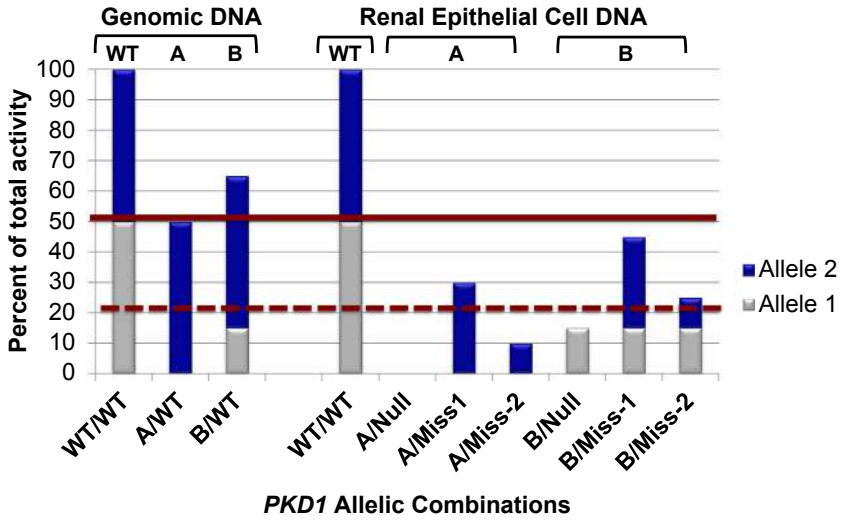

FIGURE 48.5 **The threshold model predicts that a critical level of PC1 (or PC2) is required to suppress cyst formation.** Consider two individuals (A, B) whose germline, inherited mutations have very different effects on the function of their respective mutant parental *PKD1* alleles. (A) The germline mutation results in complete loss of *PKD1* function from that parental allele ("allele 1"). This leaves the combined *PKD1* activity of the mutant and wild-type alleles at 50% as a starting point ("Genomic DNA"). (B) The germline mutation is a missense change that reduces the mutant parental *PKD1* allele's activity ("allele 1") by 70%, leaving the cell with a total of 65% *PKD1* activity. In this example, the *solid line* at 50% indicates the maximum functional *PKD1* activity of an individual that is heterozygous for a *PKD1* null mutation and the threshold that triggers cyst formation is below this level (*dotted line* at 20%). On the right, the samples are from individual renal epithelial cells of the same individuals. For (A) and (B), three "cells" that have acquired unique mutations are shown. "Miss1" and "Miss2" identify acquired missense mutations (allele 2) that reduce allelic function to 60% and 20% of normal (NL), respectively. "Null" identifies an acquired fully inactivating mutation (allele 2). In this example, (A) has two samples that fall below the 20% threshold. In contrast, (B) will only have one sample below the 20% line. In sum, individuals who have more severe germline mutations are more likely to have severe cystic disease because more types of acquired mutations will reduce total gene activity below the threshold.

The *PKD1* gene encodes a membrane receptor (Polycystin-1; PC1) and *PKD2* a nonselective cation channel (Polycystin-2; PC2), which together function as a receptor-channel complex on the cell surface, and possibly at the attachment site of the endoplasmic reticulum to mitochondria.[21,29–34] Although initial studies suggested that PC2 was most likely a calcium channel, recent studies have called this into question, suggesting the channel has higher preference for monovalent cations such as potassium or sodium, and that its activity is instead regulated by calcium.[35–38] The complex localizes to the primary cilia, a microtubule-based structure that projects from the apical surface of most cells. Cilia are thought to function primarily as cellular environmental sensors and signaling organelles. The primary cilium has emerged as a major player in the cystic field. Almost every cystoprotein (i.e. a protein encoded by a gene whose mutation results in renal cystic disease in humans or other species) has been localized to the primary cilium or the associated protein networks that regulate its formation and function (Figure 48.6).

Until recently, the prevailing model had been that primary cilia normally signal to suppress cyst formation, and the ciliary PC1/PC2 complex plays a key role in this. The polycystin complex was postulated to function as a flow sensor that signaled by triggering release of intracellular calcium stores and regulating other signaling pathways.[39,40] A recent mouse study has revealed unexpected complexities in the relationship between ciliary function and the PC1/PC2 complex. Specifically, primary cilia signaling can either suppress or promote cyst growth, depending on context.[41] This will likely complicate efforts to manipulate ciliary signaling as an approach to therapy.

The PC1/PC2 complex is thought to cap a cascade of intersecting signaling pathways that cooperate to regulate cellular growth, fluid secretion, and tubular morphology. Although a number of pathways have been directly linked to PC1 or PC2, such as mTORC1, canonical and noncanonical WNT, JAK-STAT, and heterotrimeric G-proteins, there is no consensus regarding which if any are functionally important. Although it is generally assumed that the calcium second messenger pathway is an important immediate downstream target of polycystins, how this links to the pathophysiology of cystic disease remains undefined.

Multiple other signaling pathways whose activities have not yet been directly linked to PC1 and PC2 have also been implicated in the disease. These include SRC kinase, the mitogen-activated protein kinase/extracellular regulated kinase (MAPK/ERK) cascade, and cAMP.[29,30] Alterations in level of intracellular calcium,

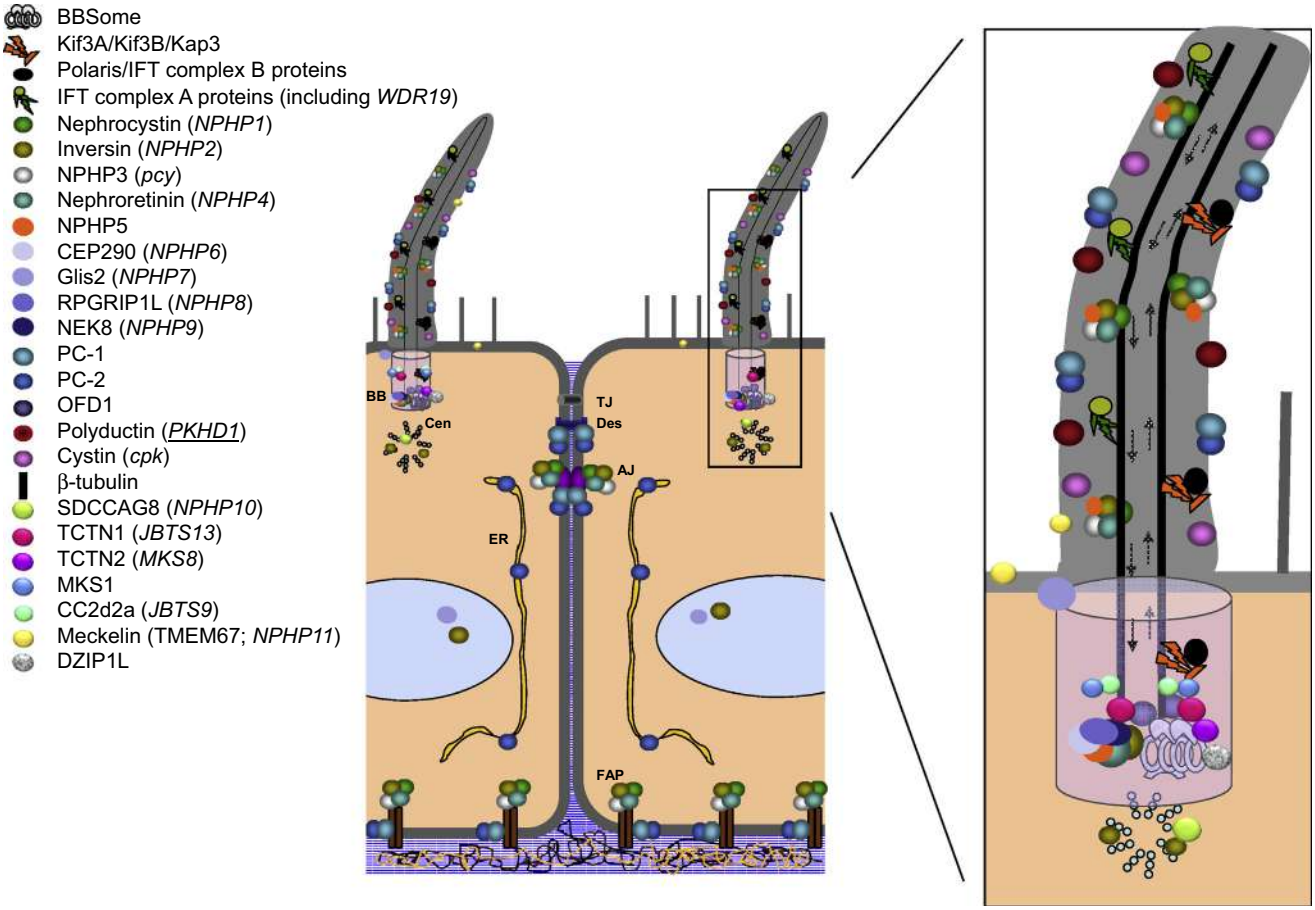

FIGURE 48.6 **Subcellular localization of cystoproteins.** Over 60 cystoproteins have been localized to the primary cilium/basal body complex (legend on top left) but many also map to other intracellular domains. The majority of genes that encode these proteins have been reported to cause a ciliopathy or cystic phenotype in both humans and rodents when mutated. Mutations in several of the genes result in a wide variety of related conditions with distinct findings (nephronopthisis [NPHP], Senior-Loken Syndrome, Joubert [JBTS], and Meckel–Gruber [MKS]). *AJ*, adherens junction; *BB*, basal body; *Cen*, centriole; *ER*, endoplasmic reticulum; *FAP*, focal adhesion plaque; *TJ*, tight junction. *Adapted from reference 29 and used with permission of Elsevier.*

resulting from decreased PC1/PC2 activity, may play a role in activating some of these systems. There has been considerable interest in these pathways, as there are FDA-approved therapies that target them.

The cAMP signaling system has been of particular interest. Its higher level of activity in cystic epithelia is thought to drive CFTR-dependent fluid secretion and increase cellular proliferation *via* the B-Raf/MEK/extracellular signal-regulated kinase pathway.[42,43] The effects on B-Raf are thought to result from the altered cytoplasmic calcium activity present specifically within cystic epithelial cells. Dysregulated calcium signaling also is thought to increase cAMP levels through opposite effects on calcium-sensitive phosphodiesterases and adenylate cyclases that are responsible for degrading and boosting cAMP levels, respectively.

These observations prompted investigators to evaluate whether interventions that reduced cAMP activity had any effects on cyst growth. They found that genetic, dietary, and pharmacologic interventions that reduced vasopressin-2 receptor (V2R) activity reduced the rate of cyst growth and the decline of renal function.[30,44] Because increased cAMP activity is thought to also drive biliary cyst growth where V2R is not expressed, investigators postulated that activation of the somatostatin receptor, which increases Gαi activity and decreases cAMP, might also be beneficial. Pilot studies of humans with severe polycystic liver disease treated with octreotide, a somatostatin receptor agonist, reported modest benefit.[45]

Finally, several recent studies suggest a role for dysregulated metabolic pathways in cyst formation and growth.[12] PC1 reportedly binds to tuberin, the gene product of the *Tuberous Sclerosis 2* (*TSC2*) locus, a known regulator of mTOR signaling.[46,47] Several studies have reported increased mTOR activity in cystic tissue, and inhibitors such as rapamycin slow cystic growth.[46,48] Other studies suggest that the activity of AMPK, both

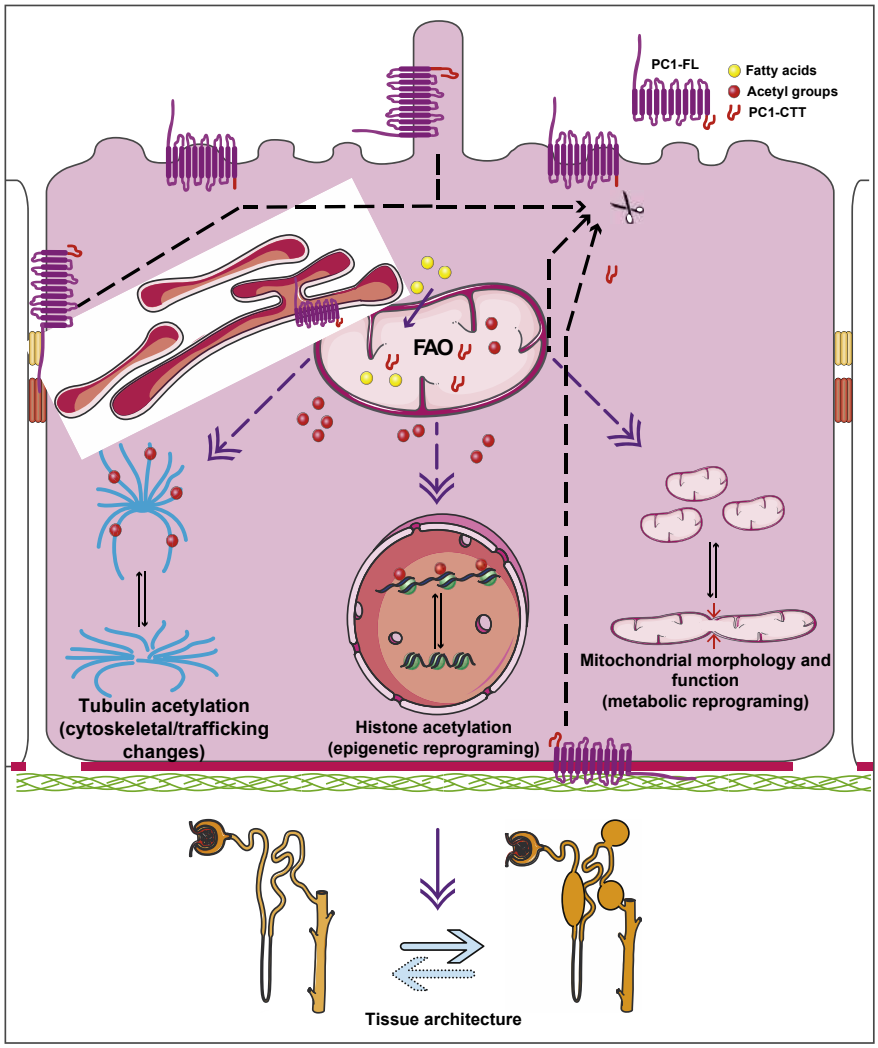

FIGURE 48.7 **Model of how PC1 signaling could regulate nephron architecture.** PC1 could respond to ligand binding or mechanical stimuli (from cilia, cell−cell or cell—matrix interactions) by modulating mitochondria activity and acid oxidation (FAO). Altered FAO could change the pool of acetyl-CoA (and possibly reactive oxygen species and NAD+/NADH), with effects on tubulin acetylation (affecting trafficking and cytoskeleton) and histone acetylation (possibly with global gene expression reprogramming), processes previously linked to PKD. A similar cascade was observed in lymphangiogenesis and planar cell polarity, processes previously linked to *Pkd1* function.[49] *Used under Copyright Commons License 4.0.*

a nutrient-sensitive kinase and regulator of CFTR, is decreased in cystic kidneys. Treatment of rodents with metformin, a known activator, slowed cyst growth.[50] Clinical trials are underway testing this thesis in humans (NCT02656017, NCT02903511). Transcriptomic and metabolomic analyses of normal and cystic murine kidneys suggest that multiple metabolic pathways, including glycolysis and fatty acid metabolism are dysregulated in cystic tissue, and that manipulation of these pathways with drugs, diet, or genetic manipulations can slow renal growth.[51−55] Moderate to large caloric restriction in rodents also has been shown to be highly effective in slowing progression, even reversing disease.[56,57]

Recent studies suggest mitochondrial dysfunction might play a central role in the pathogenesis of disease. Human and mouse cystic kidneys have abnormal mitochondria structure.[49,58] A portion of PC1 is reported to localize to the mitochondria, where it may regulate mitochondrial network structure and calcium uptake.[34,49]

Figure 48.7 presents one model of how PC1, acting through cellular metabolism, could result in changes in nephron tubular structure. PC1 may detect mechanical or other signals at cilia, cell−cell and/or cell−matrix sites of interaction and transmit this information to mitochondria through release of a cleavage product. The latter may regulate mitochondrial function and affect cellular redox activity, NAD+/NADH levels, and acetyl-CoA levels. Loss of PC1 activity could result in metabolic reprogramming and alterations in acetyl-CoA levels, which can, in turn, mediate epigenetic or

cytoskeletal changes. Collectively, these effects could disrupt the normal activity of the many signaling pathways that maintain cellular structure and function under homeostatic conditions and result in the cystic phenotype that is characterized by numerous dysfunctional signaling pathways.[49]

ARPKD

Molecular Basis of Disease—PKHD1

All typical forms of ARPKD are caused by mutations in *PKHD1*, a large ~500 kb gene with a complex splicing pattern.[59,60] Mutations have been identified along the entire length of the *PKHD1* gene, and multiple mutation types have been described as pathogenic. To date, more than 700 pathogenic mutations have been cataloged in the ARPKD Mutation Database (http://www.humgen.rwth-aachen.de),[61] of which approximately half are missense changes. The most common mutation overall is a missense mutation in exon 3, c.107C>T (p.Thr36Met), which accounts for approximately 20% of all mutated alleles.[62] Aside from this mutation, which has been observed in a large number of unrelated patients, there do not appear to be any mutational hotspots. Indeed, a large proportion of mutations are unique to a single pedigree.[63]

Multiple studies have examined ARPKD cohorts for potential genotype–phenotype correlations. Given the diversity of *PKHD1* mutations, most patients are compound heterozygotes, and the functional effect of any particular mutant allele can be difficult to discern. Nevertheless, some broad themes have emerged. Notably, patients with two truncating mutations typically have a severe phenotype leading to perinatal or neonatal mortality.[63] However, there are notable exceptions, e.g. a child who is homozygous for a large *PKHD1* deletion surviving well past the neonatal period.[64] Moreover, not all missense mutations lead to a more benign outcome. A number of missense mutations result in severe phenotypes when present with a truncating mutation or in homozygous form.[63] Genetic modifiers likely also play a significant role in disease expression, as illustrated by significant phenotypic variability in subsets of families. For example, in a study of 126 unrelated families, 20 sibships showed widely discordant phenotypes (perinatal lethality in one sibling and survival into childhood in the other).[62]

Taken together, these genetic features pose particular challenges for genetic counseling of ARPKD families.

Atypical ARPKD and Phenocopy Disorders

Although ARPKD is generally considered a genetically homogeneous disease, a recent report described seven children from four unrelated, consanguineous families with an atypical form of ARPKD that results from mutations in a second gene, *DZIP1L*.[11] The children presented with hypertension and large, cystic kidneys; some had progressed to ESRD. A distinguishing feature of this ARPKD phenotype is the more moderate renal disease and the absence of clinically apparent liver disease.

The *DZIP1L* gene spans about 53 kb and encodes a 767 amino acid ciliary transition zone protein, DAZ interacting protein 1-like (DZIP1L). Among the four reported families, two families had different homozygous missense changes predicted to be pathogenic, while the other two had distinct, homozygous truncating mutations. While the function of DZIP1L is largely unknown, it is implicated in hedgehog signaling and ciliogenesis.

ARPKD is the prototype of the hepatorenal fibrocystic diseases (HRFDs), a subset of recessively transmitted cilia-related disorders, or ciliopathies, which are characterized by renal cystic disease and can be associated with congenital hepatic fibrosis and/or Caroli syndrome as well as extrarenal manifestations.[65] These rarer disorders in which the kidney disease can phenocopy ARPKD include nephronophthisis (MIM 256100), Joubert syndrome (MIM 213300), Bardet–Biedl syndrome (MIM 209900), Meckel–Gruber syndrome (MIM 249000), and oro-facial-digital syndrome I (MIM 311200). As with FPC and DZIP1L, the proteins disrupted in these disorders are critical in the structure/function of the primary apical cilium.[66]

Finally, a form of PKD that can mimic either ARPKD or ADPKD and is associated with hyperinsulinic hypoglycaemia (HIPKD) has been described in 11 pedigrees, who had biallelic mutations in *PMM2*, which encodes phosphomannomutase 2.[67] PMM2 is a key enzyme in N-linked glycosylation. Recessive mutations in *PMM2* are usually associated with congenital disorder of glycosylation type 1a (CDG1A), which has a severe, pleiotropic phenotype.

Pathobiology

The product of the *PKHD1* gene, fibrocystin/polyductin (FPC), is a 4074 amino acid, single-membrane spanning protein with a long extracellular N-terminus and short cytoplasmic C-terminus, which appears to have multiple isoforms.[60] During fetal development, *PKHD1* is expressed widely and is found in the neural tube, bronchi, primordial gut, early ureteric bud, mesonephric tubules, adrenal cortex, and immature hepatocytes, suggesting a role in organ development and tubular morphogenesis. In adult tissues, it is expressed predominantly in the kidney (mostly in collecting ducts and thick ascending loops of Henle), liver (localized to bile ducts), and pancreas.[68,69] In renal tubular and biliary epithelial cells, FPC localizes to the apical membranes, as well as to the primary cilia/basal

body[60,68,70] and mitotic spindle.[71] A subset of membrane-bound FPC appears to undergo Notch-like proteolytic processing, with shedding of the extracellular domain into the tubular lumen and nuclear translocation of the C-terminus, where it may play a role in downstream signaling.[68,69,72] However, predictions regarding the nuclear function of the cytoplasmic C-terminus are confounded by a recently reported mouse model that was engineered to lack most of the C-terminus and is phenotypically normal, without renal or hepatic disease even when aged.[69]

The function of FPC remains unclear. In animal studies, mice-harboring mutations in both *Pkhd1* and either of the ADPKD genes (*Pkd1* or *Pkd2*) display cystic phenotypes much more severe than those seen with either mutation alone, suggesting genetic interaction *in vivo*.[27,73] However, a direct physical interaction between FPC and PC1 has not been demonstrated. The functional significance of the reported interaction of FPC with PC2[73] is uncertain, because *Pkhd1* mutant mice lacking the FPC–PC2 interaction domain are phenotypically normal.[69]

A recent study suggests that FPC may indirectly regulate the function of the C2-WWW-HECT domain E3 family of ubiquitin ligases, by affecting the subcellular localization of NDFIP2, a protein implicated in regulating the trafficking and function of the E3 ubiquitin ligase family.[74] This protein family includes SMURFs and NEDD4, which are known to regulate the activity of RhoA, TGF-β signaling, and ENaC activity, all of which have been reported to be upregulated in ARPKD renal and biliary epithelial cells. Although these data provide a unifying explanation for the observed changes in cytoskeletal structure, increased fibrosis, and enhanced sodium absorption and hypertension, the mechanism through which FPC modulates NDFIP2 function remains unknown.

The reported localization of FPC to the basal body/primary cilium provides another intriguing but incomplete insight into its function. As noted, FPC, DZIP1L, and other proteins associated with HRFD (e.g. ADPKD, nephronophthisis, and Meckel, Joubert, and Bardet–Biedl syndromes) also localize to these structures (Figure 48.6). Taken together, these data suggest a central role for the primary cilium in the development and maintenance of renal tubular architecture, perhaps *via* mechanisms such as flow sensing and establishment of planar cell polarity, but the specific function of FPC in any of these processes remains undefined.

As in ADPKD, the cAMP signaling system is activated in ARPKD,[75] as is the mTOR pathway.[76,77] Yet, efforts to translate these findings to human clinical trials have been complicated by incongruities between human disease and animal models, and the lack of noninvasive markers to track disease progression and assess outcomes. For example, although agents that target cAMP activation have been shown to be effective in attenuating cystic disease progression in the *pck* rat (orthologous ARPKD model),[78] mTOR inhibition in this rat model failed to impact progression of kidney and liver disease.[79] Thus, current research efforts are focused on optimizing the preclinical studies with targeted therapeutics in experimental models and developing noninvasive markers for human clinical trials, which assess progression endpoints and are acceptable to regulatory agencies.

DIAGNOSIS

ADPKD

Renal sonography is the diagnostic mainstay in ADPKD. It is widely available, relatively low cost, with good patient tolerance, and lack of known toxicity. The criteria used to assign a diagnosis, i.e. number of renal cysts, have been defined in studies of large cohorts of genetically well-defined families (Table 48.1). The diagnostic threshold is age-dependent, reflecting the age-dependent penetrance of disease. The original Ravine criteria, established in the 1990s, have been revised in recognition of the milder disease course typical of patients with *PKD2*-linked disease.[80,81]

In evaluating individuals presenting with renal cystic disease, a detailed family history is required, both to guide the decision process and to alert the clinician about risk for comorbidities, such as ICA. If a family history of ADPKD is established, there are well-defined standards for clinical management.[80,81]

Even with the clinical introduction of enhanced imaging techniques, there remain a significant subset of individuals for whom the diagnosis is uncertain. They may lack family history, have a borderline number of cysts, have kidneys that are not enlarged, or express other atypical features, such as asymmetric cystic disease, which increase diagnostic uncertainty. This diagnostic uncertainty is particularly problematic in evaluating at-risk family members less than 30 years old with truncating *PKD1* mutations or less than 40 years old with other classes of *PKD1* or *PKD2* mutations as potential transplant donors, because a normal renal ultrasound does not exclude ADPKD with certainty. Ultrasound is also less sensitive for individuals with large BMI. Rarely, high-resolution ultrasound may yield false positive diagnoses.[82] Contrast CT scans or noncontrast MRI may provide better sensitivity and specificity, particularly in young at-risk individuals. In one small study of 110 at-risk individuals aged 16–40 years from families with known genetic mutations (73 affected, 37 at-risk unaffected, 45 unrelated controls), a threshold of greater than 10 cysts by

TABLE 48.1 Sonographic Criteria for Diagnosing and Excluding Autosomal Dominant Polycystic Kidney Disease in Individuals With Positive Family History but Unknown Genotype

Age Group (yr)	Diagnostic Criterion	PPV (SEN)	NPV (SPEC)
15–29	>1 renal cyst	0.966 (89.3%)	0.908 (97.1%)
	>2 renal cysts[a]	0.992 (84.8%)	0.877 (99.4%)
	>3 renal cysts[a]	1.00 (81.7%)	0.855 (100%)
	>2 renal cysts in each kidney	1.00 (82.8%)	0.875 (100%)
	>1 renal cyst	0.94 (98%)	0.983 (94.8%)
30–39	>2 renal cysts[a]	0.979 (96.4%)	0.970 (98.3%)
	>3 renal cysts[a]	1.00 (95.5%)	0.964 (100%)
	>2 renal cysts in each kidney	1.00 (90%)	0.948 (100%)
	>1 renal cyst	0.897, (100%)	1.00 (93.9%)
40–59	>2 renal cysts[a]	0.967 (100%)	1.00 (98.2%)
	>3 renal cysts[a]	0.965 (97%)	0.984 (98.1%)

MRI was found to be 100% sensitive and specific. This threshold, however, has not yet been validated in large cohorts or diverse populations.[82] At present, in most situations, the two best options for the clinician are to provide standard clinical management with periodic repeat imaging or DNA testing.

Differential Diagnosis of ADPKD

The most common diagnostic challenge in considering ADPKD is determining whether an individual lacking a family history has simple cysts or a genetic cause. The proportion of the population with simple cysts increases with age, from a few percent in individuals below age 30 years to 25% of those >70 years. The latter cohort often has at least one cyst in each kidney but rarely more than three per kidney.

Some individuals have few or no kidney cysts but prominent liver cystic disease. In many cases, these patients have a family history consistent with an autosomal dominant pattern of inheritance. These individuals have ADPLD, a genetically heterogeneous disorder that results from mutation of at least six distinct genes: *PRKCSH*,[83] *SEC63*,[84] *SEC61B*,[8] *LRP5*,[85] *GANAB*,[3] and *PKHD1*.[8] The liver cystic disease is clinically indistinct from that associated with ADPKD. The two conditions are primarily distinguished by the presence or absence of significant renal cystic disease. In the unusual cases where individuals with ADPLD present with many renal cysts, the kidneys are not enlarged and they do not progress to ESRD.

Although ADPKD and ARPKD usually have distinct clinical presentations, there is a subset of the latter that presents in late childhood or adulthood with significant liver disease and focal cystic renal disease.[86] Moreover, congenital hepatic fibrosis is occasionally expressed in ADPKD.[87] ARPKD should be suspected if imaging studies indicate both biological parents are clinically unaffected.

Numerous other conditions are associated with renal cysts, including both nongenetic and genetic disorders. Those transmitted as dominant traits are typically distinguished from ADPKD by their extrarenal manifestations (Table 48.2). The majority of other renal cystic diseases are recessive disorders and thus distinguished from ADPKD by their mode of inheritance (Table 48.3).

Genetic Testing in ADPKD

Given the advances in sequencing technologies and the dramatic decrease in cost, DNA-based testing could soon emerge as the most effective and definitive diagnostic method. There are a number of important caveats, however. First, as indicated above, there are multiple *PKD1* homologues, i.e. pseudogenes, with nearly identical sequence to *PKD1*, and these sequences must be distinguished from that of the actual gene.[88] Until recently, multiple enrichment steps were required to isolate *PKD1*-specific gene fragments prior to sequencing,[89] making the method technically challenging. However, recent developments in next generation sequencing (NGS) may have overcome this problem.[90–92]

TABLE 48.2 Renal Cystic Diseases That can Mimic Autosomal Dominant Polycystic Kidney Disease

Disorder	MIM	Gene(s) Protein(s)	Inheritance	Distinct Clinical Features
Simple Cysts	Not applicable	None	None	Normal kidney size; isolated cysts, usually no more than 4/kidney at age 60
Acquired Cystic Disease	Not applicable	None	None	Develops in individuals with chronic kidney disease from other cause; kidneys usually small; can progress to renal cell carcinoma
Tuberous Sclerosis Complex	191100 613254	*TSC1*, *TSC2* Tuberin1, Tuberin2	AD	Associated with a wide variety of other clinical features involving the kidney (angiomyolipoma, renal cell carcinoma), skin (hypomelanotic macules, facial angiofibromas, shagreen patches, fibrous facial plaques, ungula fibromas), brain (cortical tubers, subependymal nodules, subependymal giant cell astrocytomas, seizures, intellectual disability), heart (rhabdomyoma, arrhythmias), lung (lymphangioleiomyomatosis)
Oro-facial-digital Type 1 syndrome	311200 300170	*CXORF5* OFD1	X-linked dominant	Lethal in males; families have female-to-female transmission. Characterized by malformations of the face (widely spaced eyes, hypoplasia of the alae nasi, micrognathia, cleft, or pseudocleft lip), oral cavity (lobed tongue, hamartomas, or lipomas of the tongue, dental abnormalities, cleft palate) and digits (duplicated hallux, polydactyly, brachydactyly, syndactyly, clinodactyly), brain (intellectual disability, agenesis of corpus callosum or cerebellum, intracerebral cysts, intracerebral cysts)
Autosomal Recessive PKD	263200 606702 617610	*PKHD1*, *DZIP1L* Fibrocystin/polyductin, DZIP1L	AR	Congenital hepatic fibrosis with hypersplenism and other signs of portal hypertension. Very early onset ADPKD (1−2% of affected children) may be clinically indistinguishable from ARPKD.
Polycystic Liver Disease	174050 608648 177060	*PRKCSH*, Glucosidase II, β subunit *GANAB*, Glucosidase II, α subunit *SEC63*, Translocation Protein SEC63 *SEC61B*, Translocation Protein SEC61b *ALG8*, α-1, 3-glucosyltransferase *PKHD1*, Fibrocystin	AD	Age-dependent expression of numerous hepatic cysts; few if any renal cysts.
Renal Cysts and Diabetes Syndrome (Maturity-Onset Diabetes of the Young Type 5)	137920	*TCF2* HNF1β	AD	Exocrine pancreatic failure and pancreatic atrophy; maturity-onset type diabetes of the young; abnormalities of the genitourinary system; hyperuricemia common. Associated with a broad range of renal abnormalities.
Von Hippel Lindau syndrome	193300 608537	*VHL* VHL	AD	Pheochromocytomas, papillary cystadenoma, renal tumors and renal cell carcinoma, hemangioblastomas of the retina, and central nervous system.

AD, autosomal dominant; *AR*: autosomal recessive; *MIM*, Mendelian inheritance in man.

TABLE 48.3 Hepato-renal Fibrocystic Diseases

Disease	Gene(s)	Renal Disease	Hepatic Disease	Associated Features
ARPKD	*PKHD1; DZIP1L*	Collecting duct dilatation	CHF*; Caroli disease	Growth retardation
ADPKD	*PKD1; PKD2; GANAB*	Cysts along entire nephron	Biliary cysts; CHF	Minimal in children
Nephronophthisis (NPHP)	*NPHP1—NPHP20*	Cysts at the corticomedullary junction	CHF	Tapetoretinal degeneration; situs inversus
Joubert syndrome (JBTS)	*JBTS1—JBTS35*	Cystic dysplasia; NPHP	CHF; Caroli disease	Cerebellar vermis hypo/aplasia with episodic hyperpnea; abnormal eye movements; intellectual disability
Bardet—Biedl syndrome (BBS)	*BBS1—BBS21*	Cystic dysplasia; NPHP	CHF	Retinal degeneration; obesity; postaxial polydactyly; hypogonadism in males; intellectual disability
Meckel—Gruber syndrome (MKS)	*MKS1—MKS13*	Cystic dysplasia	CHF	Occipital encephalocele; polydactyly
Oral-facial-digital syndrome, Type I	*CXORF5*	Glomerular cysts	CHF (rare)	Malformations of the face, oral cavity, and digits
Glomerulocystic disease	*PKD1; TCF2; UMOD*	Enlarged; normal or hypoplastic kidneys	CHF (with *PKD1* mutations)	Diabetes; hyperuricemia
Jeune syndrome (short-rib thoracic dystrophy [SRTD])	*SRTD1—SRTD20*	Cystic dysplasia	CHF; Caroli disease	Short stature; skeletal dysplasia; small thorax; short limbs; polydactyly; hypoplastic pelvis
Renal-hepatic-pancreatic dysplasia (RHPD)	*NPHP3; NEK8*	Cystic dysplasia	Intrahepatic biliary dysgenesis	Pancreatic cysts, dysplasia, and/or fibrosis; splenic abnormalities; situs inversus
Zellweger syndrome	*PEX1—3;5—7;10—14;16;19;26*	Renal cortical microcysts	Intrahepatic biliary dysgenesis	Hypotonia; seizures; agenesis/hypoplasia of corpus callosum; characteristic facies; skeletal abnormalities; neonatal death

* *CHF, congenital hepatic fibrosis.*

Second and more clinically relevant, DNA testing is reliable in identifying sequence variants in a gene of interest, but it is less effective in predicting the disease-causing potential of these sequence changes. For variants predicted to cause a truncated or absent protein, the molecular diagnosis is readily established. However, in about half of the cases, missense changes predicted to result in amino acid substitutions, small in-frame deletions, or no variants are identified.[16,17,92] Even with current bioinformatic tools, the likely pathogenicity of such variants is not clear, and a definitive DNA diagnosis is not possible.

The final challenge with current DNA testing is that it is not a good predictive tool. Although certain types of mutations are statistically associated with more severe disease (e.g. mutations in *PKD1*, and truncating changes, especially those nearer the 5′ end of *PKD1*), there is considerable heterogeneity and this information is of limited use for counseling purposes.[24]

Despite the limitations, there are circumstances where a DNA-based diagnosis may be advantageous:

- Living related donor evaluation: For younger, at-risk candidate donors whose disease status is unknown, imaging studies may yield nondiagnostic results and DNA testing can help guide decision-making.[93] In this case, the recipient is tested first to identify a definitive mutation, and if positive, then a directed test can be performed in the potential donor to determine whether the mutation is present.
- Diagnostic uncertainty: Examples include individuals with borderline clinical findings, renal dysfunction out of proportion to the degree of cystic disease, suspected *de novo* disease, and atypical disease presentations.
- Prenatal or preimplantation testing: As with pretransplant testing, this method is used only when a pathogenic mutation is identifiable in the donor of the egg or sperm.
- Early and severe disease or very large intrafamilial disease discordance: A form of very early onset ADPKD occurs in 1−2% of affected children and may be clinically indistinguishable from ARPKD.[94] These severe ADPKD cases can result from a combination of mutations in *PKD1* and hypomorphic (limited loss of function) alleles of other genes that cause cystic kidney disease.[95] Therefore, genetic testing should be considered to evaluate the contribution of other "cystogenes" to the clinical disease expression.

Diagnostic Screening in Individuals At-risk for ADPKD

In the absence of target therapy for PKD, a conservative approach has traditionally been preferred in asymptomatic at-risk individuals because there was little direct benefit in establishing a specific diagnosis, and there were practical risks regarding insurability for life, disability, and until recently in the US, health care. However, the approach differed somewhat by health system. In Europe, presymptomatic testing was relatively common. In the US it was not, with clinicians typically monitoring at-risk individuals for hypertension and pursuing diagnostic studies only after the onset of symptoms. Even in the US, there were important exceptions, where establishing the diagnosis might change clinical management (e.g. athletes participating in high-impact contact sports, individuals with a positive family history of ADPKD and aneurysms, and individuals interested in serving as a transplant donor for an affected family member) or where at-risk individuals wanted to know their status. This conservative approach, however, has been predicated on the assumption that there was little to offer other than symptomatic care. The recent approval of tolvaptan for individuals most at risk for progression changes the risk−benefit calculation, and clinicians should consider this factor when deciding whether to test.

Diagnostic screening in asymptomatic children is controversial due to the limited sensitivity of ultrasonography, particularly in children less than 5 years of age,[96] and the ethical concerns about screening asymptomatic minors. Renal imaging should be pursued primarily in at-risk children with hypertension, hematuria, and/or proteinuria. Screening for extrarenal features of the disease is not recommended during childhood.

In sum, the decision of when and how to screen asymptomatic individuals must be customized to the individual/family-specific circumstances.

ARPKD

Imaging

ARPKD is typically first detected on routine prenatal ultrasound. Suggestive features in a fetus include symmetrically enlarged, echogenic kidneys (due to multiple microscopic cysts) with loss of corticomedullary differentiation due to medullary hyperechogenicity[97] (Figures 48.2 and 48.3). Discrete cysts are sometimes evident.[98] Oligohydramnios may be present due to poor fetal urine output.[6,97] However, normal sonographic findings do not necessarily exclude a diagnosis of ARPKD because abnormalities may not be evident until late in the second trimester (or beyond), even in infants who go on to manifest a severe phenotype at birth.[6,97,99] In addition, the presence or absence of oligohydramnios does not always correlate with disease severity or degree of pulmonary insufficiency.[99]

ARPKD can often be distinguished on fetal imaging from other HRFD[65] (Table 48.3), as well as ADPKD. ARPKD kidneys *in utero* are typically hyperechogenic and display *decreased* corticomedullary differentiation due to the hyperechogenic medulla. With high-resolution ultrasound, the radial array of dilated collecting ducts may be imaged. Although the other HRFD are characterized by large, echogenic kidneys in the fetus and neonate, they can often be distinguished from ARPKD by the presence of extrarenal manifestations (e.g. central nervous system abnormalities, eye defects, and/or polydactyly).[98] In comparison, ADPKD kidneys *in utero* tend to be moderately enlarged with a hyperechogenic cortex and relatively hypoechogenic medulla causing *increased* corticomedullary differentiation.[100]

A recent International Working Group Consensus Statement recommends ultrasonography as the method of choice for assessing renal cystic disease in children, with selected indications for MRI and contrast-enhanced ultrasound. Ultrasonography yields essential diagnostic information in most cases, and in patients with ARPKD or other HRFD, abdominal ultrasonography is a useful tool for screening for and diagnosis of portal hypertension.[101] There is broad consensus that CT should be avoided in children whenever possible because of the exposure to ionizing radiation.

In children with ARPKD, kidney size typically peaks at 1–2 years of age, then gradually declines relative to the child's body size and stabilizes by 4–5 years.[102] As patients age, there is increased medullary echogenicity with scattered small cysts, measuring less than 2 cm in diameter. These cysts and progressive fibrosis can alter the usual kidney contour, causing ARPKD in some older children to be mistaken for ADPKD.[103] Contrast-enhanced MRI can be useful in delineating the renal architecture in these children. Bilateral pelvicaliectasis and renal calcifications have been reported in 25% and 50% of ARPKD patients, respectively.[86,104] In adults with medullary ectasia alone, the cystic lesion may be confused with medullary sponge kidney (Figure 48.3).

The liver may be either normal in size or enlarged. Prominent intrahepatic bile duct dilatation suggests associated Caroli syndrome. With age, the portal fibrosis tends to progress. In older children, ultrasound typically shows hepatosplenomegaly and a patchy increase in hepatic echogenicity.[105,106]

Genetic Testing in ARPKD

Molecular diagnostic analysis is rapidly becoming the gold standard for diagnosing ARPKD and distinguishing this disorder from the large number of phenocopying disorders or syndromes.[107] In practice, screening a panel of genes rather than analysis of *PKHD1* alone has become the preferred diagnostic approach.[108] Advances in NGS now enable simultaneous analysis of a large group of genes in a single test at relatively low cost. While whole exome or whole genome-based screening may become the mainstay for genetic testing in the near future, at present, targeted NGS panel testing is the most efficient diagnostic approach. Whichever methodology is used, the testing strategy should be designed to detect copy number variations such as heterozygous deletions (for example, in *HNF1B*) and to cover complex genomic regions, such as *PKD1*.

Clinical genetic testing laboratories are summarized at the NIH-sponsored Genetic Testing Registry, www.ncbi.nlm.nih.gov/gtr.

Preimplantation Genetic Diagnosis

In families who have had a previous child with severe ARPKD, preimplantation genetic diagnosis (PGD) offers an alternative to prenatal diagnosis in a current pregnancy. The procedure requires prospective identification of the *PKHD1* mutations transmitted from each parent. The couple then must undergo *in vitro* fertilization. The resulting embryo is biopsied, with removal of 1–2 embryonic cells for genetic testing.[109] PGD has guided the birth of unaffected infants in at-risk families.[110,111]

MANAGEMENT AND TREATMENT

Until recently, the clinical management of individuals with ADPKD was focused on treating disease complications, reducing the risk of cardiovascular disease, and providing genetic counseling. The hope had been that ongoing research would one day identify new therapies that slowed or even prevented cyst growth and progression to ESRD. This section will first review the current status of therapies that hold the potential to alter the disease course and then, discuss symptomatic management for ADPKD and ARPKD.

Slowing Disease Progression

The discovery of the PKD genes and the generation of genetically faithful mouse models have provided important tools and insights into disease pathobiology. The weight of the evidence strongly indicates that cell proliferation is a key step in disease pathogenesis. Presumably, if one could stop cystic epithelial cell division, one could prevent cyst expansion. Unfortunately, the very slow, progressive nature of ADPKD poses real challenges for treatment. In ARPKD, the very early disease onset poses different, but equally vexing changes. Therapies will likely have to be given for decades, they must be able to selectively inhibit cystic epithelial cells, and they must have minimal off-target effects.

In addition to the biological hurdles, there is the challenge of establishing clinical trial designs that can measure clinically significant changes in outcome in a timeline compatible with pharmaceutical industry requirements. The usual acceptable study endpoints, e.g. doubling of S[Cr] or development of ESRD, occur very late in PKD patients, typically after much of the kidney architecture has already been destroyed. It is widely recognized that therapies need to be evaluated earlier in the course of the disease. The major challenge is defining endpoints for clinical trials that are acceptable to regulatory agencies.

Although suitable predictive markers remain elusive in ARPKD, total kidney volume (TKV) is now widely accepted as an early predictor of ADPKD progression, based on the findings of the NIH-sponsored CRISP study.[9,112] This ongoing longitudinal study has carefully characterized the kidney volume and rates of increase using highly reproducible MRI imaging and correlated these variables with changes in renal function.[9] The investigators found an imperfect inverse relationship between changes in renal/cyst volume and renal function at baseline (Figure 48.1), but showed they could detect progressive changes in function that correlated with volume in the largest cystic kidneys. The Polycystic Kidney Disease Outcomes Consortium, a collaboration between the Critical Path Institute (C-Path) and several leading academic medical centers, pharmaceutical companies, patient organizations, and international regulatory agencies, recently succeeded in having TKV qualified as a prognostic biomarker with both the US Food and Drug Administration and the European Medicines Agency.[113]

Advances in knowledge about disease pathophysiology, clinical trial design, and regulatory policies culminated in approval by regulatory authorities in Japan, Canada, Europe, and the US of the first treatment for slowing disease progression. The TEMPO 3:4 study tested tolvaptan, a V2R antagonist, in 1445 ADPKD patients with well-preserved renal function (eGFR >60 mL/min/1.73 m^2) but large renal volume (>750 mL). They found the treatment modestly reduced the rate of kidney growth (from 5.5% to 2.8% per year) and eGFR decline (from −3.81 mL/min/1.73 m^2 to −2.61 mL/min/1.73 m^2 per year). Participants taking tolvaptan experienced fewer and less severe pain episodes.[13] The REPRISE study subsequently showed that tolvaptan slowed eGFR decline by a similar amount in 1370 participants with later stage ADPKD (CKD stages 2–4) randomized to placebo or study drug.[114] The drug was generally well-tolerated, with the principal side effects being polydypsia and polyuria due to the aquaretic effects of the medication. A small number (~5%) of participants also developed reversible liver function abnormalities. Several participants however met Hy's law criteria, indicating a 10% risk of developing liver failure. Based on its acceptable risk/benefit ratio, tolvaptan was approved for treatment of adults with preserved GFR at risk of rapidly progressing ADPKD with regular monitoring of liver function.

Various approaches have been proposed to identify those most likely to benefit from tolvaptan treatment. They include measurements of TKV adjusted for height, rates of change of eGFR or renal volume over time, and adjustments for age, genotype, and family history.[115–118] The Mayo Imaging Classification, based on a one-time measurement of TKV adjusted for height and age, is one of the simplest and most commonly used in the US[115] (Figure 48.8). Several groups have published practical guides that can be used to decide who to treat and then how to manage them once they start therapy.[119,120]

This begins a new chapter in the management of ADPKD. For the first time, there is something to offer those with the highest risk of severe disease that may slow progression and reduce pain. This information should be considered when counseling individuals known to be at-risk for ADPKD because of family history about presymptomatic testing. Finally, it should be noted that ultimate beneficial impact of tolvaptan will only be known in time. Follow-up of 97 individuals who had participated in the various tolvaptan trials suggests sustained and cumulative benefit for up to 11 years and models suggest that treatment may delay progression to ESRD by up to 7 years.[120] In contrast, several rodent studies found the benefits to attenuate over time.[121–123]

Whether this reflects different species effects or overly optimistic projections based on a relatively small number of people is not known. If, however, the drug is widely utilized and truly provides long-lasting benefits, we will see for the first time a change in the age-dependent incidence of renal replacement therapy (RRT).[124]

Symptomatic Care—ADPKD

Most ADPKD patients are asymptomatic for the majority of their lives, with only intermittent clinical issues. Management is focused on five aspects of care.

Hypertension and Cardiovascular Health

Most PKD patients develop hypertension, more than the proportion that develops ESRD. Cardiovascular disease is the leading cause of death. Therefore, blood pressure control and management of standard cardiovascular risk factors are paramount in caring for PKD patients. There currently are no PKD-specific recommendations for preventing or treating cardiovascular disease. For hypertension, angiotensin converting

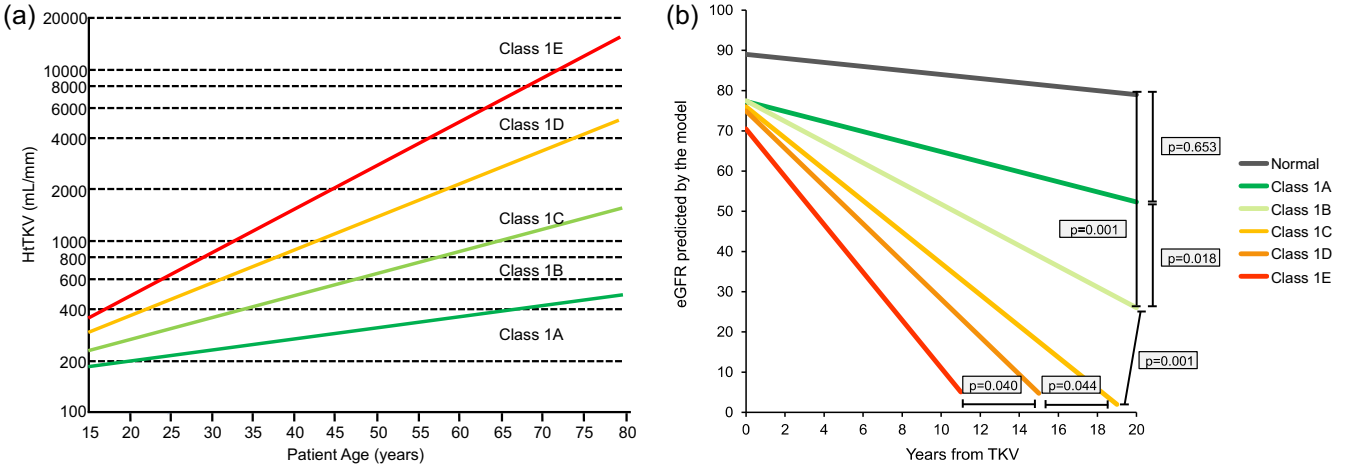

FIGURE 48.8 **The Mayo Image Classification can predict the change in renal volume and eGFR over time based on a one-time measurement of total kidney volume adjusted for height (HtTKV) and age in individuals with class 1 disease.** (a) This plot estimates the predicted increase in renal volume over time based on the class a single MRI measurement places an individual: 1A: <1.5%/year; 1B 1.5–3.0%/year; 1C 3.0–4.5%/year; 1D 4.5–6.0%/year, and 1E >6.0%/year. Note that these estimates only apply to individuals with class 1 disease, which is characterized by bilateral and diffuse cysts (i.e. typical autosomal dominant polycystic kidney disease [ADPKD] presentation). Class 2 disease has unusual features such as unilateral, segmental, or grossly asymmetric localization of cysts or renal atrophy. (b) Predicted slopes of eGFR decline in men with class 1 ADPKD vs. normal kidney donors. The estimated slopes (mL/min per 1.73 m^2/year) by subclass are −0.23, −1.33, −2.63, −3.48, and −4.78. The corresponding slopes for women are 0.03, −1.13, −2.43, −3.29, and −4.58 for women (not plotted). *(a and b) Modified and used with permission of the American Society of Nephrology.*[115]

enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) are most commonly used because the angiotensin system is thought to be upregulated in cystic tissue. There had been hope that combining therapies to block both the ACE and ARB pathways might better preserve renal function, but the NIH-funded HALT trial found no added benefit of dual therapy.[125] One arm of the study did find, however, that intensive treatment to a target of 95–110/60–75 mm Hg compared to a standard target of 120–130/70–80 mm Hg in younger patients with preserved GFR resulted in slower renal growth, greater reduction in urinary albumin excretion, and a greater decline in the left ventricular mass index, although no overall benefit with respect to the estimated GFR was detected.[126] Given that cardiovascular disease is the primary cause of death of people with ADPKD, aggressive BP control to this lower target might have long-term health benefits, but this has not yet been shown in this patient population, and this lower target can be difficult to achieve in practice.

Infections

Although most infections are easily treated, cyst infections can be particularly difficult to diagnose and treat. Imaging studies can sometimes be helpful. ^{18}F-fluorodeoxyglucose positron emission tomography scanning, where available, is the most sensitive method, but persistent fever or high clinical suspicion is sometimes the only clues[127] that an infection is present. Antibiotics that penetrate cysts well include trimethoprim-sulfamethoxazole, fluoroquinolones, clindamycin, vancomycin, and metronidazole.

Abdominal and Back Pain

The evaluation and management of abdominal or back pain in PKD patients can be challenging.[128,129] Diagnostic considerations for acute episodes include cyst rupture, cyst infection, nephrolithiasis, cyst hemorrhage, diverticulitis, and the usual causes that affect the general population. Treatment is directed at the underlying diagnosis. Chronic pain is a much more vexing syndrome. Chronic pain correlates poorly with renal size and like most other types of chronic pain can be difficult to manage. After excluding acute events, nonnarcotic-based treatments are the preferred approach. Several groups have reported that acupuncture and other nonpharmacologic approaches can provide reasonable relief. Early referral to pain management specialists also may be helpful.

Screening for Aneurysms

ICA are reported to be between two and five times more common in PKD patients than in the general population, cluster in families, and are one of the most feared extrarenal manifestations of ADPKD.[31] ICAs often present at an earlier age in ADPKD patients than in the general population and are reported to rupture at a smaller size. ICA rupture can sometimes be the presenting symptom for otherwise asymptomatic

individuals.[130] Fortunately, only a small fraction (~8%) of PKD patients develop this problem. Standard practice has been to reserve screening for a small subset of individuals: those with symptoms suggestive of ICA, members of families with a known history of ICA and PKD, patients who have had a previous ICA rupture, individuals in high-risk professions where a sudden catastrophic event could impact the lives of many others (such as commercial airplane pilots), or individuals whose life quality is compromised by the uncertainty of not knowing.

Counseling

Genetic diseases pose special challenges for patients and their care-providers. On the one hand, they offer an opportunity for early, presymptomatic diagnosis, with the potential for intervention before complications arise. For some individuals, however, a genetic diagnosis is perceived as deterministic of an ill-fated future. Part of the health care provider's role is to both educate the individual and family about the disease and its natural history and to provide treatment. Counseling must be tailored to the specific situation, but common themes include explaining genetic risk and genetic tests, counseling regarding when to test, sharing information with other family members, and discussing prognosis.

Symptomatic Care—ARPKD

A recent study using national statistics from the US calculated a 21% perinatal mortality rate in ARPKD patients, primarily due to respiratory compromise.[5] One-year survival rates of 92–98% have been reported in patients who survive the first month of life.[6,131] Clinical management should attend to several key issues.

Neonatal Pulmonary Hypoplasia

This is a major cause of respiratory compromise and neonatal mortality, although the proportion of infants requiring mechanical ventilation is not well established.[132] Pneumothoraces are relatively common, likely a consequence of the pulmonary hypoplasia. In addition to ventilatory support, aggressive management strategies have been reported, including unilateral or bilateral nephrectomy to improve ventilation and nutrition. However, while, unilateral nephrectomy can avoid the immediate need for dialysis, it may not provide adequate decompression in infants with massive renal enlargement. At present, the optimal approach for neonatal management is not well established, given that the evidence base is limited to case reports and case series and well-controlled trials have not been done.[133]

Renal Function

Most ARPKD patients progress to ESRD, but the age at onset is highly variable, depending in part on the age at initial presentation. In a recent, large European study, 9.4% of patients who presented in the perinatal period required RRT in the first year of life.[134] In older children, a case-controlled study in the Chronic Kidney Disease in Children cohort found that overall rates of GFR decline did not differ significantly in ARPKD subjects vs. CKD controls.[135] A recent study found that among patients who presented after the perinatal period, only 25% required RRT by age 32 years.[20]

Systemic Hypertension

The prevalence of hypertension in various cohorts reportedly ranges from 55 to 75%. The onset typically precedes a decline in GFR. In ARPKD patients the severity of hypertension decreases as renal function declines. The underlying mechanism in ARPKD-related hypertension remains elusive. The data, particularly regarding the role of renin–angiotensin–aldosterone system (RAAS) activation, are controversial. Studies in the *pck* rat model found a significant increase in intrarenal, but not systemic, RAAS activation.[136] This finding may explain why previous human studies had not detected increased plasma renin levels. ACEIs and ARBs are very effective as therapeutic agents, but combination therapy is not advised.[133] Multiagent therapy is often required.

The multicenter ESCAPE trial (i.e. Effect of Strict Blood Pressure Control and ACE Inhibition on the Progression of Chronic Renal Failure in Pediatric Patients) demonstrated that in children with CKD stages 2–4, aggressive blood pressure control (target 24-hour mean arterial blood pressure below the 50th percentile for age, height, and sex) may slow progression to ESRD.[137] However, although this study may have relevance for children with renal cystic disease, the specific BP target for ARPKD patients has not been established.

Other Renal Morbidities

Hyponatremia occurs in up to 25% of neonates and may be due to an inability to maximally dilute the urine. Children with ARPKD appear to be at higher risk for urinary tract infections (UTIs), possibly due to urinary stasis within the cystic, dilated collecting ducts. UTIs have been reported at rates of around 20–50% in various cohorts and are more common in females. Renal calcifications are reportedly more common in older children with ARPKD and may be related to hypocitraturia and a defect in urine acidification due to renal failure.[138]

Hepatobiliary Manifestations

ARPKD is invariably associated with congenital hepatic fibrosis, the result of a developmental defect in ductal plate development. In a subset of patients, the associated progressive portal tract fibrosis causes portal hypertension and associated complications of hypersplenism and varices.[105] Platelet counts, prothrombin time, and spleen volume have been correlated with the severity portal hypertension.[106] Liver transaminases are generally normal, with abnormalities in serum alkaline phosphatase and γ-glutamyltransferase evident in only a fraction of patients. Ascending cholangitis is another important complication, especially for patients with associated Caroli syndrome, and it is a leading cause of morbidity and mortality in ARPKD patients. In one cohort, about 7% of long-term survivors required liver transplantation, with primary indications being portal hypertension that is refractory to medical management or recurrent cholangitis.[6] The relationship between renal and hepatic disease severity in ARPKD is unclear, with most studies demonstrating no significant correlation.[139] A subset of patients with late-onset ARPKD can present with a liver-predominant phenotype with few or no manifestations of kidney disease.[86]

Transplantation

Infants with ESRD can be managed with either peritoneal dialysis or hemodialysis. Renal transplantation is limited by body size, but in experienced pediatric centers, children with a minimum weight of 10 kg can successfully receive renal grafts.[140] Rejection rates and survival beyond 3 years of age are not different in ARPKD patients compared with those with other renal diseases who undergo transplant surgery.[141] However, biliary sepsis is a significant cause of morbidity and mortality in ARPKD patients after renal transplantation.[142] Combined kidney and liver transplantation can be effective for select ESRD patients who have substantial bile duct dilatation and episodes of recurrent cholangitis.[143]

Growth Impairment

Review of the recent literature indicates that a disease-specific effect of ARPKD on growth is controversial.[6,131] Assertive nutritional support, including gastrostomy tube insertion, is often required to optimize linear growth.[144] If growth impairment occurs, treatment with growth hormone can be considered.[145]

Intracranial Aneurysms

Several case reports indicate that ARPKD patients have a low but nonnegligible incidence of ruptured intracranial aneurysms.[146] Given the potential for catastrophic outcomes of subarachnoid hemorrhage in young patients, a low threshold for early radiographic screening may be warranted.

CONCLUSIONS

Spring 2019 marks the 25th anniversary of the identification of the *PKD1* gene, which was followed over the next several years by identification of the *PKD2* and *PKHD1* genes. These discoveries heralded an era of exciting progress in our understanding of the pathogenesis of PKD, accelerated the development of clinical tools to assess disease and track progression, and spurred efforts to identify factors that predict prognosis. Therefore, the stage has been set for the next chapter, in which the efficacy of therapeutic agents that target key pathogenic pathways can be rigorously evaluated in human clinical trials. Although the studies to date have not yet yielded a cure for any of these conditions, they have established an exciting paradigm and have produced a therapy that may slow progression. Building on this paradigm, future clinical trials, using newer study design methodologies, additional predictive markers, and perhaps combinations of targeted therapeutic agents, are positioned to achieve the ultimate goal of identifying disease-specific therapies that prevent or at least arrest the inexorable progression of PKD-related morbidities.

QUESTIONS AND ANSWERS

Question 1

A 65-year-old man with ADPKD has an eGFR of 15 mL/min/1.73 m^2 and is asymptomatic. He is medically cleared for transplantation and has a 29-year-old son who is willing to be considered a potential donor candidate. The son is healthy, normotensive, has a normal eGFR, and an unremarkable urinalysis. Which of the following would be an acceptable next step, and why? (More than one answer may be correct.)

A. Decline further work-up since the son has a 50% risk of having the disease
B. Renal ultrasound
C. Abdominal CT scan with contrast
D. Abdominal MRI
E. DNA testing

Answer: B, D

While it is true that the son is at 50% risk of having the disease, there are well-established diagnostic tests and criteria that can be used to determine his true risk. If studies can determine that he does not have ADPKD, then he is a perfectly acceptable donor if other standard conditions are met. The renal ultrasound is usually the preferred initial diagnostic screening tool because it is of low cost, requires no contrast or ionizing radiation, and is the method that was used to establish the diagnostic criteria that have been validated with the largest datasets. The presence of one or more cysts in an at-risk individual less than 30 years of age makes it highly likely he has inherited the disease. A T2-weighted MRI is another acceptable screening alternative. Although it usually costs more, it provides more detailed anatomic information, greater sensitivity, and possibly better specificity for patients less than 40 years old than ultrasound.[82] Using a total of >10 cysts as the diagnostic threshold for this age group, a recent study found that MRI provided 100% sensitivity and specificity. Although the authors note that a total of <10 cysts can generally be considered sufficient for disease exclusion, they recommended a more stringent threshold of <5 total cysts in at-risk individuals.

An abdominal CT scan with contrast is another sensitive modality frequently used by transplant centers to screen at-risk individuals. It should be noted that diagnostic criteria have not yet been well established.

DNA testing is presently not the preferred initial test since it is expensive, requires analysis of both the recipient and donor, and sometimes yields ambiguous results. In DNA testing, the recipient is first screened to determine whether a definitive pathogenic mutation (i.e. protein-terminating [PT] due to stop codons, deletions that change the reading frame, or splice site mutations that disrupt reading frame or delete exons) is identifiable. If so, the test is highly reliable in determining the genetic risk of a potential donor, and the donor's DNA is then screened in a directed way for that same mutation. If the donor lacks the pathogenic mutation found in the recipient, then he is declared free of disease and is an acceptable potential donor. If the donor has the same pathogenic mutation, he is diagnosed as having the disease and thus excluded as a donor. Unfortunately, in a number of cases, the DNA test results are nondiagnostic, i.e. the test identifies variants of uncertain pathogenicity or the test fails to find any changes that are predicted to alter the DNA sequence in a meaningful way.

In sum, DNA testing is helpful when definitive (50−80%) but is more expensive and more often yields nondiagnostic results. It can be a useful second-level test, however, in situations where the ultrasound or other imaging study is nondiagnostic and the candidate donor is either the best match or the only available potential living donor. For example, the positive predictive value of ultrasound in identifying ADPKD is 100% if an individual has three or more cysts, but the negative predictive value is only 91% if no cysts are detected. This is too high a false-negative rate for most centers, so the choice is either to exclude the possible donor or pursue more definitive testing.

Question 2

A 32-year-old woman is thinking about having a child, but knows that she is at risk for ADPKD because of a positive family history. She consults you to find out whether she has the disease and if so, is it the more (*PKD1*) or less (*PKD2*) severe form. In reviewing her history, you learn that she has had occasional UTIs since becoming sexually active, rare episodes of crampy abdominal pain she attributes to menstrual cramps, but has otherwise been healthy without hypertension. Her mother was diagnosed as having ADPKD in her 50s as an incidental finding while being worked up for suspected cholelithiasis. Her mother has since progressed to ESRD at age 68. In reviewing her outside records you find that an ultrasound done by a trusted radiology practice revealed that her kidneys are on the upper end of normal for her size and she has a single cyst on the left. A CT scan with contrast detected one additional very small cyst in the left kidney and two very small cysts on the right. What do you tell her?

A. She has >99% probability of having ADPKD because she has >3 cysts in both kidneys and should consider adoption
B. She does not have ADPKD because she does not have multiple cysts in both kidneys by ultrasound.

C. She has >90% probability of having ADPKD because she has 1 cyst by ultrasound
D. If she has ADPKD, she will not develop ESRD until her late 60s because that is when her mother developed it
E. Choice "D" with either Choice "A" or Choice "C"

Answer: C

The prior probability of her having the disease is 50% because of her family history but with one cyst detected by renal ultrasound the posttest probability increases to approximately 95%. Simple cysts can be detected in 1–2% of the general population by this age, so one cannot exclude this possibility in her, but the odds of her having the disease far exceed the likelihood that this is a false positive. The reason "A" is not correct is because the diagnostic significance of the additional, small cysts seen only by CT scan with contrast is not known. If one wants to make a more definitive diagnosis, one can either rescan in a year to see if she develops additional cysts detectable by ultrasound (3> is 100% predictive), obtain an MRI, or perform genetic testing. Regardless of whether the individual is ultimately determined to have ADPKD, there is no compelling medical reason to advise this 32-year-old to forego having a child. She has normal renal function and is at low risk of having a complication (94). The reason "E" is not the best choice is because of the intrafamilial variability of its course. The fact that she does not have hypertension, proteinuria, or severe cystic disease at age 32 suggests that she is at lower risk for rapid progression to ESRD, but one cannot state with any confidence whether she will develop ESRD and if so, when.

Question 3

A 30-year-old mother of two presents with a history of occasional UTI, an unremarkable physical examination, a negative pregnancy test, and a urinalysis that was unremarkable except for microhematuria. She had been referred for an abdominal ultrasound because of intermittent abdominal pain. The ultrasound report describes increased echogenicity in the liver, splenomegaly, and several cysts in each kidney. Kidneys were slightly large for the patient's size. The patient reports that she is not aware of anyone else in the family having kidney cysts. Which of the following is the best answer?

A. Tell the patient that she has ADPKD and counsel her about the implications of having an autosomal dominant trait for other family members and her children
B. Tell the patient she has ARPKD, explain the clinical implications of the diagnosis, and reassure her that her children are unlikely to develop the disease given its recessive inheritance pattern
C. Request scans of the young woman's mother and father, and if not available or they are unwilling to be scanned, consider testing for mutations in *PKD1*, *PKD2*, and *PKHD1*

Answer: C

Although the patient technically meets the criteria for a diagnosis of ADPKD because she has bilateral cystic disease with >2 cysts in each kidney, it is important to note that these criteria are most appropriately applied in the setting of a positive family history. This individual lacks a known positive family history. So does this mean she cannot have ADPKD? Certainly not. It is quite common for individuals with ADPKD to be unaware of the health status of other family members because many affected individuals are asymptomatic until quite late in the disease. It is still possible that she could have ADPKD even if imaging studies of her 60+-year-old parents are negative because *de novo* disease accounts for 5–10% of all ADPKD.

But there is another confounding factor that also makes Choice "A" not optimal. She has hyperechogenicity in the liver and hypersplenism, indicating that she likely has hepatic congenital fibrosis (CHF) and portal hypertension. CHF is typically seen with ARPKD, and given her negative family history one might suspect this as the likely diagnosis (Choice "B"). Although historically ARPKD has been viewed almost exclusively as a disease of infants and young children, it is now appreciated that there is a wide range of severity with respect to the renal disease. Presentation in adulthood with predominantly liver disease and mild kidney involvement has been reported.[74] However, the combination of CHF and cystic disease does occur uncommonly in ADPKD, as well as in a number of other ciliopathies including Joubert syndrome, Bardet–Biedl syndrome, nephronophthisis, and COACH syndrome. Therefore, one cannot simply assume that she must have ARPKD because she has CHF and lacks a positive family history. This makes Choice "B" not optimal.

So how should one move ahead with making a more definitive diagnosis? The presence of large kidneys and the absence of other clinical features typically associated with other ciliopathies make ADPKD or ARPKD the likeliest diagnosis. The most definitive approach is to evaluate her parents and look for renal and hepatic cysts. If either parent has classic changes of ADPKD, one can be confident that she has ADPKD, and she can forego more testing given the extended Ravine criteria. Note that the CHF is not an invariant finding within an ADPKD family, so the lack of this finding in other family members is not informative. Genetic modifiers are thought to account for its variable presentation.

If the scans are negative, inconclusive (i.e. a few cysts in one or both parents) or if the parents are unavailable for testing, one can obtain DNA testing of either the ADPKD genes (*PKD1*, *PKD2*) or ARPKD (*PKHD1*) as the next step. If the test is negative, then one could evaluate the other gene. As DNA testing becomes cheaper, it is quite likely that this step-wise approach will be replaced by a single test of all PKD genes.

Question 4

A 22-year-old previously healthy primigravida presents for routine obstetrical sonography at 20-weeks gestation. Her male fetus is noted to have large echogenic kidneys; there is no evidence of other major malformations. There is no known family history of perinatal demise, individuals with renal cystic disease, or individuals requiring RRT. Follow-up maternal renal sonography revealed normal-sized kidneys with normal echo pattern. One cyst (<1 cm) was evident in her right kidney. The maternal grandparents were willing to be screened and neither had evidence of renal cysts. What do you tell the patient?

A. She has ~90% probability of having ADPKD because she has a renal cyst on ultrasound
B. Her son has >99% probability of having ADPKD because she has a kidney cyst
C. Choice "A" and "B"
D. Her son has ARPKD because he has large, echogenic kidneys *in utero*
E. The diagnosis in her son is likely to be ARPKD, but he should undergo further testing when he is born

Answer: E

Although the mother has evidence for one renal cyst, there is no family history to support the diagnosis of ADPKD. Simple cysts can be detected in 1–2% of the general population in early adulthood. Given that the mother does not meet the sonographic criteria for ADPKD, this diagnosis cannot be immediately inferred in her fetus. That said, spontaneous mutations do occur in the ADPKD genes with an estimated frequency from 1–2% to as high as 10% of affected individuals. Enlarged echogenic kidneys *in utero* are a common manifestation of ARPKD. However, this presentation can be phenocopied by very early onset ADPKD (in this case reflecting a spontaneous mutation in the fetus), as well as numerous other hepato-renal fibrocystic diseases. Therefore, the diagnostic approach once this child is born should include a careful physical examination (to exclude syndromic features) and further imaging studies.

If genetic testing is considered, the phenotypic overlap between ARPKD with syndromic HRFD must be considered. Screening a panel of genes using NGS is rapidly becoming the most efficient diagnostic approach and soon will be the most cost-effective. In the near future, it is likely that single-gene testing will become the exception rather than the rule, especially for genetically heterogeneous disorders with a broad phenotypic spectrum such as PKD.

Question 5

A 32-year-old woman presents for prenatal consultation. She and her husband have had two previous children who died shortly after birth due to respiratory insufficiency associated with severe renal cystic disease. The parents were told that both children had ARPKD based on autopsy findings in the kidney and liver. No DNA is available for either child. The parents are interested in pursuing preimplantation genetic diagnosis (PGD) for the next pregnancy. What can you advise them?

A. Because they have had two children with ARPKD, the likelihood is quite low that they would have a third affected child
B. Ultrasound is quite sensitive in detecting ARPKD early in a pregnancy and thus, imaging studies in the first trimester should demonstrate whether the current fetus is affected
C. Without documented *PKHD1* mutations in a previously affected child, PGD is impractical for future pregnancies
D. In the context of a future pregnancy, DNA extracted from tissue blocks taken at the time of autopsy in the previous children and from amniocentesis in the current pregnancy can be used for linkage studies to determine the affectation status of the current fetus
E. The parents can undergo *PKHD1* testing, and if likely pathogenic mutations are identified in each, PGD is feasible to guide the implantation of an unaffected embryo

Answer: E

In recessive disorders, every pregnancy has a 25% chance of yielding an affected child. In ARPKD, prenatal sonography can detect affected kidneys as early as 20-weeks gestation. However, normal sonographic findings do not necessarily exclude a diagnosis of ARPKD because abnormalities may not be evident until late in the second trimester (or beyond), even in infants who go on to manifest a severe phenotype at birth. Linkage studies (or haplotype analysis) have been a useful diagnostic tool for families with more than one affected child when no *PKHD1* mutations have been identified. However, this approach means testing a current pregnancy, with the attendant complexities of how to proceed if

the testing indicates that the current fetus is affected. PGD offers an alternative to prenatal diagnosis in a current pregnancy. This methodology requires the prospective identification of the *PKHD1* mutations transmitted from each parent. Thus, in the current situation, PGD is feasible if the likely pathogenic allele is identified in each parent.

Question 6

A 16-year-old girl presents for evaluation after passing tarry stool. She had an uneventful delivery and neonatal course. Her childhood has been similarly uneventful. On physical examination, she is well-grown and normotensive. Other notable findings include a liver edge palpable 3 cm below her right costal margin and a palpable spleen tip. Sonography reveals that her kidney length is within the normal limits for her age and the echotexture is normal. Her liver has a heterogeneous echo pattern and evidence of dilated bile ducts. There is no known family history of perinatal demise, individuals with renal cystic disease, or individuals requiring RRT. What do you tell the patient and her parents?

A. She likely has ARPKD
B. Her diagnosis is uncertain and she should undergo *PKHD1* genetic testing
C. She does not have PKD because there are no renal cysts evident on ultrasound
D. She may have polycystic liver disease

Answer: A

The patient's presentation with tarry stools indicates low-grade GI bleeding. In the context of her physical examination and liver sonographic findings, a variceal source is likely. A subset of patients with ARPKD can present exclusively with liver disease related to portal hypertension and no evidence of renal cystic disease. MRI studies would be a useful next diagnostic step to further evaluate the patient's kidneys and liver, as well as the extent of the bile duct dilatation. Endoscopy should be considered to identify and manage the likely varices. With the advent of NGS, a targeted gene panel that includes *PKHD1*, as well as *PKD1*, would enhance the diagnostic certainty.

In patients with congenital hepatic fibrosis (an invariant feature of ARPKD), and sonographic evidence of bile duct dilatation, the term Caroli syndrome is used to describe the liver lesion. This lesion is architecturally distinct from ADPLD, which involves gross liver cysts and is much less commonly associated with portal hypertension. Therefore, screening the genes associated with ADPLD is not likely to be informative.

Lupus Nephritis

Brad Rovin[a], *Samer Mohandes*[a], *Andrew Bomback*[b], *Jai Radhakrishnan*[b]

[a]Division of Nephrology, Department of Internal Medicine, Ohio State University Wexner Medical Center, Columbus, OH, United States; [b]Division of Nephrology, Department of Medicine, Columbia University Irving Medical Center, New York, NY, United States

Abstract

Lupus nephritis (LN) is clinically evident in 50–75% of lupus patients and is a significant cause of end-stage renal disease. Although LN is a paradigm of immune complex–mediated renal injury, its pathogenesis is complex, involving abnormalities in multiple components of the immune system including B and T cells, the complement cascade (especially the alternative pathway), and tissue enzymes that clear denatured DNA. The diagnosis of LN still hinges on the renal biopsy, with glomerular changes being the predominant feature in the classification of LN. The prognostic role of interstitial inflammation has recently been demonstrated. Treatment regimens for severe proliferative LN consist of combination therapy using corticosteroids with cyclophosphamide or antimetabolites (mycophenolate). After remission is achieved, maintenance therapy with a tapering dose of corticosteroids is combined with an antimetabolite (mycophenolate or azathioprine). LN may be refractory to standard regimens in up to 50% of patients and B-cell therapies, calcineurin inhibitors, immunomodulators, and complement inhibitors have been used in this setting with varying success.

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease that can affect multiple organs, including the skin, joints, brain, peripheral nervous system, heart, gastrointestinal tract, and kidneys. Renal involvement in SLE, generally termed lupus nephritis (LN), is a major contributor to disease morbidity and mortality. Up to 50% of SLE patients will have clinically evident kidney disease at presentation. During follow-up, renal involvement occurs in up to 75% of patients, with an even greater representation among children and young adults. LN has been shown to impact clinical outcomes in SLE both directly, *via* target organ damage, and indirectly, through complications of therapy.

THE PATHOGENESIS OF KIDNEY INJURY IN LUPUS NEPHRITIS

Immune complex accumulation in the glomeruli of patients with SLE appears to be the earliest step in the development of LN, initiating a series of events that result in renal inflammation and kidney injury. Glomerular immune complex accumulation may be due to deposition of preformed circulating immune complexes, kidney-specific nephritogenic autoantibodies directed against intrinsic glomerular basement membrane (GBM) proteins (antilaminin and anti-α-actinin), or *in situ* formation of immune complexes between antichromatin antibodies and extracellular glomerular chromatin derived from apoptotic kidney cells. Kidney-specific autoantibodies are not found in glomerular immune complexes, and circulating levels do not correlate with LN clinical activity.[1–4]

Glomerular immune deposits do contain extracellular chromatin with nicked DNA suggestive of an apoptotic origin,[1,5] and kidney cell apoptosis has been demonstrated in lupus-prone mice.[1] Chromatin derived from apoptotic kidney cells could accumulate along the GBM because the major kidney endonuclease responsible for chromatin degradation (Dnase1) is downregulated in LN, and positively charged histones bind to the negatively charged GBM with high affinity.[5,6] Although autoantibodies found in the LN kidney are generally considered to originate from the circulation, T and B cells can form aggregates, and in some cases germinal centers in the kidney interstitium. Interstitial plasma cells appear to produce antibodies in a clonally restricted fashion, suggesting kidney-relevant autoantibodies may be produced locally.[7,8]

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00049-8

The expression of autoantibodies and clearance of immune complexes in LN patients are under genetic control. For example, the HLA DR3 allele (DRB1 *0301) is associated with anti-dsDNA antibodies and with LN.[9,10] Genetic variants of immune complex clearance proteins, such as the immunoglobulin heavy chain receptors that result in higher-affinity interactions with IgG, are associated with protection against LN in SLE patients.[11,12]

Anti-dsDNA autoantibodies are predominantly IgG1 and IgG3,[13,14] the most proinflammatory IgG subtypes due to their ability to activate complement and engage leukocyte Fc receptors for IgG (FcγR). Complement-mediated kidney damage has been demonstrated directly in experimental models of LN.[15–20] These experiments indicate that the alternative pathway of complement activation is probably the effector arm of complement within the lupus kidney, a conclusion also applicable to renal injury in human LN.[21] Blocking the classical complement pathway may actually worsen LN,[18] likely because complement is not only proinflammatory but also important in clearing apoptotic debris.[22,23] Thus, if complement is to be targeted therapeutically in human LN, drugs that attenuate alternative pathway activation will probably be more successful.[24]

Complement-mediated kidney injury may occur by direct cellular damage through formation of the membrane attack complex C5b-9,[25] or more indirectly through recruitment of leukocytes to the kidney by the chemotactic complement fragments C3a and C5a. These complement fragments, along with immune complex ligation of leukocyte FcyR, can activate infiltrating leukocytes to produce proinflammatory cytokines and chemokines.[26,27] Immune complexes and complement can also induce cytokine and chemokine expression by intrinsic kidney cells. Several cytokines are known to be upregulated in LN kidneys, including monocyte chemoattractant protein-1 and macrophage inflammatory protein-1-α, IL-6, IL-10, IL-12, IL-17, IL-18, IFN-γ, TNF-α, and Eta-1/osteospontin.[28–35] The contribution of individual cytokines to kidney injury in LN has been assessed by genetically deleting or neutralizing specific cytokines in murine models and observing the effect on disease activity and kidney pathology.[36–40] These experiments provide a rationale for therapeutic targeting of individual cytokines and chemokines in human LN. Given the intrinsic redundancy of cytokine effects, finding a single cytokine target with robust therapeutic potential is likely to be challenging.

An exception may be interferon-α (IFN-α).[41] Plasmacytoid dendritic cells (pDCs) are the major source of IFN-α following engagement of their endosomal toll-like receptors 7 and 9 (TLR7, TLR9) by nucleic acids.[42,43] During LN pDCs leave the circulation and accumulate in glomeruli.[44,45] This influx is mediated in part by IL-18 and IL-18 receptor. Human diffuse proliferative LN is associated with an IL-18 promoter polymorphism that causes increased IL-18 expression.[46] The effects of IFN-α on the immune response include driving maturation of conventional dendritic cells into potent antigen presenting cells,[47] inducing B-cell differentiation to plasma cells,[48] and contributing to the development of CD4 helper T cells,[49] and CD8 central memory T cells.[50] Peripheral blood cell levels of IFN-inducible genes are associated with LN,[51,52] and a genetic variant that increases STAT4, a secondary messenger for IFN-α signaling, is overexpressed in LN.[53,54] It is plausible that the presence of glomerular immune complexes could drive pDCs to produce IFN-γ, amplifying the autoimmune response to local kidney antigens and contributing to the formation of local germinal centers. Studies in mouse models also generally support a role for IFN-γ in LN pathogenesis. Experimental LN is reduced by deletion of the IFN-γ receptor or by administration of TLR7 or TLR9 antagonists, whereas LN is worsened by administration of an IFN-α–producing vector or an agonist of TLR7 or TLR9.[55] Clinical trials of IFN-α antagonists are currently underway in SLE.

Intrarenal cytokine and chemokine production amplifies the kidney inflammatory response by recruiting leukocytes to the kidney. Neutrophils and monocytes/macrophages can damage the kidney directly through secretion of oxygen radicals and proteolytic enzymes. Neutrophils may also contribute to LN as they die and release neutrophil extracellular traps (NETS), which are chromatin structures that can bind autoantigens.[56–58] NETs stimulate IFN-α secretion from dendritic cells,[56] amplifying the intrarenal autoimmune response.

Kidney-infiltrating T cells tend to exhibit a Th1 cytokine expression profile, including IL-12, IL-18, and IFN-γ; however this is not exclusive and some Th2 cytokines, such as IL-10, also increase. Overall the Th1/Th2 ratio is increased[30,33,34,59] and correlates with histologic activity. Th1 cytokines are associated with activated macrophages and with the production of immunoglobulins that can activate complement and FcyR pathways, further amplifying renal inflammation. IL-17, from Th17 cells and $CD4^{-}CD8^{-}$ T cells, is found in the kidney in LN.[35] In addition to IL-17's role in mediating inflammation,[60–62] this cytokine may also represent a shift away from natural regulatory T cells capable of suppressing immune responses.[63]

Human regulatory T cells (Treg) attenuate immune responses, particularly autoantibody production.[64–67] In murine lupus models, adoptive transfer of Tregs can suppress LN.[68,69] Some human studies have described lower circulating levels of Tregs in SLE,[65,70] but their role in human LN remains to be determined.

CLINICAL MANIFESTATIONS OF LUPUS NEPHRITIS[71]

Clinical Presentation

Most patients with SLE have laboratory evidence of kidney involvement at some point in their disease. In about one-third of SLE patients, renal involvement first manifests with proteinuria and/or microhematuria on urinalysis. This is a harbinger of eventual progression to reduction in kidney function. However, early in the course of disease, it is unusual for patients to present with decreased kidney function (i.e. elevated S[Cr] and reduced eGFR), with the exception of very aggressive cases of LN, some of which present as rapidly progressive glomerulonephritis. Instead, patients often present initially with evidence of nonrenal organ involvement, such as malar rash, arthritis, and oral ulcers. After a diagnosis of SLE is confirmed with appropriate laboratory tests, evidence of kidney disease, if present, usually emerges within the first 3 years after diagnosis.

The symptoms of kidney involvement tend to correlate with laboratory abnormalities. For example, patients with nephrotic range proteinuria often present with edema of the lower extremities and, if severe, periorbital edema in the morning. When kidney function is impaired, as is the case with progressive forms of LN, elevated blood pressure is a common clinical finding. The rare development of dark or tea-colored urine is a sign of gross hematuria. A number of tools, such as the SLE Disease Activity Index and the British Isles Lupus Assessment Group Index, have been developed to assess the systemic severity of lupus symptoms. Although these questionnaires are primarily used to codify symptoms for clinical trial settings, they also can be very helpful to elicit a detailed history from a patient with SLE.

Laboratory Findings

The American College of Rheumatology has listed 11 diagnostic criteria for SLE: antinuclear antibodies (ANA), arthritis, immunologic disorders (including antidouble strand DNA antibody, antiphospholipid antibody, or anti-Smith antibody), malar rash, discoid rash, photosensitivity, oral ulcers, serositis, hematologic disorder, neurologic disorder, and renal disorder. Ideally, four or more of these criteria should be present to make the diagnosis of SLE, including laboratory findings of a positive ANA and/or antidouble strand DNA antibody. In addition to the ANA and double-strand DNA antibody, serum complements (C3, C4, CH50) should be checked whenever kidney involvement is suspected because these are often low when disease is active, as is usually the case with any severe proliferative LN. Antiphospholipid and anticardiolipin antibodies are useful in gauging the risk for clotting abnormalities that can accompany SLE.

Laboratory testing is used both to diagnose kidney involvement and to assess response to therapy in patients with SLE. Traditional parameters, such as S[Cr] and urinary protein excretion (quantified by either 24-hour collection or first morning urine protein:creatinine ratio), are supplemented by serial review of microscopic urinary sediment, changes in serum complement levels, and titers of ANA and double-strand DNA antibodies. Because cytopenias can often be seen with active SLE, complete blood counts should be checked regularly. A number of urine and serologic tests have been recently studied as biomarkers for SLE and, specifically, LN disease activity.[72] These include molecules specific to lupus (e.g. anti-C1q antibodies), mediators of chronic inflammation (e.g. TNF-like weak inducer of apoptosis), and generalized markers of kidney injury (urinary neutrophil gelatinase–associated lipocalin).[73] However, the clinical utility of this approach remains unproven, and no serum or urine disease markers are able to provide as much information as a kidney biopsy. Hence, virtually all patients with SLE with suspected kidney involvement will undergo one or more kidney biopsies at some point during their care.

Kidney Biopsy Findings

The classic pattern of LN is an immune complex–mediated glomerulonephritis; however, the pathology of LN can be quite varied and at times cause confusion with other immune complex-mediated glomerulonephritides. Particular biopsy findings are highly characteristic of LN, including: (1) glomerular deposits that stain dominantly for IgG with codeposits of IgA, IgM, C3, and C1q, the so-called "full house" immunofluorescence (IF) pattern; (2) extraglomerular immune type deposits within tubular basement membranes, the interstitium, and blood vessels; (3) the ultrastructural finding of coexistent mesangial, subendothelial, and subepithelial electron dense deposits; and (4) the ultrastructural finding of tubuloreticular inclusions (TRIs), which represent "interferon footprints" in the glomerular endothelial cell cytoplasm.

Although LN may affect all compartments of the kidney, glomerular involvement is the best-studied component and correlates well with the presentation, course, and treatment of the disease. Disease classification, therefore, is based largely on the glomerular alterations as assessed by the combined modalities of light microscopy (LM), IF, and electron microscopy (EM). The 2004 modifications in the International Society of Nephrology (ISN)/Renal Pathology Society (RPS) Classification refine and clarify some of the deficiencies of

the older WHO classification of LN.[74] The current approach to treating LN—and studying new therapeutic modalities—has largely been guided by histologic findings (i.e. ISN Class) with appropriate consideration of presenting clinical parameters and the degree of renal impairment.

The ISN/RPS classification recognizes six different classes of immune complex-mediated lupus glomerulonephritis based on biopsy findings.[75] These classes are not static entities but may transform from one class to another, both spontaneously and after therapy. ISN/RPS class I represents the mildest possible glomerular lesion—immune deposits limited to the mesangium, without associated mesangial hypercellularity. In class II, the mesangial deposits detected by IF and/or EM are accompanied by mesangial hypercellularity of any degree. In class III, there is focal and predominantly segmental endocapillary proliferation and/or sclerosis affecting <50% of glomeruli sampled. The active endocapillary lesions typically include infiltrating monocytes and neutrophils and may exhibit necrotizing features. In class IV, the endocapillary lesions involve ≥50% of glomeruli sampled, typically in a diffuse and global distribution. Subendothelial immune deposits are a feature of the endocapillary lesion in class III and class IV, where they vary from focal and segmental (class III) to more diffuse and global (class IV). Both class III and class IV may exhibit extracapillary proliferation in the form of cellular crescents, a feature that correlates best with a rapidly progressive clinical course. Class V denotes membranous LN. Subepithelial deposits are the defining feature, usually superimposed on a base of mesangial hypercellularity and/or mesangial immune deposits. Well-developed examples of class V typically exhibit glomerular basement membrane spikes between the subepithelial deposits. In those patients with combined membranous and endocapillary lesions, a diagnosis of both class V and class III or IV is made. These mixed classes carry a worse prognosis than pure class V LN. Class VI identifies advanced chronic disease exhibiting >90% sclerotic glomeruli, without residual activity.

Unusual kidney biopsy findings in SLE patients include "lupus podocytopathy," presenting as nephrotic syndrome with diffuse foot process effacement in the absence of peripheral capillary wall immune deposits.[76] Such cases resemble minimal change disease or focal segmental glomerulosclerosis in their histopathologic findings and response to glucocorticoids. Rare cases of LN have predominant tubulointerstitial nephritis with abundant tubulointerstitial immune deposits in the absence of significant glomerular lesions. Some cases with necrotizing and crescentic features and a paucity of peripheral capillary wall immune deposits are associated with circulating antineutrophil cytoplasmic antibody (ANCA) in addition to ANA.[77] This "pauci-immune" variant is particularly common in LN class IV-S, in which there are diffuse but segmental lesions of necrosis and crescent formation. In any patient with SLE who develops thrombotic microangiopathy affecting the glomeruli and/or vessels, the possibility of a circulating lupus anticoagulant or antiphospholipid antibody should be investigated.

TREATMENT

General Treatment Concepts

The 2003 ISN/RPS classification of LN (Table 49.1) is widely accepted and forms the cornerstone for treatment decisions. Class I and II lesions do not need specific therapy; treatment if needed is directed at extrarenal lupus manifestations. The optimal regimen for treating the aggressive forms of LN is far from established in terms of efficacy and toxicity. Treatment regimens for the more aggressive forms of LN take the form of an "induction" phase where combinations of corticosteroids and either cytotoxic agents or antimetabolites have been studied in several controlled trials. This is followed by a "maintenance" phase where the doses of corticosteroids are lowered and cytotoxic agents, if used for the induction phase, are replaced by antimetabolites. The treatment for class V LN is similar to that used for idiopathic membranous nephropathy, although large controlled trials are lacking. LN has a significant relapse rate and there is considerable morbidity (and even mortality) associated with treatment. Thus, close monitoring of patients for clinical lupus activity, laboratory indices (S[Cr], proteinuria, urinary sediment and lupus serologies), and side effects (blood counts, infections, malignancies) are important.

Proliferative Lupus Nephritis: Induction Therapy

Recent clinical studies of SLE patients with renal disease, including a number of randomized controlled trials (RCTs), have clarified the therapeutic role of a variety of immunosuppressive regimens both in proliferative and membranous LN. The goal of each of these trials has been to achieve clinical efficacy with a remission of the nephritis while minimizing deleterious side effects of treatment. The greatest amount of RCT evidence in treating LN is in the induction phase of proliferative LN.

Most patients with active proliferative LN are initially treated with corticosteroids (traditionally a "pulse" of IV steroids followed by a high dose oral regimen that begins to taper at 8 weeks) used in conjunction with other immunosuppressive agents. Clinical trials over the last

TABLE 49.1 International Society of Nephrology/Renal Pathology Society Classification of Lupus Nephritis (LN) With Corresponding Treatment Strategies

Lupus Class	Treatment Strategy
Class I Minimal mesangial LN	No specific treatment for LN. Treatment dictated by extrarenal systemic lupus erythematosus (SLE) symptoms
Class II Mesangial proliferative LN	No specific treatment for LN unless significant proteinuria, e.g. >1 g/day (short course of tapering corticosteroids may be considered) Treatment dictated by extrarenal SLE symptoms
Class III Focal LN* (<50% of glomeruli) III (A): active lesions III (A/C): active and chronic lesions III (C): chronic lesions	As in Figure 49.1
Class IV Diffuse LN* (≥50% of glomeruli) Diffuse segmental (IV-S) or global (IV-G) LN IV (A): active lesions IV (A/C): active and chronic lesions IV (C): chronic lesions	As in Figure 49.1
Class V Membranous LN	Corticosteroids with calcineurin inhibitors, mycophenolate or intravenous cyclophosphamide in patients with nephrotic proteinuria
Class VI Advanced sclerosing LN (≥90% globally sclerosed glomeruli without residual activity)	Conservative management and preparation for end-stage renal failure

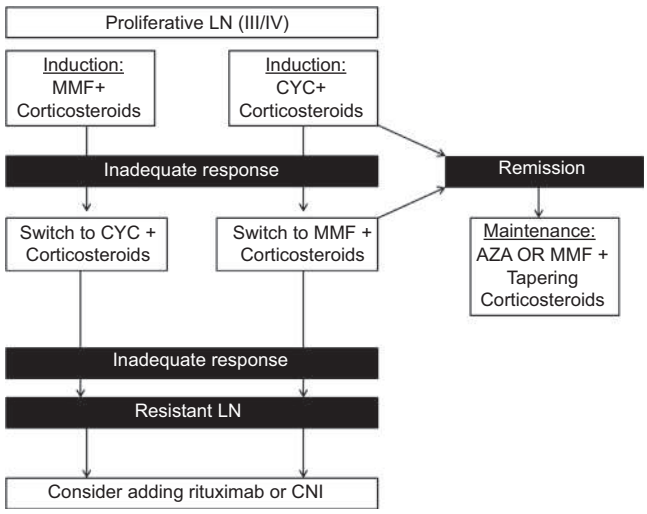

FIGURE 49.1 Suggested treatment algorithm for proliferative lupus nephritis. *AZA*, azathioprine, *CNI*, calcineurin inhibitor; *CYC*, cyclophosphamide (includes intravenous or oral regimens); *MMF*, mycophenolate mofeti.

decade have provided support for using mycophenolate mofetil (MMF) as an alternative to intravenous cyclophosphamide for induction therapy in severe LN (ISN classes IIIA, IIIA/C, IVA, and IVA/C).

Cyclophosphamide remains a reliable and effective treatment choice for inducing remission in LN. Whether oral therapy or intravenous pulses of cyclophosphamide is more effective in treating LN remains inconclusive, but intravenous therapy involves a lower cumulative exposure to cyclophosphamide, less-frequent cytopenias, enables enhanced bladder protection, and avoids problems of nonadherence. RCTs at the National Institutes of Health (NIH) in patients with severe, proliferative LN established that six pulses of intravenous cyclophosphamide (0.5–1 g/m^2) on consecutive months, followed by every third month follow-up pulses with low-dose corticosteroids, was effective and prevented relapses better than a shorter regimen limited to six doses alone. A subsequent controlled trial established that pulse cyclophosphamide, when given with monthly pulses of methylprednisolone, led to better long-term GFR than either regimen alone.[78,79] Nevertheless, side effects were significant in both therapeutic arms of this study, including ischemic and valvular heart disease, avascular necrosis, osteoporosis, and premature menopause. Major infections occurred in 33% of subjects treated with cyclophosphamide alone and 45% of subjects treated with cyclophosphamide plus steroids. Therefore, more recent studies using newer regimens have focused on achieving the high induction response rate of "NIH protocol" cyclophosphamide with fewer side effects.

A trial by the EuroLupus Group randomized 90 patients with diffuse or focal proliferative LN, or

membranous plus proliferative disease, to receive either standard six monthly pulse of cyclophosphamide (0.5–1 g/m^2) followed by every third monthly infusions or to a shorter treatment course consisting of 500 mg of intravenous cyclophosphamide every two weeks for six doses (total dose 3 g) followed by azathioprine maintenance therapy (2 mg/kg/day). Both regimens were equally effective for various renal and extrarenal outcomes. The shorter regimen had less toxicity with significantly less severe and total infections as a complication of treatment.[80] Reports from this trial with up to 10 years of follow-up continue to find no differences in outcome between treatment groups, although approximately 75% of these patients remained on some dose of steroids throughout this follow-up period. As this trial was largely performed in white subjects, questions about whether the "EuroLupus regimen" was applicable to all populations at high risk for poor renal outcomes persisted. However, a recent study examining the role of abatacept in proliferative LN added either abatacept or placebo in conjunction with the EuroLupus regimen of low-dose cyclophosphamide in 134 subjects, of whom only half (n=67) were white and almost 40% (n=52) were African American. Although this study found no benefit in using abatacept, the background response rates across all participants were high enough to lend support for using the EuroLupus regimen in nonwhite patients.[71]

Several recent controlled trials and subsequent meta-analyses have established MMF as one of the recommended, first choice regimens for inducing a remission in severe active proliferative LN. An initial report was a Chinese study of 42 patients randomized to receive either 12 months of oral MMF (2 g/day for 6 months followed by 1 g/day for 6 months) or 6 months of oral cyclophosphamide (2.5 mg/kg/day), followed by oral azathioprine (1.5 mg/kg/day) for 6 months. Both groups received concomitant tapering doses of corticosteroids. At 12 months, the rate of complete remission (81% vs. 76%), partial remission (14% vs. 14%), and relapses (15% vs. 11%) were not different between the regimens, but infections were less common in the MMF arm, and mortality was only seen in the cyclophosphamide group (0 vs. 10%).[81] Long-term follow-up of this population showed similar rates of chronic renal failure, defined as doubling of baseline S[Cr], in the MMF group (6.3%) and the cyclophosphamide-azathioprine group (10.0%), as well as similar rates of relapse and relapse-free survival. However, infection was now significantly less in the MMF group (13% vs. 40%) and mortality was still entirely in the cyclophosphamide group.[82]

A larger US induction trial, reported 5 years later in a more diverse population (over 50% African Americans), examined 140 patients with proliferative LN or membranous LN randomized to intravenous cyclophosphamide monthly pulses vs. oral MMF up to 3 g daily, each in conjunction with a fixed tapering dose of corticosteroids as induction therapy over 6 months. Although the study was powered as a noninferiority trial, complete remissions and complete plus partial remissions at 6 months were significantly more common in the MMF arm (52%) than the cyclophosphamide arm (30%).[83] Again, the side effect profile was better in the MMF group, and at 3 years, there were no significant differences in numbers of patients with renal failure, end-stage renal disease (ESRD), or mortality. Most recently, a 370-patient, international multicenter trial of induction therapy with either MMF (3 g/day) or monthly intravenous cyclophosphamide pulses showed, after 6 months of therapy, virtually identical rates of achieving complete and partial remission (56.2% of patients receiving MMF vs. 53.0% of patients receiving IV cyclophosphamide, $p = 0.58$).[84] The groups proved identical with respect to improvement of renal function (assessed by eGFR, S[Cr], proteinuria, and urine sediment) as well as nonrenal parameters (reduction in anti-DNA antibody titers, normalization of serum complement, and increase in serum albumin (S[Alb]) levels). Notably, there was no difference in mortality between the groups with a total of 14 deaths among the 370 patients. A subgroup analysis of those presenting with significant renal failure (defined as GFR <30 mL/min) found no indication that MMF was less effective than cyclophosphamide in this setting.[85]

Other agents have been explored in induction regimens, typically used in conjunction with MMF and/or steroids. Rituximab, an anti-CD20 monoclonal antibody that depletes B cells, has proven useful in inducing remissions in some patients with severe LN, including those who have failed cyclophosphamide or MMF therapy, although this strategy is not supported by data from randomized trials. The Lupus Nephritis Assessment with Rituximab (LUNAR) trial randomized 140 patients with severe LN to rituximab or placebo added to a full dose of MMF (up to 3 g/day) and tapering dose of corticosteroids.[86] Although more subjects in the rituximab group achieved complete remission or partial remission, there was no statistically significant difference in the primary clinical endpoint at Week 52. The role of rituximab remains unclear in the treatment of LN, but it may still be of use in treating resistant patients, preventing flares, or reducing the number or doses of other immunosuppressive medications.[56] For example, subgroup analyses of the LUNAR study showed higher rates of remission in African Americans and Hispanics randomized to rituximab vs. placebo, suggesting that these higher-risk populations might still receive benefit from rituximab, especially if initial induction therapy with MMF has failed to achieve sustained remission.

Another induction treatment strategy studied in small settings is to combine a calcineurin inhibitor with MMF or azathioprine plus corticosteroids. This multitargeted immunosuppressant regimen is akin to those used in protecting kidney transplants. For example, Bao and colleagues randomized 40 patients with diffuse proliferative LN superimposed on membranous LN (ISN class IV + V) to induction therapy with MMF, tacrolimus, and steroids (multitarget therapy) or intravenous cyclophosphamide plus steroids.[87] Intention-to-treat analysis revealed a higher rate of complete remission with multitarget therapy at both 6 and 9 months (50% and 65%, respectively) than with cyclophosphamide (5% and 15%, respectively). Adverse events were lower in the multitarget group. In a subsequent report using a much larger patient population drawn from 26 nephrology centers across China, this multitarget therapy at 24 weeks, compared to cyclophosphamide-based induction, also showed higher rates of complete (46% vs. 26%) and complete plus partial (84% vs. 63%) remission. The median time to overall response was shorter in the multitarget group.[88] Voclosporin, a new calcineurin inhibitor, is currently being evaluated as a treatment for proliferative LN. This agent, given in combination with MMF in a multitargeted approach similar to that used in the aforementioned Chinese studies, has shown promising results in a phase 2 study (presented in abstract form) and is now being evaluated in a larger, phase 3 study (NCT03021499).

Plasma exchange has been added to other induction therapies (e.g. cyclophosphamide) in several trials without any demonstrated clear benefit in terms of renal or patient survival.[89] Therefore, the routine use of plasma exchange is not justified in LN, although this procedure may be of value in unique individuals such as those with a refractory antiphospholipid antibody and contraindications to anticoagulation, or those with both positive lupus and ANCA serologies. For patients with life-threatening resistant disease, small pilot studies have utilized total lymphoid irradiation, and immunoablation by high dose cyclophosphamide and anti-thymocyte globulin, with or without reconstitution with autologous stem cells.[90,91] Although these approaches have led to some sustained, treatment-free remissions, they are potentially toxic and have significant treatment-related mortality. They have not been widely studied or embraced as therapy for LN.

Proliferative Lupus Nephritis: Maintenance Therapy

The two goals of maintenance therapy are provision of chronic immunosuppression after the intense induction period, and prevention of renal flares after a response has been achieved, while limiting adverse treatment effects. The main agents used for LN maintenance are MMF and AZA. If neither can be used, calcineurin inhibitors are an additional option.

The evolution of LN treatment provides context for understanding current maintenance regimens. After it was shown that cyclophosphamide plus corticosteroids was more effective than corticosteroids alone for long-term kidney health, it was found that prolonged therapy with cyclophosphamide (30 vs. 6 months) resulted in even better renal outcomes and fewer renal flares.[92] However, the toxicity of cyclophosphamide maintenance was very high. Investigating less-toxic long-term immunosuppression regimens led to the seminal clinical observation that MMF or AZA could be used instead of cyclophosphamide with similar efficacy but significantly lower morbidity and mortality.[93] This ushered in the current approach to maintenance therapy.

MMF and AZA have been compared head-to-head in two recent randomized trials to determine the drug of choice for maintenance. In the ALMS maintenance trial, after induction with either MMF or cyclophosphamide, patients who had a renal response were rerandomized to receive MMF or AZA for 3 years.[94] MMF was superior to AZA in preventing the composite treatment failure endpoint of death, renal flare, ESRD, and doubling of S [Cr]. In contrast, MMF and AZA were equivalent in preventing renal flare over more than 4 years of follow-up after induction with low-dose (Eurolupus protocol) cyclophosphamide (MAINTAIN Trial).[95,96] Although the ALMS maintenance and MAINTAIN results seem contradictory, the two trials are not strictly comparable. MAINTAIN included mainly European Caucasians, whereas ALMS maintenance followed a multiracial cohort. In summary, MMF appears to be the maintenance immunosuppressive of choice for most LN patients[97]; however, AZA can be used if MMF is not tolerated, or individual patient needs preclude its use, such as a desire to become pregnant.

The calcineurin inhibitors cyclosporine and tacrolimus provide a third option for LN maintenance therapy. Two randomized trials compared calcineurin inhibitors to AZA, and both showed that cyclosporine and tacrolimus were as effective as AZA in preventing LN flares.[98,99] Both of these trials were underpowered and had short follow-up. Calcineurin inhibitors have not yet been compared to MMF for maintenance.[97] For now, calcineurin inhibitors should be reserved for patients who cannot receive MMF or AZA. The study authors from China who reported on multitarget (MMF + tacrolimus) therapy for induction therapy have also reported an open label, multicenter study for 18 months to assess the efficacy and safety of a similar multitarget maintenance therapy in patients who had responded at 24 weeks during the induction phase.

Those induced on multitarget therapy (N = 116) remained on low-dose MMF, tacrolimus, and prednisone, whereas those induced with cyclophosphamide (N = 90) were given azathioprine plus prednisone. The multitarget and azathioprine groups had similar cumulative renal relapse rates (6% vs. 8%, respectively), and S[Cr] levels remained stable in both groups. The azathioprine group had more adverse events (44% vs. 16% for multitarget therapy).[100] The caveats for both the induction and maintenance phase of these multitarget therapy studies include (a) whether they will be generalizable beyond Asian LN populations, and (b) whether the remission rates achieved will be sustained once calcineurin inhibitors are weaned off, given the high rate of proteinuria relapse when calcineurin inhibitors have been stopped in other glomerular diseases.

The optimal duration of maintenance therapy has not been investigated by any prospective randomized clinical trial. Most patients remain on maintenance therapy for years. In a survey of several randomized clinical trials immunosuppression was continued for an average of 3.5 years (range 1.5–7 years).[80,82,92,93,101–104] LN guidelines recommend slow withdrawal of maintenance therapy beginning 1 year after a complete renal response, but continuing indefinitely in patients who only achieve a partial renal response.[105] Two small retrospective studies examined renal flares after maintenance therapy was withdrawn or tapered. One study found that patients segregated into a group that flared and a group that did not flare during a median of 17 years of follow-up after stopping maintenance therapy.[106] The nonflare group had a longer overall duration of therapy (57 vs. 30 months) and a longer duration of maintenance after remission (24 vs. 12 months). The other investigation studied timing of MMF taper after renal response. If dose reduction began within 18 months of renal remission, the risk of LN flare was several-fold higher than if the dose of MMF remained stable or was tapered after 18 months of remission.[107] Given the toxicity of long-term immunosuppression, tapering should be attempted in patients with a good clinical response. For patients who do not achieve a complete renal response, it would be reasonable to repeat the kidney biopsy to determine whether the clinical findings are due to active LN or renal scarring, in which case tapering immunosuppression is justified.

Recent data raise the possibility that with the right induction regimen maintenance therapy may not be necessary. In eight refractory lupus patients, five with LN, remissions were induced with rituximab, intravenous methylprednisolone, and intravenous cyclophosphamide, followed by a rapid oral corticosteroid taper.[108] No maintenance immunosuppressive agents were given. During an average follow-up of 36 months, only 2 had flares, 1 LN, and 1 extrarenal, at 36 and 41 months respectively.

Membranous Lupus Nephritis

Class V membranous LN is the least studied form of LN due to its relative rarity, and optimal treatment has not been established. Similar to the proliferative forms of LN, combination therapies are generally employed. A retrospective study using chlorambucil and methylprednisolone showed improved results over those achieved with corticosteroids alone.[109] In a small study using cyclosporine, there was improvement in proteinuria (decreasing from 6 to 1–2 g daily by 6 months).[110] Although repeat biopsy did not reveal cyclosporine toxicity, two patients were noted to have developed superimposed proliferative lesions. A randomized trial of 42 nephrotic patients with membranous LN found superior remission rates with cyclosporine and cyclophosphamide regimens over prednisone monotherapy.[111] However, there were more relapses after cyclosporine was withdrawn. Prednisone with azathioprine has also been studied, with 67% of patients in complete remission and 22% in partial remission at 12 years. Relapse rates were also low with 12% at 3 years and 16% at 5 years.[112] In a meta-analysis of 84 patients who had been enrolled in two similarly designed controlled trials, MMF and intravenous cyclophophamide were comparable in inducing remission at 6 months.[113] These data are somewhat similar to results in patients with idiopathic membranous nephropathy.

The treatment of membranous LN should be individualized. Patients with a good renal prognosis (subnephrotic levels of proteinuria and preserved GFR) may be treated conservatively with inhibitors of the renin–angiotensin system and statins, with perhaps a short course of a calcineurin inhibitor with low doses of steroids. For those at higher risk of progression disease (heavy proteinuria, impaired renal function), options include cyclosporine, monthly IV pulses of cyclophosphamide, MMF, or azathioprine (plus tapering doses of corticosteroids). Patients with mixed membranous and proliferative LN are treated in the same way as those with proliferative disease alone.

CONCLUSION

LN is an important cause of morbidity and ESRD in patients with LN. Rapid advances have been made in understanding the pathogenesis of this complex disease. LN is one of the best studied glomerular diseases. RCTs

have provided disease-specific data on induction and maintenance therapy, leading to impressive improvements in the care of patients with LN, resulting in diminution in mortality and progression to ESRD. However, a substantial number of patients with LN still have persistent disease despite immunosuppressive therapy. Relapse is common and is associated with side effects from prolonged immunosuppression. Therapeutic challenges underscore the need for studying targeted therapy in combination with current immunosuppressive agents, hopefully further improving the long-term prognosis for patients with this once fatal disease.

QUESTIONS AND ANSWERS

Question 1

Which statement regarding the pathogenesis of LN is NOT true?

A. Glomerular immune complexes may be due to deposition of preformed circulating immune complexes, or may form *in situ*
B. The classical complement pathway is the likely effector arm for complement-mediated kidney injury in LN
C. Genetic factors influence autoantibody formation and immune complex clearance
D. Cytokines and chemokines that contribute to kidney inflammation in LN may be from infiltrating leukocytes or renal tubular epithelial cells

Answer: B

Work with experimental models of LN suggests that amplification of complement activation through the alternative pathway is involved in kidney injury in LN. Blocking complement activation by knocking out C3 may not attenuate LN, possibly because low-level C3 activation through the classical pathway is important in clearing immune complexes and apoptotic debris. Thus B is not true and is the answer to this question. The origin of glomerular immune complexes is not known, but it has been postulated that they could arise from the circulation or be formed *in vivo*, so A is a true statement. Genetic factors influence both the propensity to form autoantibodies and the ability to clear immune complexes, so C is a true statement. Kidney inflammation is amplified by proinflammatory cytokines from both white blood cells entering the kidney and renal parenchymal cells, so D is a true statement.

Question 2

All of the following biopsy findings are highly characteristic of LN EXCEPT:

A. "Full house" IF pattern (IgG, IgA, IgM, C3, and C1q)
B. Osmiophilic and highly dense intramembranous electron dense deposits on electron microscopy
C. Coexistent mesangial, subendothelial, and subepithelial electron dense deposits on electron microscopy
D. Extraglomerular immune type deposits within tubular basement membranes, the interstitium, and blood vessels
E. TRIs in the glomerular endothelial cell cytoplasm on electron microscopy

Answer: B

The pathology of LN can be quite varied and at times cause confusion with other immune complex-mediated glomerulonephritides. Particular biopsy findings are highly characteristic of LN, however. These include: (1) glomerular deposits that stain dominantly for IgG with codeposits of IgA, IgM, C3, and C1q, the so-called "full house" IF pattern; (2) extraglomerular immune type deposits within tubular basement membranes, the interstitium, and blood vessels; (3) the ultrastructural finding of coexistent mesangial, subendothelial, and subepithelial electron dense deposits; and (4) the ultrastructural finding of TRIs, which represent "interferon footprints" in the glomerular endothelial cell cytoplasm. Highly electron dense intramembranous deposits are the hallmark of dense deposit disease and are not expected to be seen in LN.

Question 3

Limitations of the "EuroLupus" induction phase trial of cyclophosphamide include

A. Prolonged use of steroids in the majority of trial participants
B. Use of oral cyclophosphamide in doses not commonly used in clinical practice
C. Homogenous patient population with poor representation among minority patients
D. Both A and C
E. Both B and C

Answer: D

The trial by the EuroLupus Group compared a standard course of six monthly pulses of intravenous cyclophosphamide ($0.5-1\ g/m^2$) followed by every third monthly infusions vs. a shorter treatment course consisting of 500 mg of intravenous cyclophosphamide every two weeks for six doses (total dose 3 g) followed by azathioprine maintenance therapy (2 mg/kg/day). Both regimens were equally effective when various renal and extrarenal outcomes were evaluated, and the shorter ("EuroLupus") regimen had less toxicity. One of the major limitations of this trial was that it was largely performed in white subjects, and thus the "EuroLupus regimen" may not be applicable to nonwhite populations. In addition, while reports from this trial with up to 10 years of follow-up continue to find no differences in outcome between treatment groups, approximately 75% of these patients remained on some dose of steroids throughout this follow-up period. Thus, the "EuroLupus" regimen may not be applicable in patients placed on steroid-free maintenance regimens.

Question 4

Which ONE of the following statements is NOT TRUE regarding maintenance therapy of proliferative LN?

A. MMF was superior to azathioprine in a clinical trial involving a mixed ethnic population who had achieved complete remission
B. Mycophenolate and azathioprine were similar in a clinical trial in a predominately Caucasian population
C. Intravenous cyclophosphamide given every three months is comparable to azathioprine or mycophenolate
D. Calcineurin inhibitors may be used as maintenance therapy

Answer: C

Several options are available for maintenance therapy. Azathioprine has been shown to be comparable to MMF in two clinical trials (Euro-Lupus MAINTAIN trial), and mycophenolate was superior in the ALMS trial. In the Contreras study, three-monthly cyclophosphamide was inferior to azathioprine or mycophenolate. Of note, the ALMS maintenance trial was different from the Euro-Lupus MAINTAIN trial in that the former study was done in a mixed ethnic population and required that the patients were in remission at the time of enrollment. In patients who are unable to receive azathioprine or mycophenolate, calcineurin inhibitors are an option (although there has not been a head-to-head comparison in a clinical trial).

Question 5

A 27-year-old African American woman was treated with intravenous monthly pulse cyclophosphamide and steroids for biopsy-proven class IV LN. After 5 months her S[Cr] fell from 1.0 mg/dL to 0.7 mg/dL (her preillness baseline), and 24-hour urine protein excretion fell from 3 to 1.2 g. She was put on maintenance MMF after completing 6 months of cyclophosphamide. She has been on maintenance MMF for 6 months and discovers she is pregnant. Her S[Cr] is 0.5 mg/dL, and 24-hour urine shows 650 mg of protein. Her complement levels are slightly low.

What is the best option for her immunosuppressive therapy at this time?

A. Switch her to azathioprine to continue maintenance immunosuppression
B. Continue MMF maintenance but decrease the dose by 25%
C. Repeat a kidney biopsy
D. Discontinue all immunosuppression immediately

Answer: A

Of the choices listed the best option is A. The patient has done well and appears to be moving toward a complete clinical renal remission. She has not achieved complete remission yet however, and it would be unwise to stop maintenance immunosuppression, especially in light of the unexpected pregnancy. Thus D can be eliminated. MMF is contraindicated during pregnancy, eliminating B, but azathioprine and/or steroids can be used. Because the patient had fairly recent class IV LN with renal impairment, it is preferable to use azathioprine rather than steroids alone for maintenance. There is no indication for a repeat biopsy in this patient. She does not appear to have a lupus flare, and the ongoing kidney abnormalities are consistent with class IV that is responding to treatment and getting better. Thus C can be eliminated.

Question 6

A 24-year-old African American woman with systemic lupus for 2 years on maintenance hydoxychloroquine is referred with edema, 3+ proteinuria, and 4–5 RBC/HPF on urine exam. Her physical examination is notable for 2+ lower extremity edema and is otherwise normal. Her blood pressure is normal. S[Cr] is 0.7 mg/dL, S[Alb] is 2.8 g/L, and 24-hour urine protein excretion is 7 g. A renal biopsy shows thickened basement membranes on LM and mild mesangial proliferation without endocapillary proliferation. IF microscopy shows granular deposits in the mesangial and subepithelial areas (IgG, IgM, IgA, C3 and C1q), which were confirmed by electron microscopy. She was started on an angiotensin-converting enzyme inhibitor and diuretics. Which ONE of the following is the most appropriate next step in treating this patient?

A. Continue conservative therapy for 3 months and reevaluate
B. Start monthly pulse cyclophosphamide with steroids
C. Start prednisone at 1 mg/kg/day
D. Start MMF 1000 mg twice daily and increase to 1500 mg/day as tolerated, with steroids
E. Start cyclosporine 3 mg/kg/day in divided doses

Answer: D

This patient has pure class V (membranous) LN. She has a relatively high risk for progression, given her race, unremitting proteinuria, and worsening kidney function. Conservative therapy is probably not recommended given these risk factors (especially worsening renal function). Although any of the Choices B to D may be employed, we prefer Answer D—mycophenolate—at this point. Cyclophosphamide and cyclosporine were superior to steroid monotherapy in

a small randomized controlled trial, and mycophenolate was equivalent to cyclophosphamide in a meta-analysis. In this patient of childbearing age, we prefer not to use cyclophosphamide as initial therapy. The choice between mycophenolate and cyclosporine is difficult in the absence of clinical trial data; we favor mycophenolate over cyclosporine, because the latter is associated with nephrotoxicity. In the event of failure with mycophenolate in this high-risk patient, cyclophosphamide may be used. Azathioprine with steroids has also been used and may be a cheaper option compared to mycophenolate. Other therapies such as rituximab and ACTH are under investigation.

Abstract

Hemolysis, vaso-occlusion, and ischemia reperfusion represent the clinical hallmarks of sickle cell disease (SCD). Renal involvement occurs commonly in SCD. Its manifestations range from the near universal findings of hyposthenuria to various tubular and glomerular functional and anatomical abnormalities—commonly referred to as sickle cell nephropathy. With increasing longevity of SCD patients, overt chronic kidney disease (CKD) and end-stage renal disease have increasingly been observed. Possible risk factors or genetic modifiers are associated with the development and/or progression of CKD. Preventive measures and therapeutic options have been developed.

INTRODUCTION

Sickle cell disease (SCD) is an autosomal recessive hemoglobin disorder arising from the substitution of valine for glutamine at the sixth amino acid of the β-globin chain.[1] The mutation results in a poorly soluble hemoglobin tetramer, thereby enhancing its aggregation during cellular or tissue hypoxia, dehydration, or oxidative stress. Such aggregation may reduce the pliability of erythrocytes resulting in the sickling deformity, premature destruction of erythrocytes, and widespread vaso-occlusive episodes, potentially leading to acute or chronic organ damage.[1] Various kidney complications have been suggested to be a consequence of chronic sickling and hemolysis. "Increased urine volume of low specific gravity" or isosthenuria, described more than a century ago, was the first recognized renal abnormality associated with SCD.[2] Sickle cell nephropathy (SCN) encompasses a wide range of both tubular and glomerular functional and anatomical abnormalities. With the increasing longevity of SCD patients, progressive CKD leading to end-stage renal disease (ESRD) has increasingly been observed. Early detection of SCN and appropriate intervention may improve morbidity and mortality.

The various renal syndromes associated with SCD, histopathologic findings, potential pathophysiologic mechanisms, and suggested therapeutic interventions are discussed.

RENAL SYNDROMES ASSOCIATED WITH SICKLE CELL DISEASE

Patients with SCD present with a broad spectrum of renal abnormalities (Table 50.1). Well-described renal manifestations include hematuria, defective urinary concentrating ability, impaired renal acidification and potassium secretion leading to an incomplete form of distal renal tubular acidosis, and supranormal proximal tubular function. An increase in renal blood flow and glomerular filtration rate (GFR) frequently becomes apparent in infancy or early childhood but decreases with age. Progressive decline in GFR associated with increasing proteinuria may lead to glomerular injury and overt CKD or ESRD. Acute kidney injury (AKI) may occur in the presence of precipitating factors. The renal manifestations of SCD are generally less common or less severe in patients with sickle cell trait, with the exception of renal medullary carcinoma, which occurs almost exclusively in patients with sickle cell trait.

Hematuria

First described in 1948, patients with either sickle cell trait or disease commonly present with hematuria.[3]

Chronic Renal Disease, Second Edition

TABLE 50.1 Renal Manifestations of Sickle Cell Disease

Abnormalities	Comments
Hematuria	10% bilateral, left four times more than right due to increased venous pressure in the left renal vein
Renal Tubular Disorders	
1. Proximal tubular function • Increased sodium reabsorption • Increased phosphate reabsorption • Increased β2-microglobulin reabsorption • Increased uric acid secretion • Increased creatinine secretion • Decreased tubular albumin reabsorption (see text) **2.** Distal tubular function • Decreased concentrating ability (hyposthenuria) • Incomplete form of RTA • Impaired potassium secretion (intact renin-aldosterone system)	• Creatinine-based eGFR may be greatly overestimated • Tubular albuminuria may further contribute to proteinuria and SCN • Urinary diluting capacity remains preserved (see text) • RTA typically not clinically apparent but can be unmasked in the setting of mild decrement in GFR • Defect in potassium secretion typically not clinically apparent but hyperkalemia can manifest in the presence of additional insults (e.g. acute or chronic kidney injury, rhabdomyolysis, volume depletion)
Renal hemodynamics	Pathophysiology of hyperfiltration
Glomerular hyperfiltration leading to microalbuminuria, proteinuria	**1.** Viscocity−vaso-occlusion phenotype **2.** Hemolysis−endothelial dysfunction phenotype **3.** Kinin−Kallikrein system (further studies are needed)
AKI	Risk factors: sepsis, heart failure, volume depletion, acute chest syndrome, pulmonary hypertension, decrease in hemoglobin counts, NSAIDs, tubular obstruction from debris from papillary necrosis
CKD and ESRD	Prevalence increases with age ESRD therapeutic options: hemodialysis, peritoneal dialysis, kidney transplantation
Pathologic findings	See Table 50.2

Abbreviations: *AKI*, acute kidney injury; *CKD*, chronic kidney disease; *eGFR*, estimated glomerular filtration rate; *ESRD*, end-stage renal disease; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *RTA*, renal tubular acidosis; *SCN*, sickle cell nephropathy.

Patients with microscopic or macroscopic hematuria describe it as painless and self-limiting. Hematuria frequently originates from the left kidney, presumably due to the increased venous pressure within the longer left vein when compressed between the aorta and the superior mesenteric artery, the so-called "nutcracker phenomenon." The increased venous pressure leads to increased relative hypoxia in the renal medulla, hence sickling. Bilateral hematuria occurs in approximately 10% of cases. Patients with sickle cell trait have more hematuria than those with homozygous HbSS regardless of age.[4] The presence of flank or abdominal pain, or continued or persistent macroscopic hematuria with or without clots should prompt further evaluation with both cystoscopy and ureteroscopy to exclude renal medullary cancer and other common causes of hematuria, including kidney stones.

Defective Concentrating Ability

SCD patients universally present at an early age with hyposthenuria or impairment in urinary concentrating ability. The higher than usual obligatory urine output associated with hyposthenuria predisposes SCD patients to increased risk of dehydration and/or volume depletion. In children with SCD, the concentrating defect can present as enuresis or nocturia. The prevalence of enuresis in children with SCD ranges from 20% to 69%, while that of nocturia can reach 68%.[5] In young children, maximal urine osmolality can be increased by multiple blood transfusions. However, with repeated sludging of red blood cells (RBCs) causing thrombosis, progressive infarction, and necrosis of the papilla and inner medulla, the capacity to improve renal concentrating ability with blood transfusions progressively declines with age. The defect becomes generally irreversible after the age of 15 years. Adult patients with SCD can achieve maximal urinary osmolality of 400−450 mOsm/Kg under water-deprived conditions. Heterozygotes tend to have more gradual and lesser degrees of impairment. SCD patients dilute urine normally because the diluting segments of the nephron are less affected by sickled RBCs.

Renal Tubular Acidosis

In addition to defects in urinary concentrating ability, other renal functions primarily accomplished in the renal medulla, including renal acidification and potassium secretion, are also impaired in SCD patients. An incomplete form of distal renal tubular acidosis (RTA) results from defective renal acidification. Hydrogen ion excretion depends on the ability of distal nephron cells to maintain an adequate hydrogen ion excretion gradient between their basolateral and luminal membranes, an energy- and oxygen-dependent process. Furthermore, a blunted increase in urinary excretion of titratable acid in SCD patients compared with control subjects was demonstrated.[6–8] Ammonium excretion may be normal or decreased in patients with SCD.[6–8] As a result, SCD patients fail to lower their urine pH below 5.3 following ammonium chloride loading.[6,7] The suboptimal acid handling in SCD patients does not appear clinically under normal conditions but can be unmasked in the setting of mild renal insufficiency as hyperchloremic metabolic acidosis.[9] This defect was not seen in patients with sickle cell trait.[10]

SCD patients do not demonstrate hyperkalemia unless renal functional impairment or stress, such as during volume contraction, occurs during a sickle cell crisis. Like the urinary acidification defect, the defect in potassium secretion does not appear clinically under normal conditions. An intact renin angiotensin aldosterone system axis exists, suggesting the presence of a primary defect in renal potassium secretion, presumably due to ischemic damage to the potassium secreting segment of the distal nephron.[6] Nonetheless, selective aldosterone deficiency and hyporeninemic hypoaldosteronism have been described in patients with SCD.[9,11] Despite impaired potassium secretion, the serum potassium concentration (S[K]) does not increase during potassium loading in patients with SCD, suggesting an increased intracellular shift of potassium, likely *via* β-2 adrenergic stimulation.[12]

Proximal Tubular Function Disorders

SCD patients exhibit increased reabsorptive capacity of the proximal tubule. There is increased reabsorption of solutes such as β_2-microglobulin and phosphate, evidenced by the frequent development of hyperphosphatemia in SCD patients.[12] Since sodium reabsorption in the proximal tubule parallels phosphate reabsorption, an increase in phosphate reabsorption results in increased sodium reabsorption. Increased tubular secretion of uric acid and creatinine by the proximal tubules in SCD patients markedly increases urinary excretion of these substances.[12] Up to 30% of the total urinary creatinine excretion results from tubular secretion in SCD patients.[13] Consequently, serum creatinine concentration (S[Cr]) may be misleadingly low in SCD patients. Assessment of renal function using creatinine-based equations may therefore lead to an overestimation of GFR.[13] Limited studies in SCD patients suggest that GFR estimates using cystatin C (CystC) provide better prediction of renal function than creatinine-based estimated glomerular filtration rate (eGFR).

In contrast to the increased reabsorptive capacity of β_2-microglobulin and phosphate, reduced tubular uptake of albumin has been observed. Recent *in vitro* studies demonstrated that filtered hemoglobin released during hemolytic crisis competes with albumin binding to megalin/cubilin receptors in the proximal tubule and impairs albumin reabsorption. The latter leads to tubular proteinuria independent of glomerular injury, further contributing to albuminuria and SCN.[14]

Glomerular Function Disorders: Hyperfiltration and Microalbuminuria

In patients with SCD, an increase in renal blood flow and GFR frequently becomes apparent 1 year after birth. Renal blood flow and GFR decrease with age. Glomerular changes begin as early as the first decade of life and are characterized by high renal blood flow, glomerular hyperfiltration and hypertrophy, gradual loss of permselectivity leading to microalbuminuria and macroalbuminuria, and a decrease in ultrafiltration coefficient.[15–18] The decrease in ultrafiltration coefficient has been found to be associated with renal insufficiency. In addition, the ultrafiltration coefficient correlates inversely with glomerular permselectivity as assessed by the fractional clearances of albumin and IgG. SCD patients with albuminuria and preserved GFR have reduced glomerular ultrafiltration coefficient compared with normoalbuminuric control SCD subjects. Among those with depressed GFR, a severe reduction in glomerular ultrafiltration coefficient was observed, suggesting that albuminuria represents a sensitive marker of early glomerular damage.[18] The incidence of albuminuria increases over time in patients with SCD and often precedes the elevation of S[Cr].[19,20] In one single-center study of 184 adult patients with HbSS disease, albuminuria occurred in 61% of patients aged 18–30 years. Between the third and fifth decades of life, the percentage of SCD patients with macroalbuminuria doubled. Microalbuminuria was found in up to 79% of patients older than 40 years of age.[20] Albuminuria correlated with age and S[Cr], but not with blood pressure or hemoglobin levels, suggesting that sickle cell glomerulopathy does not solely relate to hemodynamic adaptations associated with chronic anemia. Nonetheless, studies in children with

SCD showed a significant association between markers of hemolysis (low hemoglobin and high lactate dehydrogenase [LDH] levels) and proteinuria.[21]

Acute and Chronic Kidney Injury

AKI associated with vaso-occlusive episodes occurs in 4%–16% of patients. In one retrospective study, 16.2% of admissions for vaso-occlusive painful crisis were associated with AKI (32/197). A larger decrease in hemoglobin from baseline to admission and the total number of days and doses of ketorolac were found to be associated with AKI. For every one-unit decrease in hemoglobin concentration, the risk of AKI increased by 49% (OR = 1.49, 95% CI 1.1–2.0). It was speculated that in the setting of a vaso-occlusive pain crisis, a larger decrease in hemoglobin increases AKI risk *via* an acute, direct toxic effect of plasma-free heme or hemoglobin.[22] In another series of 254 vaso-occlusive episodes in 161 SCD patients, AKI associated with vaso-occlusive episodes occurred in 4.3% of patients.[23] Suggested predisposing risk factors include severe volume depletion, acute chest syndrome, heart failure, sepsis, pulmonary hypertension, decrease in hemoglobin counts, and the use of nonsteroidal anti-inflammatory drugs (NSAIDs). In a population-based study involving SCD patients in California, more than 4% of emergency department visits were due to "dehydration."[24] Whether a single or repeated episodes of AKI predispose SCD patients to the development of CKD and/or CKD progression remains unknown and warrants further studies.

The incidence of CKD in patients with SCD increases with age, similar to albuminuria.[19,20] In a cohort of 98 SCD patients aged 18 years and older, baseline CKD was observed in 28.6% of patients (CKD stages and albuminuria grades were defined according to the 2012 KDIGO guidelines). In patients with eGFR >60 mL/min/1.73 m^2, CKD was diagnosed if grade A2 or A3 albuminuria was present. At a mean follow-up of 5 years, the overall CKD prevalence increased to 41.8% (17 patients developed new CKD). During the study period, CKD progression occurred in eight patients. Multivariate analysis demonstrated that baseline A3 albuminuria (odds ratio, 5.0, $p = 0.048$) and each 1 mm Hg increase in systolic BP (odds ratio, 1.04, $p = 0.039$) predicted CKD development and progression.[25] In a longitudinal cohort study of adult patients with SCD, 44% of individuals between the age of 40 and 60 years had a greater than 50% increase in S[Cr]. CKD was the major cause of death in 43% among those who died over the age of 60 years.[26]

The diagnosis of CKD among SCD patients generally occurs between 30 and 40 years of age, with ESRD developing in approximately 11% of patients. The incidence of CKD among SCD patients varies widely among different parts of the world, with a reported incidence of 2.6% in Senegal, 4.3% in Brazil, 5.9% in Cuba, 11.6% in the US, and 22.5% in Saudi Arabia.[27,28] The discrepancy in incidence rate may be explained by the differences in the definition of CKD, the duration of follow-up, the age of the population studied, hospital vs. clinic settings, and genetic factors or genetic modifiers, among others. Whether CystC-based eGFR may reveal a higher prevalence of CKD compared to creatinine-based GFR estimations among SCD patients remains to be studied. Of interest, SCD patients in the eastern region of Saudi Arabia have less severe disease compared with those in the western region. It is speculated that the presence of Arab Indian beta-globin haplotype among patients in the eastern region results in a much higher HbF level, and hence less severe disease compared with their western counterparts (who commonly have the Benin haplotype). Of 942 patients with SCD who were followed at two large centers in eastern Saudi Arabia between 2003 and 2016, only 11 patients (1.17%) developed ESRD requiring renal replacement therapy.[29]

Suggested factors associated with progression of CKD to ESRD include hypertension, nephrotic range proteinuria, severe anemia, vaso-occlusive crisis, acute chest syndrome, stroke, βS-gene haplotype, pulmonary hypertension, the presence of certain genetic variants (discussed in a later section), and parvovirus B19 infection.[30,31] Studies in older children and adolescents (aged 10–21 years) with SCD demonstrated that nocturnal hypertension and hyperuricemia (uric acid >5.5 mg/dL) were associated with lower eGFR. The mean CystC-based eGFR was 143 mL/min/1.73 m^2 among patients with hyperuricemia vs. 161 mL/min/1.73 m^2 among those with normal uric acid levels ($p = 0.02$). Whether interventions to lower serum uric acid (S[UA]) levels reduce CKD risk or modify disease progression in patients with SCD warrant further studies.[32]

Biomarkers for Early Detection of SCN

CystC elimination occurs exclusively by glomerular filtration and has been suggested to be a more accurate marker of CKD in both children and adults with SCD. In a series of 98 subjects with homozygous SS genotype (55 females; 43 males; mean age 34 ± 2.3 years), a strong association between CystC and GFR and albuminuria was demonstrated. The CystC-based CKD-EPI equation showed the greatest agreement with measured GFR using ^{99m}Tc-DTPA nuclear renal scans compared with other commonly used CystC-based or creatinine-based Modification of Diet in Renal Disease (MDRD) or Chronic

Kidney Disease Epidemiology (CKD-EPI) equations.[33] A smaller study consisting of 14 SCD patients with 33 eGFR measurements similarly demonstrated that the CystC-based CKD-EPI equation best correlated with measured GFR using iohexol renal scans compared with other CystC-based or creatinine-based equations. The latter included the Cockcroft-Gault formula, the MDRD, CKD-EPI Cr, and CKD-EPI Cr-CystC equations. Of note, however, patients with eGFR <60 mL/min/1.73 m^2 were excluded from the study, and all study subjects were on hydroxyurea and losartan therapy for persistent albuminuria. Hence, the study findings may not be generalizable to SCD patients without albuminuria, those not on hydroxyurea and/or angiotensin receptor blocker (ARB) therapy, or those with eGFR <60 mL/min/1.73 m^2.[34] Whether CystC-based equations may enable clinicians to more accurately assess renal function in the SCD population warrants further studies. It should be noted that CystC levels may be increased in high cell turnover states, such as hyperthyroidism, steroid use, malignancy, advanced age, gender and ethnicity, fat mass, and diabetes, among others.

Nephrin, a slit diaphragm protein necessary for the proper function of the glomerular filtration barrier, has long been suggested to be a useful marker of glomerular-specific renal damage in animal studies. In a mouse model of proteinuric renal disease, nephrinuria was observed prior to the development of albuminuria. Recent studies in children with SCD demonstrated an association between urinary nephrin:creatinine ratio (NCR) and albuminuria. In a series of 101 children with SCD, higher urinary NCR was found to be significantly associated with albuminuria. A NCR cut-point of 622 ng/mg (representing the 50th percentile for the population) was associated with a nearly 46 times greater odds of having albuminuria in children with nephrinuria above this value. Such NCR cut-point had a 96% sensitivity, 64% specificity, 47% positive predictive value, and 98% negative predictive value for the presence of albuminuria. The study findings suggest that urinary nephrin could be used as an early marker of glomerular disease in SCD.[35] Other suggested potential useful biomarkers of renal damage in SCD include urinary kidney injury molecule 1 (KIM-1) and N-acetyl-b-glucosaminidase (NAG). In a cross-sectional analysis for nephropathy in 116 patients with SCD, KIM-1 and NAG were found to be strongly associated with albuminuria. In contrast to acute or chronic kidney injury in other renal diseases, liver-type fatty acid binding protein (L-FABP), NAG, neutrophil gelatinase-associated lipocalin, and transforming growth factor-β1 (TGF-β) were not associated with albuminuria in patients with SCD.[36]

RENAL PATHOPHYSIOLOGIC MECHANISMS

Hematuria

Low oxygen tension, low pH, and high osmolality of the renal medullary environment predispose RBCs in the vasa recta to sickle and cause increased blood viscosity, microthrombus formation, and ischemic necrosis.[16] The latter can cause structural changes leading to RBC extravasation and hematuria. In kidneys from SCD patients removed due to protracted hematuria, severe stasis in peritubular capillaries, most marked in the medulla, and extravasation of blood, predominantly in the collecting tubules, are seen.[37] Severe medullary ischemia can cause papillary necrosis and infarction that manifests clinically as painless gross hematuria. Occasionally, sloughed papillae may obstruct urinary outflow leading to AKI and urinary tract infection.

Concentrating Defect

RBC sickling and congestion in the vasa recta leads to ischemia and associated impairment of solute reabsorption by the ascending limb of Henle's loop and the vasa recta with consequent loss of the countercurrent multiplication and exchange system of the inner medulla. The suboptimal maintenance of the high interstitial osmolality in the inner medulla reduces effective water reabsorption across the collecting tubules, resulting in reduced kidney concentrating ability. Since vasopressin synthesis and its release occur normally in SCD, the concentrating defect is not vasopressin-dependent. In contrast to the concentrating defect, the diluting capacity remains relatively preserved in patients with SCD. Urinary dilution is in part dependent on the function of water impermeable thick ascending limb of Henle's loop where active sodium chloride reabsorption occurs *via* the Na-K-2Cl cotransporter. Because the superficial cortical nephrons have short loops and peritubular capillaries of these nephrons have less vaso-occlusion than in the vaso recta found in the inner medullary regions, the diluting capacity of the kidney remains relatively intact.

Glomerular Hyperfiltration and Albuminuria

Two models have been proposed to explain the pathophysiology of glomerular hyperfiltration/albuminuria observed in SCD patients—the viscosity-associated vaso-occlusion, and the hemolysis-associated endothelial dysfunction phenotypes.

Viscosity–Vaso-Occlusion Phenotype

The inner medulla's relatively hypoxic, hypertonic, and acidotic environment predisposes to sickling of RBCs. Repeated sickling of RBCs significantly decreases medullary blood flow through vaso-occlusion. Increased GFR and renal plasma flow (RPF) have been attributed to compensatory hypersecretion of vasodilator prostaglandins and an increase in nitric oxide synthase (NOS) in response to sickling-related medullary hypoxia and ischemia. The administration of indomethacin produces significant decreases in GFR and RPF in SCD patients, but not in control subjects.[38,39] In experimental models of SCN, inducible NO synthase II (iNOS II) increases in the glomeruli and distal nephron of transgenic sickle cell mice, but not in control mice. Furthermore, urinary excretion of the products of NO (NO_2S+NO_3) and GFR increase significantly in a transgenic sickle cell murine model compared with controls.[40] NOS II may increase the synthesis of NO leading to vasodilation, which, in turn, contributes to renal hyperperfusion. The exposure of transgenic sickle cell mice to chronic hypoxia results in the activation of iNOS II, and formation of superoxide radical and peroxynitrite ($ONOO^-$).[41] These reactions may lead to nitration of tyrosine residues of some renal proteins and enhanced apoptosis, ultimately causing structural damage.

Hemolysis–Endothelial Dysfunction Phenotype

In a cross-sectional study of 280 adult homozygous SS patients, markers of intravascular hemolysis (including lower hemoglobin levels, lower hemoglobin F levels, and higher reticulocyte count) were found to be independent risk factors for glomerular hyperfiltration among nonalbuminuric patients. Albuminuric patients were excluded from the study to minimize introduction of another variable. In contrast, the prevalence of typical vaso-occlusive complications such as retinopathy, osteonecrosis, priapism, pulmonary hypertension, and leg ulcerations were not significantly different between the groups with and without hyperfiltration.[42] In another study designed to search for novel markers of hemolysis among patients with SCD and to look for the relationship of such markers with complications linked to the hemolytic process, hemolysis was found to correlate with albuminuria. The ratio between mature RBCs and reticulocyte (RET) hemoglobin (RBC-Hb/RET-Hb) was associated with RBC survival. The log (RBC-Hb/RET-Hb) describes hemolysis better than LDH and total bilirubin. Furthermore, the log (RBC-Hb/RET-Hb) in combination with LDH correlated highly with albuminuria.[43]

Although hemolysis-induced hyperfiltration seems paradoxical because hemolysis commonly induces a vasoconstrictive state secondary to decreased NO bioavailability due to NO scavenging by HbSS, hemolysis can also induce regional or systemic vasodilation due to the unstable nature of HbSS.[44] Such instability leads to the release of heme and the induction of heme oxygenase-1 (HO-1). HO-1 degrades heme to carbon monoxide (CO), which has vasodilatory and antioxidant properties, promoting hyperfiltration:

$$\text{Heme} + O_2 + \text{HO-1} \rightarrow \text{Biliverdin} + Fe^{2+} + \text{CO}$$

Although the cytotoxic properties of heme may cause glomerular injury and proteinuria, its adverse effect can be mitigated by HO-1.

Soluble fms-like tyrosine kinase-1 (sFLT-1), a member of the vascular endothelial growth factor family, was found to be elevated in SCD patients with albuminuria. In a cohort of 73 patients with SCD and 21 healthy, race-matched control subjects, sFLT-1 levels were significantly higher in patients with macroalbuminuria, compared to those with microalbuminuria and normoalbuminuria (120.1 pg/mL vs. 99.7 pg/mL vs. 85.4 pg/mL, respectively; $p = 0.016$). Such association suggests that sFLT-1 may contribute to the development of albuminuria in SCD by inducing endothelial activation and endothelial dysfunction.[45] Another marker of endothelial dysfunction, endothelin-1 (ET-1), was also found to be elevated in SCD subjects with albuminuria.[46] In a mouse model of SCD (HbSS), ET-1 was shown to mediate glomerular injury *via* increased reactive oxygen species (ROS) production. ET-1 and ET_A receptor mRNA were elevated in renal tissue from mice with sickle cell compared with mice heterozygous for sickle cell and Hb A (HbAS controls). Furthermore, sickle mice exhibited enhanced ET_A receptor binding in the renal vasculature. Because oxidative stress is well established in SCD, it is speculated that ET-1 contributes to oxidative stress and glomerular injury in this model. *In vivo* and *in vitro* treatment with ET_A receptor antagonist decreased glomerular ROS production, proteinuria, and nephrinuria.[47]

Whether the viscosity-associated vaso-occlusion or hemolysis-associated endothelial dysfunction phenotype plays a contributory or predominant role in hyperfiltration in SCD in humans remains to be studied. However, it seems plausible that SCN is characterized by both hemolysis and vaso-occlusive processes to variable degrees (Figure 50.1).

The Kinin–Kallikrein System and Hyperfiltration

The kinin–kallikrein system has been suggested to play a contributory role in the hyperfiltration seen in SCD patients, similar to diabetic subjects.[48] High serum

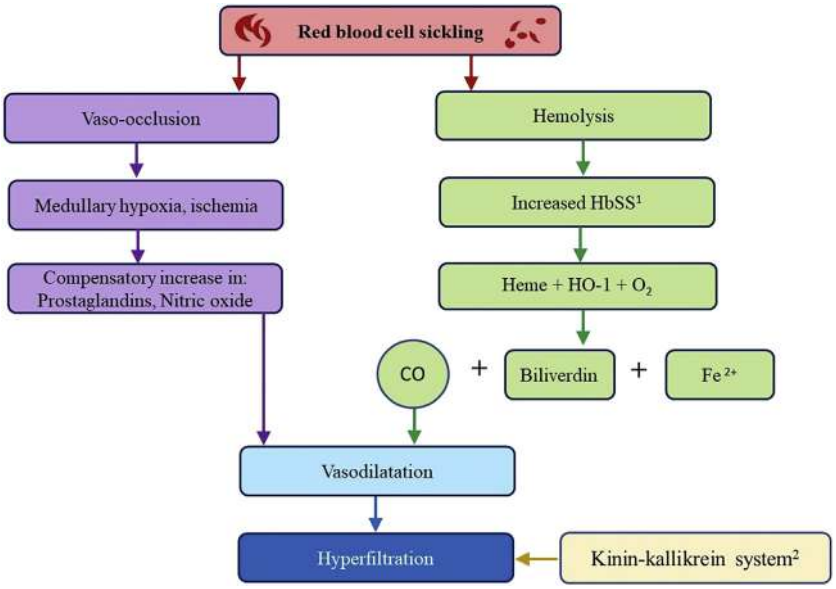

FIGURE 50.1 Suggested pathophysiological scheme for the development of hyperfiltration. [1]HbSS is an unstable structure that leads to increased release of heme and induction of heme oxygenase-1 (HO-1). HO-1 degrades heme to CO + biliverdin + Fe^{2+}. [2]Further studies are needed. *CO*, carbon monoxide; *HbSS*, hemoglobin SS; *HO-1*, Heme oxygenase-1; O_2, Oxygen.

kallikrein concentration appears in diabetic patients and streptozocin-induced diabetic rats with hyperfiltration. Chronic inhibition of renal kallikrein reduces GFR and RPF in streptozocin-induced diabetic rats.[48] In a cross-sectional study conducted to evaluate the role of renal kallikrein as a risk marker for SCN in 73 pediatric patients with SCD, urinary active kallikrein excretion correlated positively and significantly with log urinary albumin excretion rate. In this case, kallikrein, such as albumin, may be a marker of nephropathy.[49] The study had several shortcomings, including the absence of renal function measurements (eGFR or creatinine clearance) and patients with confounding factors (frequent blood transfusions reducing sickled hemoglobin load affecting renal functional impairment expected for age).[50] In children with SCD, early blood transfusion protects against microalbuminuria.[51] Whether the kinin–kallikrein system plays a contributory role in the hyperfiltration process in SCN remains to be studied.

Albuminuria and Progressive CKD

Similar to diabetic and other kidney diseases, glomerular hyperfiltration in patients with SCD can lead to microalbuminuria, proteinuria, glomerulosclerosis, and progressive CKD. Furthermore, the increased filtered sodium load and tubular reabsorption of sodium associated with hyperfiltration can augment renal oxygen consumption. Such hypermetabolic states can promote tubulointerstitial injury, in part through oxidative stress. Renovascular pathology related to chronic NO depletion from ongoing intravascular hemolysis has also been suggested to play a role in the progression of SCN. Chronic NOS inhibition caused systemic and glomerular hypertension, glomerular ischemia, glomerulosclerosis, tubulointerstitial injury, and proteinuria in experimental animal models.[52] Studies in the general population without SCD similarly suggest that CKD-induced NO deficiency contributes to the progression of chronic kidney injury.[53]

Ischemic Model of Chronic SCN

In a murine model of bilateral total renal artery occlusion-induced ischemia, transgenic sickle cell mice but not wild-type mice exhibited glomerulopathic changes including endothelialitis and mesangiolysis. The latter changes, along with the accompanying reparative responses may lead to a chronic glomerulopathy, particularly if repetitively incurred through recurrent cycles of renal ischemia.[54] Vascular congestion in wild-type mice after ischemia was mild and confined to the peritubular capillaries. In contrast, sickle cell mice exhibited massive congestion in the microcirculation involving the medullary and cortical capillaries as well as the glomerular microcirculation. Notably, the marked glomerular congestion and cortical infarction recapitulate the appearance of the glomerulus and cortical infarction observed in SCD patients with AKI. Compared with wild-type mice, sickle cell mice also demonstrated markedly increased amyloid-P component (the murine homologue of C-reactive protein).

TABLE 50.2 Pathologic Findings in Sickle Cell Anemia

Abnormalities	Comments
Papillary necrosis	Usually asymptomatic
Renal cortical infarct	Infarcted area usually small and kidney function generally not affected
Hemosiderin deposits	No correlation between the amount of these deposits and the presence of kidney disease
Glomerular enlargement and congestion	Most marked in juxtamedullary glomeruli
Glomerular lesions	
❖ FSGS: most common glomerular lesion in SCD, closely associated with glomerular hypertrophy ❖ MPGN: commonly occurs without immune-complex deposits ❖ MPGN type 1: uncertain whether cases were attributable to SCD ❖ SCD glomerulopathy: Defined as glomerular hypertrophy with or without mesangial hypercellularity ❖ TMA: associated with history of retinitis	
Tubular atrophy, interstitial fibrosis	
Medullary carcinoma (seen almost exclusively in patients with the sickle cell trait)	

Abbreviations: *FSGS*, focal segmental glomerulosclerosis; *MPGN*, membranoproliferative glomerulonephritis; *SCD*, sickle cell disease; *TMA*, thrombotic microangiopathy.

In the peritubular microcirculation, repeated episodes of marked congestion can lead to peritubular capillary loss, chronic hypoxia, and events that culminate in chronic SCN. Tubulointerstitial scarring may develop as a result of ischemia-induced upregulation of matrix-related genes (such as TGF-β and monocyte chemoattractant protein-1 [MCP-1], and extracellular matrix proteins). It is conceivable that the heightened vascular, glomerular, and tubulointerstitial injuries in sickle cell mice subjected to ischemia act to accentuate the development of SCN.[54]

RENAL MEDULLARY CELL CARCINOMA

Chronic ischemic injuries triggering recurrent degeneration and regeneration of the epithelium of the distal collecting ducts may incite formation of renal medullary cancer, an aggressive tumor specific to patients with sickle hemoglobinopathies.[5,55] Renal medullary cancer, seen almost exclusively in patients with sickle cell trait, occurs at a relatively young age, averaging 21 years.[5,55] Patients may present with gross hematuria, flank pain, and infrequently with an abdominal mass or weight loss. Therefore renal medullary cancer must be differentiated from a renal tubular abnormality associated with abnormal hemoglobinemia. Metastatic disease present at diagnosis portends a poor prognosis.

RENAL ANATOMIC AND PATHOLOGIC FINDINGS ASSOCIATED WITH SICKLE CELL DISEASE

Several major anatomic and pathologic (morphologic) changes of the kidneys occur in SCD patients (Table 50.2). The distinctive abnormalities of the renal medulla and papillae in patients with SCN result from occlusion of blood flow in the vasa recta, which may lead to medullary and papillary necrosis and fibrosis. Renal papillary necrosis (RPN) appears as a common complication of SCD with a reported incidence of 15% −50% in patients with SCD or sickle cell trait.[5] RPN generally presents as a clinically silent and slowly progressive process because of recurrent, subacute sickling in the renal medulla. Renal radiography detects RPN as an incidental finding in asymptomatic patients or during the evaluation of hematuria. Renal cortical infarctions with subsequent renal cortical scarring may develop. The infarction usually affects a small area, and renal function generally remains intact.

Prominent glomeruli distended with blood, as well as necrosis and pigmentation of tubular cells, were first described in SCD in 1923.[56] Subsequently, other pathologic lesions involving both tubular and glomerular lesions were reported. These include glomerular enlargement and congestion (most marked in the juxtamedullary glomeruli), focal scarring in the renal medulla, interstitial fibrosis, tubular atrophy, infiltration with lymphoid cells, and various glomerular

histopathologies. Tubular hemosiderin deposits appear as a universal finding in patients with SCD.[13]

Structural glomerular abnormalities exist in patients with SCD but usually not in heterozygotes. Over the years, a wide spectrum of glomerular lesions has been described in SCD patients. The most frequently identified morphologic lesion associated with SCD is focal segmental glomerulosclerosis (FSGS), which is closely associated with glomerular hypertrophy.[19] Both collapsing and expansive patterns of FSGS have been described in SCD patients.[57,58] Glomerular hypertrophy was found to be greater in HbSS patients than in idiopathic FSGS. Glomerular size did not differ between patients with and without clinical evidence of SCN. Medullary fibrosis was prominent, suggesting that SCD-associated FSGS affects mainly the juxtamedullary nephrons supplied by the vasa rectae.[57,58] FSGS in patients with SCD is thought to be a form of adaptive FSGS. Whether APOL1 high-risk alleles predispose such patients to FSGS remains uncertain.[59] Systematic study of renal histopathology in APOL1-associated SCN remains to be determined.

In one biopsy series performed to investigate progressive renal insufficiency or increasing proteinuria (>0.3 g/day) or both in 18 SCD patients, the glomerular lesions found in order of decreasing frequency included FSGS (39%), membranoproliferative glomerulonephritis (MPGN) (28%), thrombotic microangiopathy glomerulopathy (17%), and specific SCD glomerulopathy (17%). The latter represents glomerular hypertrophy with or without mesangial hypercellularity.[60] All patients exhibited albuminuria, but only 30% displayed renal functional impairment at the time of the kidney biopsy. At a mean follow-up of 28 months after the kidney biopsy, 50% of patients developed CKD and 21% developed ESRD requiring dialysis. A history of acute chest syndrome and chronic organ damage was associated with the occurrence of SCD glomerulopathy, whereas a history of retinitis was associated with thrombotic microangiopathy.

The potential associations between certain clinical characteristics and specific glomerular lesions in SCD patients remain to be explored. While MPGN was initially attributed to immune-complex injury, subsequent studies demonstrated that MPGN commonly occurred without immune-complex deposits.[19] Although definitive immune-complex deposits or MPGN type I have been described in SCD patients, it remains uncertain whether these were attributable to SCD.[19] Irrespective of the type of glomerulopathy present, renal biopsies from SCD patients show hypertrophied glomeruli with distended capillaries due to sickle blood cells. Hence, the term glomerulopathy specific to SCD describes these lesions. Such glomerular pathology can also be found in patients with SCD without clinical evidence of CKD.[4]

Ultrastructural features of the kidneys of SCD patients with nephrosis and the nephrotic syndrome and in the kidneys of rabbits following prolonged intravenous injection of saccharated iron oxide complexes led independent investigators to speculate that iron overload and possibly circulating iron–protein complexes lead to the glomerular lesions observed in patients with SCN.[61] However, glomerular lesions similar to those occurring in SCN have not been seen in β-thalassemia patients despite similar levels of iron overload, nor have they been seen in other conditions of iron overload, such as in idiopathic hemosiderosis or in patients who receive a large number of RBC transfusions. Therefore, iron overload alone fails to explain the pathophysiologic mechanisms associated with nephrotic syndrome in SCD patients.

GENETIC MODIFIERS

Renal dysfunction in SCD appears to be affected by a number of genetic modifiers of SCD. Suggested risk factors associated with progression of CKD to ESRD include APOL1 and HMOX1 rs743811 gene variants. In contrast, higher fetal hemoglobin (HbF) levels and α-globin genotype have been suggested to be protective.

HbF modulates the hematologic and clinical manifestations of SCD. Its level and distribution among sickle erythrocytes varies highly in SCD patients. Patients with the lowest HbF levels are more likely to develop renal failure and vaso-occlusive complications such as acute painful episodes, leg ulcers, osteonecrosis, and acute chest syndromes. In a cohort study of 725 HbSS patients, all patients with "sickle renal failure" had HbF levels of ≤10%.[17] Furthermore, the frequency of the Central African Republic (CAR) β^s CRA haplotype was found to be significantly increased in SCD patients who developed renal failure compared with those who did not, presumably secondary to the lower HbF levels associated with the β^s CRA haplotype.[17]

Coinheritance of α-thalassemia appears to protect against proteinuria and SCN in SCD patients. The coincidence of SCD and α-thalassemia reduces intraerythrocytic concentration of hemoglobin S and RBC volume, and reduces hemolysis. In a cohort of 424 adult African–British patients with SCD, a significant association between hemolytic markers and both the degree and prevalence of albuminuria were found. Further analysis demonstrated a negative association between the number of deleted α genes and the degree of albuminuria and prevalence of microalbuminuria, suggesting that coinheritance of α-thalassemia has a protective effect against albuminuria.[62]

Two APOL1 risk variants alleles (G1 and G2), found in 13% of African Americans, are associated with both an increased risk of nondiabetic glomerulosclerosis and FSGS and more rapid chronic kidney disease progression compared with their non-Black counterparts. In a large study consisting of more than 12,000 adult Hispanic/Latino adults, the presence of two APOL1 high-risk alleles and sickle cell rs334 variant was also found to be associated with albuminuria and/or CKD defined as eGFR $<60\ mL/min/1.73\ m^2$. When patients were grouped into Caribbean vs. Mainland backgrounds, the frequency of albuminuria was similar between the two groups, but the frequency of eGFR $<60\ mL/min/1.73\ m^2$ was approximately twofold higher among the Caribbean compared with Mainland counterparts (4.1% vs. 2.1%, respectively; $p = 5.2 \times 10^{-9}$). Notably, compared with Mainland Hispanics/Latinos, Caribbean Hispanics/Latinos had a tenfold higher frequency of two APOL1 risk alleles vs. zero/one copy (1% vs. 0.1%) and nearly threefold higher frequency of the imputed SCT rs334 risk allele versus zero copies (2% vs. 0.7%).[63] Limited studies in SCD patients similarly demonstrated that APOL1 high-risk variants are associated with albuminuria and CKD progression defined as 50% decline in eGFR or development of ESRD.[64] In a study of 152 SCD patients (age range 24–36 years) who were genotyped for APOL1 G1 G2, GSTM1, GSTT1, GSTP1, and HMOX1 gene variants, homozygous or double-heterozygous APOL G1 and G2 genotypes were found to be strongly associated with ESRD ($p = 0.003$) and higher CKD stages ($p = 0.001$). Furthermore, these genotypes were associated in an age-dependent manner with lower eGFR ($p = 0.008$), proteinuria ($p = 0.009$), and albuminuria ($p < 0.001$) but not with other SCD complications.[65] No association was found between GSTM1, GSTT1, GSTP1, or HMOX1 gene variants and SCN.

Single nucleotide polymorphism in the heme oxygenase-1 gene (HMOX1 rs743811) has been shown to be associated with SCN in some studies but not others. In a study of 221 SCD patients from the University of Illinois in Chicago and 487 patients from the Walk-Treatment of Pulmonary Hypertension and SCD with Sildenafil Therapy (Walk-PHaSST) cohort, *HMOX1 rs743811* variant was found to be associated with lower eGFR, albuminuria, and CKD stage. Of interest, in the Walk-PHaSST cohort, this variant was also associated with ESRD. Such association is independent of APOL1 variants and is thought to be due to reduced protection of the kidney from hemoglobin-mediated toxicity.[64] Nonetheless, a smaller European study ($n = 152$) consisting mainly of SCD patients of Sub-Saharan ancestry failed to show a link between the *HMOX1* variant and SCN.[65] An association between an HOXM1 variant and kidney disease warrants further exploration because of its direct effect on heme catabolism.

TREATMENT

The various clinical manifestations of SCN including hyposthenuria, hematuria, glomerular hyperfiltration, albuminuria, nephrotic syndrome, and progressive CKD leading to the development of ESRD have been well described. However, the pathogenic mechanisms of SCN and their therapeutic implications have yet to be elucidated. Maneuvers to reduce sickling crises are of unclear benefit because neither the frequency of sickling crises nor the severity of anemia has consistently been shown to predict albuminuria or CKD.[19] Nonetheless, management should be directed at specific complications. Adequate fluid intake prevents dehydration due to hyposthenuria. The theoretical benefit of NSAIDs in any patient with glomerular hyperfiltration has not consistently been shown. NSAID use in patients with SCD should be avoided due to the potential for adverse hemodynamic-related renal functional deterioration, precipitation of papillary necrosis, and the development of NSAID-associated interstitial nephritis and glomerulonephropathies.

Blood transfusions may restore urinary concentrating ability in children with SCD, but their potential to cause iron overload should not be overlooked. In patients awaiting kidney transplantation, blood transfusions can lead to allosensitization. Although preoperative blood transfusion to decrease hemoglobin S level has been suggested to decrease the incidence of posttransplant complications, aggressive RBC transfusion should be avoided because increasing RBC mass increases blood viscosity, thereby potentially precipitating RBC sickling. Whether immunosuppression use in the posttransplant period may reduce transfusion-related sensitization risk remains speculative.

There has been compelling evidence that angiotensin converting enzyme inhibitors (ACEIs) and/or ARBs effectively reduce proteinuria and slow the decline in renal function in both diabetic and nondiabetic nephropathy. Data on the effects of ACEIs or ARBs on proteinuria and the progression of CKD among patients with SCN remain limited. One small single-center study demonstrated that treatment with enalapril for 2 weeks resulted in reduction in proteinuria in adult SCD patients with mild renal insufficiency and biopsy documented evidence of glomerular enlargement and perihilar FSGS. Discontinuation of ACEI, however, led to rebound proteinuria.[66] Studies in children with SCD

similarly demonstrated that urinary albumin excretion normalized in 56% of patients treated with an ACEI.[67] The updated 2015 Cochrane database review revealed only one randomized trial comparing ACEI with placebo in SCD patients with microalbuminuria or proteinuria. Twenty-two study subjects were treated with captopril for 6 months. At 6 months, urinary albumin excretion in the captopril group decreased from baseline by a mean of 45 ± 23 mg/day, while it increased by 18 ± 45 mg/day in the placebo group.[68] There has been limited data on ARB use in SCD. In a study of 12 hydroxyurea-treated SCD patients with persistent albuminuria, treatment with losartan was associated with a significant decrease in albumin excretion rate at 1–2 month follow-up (median decrease −134 mcg/min, $p = 0.0063$). No significant differences in GFR or permselectivity were observed at short-term (1–2 months, $n = 12$) or long-term (>12 months; $n = 8$) follow-up.[69]

While evidence-based recommendations remain lacking, a trial of an ACEI and an ARB seems justifiable due to the well-established renoprotective effect of these drugs. Improving nocturia has been reported to be an additional beneficial effect of ACEIs, presumably as a result of reduction in GFR. Hypotension and hyperkalemia, particularly in the presence of impaired kidney function, may limit the use of ACEI and ARB therapy.

Some but not all studies suggest that hydroxyurea (HU) may reduce proteinuria and/or hyperfiltration. One prospective study consisting of 26 patients with SCD demonstrated that HU has a renoprotective effect by decreasing proteinuria but not albuminuria. Twenty-four hour proteinuria in HU ($n = 12$) vs. non-HU ($n = 14$) groups were 226 ± 16 vs. 414 ± 76 mg/dL, respectively, $p = 0.0001$. Urine albumin concentration in HU vs. non-HU groups was 79 ± 15 vs. 55 ± 86 mg/dL, respectively, $p = 0.35$.[70] In contrast, a cross-sectional study of 149 adult patients followed in a comprehensive sickle cell clinic showed that those using HU were less than one-third (odds ratio 0.28, $p = 0.01$) as likely to exhibit albuminuria (defined as either urinary albumin:creatinine ratios [UACRs] ≥30 mg/g or ≥1+ proteinuria on two separate dipstick evaluations).[71] A retrospective study consisting of 63 patients (7–18 years of age) with HbSS or HbSβ^0 thalassemia genotypes similarly demonstrated that HU therapy was associated with significant decrease in urine ACR in children with SCD and albuminuria. Among those with baseline microalbuminuria, the median ACR prior to HU therapy at 1 year and 2 years after treatment were 96 mg/g and 39 mg/g ($p = 0.02$), and 25 mg/g ($p = 0.03$), respectively. Albuminuria normalized in 37.5% after 1 year and in 61% after 2 years of HU therapy. Among those without albuminuria prior to HU therapy, 13% developed albuminuria during HU therapy. The study findings suggest that although HU may ameliorate urine ACR among those with baseline albuminuria, it is not protective against the development of albuminuria.[72]

A multicenter placebo-controlled trial in infants of ages 9–18 months (BABY HUG trial) demonstrated that treatment with HU for 24 months did not influence the GFR. However, treatment was associated with better urine concentrating ability and less renal enlargement, suggesting a possible renoprotective effect.[73] In contrast, in a small study of 23 children of ages 2.5–14 years (the HUSTLE study), HU at the maximum tolerated dose was found to be associated with a decrease in hyperfiltration. After 3 years of treatment, GFR measured by (99m)Tc-DTPA decreased significantly from 167 ± 46 mL/min/1.73 m^2 to 145 ± 27 mL/min/1.73 m^2 ($p = 0.016$). There was no significant change in microalbuminuria. However, only 4 of 23 patients had baseline albuminuria.[74]

Supplemental vitamin E has been suggested to be of therapeutic benefit because of its antioxidant properties. Further studies are needed. Dietary protein restriction is not recommended because of the underlying growth failure and decreased energy state in most patients with SCD.

Therapeutic options for patients with ESRD due to SCN include hemodialysis, peritoneal dialysis, and kidney transplantation.[75] Both hemodialysis and peritoneal dialysis may confer their own theoretical advantages. Hemodialysis may be used for urgent or emergent need for standard and exchange blood transfusions. In contrast, peritoneal dialysis and its inherent slow rate of ultrafiltration may minimize any acute rise in hematocrit and thus lower the risk of vaso-occlusive crisis. Kidney transplantation may offer survival advantage over those remaining on dialysis for appropriately selected patients with ESRD due to SCN. Although survival of transplant recipients with SCD appears to be inferior to that of matched African American recipients without the disease, survival of SCD patients is comparable to that of matched diabetic patients.[76] As in the general population, living donor graft survival among patients with ESRD due to SCN exceeds that of deceased donor transplants. In the current era of transplantation, desensitization protocols may allow transfusion-related highly sensitized patients to undergo a successful kidney transplant.

SUMMARY

Chronic sickling and hemolysis of RBCs in patients with SCD may result in various kidney complications. Figure 50.2 summarizes the pathogenic mechanisms underlying the development of hematuria, concentrating defects, and CKD associated with FSGS

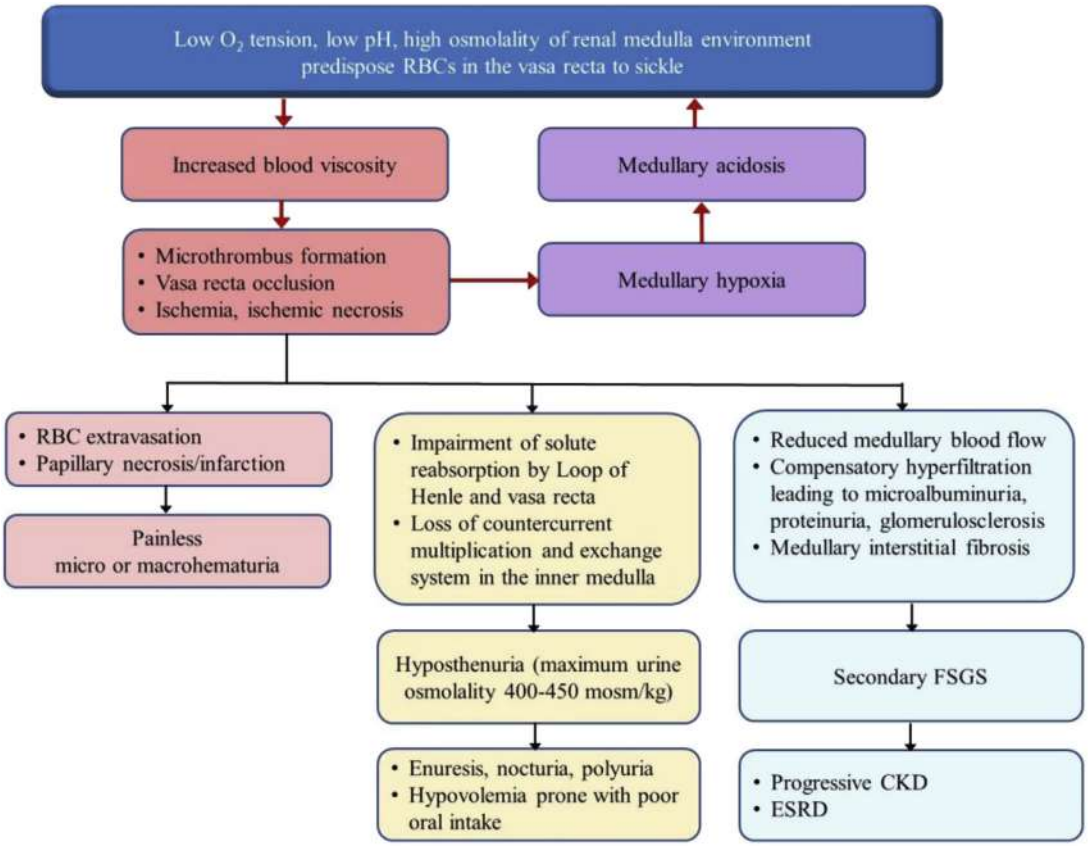

FIGURE 50.2 Pathogenic mechanisms of hematuria, concentrating defect, and CKD associated with FSGS in patients with SCD. The common inciting event is sickling in the vasa recta. *CKD*, chronic kidney disease; *ESRD*, end-stage renal disease; *FSGS*, focal segmental glomerulosclerosis; O_2, Oxygen; *RBC*, red blood cell.

in patients with SCD.[77] All segments of the nephron suffer damage, from the vascular bed, glomerular, and tubulointerstitial structures, to the collecting ducts. Functionally, this translates into signs and symptoms of kidney disease such as hyposthenuria, isosthenuria, hematuria, hyperfiltration, proteinuria, and decrements in GFR. Clinically, patients may develop acute and chronic kidney injury, glomerulonephritis, hyperkalemia, papillary necrosis, and finally ESRD. The underlying mechanisms of kidney injury primarily relate to hypoxia and ischemia. A growing body of literature suggests that intravascular hemolysis with subsequent hemoglobinuria causes kidney injury and CKD progression. Treatments to reduce RBC sickling and better diagnostic tools to detect kidney injury, such as biomarkers, may help forestall chronic kidney damage in SCD patients. Whether the more widespread use of serum CystC may allow early detection and intervention to slow CKD progression remains to be studied. Treatment targeting HbS polymerization to prevent acute and/or chronic multiorgan failure associated with erythrocyte sickling is an area for further research.[78]

QUESTIONS AND ANSWERS

Question 1

A 14-year-old African American male in good health sees his pediatrician for a preathletic physical. He attends high school and looks forward to participating in sports. He has no complaints. His vital signs include blood pressure 110/70 mm Hg, pulse 70 beats per minute, temperature 98.7°F, and respiratory rate 12 per minute. He has an unremarkable physical examination. However, on urinalysis he has 1+ heme on dipstick, and 15 RBCs per high power field on microscopic evaluation. The pediatrician reviews his records and notes that the patient has sickle cell trait.

Which **one** of the following is a plausible explanation for hematuria?

A. Urinary tract infection
B. Renal cell carcinoma of the kidney
C. Papillary necrosis
D. Kidney stone
E. Strenuous exercise or activity (march hematuria)

Answer: C

The hypoxic, acidotic, and hyperosmolar environment of the inner medulla promotes sickling of erythrocytes. Sickling of erythrocytes in the vas recta results in increased blood viscosity, impairment in renal medullary blood flow, microthrombus formation, and ischemic necrosis. Ischemic thrombi cause structural changes leading to RBC extravasation and hematuria. Papillary necrosis in patients with sickle cell trait presents with more hematuria than those with homozygous HbSS regardless of age.[79] Microscopic or macroscopic hematuria associated with papillary necrosis presents as painless hematuria and is self-limiting.

Urinary tract infection and kidney stones usually present with dysuria and flank pain, respectively. Urinary tract infection generally presents with frequency, urgency, and dysuria. Urinalysis reveals WBCs and may be accompanied by RBCs. Urine culture identifies the pathogen(s) responsible for the urinary tract infection.

Early stage cancer of the kidney does not present with pain. In the general population, renal cell carcinoma appears in older individuals. An imaging study such as an ultrasound or CT scan would be able to eliminate this diagnosis. However, renal medullary cancer occurs in patients with sickle cell trait at a relatively young age (average of 21 years).

March hematuria or march hemoglobinuria results from repetitive impact injury, such as running on a hard road, or drumming with the palm. The condition was first described in 1881 when soldiers presented with hematuria after marching for long periods of time. The repetitive nature of these types of activities cause mechanical trauma to the RBCs causing hemolysis. Urinalysis would show 1−2+ heme but no RBCs on microscopic examination. Other tests such as a depressed haptoglobin and an elevated lactate dehydrogenase and unconjugated bilirubin confirm hemolysis. Sickled RBCs result in hemolysis and could present with a similar picture.[4,5,37,55,79,80]

Question 2

A 10-year-old African American male with SCD presents for his annual checkup to update his immunization record. The patient has no new complaints or symptoms. He attends school and participates in sport activities.

He looks well-nourished and in no acute distress. His vital signs include blood pressure 100/60 mm Hg, pulse 72 beats per minute, temperature 98.6°F, and respiratory rate 12 per minute. He has pale conjunctiva. Evaluation of the lung reveals clear sounds to auscultation and percussion. He has a grade 1/6 systolic ejection murmur. He has normal bowel sounds and he does not have organomegaly. The legs have no edema. He has pale nail beds.

Laboratory tests show S[Na] 140 mEq/L, S[K] 4.0 mEq/L, S[Cl] 105 mEq/L, S[bicarbonate] 24 mEq/L, BUN 10 mg/dL, S[Cr] 0.2 mg/dL, S[Ca] 9.0 mg/dL, glucose 85 mg/dL. He has WBC count 4.8 cells/μL, hemoglobin 6 g/dL, hematocrit 18%, and platelet count 250,000/mmol. Urinalysis shows specific gravity 1.012, pH 5.0, negative for blood and protein.

Which **one** of the following is a plausible explanation for the low S[Cr] in this case?

A. Poor nutritional intake
B. Glomerular hyperfiltration
C. Liver disease
D. Rhabdomyolysis
E. Increase in fluid intake

Answer: B

Glomerular changes in patients with SCD begin as early as the first decade of life and are characterized by high renal blood flow, glomerular hyperfiltration and hypertrophy, gradual loss of permselectivity, and a decrease in ultrafiltration coefficient. Glomerular hyperfiltration results in low to normal BUN and S[Cr] levels.

Individuals with poor nutritional intake, especially low protein intake, could present with a low BUN. The patient would look malnourished. S[Cr] level would be normal if muscle mass has not been affected.

Patients with severe liver disease cannot convert nitrogenous waste such as ammonia to urea. This patient lacks evidence of severe liver disease such as

ascites, jaundice, or neurological changes associated with hyperammonemia.

Patients with rhabdomyolysis have muscle tenderness and have high serum creatine phosphokinase (CK) levels. A high CK level may result in an elevated S[Cr] but not a low one.

Patients with SCD are encouraged to remain well hydrated to prevent vaso-occlusive disease. Hydration may decrease BUN. S[Cr] rarely changes just from hydration alone. The changes in S[Cr] in this case are most likely a result of changes in GFR associated with hyperfiltration.[13,81]

Question 3

An 18-year-old African American male with SCD presents for his annual checkup as well as for his precollege immunization. The patient has no new complaints or symptoms.

His vital signs include blood pressure 110/70 mm Hg, pulse 72 beats per minutes, temperature 98.6°F, and respiratory rate 12 per minute. He has pale conjunctiva. Evaluation of the lungs reveals clear sounds to auscultation and percussion. He has a grade 1/6 systolic ejection murmur. He has normal bowel sounds and does not have organomegaly. The legs have no edema. He has pale nail beds.

Laboratory tests show S[Na] 140 mEq/L, S[K] 4.0 mEq/L, S[Cl] 105 mEq/L, S[bicarbonate] 24 mEq/L, BUN 8 mg/dL, S[Cr] 0.4 mg/dL, S[Ca] 9.0 mg/dL, glucose 85 mg/dL. He has WBC count 5.6 cells/μL, hemoglobin 7.2 g/dL, hematocrit 18%, platelet count 225,000/mmol. Urinalysis shows specific gravity 1.012, pH 5.5, trace blood, and trace protein. His UACR is 100 μg/mg.

Which **one** of the following is a plausible explanation for microalbuminuria?

A. Loss of glomerular permselectivity
B. High protein diet
C. A marker of pre−diabetes mellitus
D. Tubulointerstitial disease
E. Acute prostatitis

Answer A

Sickle cell patients have high renal blood flow, glomerular hyperfiltration and hypertrophy, gradual loss of permselectivity leading to micro- and macroalbuminuria, and a decrease in ultrafiltration coefficient. Albuminuria increases over time in patients with SCD. Microalbuminuria and macroalbuminuria are harbingers of clinically significant renal disease.[21,81]

Protein intake does not generally affect or cause proteinuria.

Clinicians use albuminuria in diabetic patients to monitor pending diabetic nephropathy. Investigators for the Diabetes Prevention Program Research Group did not find a consistent trend in incident diabetes by quartile of albumin:creatinine ratio.[82]

Patients with tubulointerstitial disease generally have a bland urine (e.g. negative for blood and protein on dipstick). Moreover, tubules secrete Tamms Horsfall proteins that are not measured with a urine dipstick.

Acute prostatitis presents with dysuria and hematuria. Proteinuria is rarely found on urinalysis.

Question 4

A 25-year-old African American male with SCD presents with leg swelling. His physician sees him frequently, especially when he has an episode of sickle crisis. The patient has 1 to 4 sickle crises per year.

He appears pale, with pale conjunctiva and nail beds. His vital signs include blood pressure 130/80 mm Hg, pulse 70 beats per minutes, temperature 98.7°F, and respiratory rate 12 per minute. Evaluation of the lungs reveals clear sounds to auscultation and percussion. He has a grade 2/6 systolic ejection murmur. He has normal bowel sounds and no organomegaly. The legs have 1+ pitting edema.

Laboratory tests show S[Na] 140 mEq/L, S[K] 4.0 mEq/L, S[Cl] 105 mEq/L, S[bicarbonate] 22 mEq/L, BUN 20 mg/dL, S[Cr] 1.0 mg/dL, S[Ca] 9.0 mg/dL, glucose 85 mg/dL. He has WBC count 6.1 cells/μL, hemoglobin 6.4 g/dL, hematocrit 19%, platelet count 245,000/mmol. Urinalysis shows specific gravity 1.010, pH 5.5, 1+ heme, and 2+ protein. Microscopic evaluation shows eight RBCs per high power field, but no casts. Urine protein:creatinine ratio (UPCR) is 3.8 g/g creatinine.

Which **one** of the following is a plausible explanation for proteinuria?

A. Glomerular hyperfiltration
B. AKI
C. Papillary necrosis
D. ESRD
E. Glomerulonephritis

Answer: E

Glomerulonephritis presents with proteinuria, hematuria, hypertension, abnormal renal function, and edema. The patient has several signs and symptoms associated with the syndrome of glomerulonephritis, and the UPCR suggests nephrotic range proteinuria.

An increase in renal blood flow leads to glomerular hyperfiltration and glomerular hypertrophy during the first decade of life in patients with SCD. Glomerular hyperfiltration presents with low BUN and S[Cr] values.

Leg swelling would be unusual with supernormal kidney function unless the patient has decompensated heart failure from chronic severe anemia. This clinical history was not given.

Both AKI and ESRD can present with leg swelling. More importantly, both disorders present with elevated BUN and S[Cr].

Papillary necrosis generally presents with hematuria and rarely with nephrotic range proteinuria.[57,58,60,61]

Question 5

A 25-year-old African American male with SCD presents with proteinuria. His physician sees him regularly. The patient has 1 to 4 sickle crises per year. The patient has some leg swelling.

His vital signs include blood pressure 140/90 mm Hg, pulse 70 beats per minutes, temperature 98.7°F, and respiratory rate 12 per minute. He has pale conjunctiva. Evaluation of the lungs reveals clear sounds to auscultation and percussion. He has a grade 2/6 systolic ejection murmur. He has normal bowel sounds and does not have organomegaly. The legs have 1+ pitting edema. He has pale nail beds. He has hyperpigmented skin lesions near both ankles.

Laboratory tests show S[Na] 140 mEq/L, S[K] 4.0 mEq/L, S[Cl] 105 mEq/L, S[bicarbonate] 22 mEq/L, BUN 20 mg/dL, S[Cr] 1.0 mg/dL, S[Ca] 9.0 mg/dL, glucose 85 mg/dL. He has WBC count 4.2 cells/μL, hemoglobin 5.9 g/dL, hematocrit 20%, platelet count 255,000/mmol. Urinalysis shows specific gravity of 1.009, pH 5.5, 1+ heme, and 2+ protein. Microscopic evaluation shows eight RBCs per high power field, but no casts. The UPCR is 3.8. The patient undergoes a kidney biopsy.

Which **one** of the following is a plausible finding on kidney biopsy?

A. Minimal change disease
B. FSGS
C. Papillary necrosis
D. Membranous glomerulopathy
E. Tubulointerstitial nephritis

Answer: B

A wide spectrum of glomerular lesions has been described in patients with SCD. The most frequently identified morphologic lesion in patients with nephrotic range proteinuria associated with SCD is FSGS. Other glomerular lesions include membranoproliferative glomerulonephritis and SCD glomerulopathy.

Minimal change disease occurs in the very young and very old. Effacement of the basement membrane appears on electron microscopic evaluation. Renal function tends to be normal. The presence of urinary RBCs makes minimal change disease unlikely. A kidney biopsy helps differentiate minimal change disease from other glomerular disorders in this age group.

Papillary necrosis results in concentrating defects. Urinalysis generally reveals hematuria, but rarely nephrotic range proteinuria. Imaging studies identify the lesion.

Membranous glomerulopathy presents mostly in middle-aged Caucasians and is not associated with SCD.

Patients with tubulointerstitial nephritis usually do not have blood or protein on urinalysis. This patient has nephrotic range proteinuria, suggesting a glomerular lesion.[58,60,61]

Question 6

A 30-year-old African American male with SCD presents with nausea, vomiting, and dysgeusia. He was diagnosed with FSGS approximately 5 years ago. He also has pruritis and insomnia.

He has high blood pressure and takes five different antihypertensive medications. He has 1 to 4 sickle crises per year.

His vital signs include blood pressure 160/100 mm Hg, pulse 70 beats per minutes, temperature 98.5°F, and respiratory rate 20 per minute. He has pale conjunctiva. Evaluation of the lungs reveals clear sounds to auscultation and percussion. He has a grade 2/6 systolic ejection murmur. He has normal bowel sounds and does not have organomegaly. The legs have 2+ pitting edema. He has pale nail beds.

Laboratory tests show S[Na] 139 mEq/L, S[K] 5.0 mEq/L, S[Cl] 104 mEq/L, S[bicarbonate] 19 mEq/L, BUN 80 mg/dL, S[Cr] 8.0 mg/dL, S[Ca] 8.0 mg/dL, glucose 88 mg/dL. He has WBC count 5.8 cells/μL, hemoglobin 5 g/dL, hematocrit 15 percent, platelet count 230,000/mmol. Urinalysis shows specific gravity 1.010, pH 5.5, 1+ heme, and 2+ protein. Microscopic evaluation shows 10 RBCs per high power field, but no casts. The UPCR is 1.3. Renal ultrasound does not show hydronephrosis. The right kidney measures 9 cm and the left kidney measures 9.3 cm, both with increased echogenicity.

He starts dialysis for ESRD.

Which **one** of the following is NOT a plausible explanation for renal failure?

A. Diabetic nephropathy
B. Hypertensive nephrosclerosis
C. Papillary necrosis
D. Analgesic nephropathy
E. FSGS

Answer: A

He does not have a history of diabetes mellitus or hyperglycemia.

All the other entities may be present given his history of SCD. He has poorly controlled hypertension despite taking five medications. Compliance with medications may be involved. In addition, he has volume overload as demonstrated by 2+ pedal edema.

Hematuria may be related to papillary necrosis or FSGS.

Patients with SCD take large quantities of analgesic for pain management during crises. Cumulative dose of analgesic ingested, especially combinations, may lead to analgesic nephropathy. Generally, patients with analgesic nephropathy have a bland urine, consistent with tubulointerstitial damage.

ESRD is a common outcome if SCD patients develop FSGS. Nonspecific medical management for FSGS might include an ACEI or ARB. Various treatment regimens for primary FSGS include steroids immunosuppressive and cytotoxic agents. These agents would not be recommended for FSGS from SCD.[19,83]

CHAPTER

Approach to Chronic Kidney Disease in the Diabetic Patient

Farsad Afshinnia[a], *Frank C. Brosius, 3rd*[a,b]

[a]Division of Nephrology, Department of Internal Medicine, University of Michigan, Ann Arbor, MI, United States;
[b]Division of Nephrology, University of Arizona College of Medicine, Tucson, AZ, United States

Abstract

The diagnosis of diabetic kidney disease (DKD) is generally made clinically, either by increased urinary albumin excretion (>30 mg/day) or declining glomerular filtration rate, usually in the presence of diabetic retinopathy. All diabetic patients should undergo annual measurements of serum creatinine concentration (S[Cr]) and urinary albumin concentration and have their estimated glomerular filtration rate (eGFR) calculated. Control of blood glucose to achieve an HbA1c of 7%, and blood pressure aimed at a level less than 130/80 mm Hg, as tolerated, can delay or prevent onset of DKD. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are first-line treatments in hypertensive and nonhypertensive DKD patients, especially those with increased urinary albumin excretion. The use of sodium-glucose cotransporter 2 inhibitors also prevents DKD progression in patients with both preserved and decreased eGFR. Lipid-lowering therapy is beneficial in the primary prevention of cardiovascular events in DKD patients. Dietary protein restriction should also be considered for DKD patients. All patients with stage 4 or 5 CKD should be evaluated for potential renal replacement therapy (RRT) by a nephrologist. Proper candidates should be prepared for end-stage renal disease therapy by discussing modalities of RRT, including renal transplantation, providing necessary education, creating dialysis access when appropriate, and making necessary referrals.

INTRODUCTION

Over 44% of the new cases of end-stage renal disease (ESRD) in the US are attributed to diabetes mellitus (DM), making it the leading cause of ESRD in the US[1] and in many parts of the world. According to the 2017 US Renal Data System report, in spite of stabilization of adjusted incidence rates, the total number of patients with ESRD from diabetes has continued to increase.[1] The reasons for continued growth in ESRD from diabetic kidney disease (DKD) include the inability to identify patients at high risk of progression of chronic kidney disease (CKD) at relatively early stages, as well as the lack of substantial advances in the treatment of DKD during the past 25 years. It is likely that the incidence of DKD will increase again as the recent major increase in type 2 diabetes, especially in children and young adults, leads to more nephropathy over the next two decades.[2] The diagnostic and prognostic biomarkers of DKD in current clinical practice (S[Cr], cystatin C, estimated glomerular filtration rate [eGFR], and urinary albumin excretion) lack desired sensitivity and specificity, but new useful biomarkers will likely be available soon. Moreover, our general understanding of pathogenic signaling pathways leading to progressive DKD continues to expand.[3] There is new evidence of the substantial therapeutic effect of sodium-glucose cotransporter 2 (SGLT2) inhibitors and other new interventions in slowing the progression of DKD.[4] Continued elucidation of the various molecular signaling pathways and networks that lead to DKD will allow us to test and develop even better diagnostic biomarkers and more effective preventive and therapeutic strategies in the not-too-distant future.[3]

NATURAL HISTORY OF DKD

Glomerular hyperfiltration, i.e. a higher-than-normal glomerular filtration rate (GFR), occurs shortly after diagnosis in most patients with type 1 DM. Hyperfiltration is due to the relative vasodilation of renal glomerular afferent arterioles, leading to increased glomerular

Chronic Renal Disease, Second Edition
https://doi.org/10.1016/B978-0-12-815876-0.00051-6

pressure and a resultant increase in GFR. Hyperfiltration is improved or eliminated with good glycemic control.[5] Hyperfiltration also occurs in early type 2 diabetes,[6] but its presence is less consistent. Although hyperfiltration predicts albuminuria and a generally worse prognosis in diabetic patients, there are no convincing long-term prospective studies that establish whether hyperfiltration, *per se*, causes enhanced glomerular or tubular pathology and progression of DKD. The most common initial indicator of DKD is albuminuria, defined as urinary albumin excretion over 30 mg/day. Abnormal urinary albumin excretion usually develops between 5 and 15 years after the diagnosis of diabetes in many type 1 patients who develop nephropathy, and is not present at the onset of diabetes,[7] unless some other kidney disease is present. In contrast, up to 20% of patients with type 2 diabetes may have increased albumin excretion at the time of diagnosis, suggesting the presence of another cause of CKD, such as obesity-related glomerulopathy, or early DKD. Historical data suggest that, without treatment, up to 80% of albuminuric patients with type 1 diabetes develop more significant levels of albuminuria (>300 mg/24 h, historically called macroalbuminuria). Of such patients, 50–75% reach ESRD within 10–20 years. In type 2 diabetes, in contrast, approximately 40% of patients with albuminuria show further increases in albuminuria levels and 20% reach ESRD within the same time frame.[8]

Over the past decade or more, it has become evident that the natural history presented above is not always followed by patients with progressive DKD. In the Diabetes Control and Complications Trial and the follow-up Epidemiology of Diabetes Interventions and Complications study of participants with type 1 diabetes, 28% of the patients with an estimated GFR <60 mL/min/1.73 m^2 did not have abnormal albuminuria.[9–11] It appears that somewhere between 5% and 30% of type 1 DKD patients develop only transient albuminuria or never develop albuminuria, yet still develop progressive nephropathy that is similar pathologically to that in patients with albuminuria and progressive DKD.[12,13] Similarly, a progressive decline in GFR to ESRD in the absence of albuminuria progression occurs in up to 50% of type 2 diabetic patients.[14,15] These changes in DKD patterns may be the result of widespread use of agents such as angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) that reduce proteinuria but fail to retard progression of disease in some patients. Moreover, enhanced hypertension control in diabetic patients can reduce albuminuria and may have contributed to the generalized reduction in albuminuria seen in DKD patients. Finally, a number of type 2 diabetic patients develop albuminuria before the onset of their diabetes. In some of these individuals, this reflects the presence of generalized endothelial dysfunction rather than glomerular pathology.[16] In addition, kidney disease can result directly from obesity, insulin resistance, and the metabolic syndrome,[17,18] all of which routinely precede the onset of type 2 diabetes. The type of kidney pathology seen in such individuals diverges in several aspects from that of DKD.[19,20] Little is known about the prognosis for kidney disease in such patients in the absence of diabetes. Finally, there is evidence that a number of patients, especially those with type 2 diabetes, develop either nondiabetic kidney diseases or a modified form of DKD, and therefore follow a different clinical course than "typical" DKD patients.

DIAGNOSIS OF DKD

The diagnosis of DKD is made provisionally by detection of persistently elevated albuminuria and/or decline in eGFR in patients with type 1 DM 5 or more years after the onset of DM, or in patients with type 2 DM at or after the time of diagnosis. The American Diabetes Association (ADA) recommends that urinary albumin excretion and eGFR be assessed at least once a year in patients with type 1 diabetes with duration of ≥5 years, in all patients with type 2 diabetes, and in all diabetic patients with comorbid hypertension.[21] Urinary albumin excretion has a wide intraindividual variability, due to a number of reasons, including exercise within 24 h, fever, urinary tract infection, uncontrolled hypertension, marked hyperglycemia, menstruation, and congestive heart failure, all of which can elevate albuminuria independently of kidney damage. Because of this variability, the diagnosis of albuminuria requires its detection in at least 2 out of 3 tests performed over a period of 3–6 months. To detect albuminuria, measurement of a random spot urinary albumin:creatinine ratio (UACR) is preferred for convenience. According to the ADA, timed or 24-hour collections are more burdensome and add little to prediction or accuracy.[21] Once the diagnosis of persistent albuminuria is established, yearly or more frequent measurement of albumin:creatinine ratio (ACR) or urinary protein:creatinine ratio (UPCR) should be performed for monitoring of clinical response or assessment of progression of CKD.[21]

S[Cr] values and estimation of GFR should be obtained at baseline and at least annually. Most eGFR formulae are based on S[Cr] and the patient's age, gender, and ethnicity. Both the Modification of Diet in Renal Disease (MDRD)[22] and Chronic Kidney Disease-Epidemiology Collaboration (CKD-EPI)[23] formulae provide reasonable estimates of true GFR in patients with GFRs significantly below normal. However, such creatinine-based formulae are increasingly inaccurate

when the GFR is above 60 mL/min[22,23] and appear to systematically underestimate measured GFR.[24] They also are inaccurate in patients with cachexia where S [Cr] is substantially influenced by muscle mass. In these circumstances, use of a cystatin C-based eGFR formula may be helpful[25] and may better predict cardiovascular events in diabetic populations[26] although its superiority over the creatinine-based CKD-EPI formula for estimation of true GFR has not been uniformly confirmed.[27] Longitudinal data also suggest that the degree of decline in GFR in diabetic patients may be underestimated using eGFR formulae.[28]

The diagnostic evaluation of DKD requires a baseline history, a thorough physical examination, including accurate measurement of resting seated blood pressure, assessment of retinopathy, and laboratory evaluation that includes measurement of urinary albumin, and estimation of GFR. Genitourinary complications such as neurogenic bladder, papillary necrosis, and hydronephrosis are common in diabetic patients, so obtaining a baseline kidney ultrasound may be informative. In patients with type 1 diabetes, the diagnosis of DKD is made largely on clinical grounds, as a patient with a history of diabetes for over 10 years and albuminuria, and some degree of diabetic retinopathy has greater than a 90% likelihood of manifesting DKD,[29] and other types of kidney disease are unusual in this group.

In contrast, diabetic retinopathy coexists less frequently with early DKD in type 2 diabetic individuals. In some reports, over 50% of type 2 diabetic patients were found to have evidence of other types of kidney disease, often in addition to DKD.[30,31] However, these reports have been based on kidney biopsies performed for clinical reasons and have been limited by their lack of racial diversity. Therefore, it is not clear that they are representative of typical type 2 diabetic patients. There is a general impression that the prevalence of nondiabetic forms of CKD in North American patients with type 2 diabetes is lower than the figures suggested by these reports. More precise data will be obtained as more trials that include kidney biopsies of diabetic patients are performed, such as are planned by the Kidney Precision Medicine Project (https://kpmp.org). At present, there needs to be an individualized and nuanced approach to the diagnosis of nephropathy in type 2 diabetic patients, including the performance of kidney biopsies, particularly in those patients who manifest nephropathy very early in the course of their diabetes, develop early and progressive nephrotic range proteinuria, demonstrate substantial glomerular hematuria (as demonstrated by dysmorphic red blood cells or red blood cell casts), or who have a rapid decline in GFR.

MANAGEMENT OF DKD

Glycemic Control

The ADA recommends a target HbA1c of <7% to prevent or retard nephropathy and other microvascular complications of diabetes.[32] As red blood cell survival is reduced in progressive CKD, reliance on HbA1c should be limited, and the clinician should depend more on random or continuous home blood glucose monitoring in patients with advanced CKD and ESRD.[33] The role of intensive control of blood sugar in prevention of DKD was tested in two landmark trials.[34,35] The DCCT/EDIC studies showed a 39% decrease in development of albuminuria of <300 mg/day and a 54% reduction in rate of albuminuria of >300 mg/day in type 1 diabetic patients.[34] The United Kingdom Prospective Diabetes Study (UKPDS) revealed a 25% risk reduction in the composite microvascular complication endpoint in the groups that underwent intensive control of blood sugar compared to patients receiving what was standard control in the 1980s and early 1990s in type 2 diabetes.[35] A smaller trial in Japanese type 2 patients, the Kumamoto trial, revealed a 60% reduction of albuminuria >300 mg/day with intensive glycemic control in type 2 diabetes.[36] Both DCCT and UKPDS cohorts showed that intensive therapy early in the course of diabetes led to a substantial and significant reduction in the incidence of microvascular complications for decades after the difference in glycemic control between the two groups had been eliminated. This phenomenon, known as "metabolic memory," may be responsible for the reduction in the annual incidence of DKD development over the last two decades.[37,38] However, some prominent investigators have argued that intensive control has merely delayed the onset of DKD and not altered the percentage of patients who ultimately develop this complication, or the rate by which it progresses.[39]

It appears that the most beneficial impact of tight glycemic control is achieved if applied early in the course of diabetes. In elderly patients (aged over 65 years) and in those with longstanding diabetes and cardiovascular disorders, evidence does not support intensive lowering of blood sugar.[40,41] In fact, there is some evidence for harm associated with intensive lowering of blood sugar in patients with type 2 diabetes. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial showed no significant reduction in cardiovascular events but revealed a higher mortality by targeting HbA1c below 6% compared to its conventional target of 7–7.9%.[41] There is no identified cut-point for HbA1c below which the beneficial effect of blood glucose–lowering strategies levels off, but increased risk of

hypoglycemia and mortality at lower levels of HbA1c can be counterproductive. Therefore, the appropriate target HbA1c should be individualized according to features such as age, stage of CKD, and comorbid conditions, reserving control of blood sugar with HbA1c <7% for younger patients without other comorbidities and levels >7% for older patients with advanced stages of CKD and cardiovascular comorbidities.

As recommended by the ADA, metformin is the first-line pharmacologic agent for treatment of hyperglycemia in patients with type 2 diabetes,[4] including those with DKD. Metformin is effective, safe, and inexpensive, and may reduce the risk of cardiovascular events and death.[42,43] Compared to sulfonylureas, metformin has beneficial effects on A1C, weight, and cardiovascular mortality.[42] In the past, metformin was felt to be contraindicated in CKD patients with S[Cr] >1.5 mg/dL, because of its structural similarity to phenformin, which caused lactic acidosis in diabetic patients. However, there is substantial evidence that this prohibition was overly restrictive. Importantly, significant lactic acidosis appears to be no more common in patients prescribed metformin than in those who received other glucose-lowering agents.[44] In response to these observations in 2016, the Food and Drug Administration (FDA) changed the guidelines for metformin use with the following points: (1) metformin use in CKD patients should be based on eGFR and not S[Cr]; eGFR screening should be performed before and at least annually during metformin treatment; (2) metformin can be used when the eGFR is <60 mL/min/1.73 m^2, should be monitored closely when eGFR is <45 mL/min/1.73 m^2, should be stopped when the eGFR reaches 30 mL/min/1.73 m^2, and should not be started between eGFRs of 30 and 45 mL/min/1.73 m^2; (3) metformin should be held before iodinated contrast procedures if the eGFR is 30–60 mL/min/1.73 m^2 or if there is any liver disease, alcoholism, or heart failure, or if intraarterial contrast is used. If held, recheck the eGFR 48 h after the procedure and restart metformin when renal function is stable (https://www.fda.gov/Drugs/DrugSafety/ucm493244.htm). In addition, periodic measurement of vitamin B12 should be considered with long-term use of metformin, especially in the presence of anemia and peripheral neuropathy, as it may be associated with vitamin B12 deficiency.[4]

In addition to lifestyle modification, antihyperglycemic therapy, and metformin, addition of agents with proven effect on reduction of cardiovascular events, such as SGLT2 inhibitors and glucagon-like peptide-1 (GLP-1) receptor agonists, should be considered for glycemic control in patients with type-2 diabetes and established atherosclerotic cardiovascular disease.[4] SGLT2 inhibitors (empagliflozin, canagliflozin, and dapagliflozin) lower glucose levels by blocking glucose reabsorption by the proximal renal tubules. In addition to glucose-lowering properties, and cardiovascular protection, they also promote weight loss and reduce blood pressure. In the EMPA-REG OUTCOME trial, the primary composite outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke was significantly lower in the empagliflozin arm.[45] In the CANVAS trial, canagliflozin showed a similar cardiovascular protection by lowering major cardiac events compared to standard care.[46]

There is also a strong indication from these trials that SGLT2 inhibitors prevent eGFR decline and development of albuminuria. More convincing renal protection has recently been reported by the Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE) trial which studied the effects of canagliflozin treatment in macroalbuminuric patients with DKD and eGFR between 30 and 90 mL/min/1.73m^2 already receiving maximum tolerated standard treatment (including ACEIs or ARBs). In this trial, canagliflozin reduced the development of ESRD, doubling of S[Cr] and cardiovascular or renal death by 30%.[47] While currently SGLT2 inhibitors are approved only for patients with eGFRs >45 mL/min/1.73 m^2 this restriction may well be altered in the near future based on the demonstrated efficacy of canagliflozin on renal outcomes in participants with eGFRs down to 30 mL/min/1.73 m^2. It should be noted that SGLT2 inhibitors are contraindicated all type 1 diabetic patients, due in part to the higher incidence of diabetic ketoacidosis in patients using these drugs.[48,49]

GLP-1 receptor agonists, such as lixisenatide, liraglutide, semaglutide, exenatide, lower glucose by stimulating glucose-dependent insulin secretion, suppressing glucagon secretion, slowing gastric emptying, and reducing appetite.[50] Liraglutide, in the LEADER trial,[51] and semaglutide, in the SUSTAIN-6 trial,[52] were shown to decrease the rate of major cardiac events, and both are approved by the FDA as adjunct agents for lowering blood glucose in patients with type 2 diabetes.[53,54] It is yet unclear whether GLP-1 receptor agonists prevent progression of CKD to ESRD. Like the SGLT2 inhibitors, GLP-1 agonists are contraindicated in patients with eGFR <30 mL/min/1.73 m^2 and cannot be prescribed for type 1 diabetic patients.

Blood Pressure Control and ACEI and ARB Therapy in DKD

In patients with type 1 diabetes, hypertension usually develops around or after the time of the appearance of DKD, but in type 2 diabetes patients it frequently precedes the onset of DKD, often as a manifestation of the metabolic syndrome or due to obesity.[8] Home blood

pressure measurement in hypertensive patients has been endorsed by a number of international societies and often provides a better picture of blood pressure control by providing more numerous readings and elimination of the "white coat" effect.[55,56] Reliance on home BP measurements requires adequate education regarding proper timing and technique, but many studies have demonstrated the reliability of such data and its superiority over routine clinic BP measurement.[57,58] Such monitoring appears to result in improved BP control when coupled with cointerventions, systematic medication titration, education, and lifestyle counseling.[59] As autonomic dysfunction is a common finding in patients with diabetes, orthostatic BP measurements should be obtained.

Reduction of BP in hypertensive patients with DKD has been uniformly found to reduce the incidence of major cardiovascular events and to delay the progression of DKD.[60–64] The optimal range of BP control in hypertensive patients with diabetes has been an area of controversy, and the subject of several clinical trials in the past decade. The ADA currently recommends that most patients with diabetes should have an average seated BP of <140/90 mm Hg, although lower BP targets may be appropriate for individuals at high risk of cardiovascular disease.[65] This necessitates initiation of at least one antihypertensive medication besides lifestyle modification, if the confirmed measure of office BP is ≥140/90 mm Hg, and two antihypertensive medications if the level is ≥160/100 mm Hg.[65] The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for BP control, which were last updated in 2012, also recommend reduction of BP to ≤140/90 mm Hg, using blood pressure–lowering agents if the daily urinary albumin excretion is <30 mg, but recommend further reduction to ≤130/80 mm Hg if daily albumin excretion is >30 mg.[66] Conversely, the newer American Heart Association/American College of Cardiology guidelines issued in 2017 argue for more aggressive control of BP and redefine hypertension as an average seated BP of 130/80 mm Hg or above.[67] Other than the KDIGO guidelines, none of these are specific for CKD patients, and none of the current guidelines have specific guidelines for DKD. The ACCORD trial showed no consistent benefit of lowering systolic BP to <120 mm Hg vs. to <140 mm Hg for diabetic patients including those with early DKD.[68] Specifically, this study found no significant difference in the composite outcome of fatal and nonfatal major cardiovascular events in patients randomized to a systolic blood pressure of <120 mm Hg compared to a less-intensive target of range of <140 mm Hg. Although intensive lowering of blood pressure was associated with a significantly lower incidence of stroke, it was also associated with a significantly higher number of severe adverse outcomes including deaths, life-threatening events, persistent or significant disabilities, hospitalizations, and prolongations of hospital stay, which were numerically greater than the reduction in the number of strokes.[68] Conversely, the SPRINT study, which studied participants at high cardiovascular risk (including CKD patients) but not diabetic patients, found a significant improvement in cardiovascular outcomes with lowering of systolic BP to ≤120 mm Hg.[69] Our conclusion from these conflicting data is that BP control in DKD patients needs to be individualized. The lower the systolic BP, the lower will be the likely cardiovascular risk, but the higher will be the risk of adverse events, including acute kidney injury. Therefore, a more aggressive target than BP of ≤140/90 mm Hg should be individually applied, with the active participation of the patient until more definitive data from future randomized controlled trials (RCTs) are obtained (Table 51.1).

Uncontrolled hypertension is a major contributing factor to progression of DKD.[70] In established DKD patients with hypertension and albuminuria >300 mg/day, well-designed RCTs have shown a beneficial effect of ACEIs or ARBs compared to other antihypertensives on the progression of DKD.[60,63,64] The Collaborative Study Group trial of patients with type 1 DKD randomized to either captopril 25 mg three times a day or placebo showed a reduction in the primary endpoint of doubling of S[Cr] by 56%, and the combined endpoints of death, dialysis, and transplantation by 50%.[63] ARBs were tested in most clinical trials of type 2 DKD, because these studies came after ACEI therapy was already standard of care for treatment of DKD. In general, these studies showed a less-dramatic effect on the progression of DKD in type 2 patients than did the ACEI studies in type 1 patients. For example, the Irbesartan Diabetic Nephropathy Trial (IDNT) randomization of DKD subjects with hypertension to three subgroups (irbesartan 300 mg/day, amlodipine 10 mg/day, or placebo), revealed a 20% reduction with ARB treatment in the primary composite outcome (doubling of S[Cr], development of ESRD, or death) compared to placebo, and 23% reduction compared to amlodipine, over a mean follow-up period of 2.6 years.[64] In the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan Study (RENAAL), type 2 DKD subjects were randomized to losartan vs. placebo. The risk of doubling of S[Cr] was reduced by 25% and incident ESRD by 28% in the losartan group.[60] This difference in effect size in type 1 and type 2 DKD was assumed to be due to differences in the patient populations tested. Although there has never been a head-to-head comparison of ACEIs and ARBs, there is no evidence that one class works better than the other for DKD associated

TABLE 51.1 Recommendations for Management of Diabetic Kidney Disease (DKD).

Management Item	Recommendation
Prevention	The target for adequate glycemic control is an HbA1c of ≤7%.
	An average seated blood pressure of <140/90 mm Hg should be maintained.
	Metformin is the first-line agent for glycemic control in type 2 diabetic patients with eGFR >45 mL/min/1.73 m^2. Given recent findings regarding their cardiovascular and renal protective effects, SGLT2 inhibitors should be considered as second line agents for this subset of type 2 diabetic patients.
	ACEI or ARB therapy is not recommended for primary prevention of DKD. However, ACEIs and ARBs are among the recommended agents for treatment of hypertension in type 1 and type 2 diabetic patients without nephropathy.
Screening and Diagnosis	Measurement of S[Cr] and monitoring for albuminuria (UACR >30 mcg/mg) should be performed annually starting 5 years after diagnosis of type 1 diabetes and at the time of diagnosis of type 2 diabetes.
	Confirm persistent albuminuria by two of three positive tests within a 3–6-month period after eliminating spurious causes of albuminuria.
	Type 1 diabetes: Persistent albuminuria and/or elevated S[Cr] (reduced eGFR) along with diabetic retinopathy is consistent with the diagnosis of DKD.
	Type 2 diabetes: Persistent albuminuria and/or elevated S[Cr] (reduced eGFR) with diabetic retinopathy is consistent with the diagnosis of DKD. Kidney biopsy should be considered when diagnoses other than DKD are suspected.
Treatment	Control of BP to a seated average BP of <140/90 mm Hg will prevent progression of DKD and the incidence of major cardiovascular events. Targeting a BP level of <130/80 mm Hg is encouraged when safe for individual patients.
	ACEIs or ARBs are the first-line antihypertensive therapy for nonpregnant hypertensive patients with DKD to reduce the incidence of major cardiovascular events and progression of DKD. Combined ACEI and ARB therapy is not recommended.
	Normotensive nonpregnant patients with DKD should also be treated with an ACEI or ARB, as tolerated, to reduce progression of DKD.
	Diuretics, mineralocorticoid receptor antagonists, calcium channel blockers, and beta blockers can be used in combination with ACEIs or ARBs to control blood pressure.
	A daily protein intake of 0.8 g/kg body weight is recommended for all nondialysis-dependent DKD patients.
	Lifestyle modification including exercise, weight loss, smoking cessation, and dietary consultation. Reduction of daily protein intake to 0.8–1.0 g/kg body weight should be considered in DKD patients with eGFR >30 mL/min/1.73 m^2 and further reduction to 0.8 g/kg/body weight is recommended in patients with stage 4 or 5 DKD.
	Preparation for renal replacement therapy, including referral to a nephrologist at stage 4 CKD to allow adequate time for required education, and choice of therapy including transplantation, and creation of dialysis access, if indicated is recommended. Lifestyle modification including exercise, weight loss, smoking cessation, and dietary consultation should be recommended.

ACEI, angiotensin-converting enzyme inhibitor; *UACR*, urine albumin:creatinine ratio; *ARB*, angiotensin receptor blocker; *CKD*, Chronic kidney disease; *eGFR*, estimated glomerular filtration rate; *S[Cr]*, Serum creatinine; *SGLT2*, sodium-glucose cotransporter 2.

with either type 1 or type 2 diabetes. ACEIs are often used preferentially due to lower cost and more extensive track record. However, in general the choice of class and specific agent for treatment should depend on tolerability, affordability, and physician and patient preference.

An increase in the level of S[Cr] of approximately 30% above baseline with initiation of renin–angiotensin–aldosterone system blockade is expected and is associated with better preservation of renal function in the long term. However, a more severe decline in renal function, particularly if associated with flash pulmonary edema, may reflect underlying renal artery stenosis. In these rare circumstances ACEI or ARB therapy should be immediately halted. Sometimes, at advanced stages of CKD, ACEIs or ARBs may be withdrawn to help extend the time off dialysis, to mitigate severe hyperkalemia or for other reasons. However, the relative benefits of this approach vs. maintaining ACEI or ARB therapy is not known. To date there have been no published studies assessing the benefits of ACEI/ARB therapy in cardiovascular risk reduction or CKD progression in advanced nondialysis CKD. An

ongoing clinical trial, the STOP ACEI study, should help elucidate the relative benefits and risks of ACEIs/ARBs on renal function and cardiovascular outcomes use in advanced CKD.[71]

Because dual therapy with an ACEI and an ARB results in more complete inhibition of angiotensin II signaling, better control of blood pressure, and a greater reduction in proteinuria, it was hoped that dual ACEI and ARB therapy would lead to even better outcomes in DKD than seen with use of either class of agents alone. However, several randomized controlled trials in the last decade have shown this not to be the case. Both the ONTARGET[72] and NEPHRON-D[73] studies of dual ACEI and ARB therapy showed no significant improvement in cardiac or renal outcomes with combined therapy. Although the ONTARGET trial included few patients with DKD, the NEPHRON-D study focused on this population. In both studies combination therapy was significantly associated with adverse events, including hyperkalemia, hypotension, and acute kidney injury. Thus, dual therapy with an ACEI and ARB is not generally indicated for patients with DKD.

Control of blood pressure in patients with diabetes usually requires prescription of two or more antihypertensive medications. Thiazide diuretics in combination with an ACEI or ARB have been shown to provide additional benefit by providing better reduction of blood pressure, lowering the risk of hyperkalemia, and better augmentation of the antiproteinuric effects of RAAS blockade.[74] Although increased insulin resistance and hyperuricemia often accompany thiazide treatment, the favorable cardiovascular outcomes in diabetic subjects who received the thiazide-like diuretic, chlorthalidone, compared to those who received amlodipine or lisinopril in the ALLHAT study suggest that such metabolic side effects are outweighed by the protective effects of the diuretic.[75] The combination of thiazides with loop diuretics may provide better diuresis and blood pressure control, particularly in patients with salt-sensitive and volume-sensitive hypertension and in more advanced stages of CKD.

Mineralocorticoid receptor antagonists (MRAs), including spironolactone, eplerenone, and finerenone, appear to be underutilized in patients with DKD who are already on ACEI/ARB therapy. Aldosterone has a direct detrimental effect on renal function in diabetes independent of its effects on BP, possibly by enhancing MAP kinase activity and increasing TGF-β expression. Both processes have been implicated in the development of tubulointerstitial fibrosis.[76,77] Patients may develop a rebound increase of aldosterone levels within weeks to months of initiation of ACEI or ARB treatment, a process referred to as aldosterone escape.[78,79] Patients with aldosterone escape appear to have a faster decline of renal function.[80]

The addition of MRAs to ACEIs or ARBs in the treatment DKD patients has been tested in a few small RCTs. Collectively, these studies suggest significant sustained decline in proteinuria, better control of hypertension, and better preservation of renal function.[81–84] Although a significant decline in eGFR occurred immediately after initiation of MRAs in this setting, eGFR then stabilized as opposed to the continuous decline of kidney function found in patients receiving placebo.[84,85] It appears possible to minimize side effects such as hyperkalemia and gynecomastia while maintaining beneficial effects.[81] Two ongoing clinical trials, FIGARO-DKD and FIDELIO-DKD, will determine whether the MRA, finerenone, in addition to standard ACEI or ARB therapy will improve cardiovascular or renal outcomes in participants with progressive DKD (https://clinicaltrials.gov/ct2/show/NCT02545049).

Calcium channel blockers (CCBs) are often used, either with or without ACEIs or ARBs, for BP control in patients with DKD. The safety, efficacy, and similar impact of both dyhidropyridine and nondihydropyridine CCBs on cardiovascular mortality, cardiovascular events, and stroke compared to diuretics, betablockers, or their combinations have been demonstrated in several RCTs.[75,86,87] However, in type 2 diabetic hypertensive participants with or without DKD, there was a higher incidence of fatal and nonfatal myocardial infarction, in those treated with nisoldipine compared to those receiving ACEI or ARB therapy.[88] Similarly, there was a higher rate of the composite outcomes of doubling of S[Cr], ESRD, or death with amlodipine than with irbesartan in the IDNT study of patients with moderate DKD, though this rate was not higher than those treated with placebo.[64] However, a trial of over 11,000 patients with hypertension (approximately 1100 with CKD, and approximately 60% with diabetes) who were at high risk for cardiovascular events showed that the addition of amlodipine compared with the addition of hydrochlorothiazide to maximal ACEI therapy resulted in a major improvement in both cardiovascular and prespecified kidney endpoints.[89,90] Thus, it appears that therapy with CCBs may be beneficial in DKD patients already treated with an ACEI or ARB.

A recent large comparative effectiveness study from four integrated health care systems reinforced this approach. The study showed that CCBs have the best add-on effect to ACEI or ARB therapy in diabetic patients who have better cardiovascular and renal outcomes.[91] In this study, CCBs were associated with a lower risk of significant kidney events, a similar risk of cardiovascular events, and a suggestion of a lower risk of death, over 5 years of follow-up, compared with thiazide diuretics. Although beta blockers were also associated with a lower risk of significant kidney events, they

were associated with a higher risk of cardiovascular events compared with thiazide diuretics. These more recent studies are in accord with the now common practice of adding a CCB as the second antihypertensive agent after maximizing ACEI or ARB therapy in patients with DKD.

Beta blockers appear to be a less-favorable class of antihypertensive medications, due to their reduced effectiveness in preventing cardiovascular events, as well as their adverse metabolic side effects, such as an unfavorable lipid profile, hypoglycemic unawareness, and erectile dysfunction. However, they may help reduce sympathetic overactivity in CKD and therefore may be an effective adjunct therapy in DKD patients who require an additional antihypertensive medication after achieving maximal RAAS blockade[92] or when secondary prevention of cardiac outcomes is warranted.

Direct renin inhibitors also appear to be a less-favorable class of antihypertensives as they have no advantage over ACEI or ARB therapy and can cause significant adverse effects in combination with ACEIs or ARBs.[93,94] Thus, current FDA guidelines recommend avoidance of aliskiren in conjunction with ACEIs and ARBs in patients with DKD (https://www.fda.gov/Drugs/DrugSafety/ucm300889.htm).

Several trials have demonstrated that preemptive treatment with ACEIs or ARBs in normotensive diabetic patients without albuminuria does not reduce the incidence or severity of DKD. Therefore, ACEIs and ARBs are not recommended for primary prevention.[95,96] However, in normotensive diabetic patients with albuminuria, ACEIs or ARBs may be beneficial for patients at high risk of progression of DKD. Such high risk conditions include increasing albuminuria, decreasing GFR, increasing blood pressure, presence of retinopathy, worsening lipid profile, increasing uric acid, family history of hypertension, macrovascular disease, or DKD.[96] Moreover, the ADA recommends ACEIs, ARBs, thiazide diuretics, or dihydropyridine CCBs as first-line pharmacologic therapy for hypertension in diabetic patients without nephropathy.[65]

Lipid Control

The ADA recommends the use of lifestyle modification in all patients with diabetes, consisting of application of weight loss (when indicated), the reduction of saturated fat, trans fat, and cholesterol intake, increase of dietary n-3 fatty acids, viscous fiber, and plant stanols/sterols intake, and increased physical activity aimed at improving lipid profile.[65] For patients with atherosclerotic cardiovascular disease at all ages, high-intensity statins (atorvastatin 40–80 mg/day or rosuvastatin 20–40 mg/day) should be added to lifestyle modification regardless of lipoprotein levels. For patients with diabetes aged <40 years with atherosclerotic cardiovascular disease risk factors, any patients between 40 and 75 years, and those >75 years without atherosclerotic cardiovascular disease, use of moderate intensity statins can be considered (atorvastatin 10–20 mg/day, rosuvastatin 5–10 mg/day, simvastatin 20–40 mg/day, or pravastatin 40–80 mg/day).[65] In patients with atherosclerotic cardiovascular disease, if LDL is ≥70 mg/dL on maximally tolerated dose of statins, addition of another LDL lowering agent such as ezetimibe or PCSK9 inhibitor to the therapeutic regimen should be considered.[65] Despite demonstrated effectiveness of lipid-lowering medications in preventing cardiovascular events in patients with diabetes, similar efficacy in diabetic CKD patients has been demonstrated only in the last decade.[97–102] The Study of Heart and Renal Protection (SHARP) examined the effects of dual treatment with simvastatin and ezetimibe in CKD and dialysis patients, including those with diabetes.[97] This study clearly showed that the combination of simvastatin and ezetimibe led to a significant reduction in major atherosclerotic cardiovascular events but did not appear to reduce the progression of CKD. Despite the observed beneficial effect in nondialysis CKD patients, a subgroup analysis in dialysis patients revealed no cardiovascular benefit with use of statins.[97] This is consistent with results from the 4D, AROURA, and ALERT trials in which no cardiovascular survival benefit was noted in ESRD patients with use of statins.[103–105] The reasons for the lack of beneficial effects from statins on cardiovascular outcomes in dialysis patients are poorly understood and could be due, in part, to impaired reverse cholesterol transport system in ESRD[106] or may be due to differences in the type of cardiovascular events that affect dialysis patients.

Gemfibrozil and fenofibrate are also used frequently in DKD patients. The Diabetes Atherosclerosis Intervention Study and the Fenofibrate Intervention and Event Lowering in Diabetes Study reported a decrease in albuminuria and its regression toward normoalbuminuria with the use of fenofibrate.[107,108] In *post hoc* analysis of the Veterans' Affairs High-Density Lipoprotein Intervention Trial, gemfibrozil reduced the primary composite outcome of coronary death and nonfatal myocardial infarction, but not the need for revascularization or all-cause mortality in CKD.[109] Gemfibrozil when combined with statins increases the risk of increased transaminases and rhabdomyolysis. Gemfibrozil therefore should not be given combined with statins. It is not recommended for use in patients with severe reduction in GFR as well.

Dietary Protein Restriction

High intake of nondairy animal protein may accelerate reduction of renal function.[95] A number of studies, mostly conducted in the 1980s or 1990s, showed that moderate protein restriction reduced the progression of established DKD in terms of GFR decline, albuminuria, and occurrence of ESRD in both type 1 and type 2 diabetic patients.[110–112] Generally, dietary protein was restricted to 1 g/kg body weight/24 h or less in these studies. As current management of DKD has emphasized blood pressure control and ACEI or ARB treatment, it is unclear whether dietary protein restriction provides much additional benefit. Indeed, relatively small studies reported after 2001 have not confirmed a significant improvement in outcomes with similar degrees of dietary protein restriction.[113] However, modest dietary protein restriction may be helpful in a number of DKD patients and will likely do no harm. The ADA currently recommends a daily dietary protein intake of approximately 0.8 g/kg in individuals with nondialysis-dependent DKD.[21]

Other Lifestyle Modifications

In addition to calorie and protein intake, dietary evaluation and recommendations should emphasize sodium restriction in hypertensive DKD patients, as well as in potassium and phosphorus intake when CKD progresses. Exercise should be part of lifestyle modification as tolerated. Supplementation with monounsaturated and polyunsaturated fats have improved glycemic control, lowered blood pressure, reduced albuminuria, and altered high-risk inflammatory biomarkers in the general population and may be beneficial in patients with diabetes and CKD.[33] Smoking cessation and weight loss are integral parts of lifestyle modification, as smoking cessation ameliorates progression of early stage DKD.[114] Weight loss has beneficial renal effects by reducing proteinuria and decreasing blood pressure in patients with mild to moderate CKD with or without diabetes.[115,116] Aspirin (dose of 75–162 mg/day) is indicated for primary prevention of cardiovascular morbidities in all patients with cardiovascular risk factors (aged >50 years with family history of premature atherosclerotic cardiovascular disease, hypertension, dyslipidemia, smoking, or albuminuria), as well as for secondary prevention in patients with a history of atherosclerotic cardiovascular disease.[65] Similarly, low-dose daily aspirin is indicated in all pregnant patients with type 1 and type 2 diabetes, starting from the end of the first trimester until the birth of the baby, aimed at reducing the risk of preeclampsia.[117]

DIABETES IN ESRD

Between 2001 and 2015, adjusted mortality rates in the dialysis and kidney transplant populations declined by 28% and 3%, respectively. After accounting for changes in population characteristics, the adjusted mortality rates decreased by 40% for transplant recipients. These decreases in mortality likely reflect improved care along with an increase in the number of prevalent ESRD patients. In spite of this trend, up to 21.7% of diabetic patients die in the first year after initiation of dialysis and have a 5-year survival rate of only 37.9%,[118] giving ESRD patients with diabetes the highest mortality among all ESRD patients. Preparation for ESRD should start at least 6 months before the start of renal replacement therapy (RRT) is contemplated. Preparation should include education of patients and families regarding the process, prognosis, and different modalities of RRT and projected lifestyle changes. Consultation with a nephrologist for patients who reach stage 4 CKD reduces costs, improves quality of care, and delays dialysis.[119] Decision-making about the modality of RRT should be similar to that in other ESRD patients. Survival rates are much better in patients receiving kidney transplants compared to those treated with dialytic modalities.[120,121]

SUMMARY

DKD remains the leading cause of ESRD in the US and most developing countries. Table 51.1 provides a summary of the approach to prevention, screening, diagnosis, and treatment of diabetic nephropathy. Excellent glycemic control with an HbA1c of ≤7% can prevent or delay the development of DKD. Treatment with an SGLT2 inhibitor should be strongly considered for those patients with eGFR >45 ml/min/1.73 m^2. Treatment of elevated blood pressure to <140/90 mm Hg can also reduce the development and progression of nephropathy. Targeting a BP of <130/80 mm Hg should be considered when it is safe and tolerable. ACEI or ARB therapy is not recommended for primary prevention of DKD in normotensive patients with diabetes as it does not forestall nephropathy. However, ACEIs and ARBs are among the recommended agents for treatment of hypertension in type 1 and type 2 diabetic patients without nephropathy.

Diabetic patients should be monitored for the development of DKD. Measurement of S[Cr], calculation of eGFR, and monitoring for albuminuria (UACR >30) should be performed at least annually starting 5 years after diagnosis of type 1 diabetes, and at the time of diagnosis of type 2 diabetes. Persistent albuminuria should

be confirmed by 2 of 3 positive tests within a 3–6-month period, after eliminating spurious causes of albuminuria. The presence of persistent albuminuria and/or reduced eGFR along with diabetic retinopathy is consistent with the diagnosis of DKD in type 1 diabetic patients. The presence of persistent albuminuria and/or reduced eGFR with diabetic retinopathy is also generally consistent with the diagnosis of DKD in type 2 diabetic patients. However, there is a higher incidence of non-DKD in type 2 diabetic patients. Thus, other diagnoses should be considered, especially if there are acute or subacute increases in albuminuria or acute or subacute decreases in eGFR. Additional evaluation, including kidney biopsy, should be considered when a diagnosis other than DKD is suspected.

Control of blood pressure to a seated blood pressure of less than 140/90 mm Hg will prevent progression of DKD and decrease the incidence of major cardiovascular events. Reducing blood pressure to <130/80 mm Hg is encouraged if tolerated and not contraindicated for other medical reasons. Use of an ACEI or ARB as the first-line antihypertensive therapy is recommended for nonpregnant hypertensive patients with DKD to reduce the incidence of major cardiovascular events and progression of DKD. Combined ACEI and ARB therapy is not recommended. Normotensive nonpregnant patients with DKD should also be treated with an ACEI or ARB, as tolerated, to reduce progression of DKD. Diuretics, MRAs, CCBs, and beta blockers can be used in combination with ACEIs or ARBs to control BP.

Reduction of daily protein intake to 0.8 g/kg body weight is recommended in DKD patients who are not treated with dialysis. Lifestyle modification, including exercise, weight loss, smoking cessation, and dietary consultation should be incorporated into a multidisciplinary approach to treatment for DKD patients. Preparation for RRT, including referral to a nephrologist, should begin when patients reach stage 4 CKD to allow adequate time for required education, and choice of RRT including transplantation, and creation of dialysis access, as indicated.

QUESTIONS AND ANSWERS

Question 1

A 58-year-old man is referred for evaluation of kidney disease associated with diabetes. He reports having type 2 diabetes for over 25 years. His diabetes has been under good control. He has chronic hypertension and hyperlipidemia. Six months ago S[Cr] was 1.0 mg/dL and UPCR was 0.12. On a routine clinic visit he is asymptomatic. His medications include lisinopril 20 mg a day, furosemide 20 mg a day, insulin glargine 10 units SQ at night, and atorvastatin 40 mg every night. On physical examination, seated blood pressure is 139/88 mm Hg, heart rate 80 beats per minute, weight 108 kg, and BMI 33 kg/m^2. There is no retinopathy or JVD. Heart sounds are normal and lungs are clear. Abdomen is soft and nontender without evidence of organomegaly. There is 3+ lower extremity pitting edema.

The following labs are obtained:

Serum chemistries
S[Na] 136 mEq/L
Serum potassium concentration (S[K]) 4.8 mEq/L
S[Cl] 103 mEq/L
tCO2 22 mEq/L
BUN 38 mg/dL
S[Cr] 1.5 mg/dL
Glucose 183 mg/dL
HbA1C 7.8%
LDL cholesterol 160 mg/dL
HDL cholesterol 34 mg/dL
UPCR 5.3
Urine microscopy: no cells, casts, crystals, or other abnormalities

Which one of the following is correct in this patient?

A. Addition of losartan 25 mg/day further reduces major cardiovascular events in presence of heavy proteinuria
B. Addition of valsartan 40 mg/day preserves kidney function over the long-term by reducing glomerular hyperfiltration
C. Addition of ezetimibe to atorvastatin delays progression of CKD by better control of the lipid profile
D. A multidisciplinary approach incorporating life-style modification with weight loss, optimization of blood pressure, and blood sugar will result in halting progression of proteinuria
E. Work up for nondiabetic glomerulopathies including age-specific cancer screening and, potentially, a kidney biopsy should be performed.

Answer: E

The subacute onset of proteinuria in the absence of diabetic retinopathy and the presence of type 2 diabetes without nephropathy for 25 years suggest causes of kidney disease other than DKD. Membranous nephropathy is the most common primary glomerulopathy in Caucasian men of this age[122] and is frequently observed in association with malignancy. Therefore, age-specific cancer screening is appropriate in this case. After serologic and other blood and urine testing, a kidney biopsy is likely indicated to help diagnose the glomerulopathy, especially because eGFR has decreased.

The ONTARGET study suggests that dual therapy with ACEI and ARB does not improve the composite outcome of cardiovascular death, myocardial infarction, stroke, or hospitalization for heart failure compared to single agent therapy in high-risk patients.[72] Such therapy may also result in increased frequency of hypotension, hyperkalemia, and renal insufficiency. This makes Answers **A** and **B** incorrect.

The beneficial effect of lipid-lowering agents in diabetes is mainly by primary prevention of major cardiovascular events. The SHARP trial found no evidence that ezetimibe plus a statin delayed progression of CKD,[97] making **C** an incorrect answer.

A multidisciplinary approach is necessary and essential in management of DKD. However, such an approach may not necessarily halt progression of proteinuria, making Answer **D** incorrect.

Question 2

A 45-year-old man with newly diagnosed type 2 diabetes does not have a history of hypertension, coronary artery disease, stroke or peripheral arterial disease. He does not report blurred vision. On physical examination his sitting blood pressure is 116/78 mm Hg, pulse 78 beats per minute, weight 110 kg, and BMI 32 kg/m^2. Examination of retinas, heart, lungs, abdomen, and extremities is unremarkable. Neurologic examination is normal.

Serum chemistries
S[Na] 142 mEq/L
S[K] 4.2 mEq/L
S[Cl] 108 mEq/L
tCO2 24 mEq/L
BUN 20 mg/dL
S[Cr] 1.0 mg/dL
glucose 221 mg/dL
HbA1C 8.5%
Urinalysis: no protein or blood by dipstick. Spot UACR is 0.07. Urine microscopy: no cells, casts, crystals, or other abnormalities.

Which one of the following is correct in this patient?

A. Initiation of lisinopril reduces the risk of the new onset of microalbuminuria
B. In type 2 diabetes losartan is more effective than lisinopril in reducing the risk of DKD
C. Intensive lowering of blood glucose is an effective preventive strategy to delay incident DKD
D. Intensive lowering of blood glucose prolongs longevity by decreased risk of major cardiovascular events
E. Metformin is contraindicated as it increases risk of lactic acidosis in diabetic patients

Answer: C

The role of intensive lowering of blood glucose in primary prevention of DKD has been shown in both type 1 and type 2 diabetes.[34,35]

Several studies have shown that in normotensive diabetic patients without albuminuria, ACEI or ARB treatment does not reduce the incidence of DKD, making Answer **A** and **B** incorrect.

In type 2 diabetes intensive lowering of blood sugar does not reduce cardiovascular events.[40,41]

A number of systematic reviews and meta-analyses revealed safety of metformin along with no evidence for increased risk of lactic acidosis compared to other oral hypoglycemic agents.[42–44] Therefore, metformin is not contraindicated in type 2 diabetic patients with normal or moderately reduced kidney function.

Question 3

A 55-year-old woman with recently diagnosed type 2 diabetes is referred for counseling regarding kidney disease in diabetes. She denies a prior history of hyperlipidemia, or heart or lung disease. She has an older sister with a history of diabetes and advanced CKD. She had a UACR of 88 noted on annual screening 4 months ago. Currently, on physical examination her blood pressure is 130/85 mm Hg, heart rate 86 beats per minute, weight 85 kg, and BMI 31 kg/m^2. Examination of heart, lungs, abdomen, and extremities is unremarkable. S[Cr] is 1.2 mg/dL. UACR is 106. Which one of the following is correct in counseling her regarding clinical course of kidney disease in diabetes?

A. The probability of progression of DKD to ESRD is over 50% in her lifetime
B. Without specific treatment of nephropathy, the likelihood of development of ESRD increases to over 80%
C. Sustained intensive control of blood sugar should now be employed as excellent glycemic control is most effective at delaying progression of DKD rather than preventing its occurrence
D. Initiation of an ACEI or ARB is indicated given the presence of high urinary albumin excretion
E. Decrease of blood pressure to less than 120/80 mm Hg as compared to her current blood pressure delays progression of CKD

Answer: D

Initiation of ACEI or ARB treatment in nonpregnant type 2 diabetic patients with persistently increased urinary albumin excretion is recommended even in normotensive patients.

In type 2 diabetes up to 40% of patients with microalbuminuria develop overt proteinuria, of whom 20% may progress to ESRD over 10–20 years.[8,9] Thus, Answers **A** and **B** are incorrect.

The DCCT/EDIC and UKPDS studies have shown that the sustained tight control of blood sugar early during the course of diabetes in both type 1 and type 2 diabetic patients leads to prolonged preservation of kidney function even if such tight control does not persist.[37,38] This phenomenon is referred to as metabolic memory. Therefore, tight control of blood sugar is most beneficial earlier during the course of diabetes before increased albumin excretion occurs, rather than after development of DKD, making **C** incorrect.

The ACCORD-BP trial found no evidence for improved preservation of renal function or delay in progression of CKD with more intensive treatment of BP to <120/80 mm Hg compared to less-intensive treatment of BP to <140/90 mm Hg,[68] making Answer **E** incorrect.

Question 4

A 61-year-old woman had type 2 diabetes diagnosed 15 years ago. She does not comply with a low-salt diet and often eats in restaurants. She denies chest pain, orthopnea, or dyspnea on exertion. Recently she has had difficulty in control of her blood pressure. Her home medications include 20 mg lisinopril daily, 25 mg hydrochlorothiazide daily, 15 units insulin glargine daily at night, 20 mg simvastatin daily, and 81 mg aspirin daily. On physical examination her seated blood pressure is 164/95 mm Hg, heart rate 88 beats per minute. There is no rub or murmur, but there is mild jugular venous distension. There are bibasilar crackles. Abdomen is soft with normal bowel sounds. Lower extremities have 2+ pitting edema.

Serum chemistry
S[Na] 134 mEq/L
S[K] 4.5 mEq/L
S[Cl] 102 mEq/L
tCO2 23 mEq/L
BUN 42 mg/dL,
S[Cr] 2.1 mg/dL

glucose 193 mg/dL
HbA1C 8.1%
CKD-EPI eGFR: 29 mL/min/1.73 m^2
UPCR 2.5
Urine microscopy: no cells, casts, crystals, or other abnormalities

Which one of the following is NOT correct in management of the patient?

A. Consultation with a nephrologist at this point may reduce cost, improve quality of care, and retard progression to ESRD
B. Initiation of spironolactone at 25 mg/day will further reduce proteinuria
C. Continued decline of GFR with initiation of spironolactone will preclude effective use of this medication
D. Combination of a thiazide with a loop diuretic will be more effective than use of a thiazide alone in control of her blood pressure
E. Addition of direct renin inhibition with aliskiren would be associated with an increased risk of adverse renal outcomes and nonfatal stroke

Answer: C

Short-term randomized clinical trials have shown that treatment with MRA such as spironolactone can acutely reduce the GFR in diabetic subjects, which stabilizes over time, compared to continued decline of GFR in placebo-treated subjects.[81,84] This may potentially translate to better preservation of kidney function and therefore does not preclude its use.

Referral to a nephrologist is indicated by the time patients with CKD progress to stage 4, as studies have shown long-term outcomes and planning for ESRD are better in this setting.[123,124] Therefore, Answer **A** is a true statement.

Initiation of MRA can further reduce proteinuria and provide better control over blood pressure[81–84]; therefore, Answer **B** is a true statement.

In salt-sensitive hypertension a combination of a thiazide and a loop diuretic may provide better diuresis and control of hypertension[74]; hence Answer **D** is true. Dietary counseling to reduce salt intake should accompany treatment with diuresis.

The ALTITUDE trial of aliskerin in DKD was terminated early due to higher incidence of hypotension, hyperkalemia, renal complications, and nonfatal stroke in association with aliskiren; hence Answer **E** is a true statement.

Question 5

A 51-year-old man with a history of type 1 diabetes for over 35 years presents with progressive DKD. He does not report a change in appetite, presence of a sleep disturbance, reduced energy level, metallic taste, shortness of breath at rest, or orthopnea. His S[Cr] has slowly and steadily increased to 3.5 mg/dL from 2.8 mg/dL last year. His UPCR is increased to 9 from 3.5 last year.

Which one of the following is correct in discussion of preparation of the patient for RRT?

A. Preparation for ESRD including choice of RRT, vein mapping, and access creation should start at stage 4 CKD in anticipation of progression to ESRD because starting these processes early will improve morbidity and mortality after onset of ESRD
B. There is no reason to push for early listing for kidney transplantation in the absence of a living kidney donor because deceased donor kidney transplantation is not associated with improved survival compared to maintenance hemodialysis (HD) in patients with ESRD from long-lasting diabetes
C. HD is the preferred modality for this patient because peritoneal dialysis (PD) is associated with increased risk of hyperglycemia, hypertriglyceridemia, and weight gain
D. When dialysis is initiated more aggressive ultrafiltration should be well-tolerated by this patient because diabetic patients are more likely to be volume overloaded than patients with other causes of ESRD
E. In-center HD is preferred because short daily home HD provides inadequate clearance compared to traditional in-center HD.

Answer: A

Preparation for ESRD should start when stage 4 CKD is reached. If the decision is made for HD as the preferred modality of RRT, patients should undergo vein mapping and be referred for access creation in anticipation of progression to ESRD. Ideally, patients should start HD through an established arteriovenous fistula (or a graft when a fistula is not feasible). However, urgent indications for initiation of dialysis, delays in access creation and maturation, or absence of nephrologist involvement in ESRD planning may lead to initiation of HD using a catheter. HD using tunneled catheters is associated with higher risk of infective complications and therefore is less favorable.

Deceased donor kidney transplantation provides significant survival benefit in diabetes compared to other modalities of RRT,[120,121] so Answer **B** is incorrect.

Although increased risk of hyperglycemia, hypertriglyceridemia, and weight gain is associated with PD in diabetic patients, PD outcomes are not clearly worse than HD outcomes and choice of modality of RRT is not different in DKD compared to other etiologies of ESRD,[125] so Answer **C** is incorrect. Patient preference

after consultation with the nephrologist should guide modality choice.

Autonomic dysfunction is a common complication in diabetic patients, which makes effective ultrafiltration with dialysis more difficult and challenging,[126] so Answer **D** is incorrect.

Short daily dialysis has similar patient/treatment survival compared with traditional in-center dialysis[127] and can be preferable when ultrafiltration of large volumes with each dialysis becomes difficult, making Answer **E** incorrect.

Question 6

A 32-year-old woman with type 1 diabetes for 25 years developed albuminuria at age 24 and has been on lisinopril 40 mg daily ever since. Her medication regimen includes humulin insulin *via* an insulin pump, which she has been adjusting over the past 2 months due to large glycemic swings, hydrochlorothiazide 25 mg daily, atorvastatin 10 mg daily. Her urinary albumin excretion is now greater than 800 mg/day. Her home blood pressure readings are between 120 and 130/60−70 mm Hg. On physical examination her seated blood pressure is 125/75 mm Hg, heart rate 96 beats per minute. There is no rub, murmur, or jugular venous distension. Lower extremities have 1+ pitting edema. The following labs are obtained:

Serum chemistries
S[Na] 136 mEq/L
S[K] 4.5 mEq/L
S[Cl] 101 mEq/L
tCO2 25 mEq/L
BUN 42 mg/dL
S[Cr] 1.6 mg/dL
glucose 142 mg/dL
HbA1C 9.4%
UACR 874
